Over the next 6 years, Mr. B continued to take AAS about "80% of the time," by his account—but from ages 35 to 37, he used AAS continuously, remaining on a modest dose of testosterone cypionate even during the spaces between the cycles. He described increasingly "brittle" mood swings, with periods of euphoria, irritability, and increased self-confidence alternating with sudden dips into depression with suicidal ideation. At times, Mr. B described a mixture of affective symptoms where he would experience euphoria, irritability, and suicidal thoughts almost simultaneously. Over the course of these years, his physician tried several other antidepressants (citalopram, venlafaxine, and duloxetine), plus several concomitant medications for mood stabilization (lithium carbonate, valproate, and lamotrigine), with inconsistent benefit—partially because Mr. B would often become noncompliant. Also, Mr. B began drinking alcohol almost daily and began to use increasing amounts of controlled-release oxycodone to self-treat his dysphoric moods. Mr. B also became increasingly impulsive and on one occasion, took a substantial overdose of citalopram, necessitating a 3-day hospitalization in a psychiatric unit.

Following this hospitalization, Mr. B became more consistently compliant with a regimen of duloxetine and lithium carbonate. He continued to be highly focused on weightlifting and his body appearance. However, he still used oxycodone frequently and continued to complain of sharp "dips" of severe depression. During one of these "dips," shortly after tapering down from high-dose AAS to his usual "maintenance" level of testosterone cypionate, he made a second, nearly successful suicide attempt with a combination of illicitly obtained oral opiates. He was again hospitalized, treated with ECT, and responded well. A cardiac evaluation during this hospitalization,

using Doppler echocardiography, revealed evidence of dilated cardiomyopathy judged likely attributable to AAS.

Mr. B has resolved not to resume taking AAS, but 6 months after hospital discharge, he is already contemplating going back on a low dose of AAS because he is distressed by his deteriorating physique.

Mr. B's case exemplifies several AAS-related disorders, including apparently AAS-induced bipolar disorder, AAS withdrawal, and AAS dependence. In addition to physiologic withdrawal, Mr. B met several other diagnostic criteria for AAS dependence: taking more AAS than originally intended, resuming use after several attempts to stop completely, requiring increasing doses of AAS (tolerance), and continuing use despite knowledge of adverse consequences such as divorce. Another important aspect of this case was his concurrent use of alcohol, opioids, and cocaine. All four classes of substances share a final common pathway of dopamine augmentation; in addition, alcohol, opioids, and AAS have effects on the endogenous opioid system; and alcohol and AAS both also act as GABA receptor modulators. Taking these drugs in combination typifies the loss of control commonly seen with addiction but also may reflect an attempt to enhance the rewarding effects of AAS (dopamine and opioid systems) and analgesic aspects of AAS (opioid system) while minimizing some of the hyperactivating effects of AAS (via the antianxiety/sedative effects of GABA and opioid systems).

Schizophrenia and Other Psychotic Disorders

12.1 Introduction and Overview

CAROL A. TAMMINGA, M.D.

Schizophrenia is arguably one of the most puzzling yet disabling of all brain diseases, with its severe and persistent psychotic manifestations accompanied by variable cognitive dysfunction and profound psychosocial impairment. Its disease onset, at least of the psychotic manifestations, occurs at an unusual time of life in late adolescence/early adulthood. Its symptoms are often undetectable in early life, are at their worst during child-bearing years, and often improve, to a degree, with aging. People with psychotic illnesses, in general, suffer greatly throughout life and medical need worldwide continues to be very high. Fortunately, in the pages of this section, the broad aspects of this condition are described and discussed, as far as they are known, by experts in the field.

Substantial progress in understanding and treating schizophrenia will depend on discovering the neural mechanisms of the elements of the condition, one of those being the mechanism for psychosis. This understanding is necessary for developing drug targets, novel therapeutics, and biologically based disease definitions. It is hard to conceive of the exact neural mechanisms whose dysfunction could interfere so extensively with such broad cognitive functions as does

psychosis. This section lays out current perspectives of schizophrenia presentation, treatment, and biology that include much of what is known about its disease manifestations today and brain dysfunctions in the illness. What provides clear hope of progress for the future is not only the quality of the tools available to study mammalian brain function but, in particular, the wealth of basic neurobiology available and the extent to which this understanding of basic brain mechanisms translates to human diseases. In this section, the curious reader will find the facts of psychosis presentation and the sum of the manifestations and biomarkers that any model needs to consider in formulating a disease model. Of course, blatant heterogeneity exists in the different psychotic illnesses, with nearly as much heterogeneity within a diagnosis as between, along with a lack of distinguishing biologic characteristics. Several scientists represented in this section speculate on the use of alternative strategies for classification, attempting to increase biologic homogeneity within disease-like clusters to advantage mechanistic discovery.

It is always poignant to review the long history of psychotic illness, including its most severe variant, schizophrenia. Descriptions of schizophrenia can be found in works of literature from the earliest human times. Schizophrenia-like symptoms are described in individuals labeled as seers and prophets, as well as witches and devils. The perspective of schizophrenia being a human brain disease did not develop until the 19th century. Then, “humane” treatment was prescribed for “insanity,” an approach that advocated care, protection, and human understanding for those afflicted. It was not until the middle of the 20th century that antipsychotic medications became widely available. Now in the early 21st century, two, maybe three, generations of antipsychotic medications were developed, several known risk genes discovered, an evolving anatomy discussed, and several regional human brain-based models for symptoms manifestations of cognitive dysfunction (prefrontal cortex) and psychosis (hippocampus). Meanwhile, the focus of inquiry into the illness has moved from conventional diagnostic criteria to dimensions of dysfunction, and a fundamental understanding of the neural basis of complex functional brain diseases has developed. Therefore, it might be optimistically predicted that it will eventually be possible to describe the genes, circuits, cellular and molecular mechanisms, and rational treatments for psychosis manifestations over the next several decades.

The articulation of a modern biologic hypothesis for schizophrenia began with dopamine. The pivotal observation that drugs that diminish dopamine-mediated neurotransmission in the brain reduce psychotic symptoms was made only in the mid-20th century. The first antipsychotic drug (chlorpromazine) was discovered serendipitously but with a strong clinical rationale and astute observation. The experimental result that implicated the action of chlorpromazine connected to dopamine receptor blockade was a hypothesis that fueled decades of drug discovery and was the basis for a related etiologic hypothesis that dopamine was indeed the core pathophysiology of schizophrenia. This speculative extension of a well-supported treatment hypothesis has been harder to prove and establish as the basis for schizophrenia pathophysiology, although ideas are still being tested. Although data have consistently supported the dopamine mechanism of antipsychotic drug action, support for the dopamine hypothesis of pathophysiology has been inconsistent.

At the same time, understanding the pharmacology and basic biology of human cognition and its dysfunctions has evolved into a very intricate picture, one unlikely to be explained simply as overactivity of dopamine. A component of cognition like declarative memory, which has been intensively studied since Henry Molaison (known in the clinical literature as H. M.) lost declarative memory function, is understood now to be served by alterations in synaptic strength, postsynaptic calcium interactions with receptor trafficking, and epigenetic remodeling in hippocampus and the memory neocortex. An alteration in this process of memory physiology could be the basis of a model of psychosis. Many speculations have emerged that multiple manifestations of psychotic illness may be associated with distinct pathophysiologies, for example, one for psychosis and another for cognitive dysfunction. Most would agree that psychosis itself will have multiple etiologies, much like “fever.” Anyone interested in the pathophysiologic basis of psychiatric conditions will have to understand normal brain processes already being articulated within neuroscience laboratories worldwide. Full attention will have to be directed to these discoveries in basic neuroscience to understand modern articulations of brain-based pathophysiologies for psychosis and cognitive dysfunction.

In clinical research on schizophrenia, there has been a willingness to abandon conventional diagnostic categories, experimentally and hypothetically, to examine alternate views of pathophysiology, etiology,

and treatment. This has focused on the pathophysiology of *dimensions* of dysfunction for postulating mechanisms and exploring treatments. Not that the dimension will be the final explanatory element, but that it will allow a resorting among similar disease manifestations to gain biologic homogeneity. Dimensions of normal cerebral function have been proposed, connected with known neural systems, a dysfunction or perversion that would generate psychopathology. Specifically, the independence of symptom domains such as psychosis, cognitive dysfunction, affective disturbance, and negative symptoms is now being explored in a research domain criteria (RDoC) framework. The implication of this formulation, which is now being explored, is that each of these composite symptom complexes will have its own etiology, mechanism, and selective treatment and can be treated independently and individually. Personalized medicine, as well as new disease formulations, are likely to spring from these approaches.

The field of schizophrenia practice and research needs to understand some obvious areas. First, effective diagnostic and treatment algorithms for the early detection and treatment of psychotic young adults need to be established. Effective medications are necessary, even when optimized across each individual person, but they are by no means sufficient. Psychotic illness needs broad, diverse, and comprehensive treatment, especially at its inception or when it threatens to break through. This kind of comprehensive treatment extends beyond antipsychotic medication to include cognitive remediation approaches, psychosocial treatments, behavioral therapies, family training, and community involvement. The newest study in the treatment of early psychosis, the Recovery After an Initial Schizophrenia Episode (RAISE) study, found that implementing all of these treatments early on in disease manifestations generates better outcomes sooner in young people. Treating a psychotic illness such as schizophrenia “piecemeal” generates only partial gains and falls short of the success that comes with a comprehensive plan allowing potentiated gains.

It would certainly be useful if more were known about the mechanism of action of the effective drugs used for psychosis, all of which are dopamine receptor antagonists. What actually do these antidopaminergic drugs do in the brain that quiet the storms of psychotic symptoms? This would be an approach to discovering disease pathophysiology. One of the single issues that affect psychotic illnesses most adversely is the lack of disease

understanding. What the field needs is a simple, direct, and concrete presentation of the mechanism(s) of psychosis to combat stigma, direct treatment development, and on which to base behavioral and cognitive treatment approaches.

What if there were biologic formulations of psychotic diseases that were confirmed and demonstrated? How different would that be for the serious mental illnesses that psychiatrists treat? To answer this question, medical conditions that changed after full disease understanding could be examined. For example, there was once a disease called “dropsy” in the late 19th century, which was the presentation of morbid edema that progressed rapidly and caused extreme morbidity and finally death. Its determinants and treatments have been progressively understood and more precisely treated by medical discoveries throughout the 20th and 21st centuries. Dropsy can be explained by a plethora of cardiac, pulmonary, renal, and metabolic conditions, some genetic, others developmental, and others metabolic or structural. Its association with specific organ failures focused attention on a component of the dropsy cases (all phenomenologically quite similar, if not identical) on dysfunctions of the particular organ systems. Some treatments are specific for treating the diseased organ, and some medications are specific for the edema. Now edema rarely becomes morbid anymore. And our increased understanding of *prophylaxis* directed toward cardiac, metabolic, and diseases has improved health and helped avoid dropsy-like conditions. These kinds of disease structures and their determinants need to be uncovered in cognitive and affective brain diseases so that the same kind of understanding can be gained for psychosis brain health.

12.2 Phenomenology of Schizophrenia

Stephen F. Lewis, B.S., M.D., Rodrigo Escalona, M.D., and Samuel J. Keith, M.D.

Schizophrenia continues to be defined and diagnosed as a psychiatric disorder solely based on its clinical phenomenology. Efforts to include the use of biomarkers to make the diagnosis and predict treatment response or course of illness have not been successful thus far. The concept of schizophrenia as a distinct clinical entity is a recent historical development. However, detailed descriptions of psychotic disorders can be found through centuries of written history, with early Greek physicians documenting cases that resemble schizophrenia in its current form. Psychosis only emerged as a medical condition worthy of scientific study and treatment during the 18th century in Europe. At that time, the concept of psychosis included a large undifferentiated group of disorders, including psychotic symptoms secondary to medical conditions–general paresis and syphilitic insanity, as well as primary or “functional” psychoses such as affective psychosis and schizophrenia. It would take at least another half century for a more consistent and systematic classification of psychotic disorders to appear and set the basis for modern psychiatric diagnoses.

DIAGNOSTIC CRITERIA

History

Emil Kraepelin (1856 to 1926) pioneered the psychiatric nosology that would set the foundation for the development of modern psychiatric diagnostic systems. He first separated, from the broad group of psychosis,

the organic psychoses such as syphilitic insanity and general paresis, and then most importantly, he described two major groups of primary psychotic disorders: The *manic depressive psychosis* and *dementia praecox* (dementia of the young, a term coined earlier by Morel). He used the long-term prognosis and course of illness as principal features to define the two distinct categories. The assumption at that time was that all affective psychosis had a nondeteriorating course as opposed to dementia praecox, which was deemed as deteriorating and irreversible. He believed that dementia praecox was a loss of the inner unity of the activities of intellect, emotion, and volition. He included in the concept of *dementia praecox* a broad group of disorders known separately at that time, such as paranoia, catatonia, and hebephrenia, and defined them as subtypes of the same illness.

In 1911, the term *schizophrenia,* as the disease is known today, was introduced by Eugen Bleuler (1857 to 1939). He proposed the name to denote a “splitting” of psychic functions, which he considered to be the core feature of the illness. He was less concerned with the course of illness than Kraepelin had been and much more concerned with the understanding of the psychological mechanisms underlying the disease process. His description of the illness included primary and secondary symptoms. His four primary symptoms (“the Four As”) were *abnormal associations, autistic behavior and thinking, abnormal affect,* and *ambivalence.* Bleuler considered the loss of harmonic coordination among thought, emotion, and behavior to be the hallmark of the illness. For Bleuler hallucinations, delusions, social withdrawal, and diminished drive were secondary manifestations of the illness that depended on the adaptive capacity of the individual and environmental circumstances. Thus, according to Bleuler, the most obvious and striking manifestations of schizophrenia were only “accessory symptoms.” In addition, he saw the symptoms of schizophrenia as a continuum with normal behavior, a concept that led to major diagnostic controversies among psychiatrists around the world for decades, until the recent formalization of diagnostic criteria.

Kurt Schneider (1887 to 1967) in his classification of thought disorders attempted to make the diagnosis of schizophrenia more reliable by identifying a group of symptoms that were the most characteristic of the illness. His so-called first-rank symptoms included various forms of hallucinations, thought withdrawal, thought insertion, thought

broadcasting, delusional perceptions, and experiencing feelings and actions as made or influenced by external agents (Table 12.2–1). The presence of one of these symptoms, in the absence of intoxication, brain injury, or clear affective illness, was sometimes taken as sufficient for making the diagnosis of schizophrenia.

The different conceptualizations of the illness and diagnostic criteria used in clinical practice and research led to wide disparities in the rates of diagnosis of schizophrenia among clinicians and researchers around the world. This problem ignited a search for agreements and conventions to facilitate communication and define more formal and reliable diagnostic criteria giving birth to modern nosology.

Modern Diagnostic Criteria

In the United States, the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) of the American Psychiatric Association (APA), in its second edition (DSM-II), was heavily influenced by Bleulerian criteria to make the diagnosis of schizophrenia. The predominance of psychological and psychosocial theories in the field at the time, such as the theories of Adolph Mayer, Harry Stack Sullivan, and the Freudian followers, were fertile ground for the adoption of a view of schizophrenia according to Bleuler. The consequences of adopting such concepts led to broad and arbitrarily applied criteria to diagnose schizophrenia, sometimes making the rate of diagnosis rather high. Many conditions now classified elsewhere were included in the diagnosis of schizophrenia according to the DSM-II. As a consequence, studies performed during the 1960s and 1970s in the United States and in Europe showed that the reliability of diagnosis locally or across countries was very low. In the United States, the more inclusive diagnostic criteria for schizophrenia led to rates that were much higher than in Europe, where many more patients were instead diagnosed with affective psychosis. Through the middle of the 20th century, the rate of schizophrenia as an admission diagnosis for psychiatric facilities in London stayed similar over a 40-year period, whereas the diagnosis of schizophrenia appeared to be increasing as an admission diagnosis in New York City, with no clear explanation for the differences. The United States–United Kingdom Cross National Project study of hospitals in London and New York showed that approximately 60% of the admissions in New York State hospitals were diagnosed with schizophrenia, whereas in London hospitals, admissions with the

diagnosis of schizophrenia were about half that rate. When standardized diagnostic interviews were applied in these settings, the rates of schizophrenia in New York decreased to levels that matched the rates in London. These findings triggered the need to define more standardized diagnostic criteria on both sides of the Atlantic. A later groundbreaking study that propelled the adoption of explicit diagnostic criteria was the International Pilot Study of Schizophrenia (IPSS) sponsored by the World Health Organization (WHO). One thousand two hundred patients with psychotic disorders from nine countries were interviewed using a structured diagnostic interview, the present state examination (PSE). This study showed that schizophrenia manifested itself in similar ways across very diverse cultures, with similar rates of hallucinations, delusions, first-rank symptoms, and affective symptoms among people with schizophrenia in developing and developed countries. The findings from this study reaffirmed the belief that useful and uniform formal criteria could be developed and would contribute to better communication among clinicians and researchers alike.

Table 12.2–1.
First-Rank Symptoms of Kurt Schneider

Audible thoughts	Auditory hallucinations of a person's voice being spoken aloud
Voices arguing or discussing	Auditory hallucinations of two or more voices arguing or discussing, usually about the person experiencing the hallucination
Voices commenting on patient's actions	Auditory hallucinations commenting on a person's behaviors
Somatic passivity	Tactile or visceral hallucinations that are imposed by some external agent; can be combinations of different somatic hallucinations
Thought withdrawal	Sensation of thoughts being actively removed from a person's mind
Thought insertion	Thoughts inserted into a person's mind by some external agent
Thought broadcasting	The sense that a person's thoughts are experienced as real phenomena by others—the thoughts are made audible or may be experienced by others through telepathy
Made feelings	Feelings that are not a person's own are imposed on that person by an external agent
Made impulses or drives	An impulse for action is imposed on a person by some external agent
Made volitional acts	A person's actions are from and are controlled by an external agent; the person is a passive participant in the action
Delusional perception	A perception that has a unique and idiosyncratic meaning for a person, which leads to an immediate delusional interpretation

The changes between DSM-II to DSM-III in the diagnostic criteria of schizophrenia represent the biggest conceptual departure from previous diagnostic classification systems and set the foundation of current nomenclature. This was a major break with decades of American and European nosologic tradition. The result was a much narrower definition of the disorder. This major conceptual change was possible due to the efforts published in 1972 by the Washington University psychiatry research group in St. Louis, Missouri, that introduced a diagnostic classification system aiming at greater validity and reliability of diagnoses. These criteria, known as the Feighner criteria after the first author of the initial report, were rigorous in trying to define homogeneous diagnostic groups. The principles underlying this classification system were (1) clinical description, (2) laboratory study, (3) delimitation from other disorders, (4) follow-up studies, and (5) family studies. The next major step toward current diagnostic criteria was the introduction of the research diagnostic criteria (RDC) in 1978. This effort borrowed many concepts from the Feighner criteria and the Schneiderian tradition. The RDC emphasizes the temporal length of observable psychopathology and differentiation based on the presence or absence of mood symptoms. The main difference between the Feighner and the RDC criteria was the reduction of the duration of active symptom phase from 1 month in the Feighner criteria to 2 weeks in the RDC. The duration of illness was kept at 6 months to reach diagnosis. In addition to the definition of formal criteria for schizophrenia, a structured diagnostic interview was developed (Schedule for Affective Disorders and Schizophrenia, or SADS). This kind of structured diagnostic interview became the precursor to several instruments currently in use in research.

The DSM-III, published in 1980, for the first time defined schizophrenia much more narrowly, placed more emphasis on Schneiderian concepts, and included a multiaxial diagnostic system. Dimensions such as secondary diagnosis, impact of functioning, and relevant medical illness and severity were now included in the formal diagnosis. In addition, clear exclusion criteria were described, and the maximum age of onset at 45 years was eliminated. The principles used to guide the development of DSM-III were also used for the development of DSM-IV and DSM-5. Among the many important features considered to make the diagnosis of schizophrenia, there was a new emphasis on using course of illness in addition to cross-sectional symptoms in an effort to improve reliability and

validity of the diagnosis. A requirement for symptoms of at least 6 months' duration was added as a requirement for the diagnosis of schizophrenia.

Current Diagnostic Criteria

The current versions of the DSM and *International Classification of Diseases* (ICD) diagnostic systems are the DSM-5 TR and the ICD-11. In spite of some differences, both systems have a great deal of concordance in terms of the definition of schizophrenia. Both systems reflect a clear narrowing of the diagnosis of schizophrenia compared to previous diagnostic practices, especially in the United States. One of the major differences between them is the longitudinal course criterion. The DSM-5 TR requires a minimum duration of the illness of 6 months (with at least 1 month of active symptoms) as opposed to only 1-month total duration of illness in the ICD-11. Also, the DSM-5 TR requires deterioration in social and occupational function, in contrast to the ICD-11, which does not have such a requirement for the diagnosis of schizophrenia. The DSM-5 criteria for schizophrenia, unchanged in DSM-5 TR, were released in 2013 and included some important changes while retaining the core structure of DSM-IV. The symptom threshold for the diagnosis was raised from needing one core symptom in DSM-IV-TR to at least two symptoms. Core symptoms continue to be delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and negative symptoms. Both DSM-5 TR and ICD-11 eliminated the special diagnostic importance for first-rank Schneiderian symptoms such as running commentary hallucinations, two or more voices conversing with each other, and having bizarre delusions. Delusions are now treated equally toward the diagnosis of schizophrenia regardless of their content. Also a major departure from previous editions of the DSM and ICD was the elimination of all subtypes of schizophrenia due to lack of data supporting their stability over time and any clinical or research predictive value.

Diagnostic Criteria: Functioning. In addition to the cross-sectional criteria, DSM-5 TR requires the presence of significant deterioration in one or more major areas of functioning, such as work, interpersonal relations, or self-care. In contrast, ICD-11 does not require functional deterioration for a diagnosis of schizophrenia and in fact, states that deterioration is not inevitable.

Diagnostic Criteria: Duration. The DSM-5 TR criteria require a total duration of 6 months. Within this 6-month period, there must be at least 1 month of active-phase symptoms (overt psychotic symptoms). A shorter duration of the active phase is allowed only if successful treatment is instituted. The rest of the 6-month period may include continuing psychotic symptoms, prodromal symptoms preceding clear-cut psychosis, or residual symptoms after the resolution of the psychotic symptoms. Residual symptoms are defined as attenuated forms of psychotic or disorganization symptoms, such as odd beliefs, magical thinking, ideas of reference, odd perceptual experiences, peculiar or concrete thinking, vague speech, or odd behavior. Negative symptoms may also be included as residual symptoms. If the 6-month duration criterion is not met, but the other criteria are present, the diagnosis of schizophreniform disorder should be made instead.

In contrast, ICD-11 requires only a minimum duration of 1 month. This time does not include the prodromal phase and does not consider treatment as a variable to shorten the duration of the acute phase. If this duration requirement is not met, the diagnosis of other primary psychotic disorders should be made instead.

Diagnostic Criteria: Exclusions. The DSM-5 TR criteria require that mood and schizoaffective disorder be ruled out to make the diagnosis of schizophrenia. The patient should not meet criteria for a manic or depressive episode during the psychotic phase, or if there is a concomitant mood episode with active phase symptoms, the duration of the mood episodes should be brief relative to the duration of the psychotic illness. This includes residual symptoms. In contrast, according to ICD-11, a patient with a depressive or manic episode can still meet criteria for schizophrenia, if criteria for schizophrenia were met before the onset of the mood episode.

DSM-5 TR excludes a diagnosis of schizophrenia if the symptoms are the result of a direct physiologic effect of a substance, a drug of abuse, or a medication, as well as when the symptoms are due to a neurologic or medical condition. ICD-11 includes very similar exclusion criteria and now classifies psychotic syndromes with a known cause as secondary psychotic syndromes and place them under their respective medical or psychiatric categories.

Diagnostic Subtypes

The diagnostic subtypes of schizophrenia were dropped in DSM-5 TR and ICD-11. Schizophrenia subtypes have been controversial constructs and their clinical utility has been consistently questioned. They have a weak relationship to biologic variables, poor long-term stability, and poor predictive value. The paranoid subtype appears to have greater stability than the other subtypes and was used more often in clinical practice along with the undifferentiated type. Instead, in order to capture the rich and diverse clinical presentation of schizophrenia with heterogeneous symptoms and signs that vary over time, the DSM-5 included in its assessment measures section, the Clinician-Rated Dimensions of Psychosis Symptom Severity, an assessment measure that allows quantifying the five core dimensions that define schizophrenia spectrum disorder (hallucinations, delusions, disorganized speech, abnormal psychomotor behavior, and negative symptoms) plus impaired cognition, depression, and mania. Each dimension is rated on a 0 (not present) to 4 (present and severe) scale and can be used for treatment planning, outcomes, and longitudinal follow-up. Catatonia was designated as a separate category in DSM-5 and remains a separate category in DSM-5 TR, that can now be linked to multiple disorders such as schizophrenia, schizoaffective disorder, and mood disorders. ICD-11 now has a similar approach to characterized individual symptoms over time.

SYMPTOMS OF SCHIZOPHRENIA

The descriptive power of Kraepelin dementia praecox and the explanatory power of Bleuler schizophrenia took hold in psychiatry during the first half of the 20th century. By the middle of the century, varying conceptual orientations among psychiatrists led to widely differing applications of the diagnosis of schizophrenia. Schizophrenia was broadly applied, with the diagnosis given to both chronically hospitalized patients with constant hallucinations and bizarre behaviors and independent working people with problems of histrionic behaviors and difficulty making empathic connections with their therapists. With the introduction of new medical therapies to treat the symptoms of depression and psychosis in the 1950s, it became essential to define which symptoms were associated with which illnesses, so that the right treatments could be applied to the right illnesses and treatment responses could be determined.

To apply statistics to the severity of symptoms and treatment responses in psychiatric illnesses required that both symptoms and responses be quantified, and the tool for quantification arose with the generation of rating scales for psychiatric disorders. The first broadly used symptom scale was the Brief Psychiatric Rating Scale (BPRS) from Overall and Gorham, published in 1962. This scale was derived from earlier scales and from the evaluation of hundreds of patients and assessed aspects of psychopathology that were familiar to most clinicians. It was short (its first form consisting of just 16 items), easy to administer, and reliable. Initially intended to provide efficient assessment of treatment response for patients in inpatient settings, its utility led to wide use in measuring treatment responses of severely ill patients across clinical settings. The BPRS was the standard tool for measuring treatment response in psychotic disorders for decades, and it remains widely used in research and as an aid to clinicians treating chronically and severely ill patients.

At about the same time the BPRS was being developed, John Wing and his colleagues were trying to address the poor reliability of psychiatric diagnoses with creation of the PSE. The PSE is a much longer instrument than the BPRS and evaluates 140 signs and symptoms and requires experienced clinicians for reliable administration. Algorithms to facilitate computer-based interpretation of the large bodies of data generated were developed in parallel, with the aim of using the PSE to identify groups of patients united by similar symptom patterns. Despite the time involved in administering the PSE and the large bodies of data created when administered to groups, the PSE was used in both the New York–London project and in the IPSS, and its use helped define the parameters of schizophrenia. Like the BPRS, the PSE was intended to be an instrument applicable across a broad range of psychiatric disorders, but it has its greatest impact on studies of schizophrenia.

Reliable rating scales of symptoms and psychopathology, such as the PSE and BPRS, were essential to the progress made in understanding the treatment and course of schizophrenia and finding the biologic and social correlates of the illness. The authors of the BPRS and the PSE, and the authors of the many rating scales that followed, were all motivated to address particular questions about illness and treatment, and none of them intended to constrain the clinical interview of patients suffering from schizophrenia. But the reliability and utility of these scales and the diagnostic criteria derived from them have nonetheless had the effect of

focusing researchers' and clinicians' attention on the questions asked by the scales and diverting attention from the stories patients have to tell. Kenneth Kendler has reviewed the development of the concept of schizophrenia at length and found that early descriptions included a broad number of symptoms, and more so particular signs, that have been lost in the diagnostic criteria of schizophrenia and so also lost in teaching and routine assessment. The scales, like the brief and reliable contemporary diagnostic criteria psychiatrists, apply, have become the definition of illness in the mind of many mental health clinicians, and this view limits inquiry about the individual experience of patients.

An early application of the PSE was in the WHO's IPSS. The results of the IPSS showed that populations of patients sampled in a range of rural and urban sites around the world all had similar profiles of symptom types, although individual participants displayed widely varying clinical presentations. Across sites the most common symptoms were lack of insight and an inadequate description of problems, suspiciousness, unwillingness to cooperate, ideas of reference, flat affect, persecutory delusions, delusional mood, poor rapport, a range of auditory hallucinations including verbal hallucinations, thought alienation, and gloomy thoughts. Subsequent follow-up studies, other studies conducted across countries, and studies of different cultures within individual countries confirmed that when studied as groups there was a similar overall distribution of symptoms within populations.

By the 1970s the body of data produced through the use of the PSE in large samples led to new efforts to find correlates between the symptoms of the disease and functional outcomes. Strauss, Carpenter, and Bartko made an early attempt to find patterns in the expression of the symptoms of schizophrenia. In their studies, the PSE-rated symptoms of schizophrenia clustered into groups of positive and negative symptoms and into a group of symptoms associated with "disorders of relating." An advantage of the PSE is complexity of patients' experience captured by its number range of symptoms and signs, but as the utility of rating scales for clinical practices, and especially for pharmacology studies became apparent, the BPRS, and later the Positive and Negative Syndrome Scale (PANSS), were adopted as reliable options that were easier to administer and interpret.

By the mid-1980s factor analytic techniques were broadly applied to the assessment of the symptoms of schizophrenia, and separate investigators

found that three dimensions or subsyndromes of schizophrenia could be derived from rating scales. These dimensions were psychotic symptoms (hallucinations and delusions), negative symptoms (e.g., social withdrawal, blunting of affect, interest, and motivation), and disorganization symptoms (disorganization of thought and behavior). A similar clustering of symptoms was found to exist in studies of populations from around the world. Later studies showed that the negative syndrome especially and to a lesser extent the disorganization syndrome showed temporal stability, and that each subsyndrome had its own distinct relationship to demographic factors, cognition, and heritability.

It has become clear that the number of subsyndromes within schizophrenia is defined in part by the number of signs and symptoms measured, so that more thorough ratings with larger numbers of symptoms lead to finding more subsyndromes. Scales or combinations of scales that include more symptoms lead to the reliable derivation of psychotic, negative, disorganization, depression and anxiety, and agitation dimensions. There have been many thousands of patients enrolled in studies using the PANSS conducted across continents and cultures that reliably find these same five factors. The meaning of an individual patient's symptom might vary across cultures but the structure of symptoms within the illness seems remarkably consistent. For the most commonly used rating scales, age, symptom severity, duration of illness, and short-term medication withdrawal do not seem to affect the finding of separate subsyndromes.

This dissection of the syndrome of schizophrenia into subsyndromes will multiply as more and more elaborate assessments of signs, symptoms, and history are completed. As an example, a study that detailed premorbid and prodrome histories along with routine assessments of clinical symptoms found separate factors for educational achievement and premorbid function with unique heritability. More detailed assessment of disorganization symptoms finds subfactors for motor and verbal disorganization, and when a larger number of mood and anxiety questions are asked, mood and anxiety may be split into separate factors. However, symptoms in each subfactor are most highly correlated with the other symptoms in the same class. At this time, the inclusion of additional factors, or the division of the five PANSS factors into separate subfactors, is primarily important for investigators with a narrow focus on therapeutics or neurobiology applied to a particular subfactor—the five-factor model is

a valid and useful way to organize the clinical symptoms that are assessed to make decisions about patient's care.

Psychotic Symptoms

The psychotic symptoms of schizophrenia define schizophrenia for the general public and for many clinicians. They are the obvious and dramatic symptoms of the illness, and for most people, they are what is fascinating and frightening about schizophrenia. Within psychiatry the interest in delusions and hallucinations has overshadowed investigation and treatment of the other facets of the psychopathology of schizophrenia. This emphasis on psychotic symptoms was reinforced with the break from the impressionistic diagnostic scheme of DSM-II to a symptom-based diagnosis in DSM-III, when the diagnosis came to depend in large part on clinicians' ability to recognize the psychotic symptoms considered characteristic of schizophrenia.

It is now clear that there is no particular sign or symptom, not even the most carefully specified kind of hallucination or delusion, which by itself justifies a diagnosis of schizophrenia. It is also clear that a focus on psychotic symptoms to the exclusion of the other signs and symptoms of schizophrenia will ignore significant sources of morbidity and likely exacerbate other forms of psychopathology and disability. Nonetheless, psychotic symptoms, because of their unique nature and easy identification, aid assignment of diagnoses and serve as markers of treatment response, and these symptoms will remain at the core of concepts about the nature of schizophrenia.

The use of the term psychotic in relation to symptoms should be restricted to hallucinations and delusions. In the past, symptoms of inappropriate affect, purposeless activity, and disorganization of speech and behavior were also considered psychotic symptoms, but it is clear these are better considered in the separate disorganization dimension. Psychotic symptoms are also not synonymous with the term "positive symptoms," which has traditionally included symptoms such as incoherence and loosening of associations, or motor restlessness, properly assigned to disorganization and agitation factors. Similarly, the symptoms in the original PANSS "Positive" subscale are a composite of psychotic, disorganization, and agitation factors. There is no reason to use the original PANSS positive subscale.

The responsiveness of psychotic symptoms to antipsychotic medications has led to unforeseen costs in attempts to effectively treat schizophrenia. The focus on psychotic symptoms of schizophrenia that arose with the adoption of the diagnostic scheme of Kurt Schneider and its emphasis on "first-rank" symptoms of psychosis (Table 12.2–1) became prominent in the United States at about the same time the demonstrable benefits of antipsychotic medications became clear to most practicing psychiatrists. This evolved into a seemingly reasonable treatment approach that focused on maximizing antipsychotic doses to minimize or eliminate the psychotic symptoms that were judged to define the illness. The costs of this approach were not apparent to most clinicians, and only in the 1970s and 1980s were there psychiatrists who suggested that high-dose medication treatments might impose burdens such as secondary negative symptoms, dyskinesias, and increased rates of medical complications that were not always offset by the benefits achieved with decreased psychosis.

Hallucinations. The earliest descriptions of schizophrenia did not share the contemporary emphasis on psychotic symptoms, but there was certainly clear awareness of the burden hallucinations impose. Bleuler considered hallucinations accessory symptoms but in his *Textbook of Psychiatry* (1924), he evoked the disruption that hallucinations must impose on the inner life of those afflicted with schizophrenia.

> The patients hear blowing, roaring, humming, rattling, shooting, thundering, music, crying and laughing, but above all whispering, speaking, calling; they see individual things, landscapes, animals, people and all sorts of impossible figures; they smell and taste all sorts of pleasant and unpleasant things; they touch things, animals and people and are struck by rain drops, fire, and bullets, they feel all the tortures and perhaps all the pleasant things also that our bodily sensations can transmit.

Although an exclusive or predominant focus on the psychotic symptoms of schizophrenia is not appropriate, hallucinations do hold a special place in the experience of people with schizophrenia. Perceptions that can cause people to "feel all the tortures and perhaps all the pleasant things" will certainly influence behavior, and what seems incomprehensible in schizophrenia may become understandable when a patient's experiences with hallucinations are revealed. Hallucinations also drive some of the understanding of illness that patients, their families, and their physicians share or do not share. Families and health care providers may not have

the overwhelming experience of distorted perception that people with schizophrenia often have, but families and providers have dreams and vivid perceptions, and these experiences can help them imagine something of what happens with patients. Alternatively, families may chide patients for listening to people who are not there, and physicians will hurry through cursory encounters with patients who seem to pay more attention to voices of intangible people than they do to the doctor in front of them.

Many of Kurt Schneider's first-rank symptoms, proposed to specify a diagnosis schizophrenia—hearing one's thoughts spoken aloud, voices referring to oneself, a running commentary on the patient's thoughts or behaviors, a sense of being the recipient of externally imposed sensations—are hallucinations and were initially considered to make a diagnosis of schizophrenia likely in the absence of identifiable brain pathology. In fact, hallucinations are common in other psychiatric illnesses, and their presence appears to be an indicator of overall illness severity across mood, anxiety, personality, and eating disorders. The first-rank symptoms have been found to vary from a minority of patients to very high rates in both schizophrenia and other psychiatric disorders, depending on the population being studied. Although there is no particular unique feature of hallucinations in schizophrenia there is typically an earlier age of onset and greater chronicity than found in other psychiatric illnesses.

Hallucinations and other psychotic symptoms are not rare in the general population. A meta-analysis put the rate of "psychosis-like experiences" in the general population slightly greater than 7%, and in a large nonclinical sample comprising populations from around the world hallucinations were about four times more common than delusions. In the general population symptoms of anxiety are particularly associated with hallucinations, and auditory hallucinations predominate. Not surprisingly substance abuse is also associated with all kinds of hallucinations, but a particular association between substance abuse and auditory hallucinations is not found. Conceiving hallucinations as a discrete manifestation of psychopathology that establishes the presence of a mental illness might be a convenient assumption that provides security to diagnosticians' but does not in fact reflect the nature of the experience. Younger age, living in an urban environment, low income, less education, unemployment, female gender, and being single are all associated with increased rates of hallucinations. Most of these demographic factors seem similar to those of people who will develop schizophrenia. Also similar is the finding that in the general

population hallucinations predict the presence of delusions, and that acute stressors increase the likelihood of hallucinations. It has been clear for decades that hallucinations do not confirm or exclude schizophrenia versus any other psychiatric diagnosis, and the presence of hallucinations does not by itself confirm psychiatric illness.

Since the time of Karl Jaspers there has been a view that hallucinations that seem to arise from outside the body are “true” hallucinations, while hallucinations that seem to arise inside the body are pseudo-hallucinations; that this is a distortion of Jaspers’ actual discussion has not affected views. There is a similar view among some that good insight into hallucinations means that the perceptions are not really hallucinations. Neither of these distinctions, nor the volume, number of voices heard, or content of the hallucinations, has diagnostic significance or demographic correlates. Many patients will describe auditory hallucinations that arise both inside and outside their heads or will develop insight into the nature of their hallucinations only after decades of full belief in their external reality. When considering patients, these distinctions should not be used to make a diagnosis or generate a treatment plan.

There is more information about the nature of psychosis than any other symptoms of schizophrenia, but even in the study of hallucinations, there are large gaps in the current knowledge. Most investigations focus on the presence or absence of a symptom, and when there is a more detailed inquiry, it is typically limited to questions about frequency. There is literature dealing with questions of when hallucinations arise, what provokes them, how patients cope with them, or what other perceptions or thoughts are associated with hallucinations, but the answers to these questions arise from a surprisingly limited number of studies.

Studies that examine the prevalence of hallucinations across cultures come up with similar rank orders, though the exact prevalence of each type of hallucination in each setting varies. Auditory hallucinations are the most common type, followed by visual hallucinations, and tactile (or *haptic*), olfactory, and gustatory hallucinations are less common. Visceral and other deep tissue hallucinations (*cenesthetic* hallucinations) can provoke odd descriptions that are inconsistent with the internal sensory apparatus, with complaints of burning in the brain or movement of the thoracic organs to new positions, and are likely the least common type of hallucination in schizophrenia. There has been an emphasis in clinical assessment and research in schizophrenia on auditory hallucinations that

have obscured the frequent experience of hallucinations across multiple sensory modalities. A study of a large and well-characterized population in the Netherlands found that about two-thirds of patients had the experience of hallucinations in more than one sensory modality, and 25% had experiences in three or more senses.

AUDITORY HALLUCINATIONS. In schizophrenia, auditory hallucinations are clearly the most common type of hallucination. This may not always have been the case; a century ago, visual hallucinations were more common than auditory hallucinations in London, and visual hallucinations have been decreasing in frequency, and auditory hallucinations have been increasing in frequency over the past century in Vienna. Auditory hallucinations are relatively less common, and visual hallucinations are relatively more common in African, Near Eastern, and some Asian populations than in Western societies. Nonetheless, evidence from the IPSS and other sources confirms that the most prevalent type of hallucination and the most common symptom of psychosis in schizophrenia is auditory hallucinations.

In keeping with their prevalence, auditory hallucinations are the best-characterized of the psychotic symptoms. The IPSS studies suggest that internationally, more than 70% of people with schizophrenia have auditory hallucinations, and that percentage is probably higher in industrialized societies. As with many symptoms, careful questioning in prospective studies is associated with a higher rate of reporting—for auditory hallucinations leading to a prevalence of 98% in one report.

Patients generally believe that their hallucinations are real manifestations of someone, somewhere, talking to them or transmitting a voice or voices. Patients frequently attempt to test the reality of their voices, but patients' tests often rely on attempts to confirm that the voices truly know what the patient is thinking, doing, or planning. Since the voices inevitably do manage to know such things, their reality is proved to the patient. Even when voices fail their experiments (e.g., failing to accurately predict what will be served for supper) a delusional explanation may be generated that confirms the reality of an external cause. Ideas of reference and other delusions further reinforce these interpretations of the hallucinations. Although there have been decades of speculation about why the content of auditory hallucinations is so often threatening or

demeaning, there is at present no clear explanation for the generally negative content of the auditory hallucinations.

Verbal auditory hallucinations, both in words and in prosody, are generally derogatory or threatening and often quite profane. Patients will hear expletives, threats, demeaning personal comments, and accusations of vile thoughts or behaviors; this kind of negative content comes more commonly from male voices. Patients are often distressed and frightened, or angered by these experiences, and can have a complicated sense of guilt, depression, or belligerence in response. Patients typically feel less control over the experience of negative hallucinations than they do over benign or positive hallucinations, and severity of delusions and negative symptoms can further inhibit coping with hallucinations. In cultures that have socially accepted explanations for the experience of auditory hallucinations, the affective tone appears more benign, and there is less distress associated with the experience of hallucinations.

Emotional experiences, often sadness or apprehension, often precede hallucinations, but patients also often experience somatic symptoms of anxiety, fear, or anger, before the recurrence of hallucinations. Social stressors, physical illness, insomnia, and chronic pain can all increase the frequency of hallucinations and the intrusiveness and dysphoria associated with the experience. Hallucinations can be unremitting and last from waking until bedtime or can come in irregular, infrequent periods of seconds or minutes a few times a month. Although it is not a rule, hallucinations are generally less frequent and shorter in duration in the morning and become progressively more frequent and more extended in duration through the day until peaking before retiring for the night. It is common that people with schizophrenia have some period during their illness when their auditory hallucinations are present for the majority of the day.

Voices are the most common kind of hallucination and tend to be clear and understood, but unintelligible sounds of whispers or distant conversations are not rare. Patients can also hear footsteps, telephones ringing, the sounds of pebbles hitting a window, helicopters, buzzing, clicking, and musical phenomena that range from single notes present throughout the day to complex passages of orchestral music. Bleuler described "*extracampine* hallucinations" in which the perception was received by the patient outside the sensory apparatus—for example, a sound is appreciated through the knee.

When it is voices that are heard, single words are probably the most common. Although there is an enormous range in the number of voices that are heard by different patients, the mean number is estimated to be 3. The gender of the speaker can usually be identified. The person afflicted often hears voices that are interpreted as coming from a person who has more social status than the patient. Younger patients will tend to hear somewhat younger voices, while older patients hear somewhat older voices. The person afflicted by them often reliably assesses the location, loudness, and clarity of the voices, and in general, persistent auditory hallucinations will eventually lead the patient to settle on identities for their voices.

With the passage of time, most patients will experience a decrease in the frequency of their hallucinations or a change in the nature of their hallucinatory experience. Where hallucinations are initially very upsetting, provoking anger or panic, after the first stages of illness have subsided patients may generate coping strategies through a process of trial and error over a period of years and can come to mitigate the effects of hallucinations on their lives. Simple strategies such as yelling at the voices can sometimes decrease or stop the experience, though clinicians and families may see this as a distressing sign of deterioration. Less disturbing to people around the patient, singing, humming, or listening to music can block the experience, and sometimes shifts in posture or talking to someone else can help. Unfortunately for those afflicted the only available regular contact with the voices of other people may be online or by television, and for some, these can reliably exacerbate hallucinations. After years or decades, patients often start to question the content of their hallucinations and if their questions do not lead to insight, at least they sometimes provoke awareness that the threats or predictions rarely come true. Some patients can gain limited control of their hallucinations and can shift the prosody or content of the discussion, and there is a sizable minority of patients who can regularly start and stop their hallucinations at least some of the time. Religious themes are common in auditory hallucinations, and while they commonly start with a focus on the sins of the patient, with time there can be a conversion to a view of the patient having a special relationship with their god or gods, or that the individual might have some special message to spread or task to perform.

As a person gets used to the presence of their hallucinatory voice or voices, they can become companions, and given the frequent social

isolation that is experienced in schizophrenia, this companionship can be welcome. The voices can take on the role of a guide through daily life for the person with schizophrenia, often in middle age or later so that the hallucinations will tell a person what to buy at the grocery store, how to structure their day, sometimes even how to respond in social interactions. The voices might even take on a moral role for the patient, suggesting the emotional consequences of particular behaviors or acting as a conscience that spurs generosity or remorse in response to the patient's actions. Although some people with schizophrenia will, with time, develop a good insight into the nature of their hallucinations, despite ongoing delusions or negative symptoms, other patients with predominately positive symptoms or residual schizophrenia will go through long periods with few obvious symptoms and no hallucinations but retain a full delusional interpretation of their past hallucinatory experiences.

COMMAND AUDITORY VERBAL HALLUCINATIONS. Sensational violent crimes committed by people with severe mental illnesses have led to an increased popular and clinical focus on the phenomenon of command verbal auditory hallucinations. Command auditory verbal hallucinations are very common, present at some phase of the illness for at least one-third and maybe as many as three-quarters of patients with schizophrenia; there are estimates that the lifetime prevalence of command hallucinations approaches the prevalence of auditory hallucinations as a whole. The emphasis on command hallucinations in clinical assessments of risk is unfortunate, because other clinical symptoms and features of the illness history that contribute more to the risk of violence are neglected once a patient's experience, or lack of experience, with command hallucinations is elicited in the clinical interview. There is a consensus that patients are more likely to comply with command hallucinations if (1) the voice is believed to be a real communication from someone else, especially if there is an identity for that person, (2) voices have benevolent intentions toward the patient or the action described will help the patient, (3) the voice has some omnipotence or other power greater than the patient, (4) there are adverse consequences to the patient for not complying, and (5) the command is for a nonviolent action. Patients with few coping strategies and a sense that the hallucinations are beyond their control are more likely to act on the commands. Trait anger and impulsivity also increase the risks of compliance. A patient's delusional

structure in relation to command hallucinations is important–without some belief that a command should be followed, there is little reason for someone to act on the command.

VISUAL HALLUCINATIONS. Visual hallucinations are less common than auditory hallucinations in schizophrenia, but they are not rare. Estimates of the prevalence of visual hallucinations do not generally exceed 55%, and an estimate of about 40% of people with schizophrenia having visual hallucinations at some point in their illness appears consistent with the available evidence. As is the case with other psychiatric symptoms, careful investigation can sometimes elicit a history of visual hallucinations when casual questioning fails to detect their presence. Up to two-thirds of those who have auditory hallucinations will also have visual hallucinations, but it is relatively uncommon for someone with schizophrenia to have visual hallucinations in the absence of auditory hallucinations. Visual hallucinations have been suggested to predict a more severe illness, and there are some data to support this contention. It may be that patients with predominately psychotic symptoms are less likely to have visual hallucinations than patients with significant primary negative symptoms or disorganizations symptoms.

There is a broad range of visual experiences that afflict people with schizophrenia. The most commonly reported visual hallucinations are formed images of animate objects, people, or parts of people (especially heads and faces), religious images, animals, and fantastic creatures that may be similar to images in movies or television. Inanimate objects are less common, but flashes of light, streaks of color, or grids or lines in the visual field may also be described. Images can be in color or black or white, and hallucinations in only shades of white have been described. Visual hallucinations are generally more discrete and more limited in duration than auditory hallucinations, but there are patients who will experience visual hallucinations throughout the course of a day. Some particularly unfortunate people will have fluctuating periods of dramatic distortions of the world itself; the ground beneath someone will seem to be at angles that are inconsistent with the patient's proprioceptive awareness, sidewalks will briefly appear to point into the air, and walls will appear or disappear in buildings. Lilliputian hallucinations—hallucinations of small people, frequently busy attending to some task—are generally considered a sign of an encephalopathy but they are sometimes present

in schizophrenia. In vision, the continuum with illusions (distortions of objects seen in the environment) is more obvious than it is with auditory perceptions. Shadows that seem like people or animals but reveal themselves as only shadows with closer inspection, objects that change size or shape, outlines of objects that seem to float just outside the object itself, and objects that have acquired some transparency are all kinds of visual distortions that are reported.

The content of auditory and visual hallucinations is often dependent on the culture of the person experiencing hallucinations, but there seem to be some culturally appropriate visual hallucinations in non-Western societies that have only parallels to religious-themed hallucinations in the West. Even in cases of unequivocal schizophrenia, in non-Western societies, there can be a social acceptance that the hallucinatory experience is an extension of a commonly shared reality. It seems plausible, though not demonstrated, that cultural acceptability might influence the sensory mode of hallucinations experienced (e.g., visual instead of auditory), as well as the content of the hallucinations.

OLFACTORY, GUSTATORY, TACTILE, AND VISCERAL HALLUCINATIONS. Tactile hallucinations are present in a range of 15% to 25% of people with schizophrenia, with no clear pattern of variation across cultures. Particular tactile hallucinations, such as the sense of bugs crawling on or under the skin (*formication*), are found in a variety of mental illnesses and encephalopathies. Like auditory and visual hallucinations, the tactile hallucinations of schizophrenia can take on a broad variety of forms. Feelings of being touched, burned, and cut are common, and there are surprising numbers of patients who will feel as though they are subject to a kind of sexual assault, inflicted on their genitals or anus by unseen (and sometimes seen) entities. Less localized sensations of electric shocks or tearing or stabbing in the limbs and torso also occur. Patients with tactile hallucinations can also have a physical sense that somehow other people or magical beings enter into and exit their bodies, and while they can communicate that this sense is very distressing, articulating what it actually feels like may be very difficult.

Olfactory and gustatory hallucinations tend to be reported by a small minority of patients, with olfactory hallucinations the more common of the two types. As with other kinds of hallucinations the experience tends to be unpleasant for most patients, with the smells of rotting meat, garbage, and

feces common, and the taste of blood or metal frequently described. Often tastes and smells will go together in an unpleasant combination. Visceral hallucinations are rarely noted in contemporary studies of hallucinations; whether this is due to a change in the nature of schizophrenia or a failure to fully investigate the experience of our patients is not known.

Delusions. Like hallucinations, delusions hold a special place in both the medical and popular perception of schizophrenia, with a view that delusions are a discrete category of thought that is generated and maintained through unique mechanisms and consisting of ideas that are inaccessible to normal reason. A standard definition of delusions is frequently reduced to calling them “fixed false beliefs.” In the glossary for DSM-5, delusions are defined as “A false belief based on incorrect inference about external reality that is firmly held despite what almost everyone else believes and despite what constitutes incontrovertible and obvious proof or evidence to the contrary” and “not ordinarily accepted by other members of the person’s culture or subculture.” This emphasis on falsity and imperviousness to argument owes its origin in large part to the influence of the German psychiatrist and philosopher Karl Jaspers. In *General Psychopathology,* Jaspers wrote that delusions were “held with an extraordinary conviction, with an incomparable, subjective certainty,” that they were “impervious to other experiences and counter-argument,” and that their content is “impossible.” This description makes a delusion sound like something entirely unlike ideas generally held and understood, which we like to believe are arrived at through considered investigation and reasoned thought. Jaspers further argued that “delusions proper” arose from a unique kind of knowing or experiencing the world—not from the exercise of faulty judgment about personal experience but from a novel sort of experience that intrudes itself into the mind, a “direct experience of meaning.” This exists on no continuum with the experience of the general population, who derive meaning for their experiences from context, history, emotion, cognitive style, and state of mind. However, the variability in the type and character of delusions presented by patients has confronted the notion that delusions arise de novo, immutable, and impervious to reason or experience. To deal with this incompatibility between observation and theory, the awkward idea of “delusion-like-ideas” has been introduced.

Like hallucinations, delusions are not experiences that happen only to the mentally ill. When a representative sample of the German population was asked about their beliefs with a questionnaire, a quarter reported that they had special abilities or powers, and a third endorsed a belief in telepathy. Experiences as diverse as childhood trauma and sleep deprivation can provoke delusions in nonclinical populations, and as is the case in people with schizophrenia, the content is often paranoid. Reflection on daily life shows that many people clinicians know outside of clinical settings, and clinicians themselves frequently hold ideas that have no grounding in a shared external reality.

Furthermore, the delusions that are held by persons with schizophrenia are frequently quite flexible, and while argumentative confrontation accomplishes little, life circumstances or shifting attention can change delusions in dramatic ways. There are patients who will cling tenaciously to the idea that they have been persecuted by agents of a foreign government or who have had chips implanted in their brains by aliens from space, but every day around the world, other patients will check out fantastic ideas with family, friends, nursing staff, and doctors, and happily accept the assurance that their odd concerns are unfounded.

When delusions are examined as they exist in schizophrenia, there is a clear continuum with the overvalued ideas everyone is prone to. Delusions can vary from fleeting concerns about personal meanings taken from the way a television reporter intoned a particular word to a preoccupation with ideas about how giant corporations and governments are organized to persecute the individual with schizophrenia. The delusions found in schizophrenia frequently are different from the overinvested ideas that almost everyone has, but the differences do not seem to arise from a novel process that is found only in schizophrenia. Contrary to Jaspers' formulation, delusions in schizophrenia often develop from normal cognitions, and the path by which delusions are developed often seems quite clear to clinicians when the circumstances and state of mind of the patient are described. Delusions encountered in clinical settings can be presented as impressions that quickly abate, and it is a common experience for clinicians to inquire about a delusional concern previously reported by a patient, only to find that the patient has dismissed their old idea, as though it is of no consequence, and now has new preoccupations. Instead of arising from a new kind of perception, delusions often arise from social stressors, and threats to self-esteem

seem particularly prone to provoke persecutory or grandiose delusions in response.

What does seem to distinguish delusions in schizophrenia is analogous to what distinguishes schizophrenia itself: the frequency, severity of the impact of the symptom, and the pattern in relation to other symptoms, instead of any unique or pathognomonic content or structure. The number of delusional beliefs, the strength of preoccupation with delusions, and the amount of distress they cause for patients all seem to distinguish delusions in schizophrenia. Although delusions in schizophrenia are not always "firmly sustained," there is in general a stronger conviction that the delusional belief is accurate despite contradictory views from others. Delusions are common in many psychiatric syndromes but tend to be held more strongly, preoccupy more time, and are more pervasive in their influence on patient cognition than is found in other psychiatric illnesses. Most people with schizophrenia will have delusions, and the percentage of people who will experience clinically significant delusions may exceed 70%. In Martin Harrow's long-term follow-up studies, 25% of patients had delusions at all assessments over a 20-year period. As is the case with hallucinations, many patients will moderate the effects of delusions on their lives, often by titrating amounts of social contact. This increasing engagement can decrease their preoccupation, although when the delusions center on concerns of persecution this relief may not be available. For most patients, the presence of one delusion predicts the presence of other delusions.

CONTENT OF DELUSIONS. It is an unfortunate feature of delusions in schizophrenia that the focus of the delusion is so often based on fears of persecution or threats to a person's safety. People with schizophrenia are more likely than people in the general population to fear that people look at them in an unusual or odd way, to believe that they are being watched or being harmed, or that their feelings and actions are not under their control. In schizophrenia, most delusions will fall into some broad patterns of content. The most common delusions in schizophrenia are delusions of persecution, which are estimated to lead to about half of help-seeking encounters, and are endorsed by up to 80% of inpatients. These persecutory fears can range from transient doubts about the intentions of strangers around them to profound convictions that charitable organizations or family members are plotting to have the patient tortured

or killed. These may arise from misinterpretation of social interactions or social events or from misattribution of intent on the part of others.

A sizable literature has arisen around the formation of persecutory delusions. Patients with paranoia tend to have a worried thinking style, sleep disturbance, and anomalous internal experiences. They have increased interpersonal sensitivity and negative beliefs about themselves and are influenced by life experiences and social circumstances to view the world as threatening. Living in urban environments and co-occurring substance abuse seem to exacerbate the problem.

Other highly prevalent delusions, such as delusions of bodily control and of having one's thoughts audible to others, are also delusions that can lead to persistent dysphoria. *Delusions of reference* refer to delusions in which neutral stimuli or events or people take on a particular significance in reference to the person who experiences the delusions; in the DSM-5 glossary, they are "a delusion in which events, objects, or other persons in one's immediate environment have a particular and unusual significance." There is usually a persecutory slant to these delusions, but there may also be self-aggrandizing or religious meaning derived from them. In DSM-5 TR, they are considered distinct from *ideas of reference,* "feeling that causal incidents and external events have a particular and unusual meaning that is specific to the person." As already discussed, delusional ideas lie on a continuum with normal beliefs, so the distinction between delusions of reference and ideas of reference seems of little value in clinical settings and is a source of unreliability in assessments for research purposes. As important, "delusions of reference" and "ideas of reference" are frequently treated as synonyms by clinicians. Other common delusions encountered in schizophrenia, whose names do not clearly define their meaning, include *thought broadcasting* and *thought insertion.* These refer to a delusion that the afflicted person's thoughts are audible to others and a delusion that certain thoughts are not the person's own but are inserted into the deluded person's mind, respectively. Also common are grandiose ideas of personal power or significance and religious themes, which can be persecutory as often as grandiose in their content. There are a series of eponymous delusions, most commonly referring to delusions that focus on questions of the identity of the deluded person or those around them or referring to a particular impossible state of existence. When first identified, each of these eponymous delusions was supposed to define a particular

diagnostic association with schizophrenia, but since they can be found in almost any medical or psychiatric condition where delusions arise, there is little value in knowing each particular name.

A type of delusion that holds special significance in schizophrenia is the concept of “bizarre delusions.” In DSM-III and DSM-IV, the presence of bizarre delusions was deemed important enough that its existence, in isolation from other characteristic symptoms, was sufficient to meet Criteria A for schizophrenia. Like the idea that auditory verbal hallucinations of voices conversing or commenting, the significance of these delusions arose from the tradition of Schneider’s first-rank symptoms. Bizarre delusions are those that are considered implausible by people who share the patient’s culture, and this is generally taken to mean something that is judged physically impossible. There have been many criticisms of the concept of bizarre delusions, the most prominent being that when assessing presence or absence, the interrater reliability varies from fair to very low, even among trained raters. Bizarre delusions are not a universal finding and are not pathognomonic of any disorder, but they are more common in schizophrenia than in any other psychiatric illness. However, when included in diagnostic criteria, they do not affect the reliability of the diagnosis of schizophrenia versus other illnesses with psychosis, and the special status of bizarre delusions was dropped in DSM-5.

Although the most common theme in the delusions found in schizophrenia is persecutory, it might be that the most common inciting event for the formation of a delusion is the need to explain the experience of auditory hallucinations. The validity of the hallucinatory experience seems self-evident to most patients, but there is frequently considerable difficulty generating any clearly communicated idea about how the sounds of someone else’s voice is perceived by the patient and the patient alone. A common resolution is for the patient to invoke a fantastic explanation about science and technology and conspiracies; in less technologically focused societies, magic and witchcraft and religion are the most common explanations. In both settings, the explanations fall into culturally validated explanations for otherwise incomprehensible phenomena. Complex and persistent hallucinations are associated with complex and systematized delusions, where contradictions and conflicts with the reality of a patient’s situation have ready answers in the form of ever more elaborate and internally consistent delusions. In these circumstances, the power of a

delusional idea can be impressive and sufficient to make patients discount widely shared knowledge possessed for most of their lives. Systematized delusions are most common in middle age, and this may be a reflection of how much time it takes after the onset of schizophrenia to accommodate a new reality of the illness. Other hallucinatory experiences and other severe symptoms of schizophrenia can also provoke delusional interpretations from patients. Olfactory and gustatory hallucinations in particular may predict more severe delusions.

As noted earlier, careful application of detailed assessments can lead to hallucinations and delusions being considered separate subfactors in the general class of psychotic symptoms. Outside of research settings, the separation seems to have little utility. Hallucinations and delusions together remain the most treatable cluster of symptoms in schizophrenia, and the severity and change in one symptom class are highly correlated with change in the other.

Potentially less distressing themes, such as grandiose and religious content in delusions, are experienced by half or fewer people with schizophrenia. It seems that awareness of the frequent occurrence of grandiose delusions in schizophrenia is being lost in clinical settings; like the tendency in the past to diagnose anyone experiencing hallucinations with schizophrenia, it has become common to diagnose everyone with grandiose delusions with bipolar disorder, disregarding other diagnostic discriminators. It can be generally expected that delusions of persecution or religious content will have the most effect on a patient's behavior, although the response of each patient to each thought is dependent on that person and that situation.

DELUSIONS AND COGNITION. There does appear to be a route to delusions that can be understood outside the idiosyncratic experience of the patient who experiences a "direct experience of meaning." Although the ultimate cognitive deficits underlying delusions remain the subject of conjecture, it is clear that contrary to Jasper's position, there are reasoning errors that accompany delusion formation in schizophrenia. When tested, people with schizophrenia who have delusions will make decisions based on less information than people with schizophrenia, and based on less information than people in normal populations. Despite being poorly supported, these judgments are held in greater confidence than the decisions of control groups. There is a cognitive stance that externalizes causal attribution for

events and judges people and neutral stimuli as hostile or threatening. It is not the case that people with schizophrenia and delusions are incapable of making reasoned judgments because when patients are instructed to hold on to their decision-making until all information is presented, they tend to make the same decisions as controls. This “rush to judgment” is a trait characteristic that does not disappear when delusions remit, and in schizophrenia, it may for a common cause for the formation of delusions.

Negative Symptoms

Negative symptoms remain under-recognized and underappreciated as a cause of disability in schizophrenia. It could be claimed that negative symptoms are the most important clinical symptoms in schizophrenia because the severity of negative symptoms predicts short-term and long-term disability and quality of life, better than the severity of psychotic or disorganization symptoms. Negative symptoms appear to be the most significant predictor of social function and are more stable across time than positive and disorganization symptoms. Negative symptoms “represent a loss or diminution of normal functions” and stand in contrast to positive symptoms where there are perceptions and cognitions and behaviors added to normal mental functions.

In the original conceptions of schizophrenia, negative symptoms held a more prominent place. In *Dementia Praecox and Paraphrenia,* Kraepelin remarked on “emotional dullness” and related it to “the loss of interest, the loss of inner sympathy, with the giving way of those emotional main-springs which move us to exert our mental powers, to accomplish our tasks, to follow trains of thought.” For Bleuler “‘emotional deterioration’ stands at the forefront of the clinical picture.” Kurt Schneider appreciated the emotional withdrawal and lack of empathy that clinicians frequently experienced in dealing with patients with schizophrenia but did not include these disturbances in his characteristic symptoms of schizophrenia. Following Schneider, the emphasis on reducing or eliminating hallucinations and delusions as the primary goal in the treatment of schizophrenia led to the under-recognition and undertreatment of negative symptoms, and that lack of recognition and treatment persists to the present.

The publication of DSM-III did little to change the emphasis on positive symptoms. The only acknowledgment of negative symptoms came in a reference to blunted or flat affect, which could elevate a formal thought

disorder to status of a symptom when they occurred together. But the accumulating research of John Strauss and William Carpenter, T. J. Crow, Nancy Andreasen, and others through the 1970s and 1980s led to an acknowledgment of the role of negative symptoms in schizophrenia, and flat affect was added to the diagnostic criteria for schizophrenia in DSM-III-R. In the DSM-5 TR diagnostic criteria, negative symptoms manifest in "diminished emotional expression or avolition" to constitute one of the characteristic signs or symptoms necessary for fulfilling Criteria A for the diagnosis of schizophrenia. Adding negative symptoms to the diagnostic criteria in the DSM has not increased the incidence of schizophrenia, an indirect confirmation that these symptoms have been present but unrecognized throughout the period of modern diagnostic criteria.

The two-syndrome concept as formulated by T. J. Crow was especially important in spurring research into the nature of negative symptoms. Crow's formulation of two separate dimensions of psychopathology, with a treatment-responsive set of positive symptoms and a less-responsive and potentially irreversible set of negative symptoms tied to demonstrable neuropathology, led to the generation of testable hypotheses and research efforts that continue to be active to this day. These investigations were facilitated by the creation of reliable and valid rating scales that extended a focus on negative, as well as positive, symptoms, with the Scale for the Assessment of Negative Symptoms (SANS) and the Scale for the Assessment of Positive Symptoms (SAPS) of Nancy Andreasen, and later the PANSS as the most important of these new tools. It would be shown that the groupings of symptoms into negative and positive subsyndromes in the SAPS, SANS, and PANSS, did not reflect the reality of the five different subsyndromes—psychotic, disorganization, negative, mood and anxiety, and agitation—but this does not diminish the creative efforts that led to these scales or importance of these scales for research. In fact, it was only through careful analysis of the structure of symptoms in these scales that a more accurate characterization of the phenomenology of schizophrenia was possible.

Negative symptoms do not exist only in schizophrenia or only in psychiatric illness. A full range of negative symptoms are seen in people who have had brain injuries, and mild expression of these symptoms is seen in 5% to 10% of the population who do not meet criteria for a psychiatric illness. A significant negative syndrome does seem to be much more common in schizophrenia than in other psychiatric diagnoses,

including in comparison with mood disorders, and in psychiatric illnesses the pattern of multiple enduring negative symptoms not due to medication or social effects appears most often in schizophrenia. In chronic populations about half the patients will have at least one overt negative symptom. In Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE), 40% of patients had significant negative symptoms, and of those, only one-half had significant positive symptoms. Although our diagnostic schemes are tied firmly to psychotic and disorganization symptoms, negative symptoms may better distinguish schizophrenia from other psychiatric syndromes, and it appears that negative symptoms are most reliably associated with outcome in schizophrenia.

There is a range of demographic, treatment, and symptom variables associated with the presence of significant negative symptoms. These include male gender, poor premorbid education and vocational function, earlier onset of illness, longer duration of untreated illness, a small or absent social network, and a lower likelihood of romantic relationships. Negative symptoms can, in some patients, predate the prodrome, and presence at onset predicts persistence. There is a reciprocal relationship with affective symptoms, where more prominent affective symptoms are associated with a milder severity of negative symptoms.

It is possible to conceive that any function of the mind might be lost, and it seems that the range of negative symptoms could be vast. In patient populations, the number of negative symptoms is fairly circumscribed. Many functions of the kind assessed with cognitive testing are impaired in schizophrenia, but except for deficits in recognition of emotion, these functions are generally not included in the negative symptoms. There is a modest but consistent correlation between negative symptoms and cognition, but neither is well explained by the other, and they should be considered separate domains of psychopathology. Importantly, the kinds of function lost in negative symptoms of schizophrenia have been consistent in studies conducted at various times in various sites around the world.

There is a weak but consistent relationship between levels of negative symptoms and levels of disorganization symptoms in populations with both kinds of symptoms. In both groups of symptoms, there is a greater increase in familial risk than is seen for psychotic symptoms. There is a greater concordance in monozygotic twins for negative versus psychotic symptoms, and there is an overall increase in negative symptoms in the

relatives of patients with negative symptoms. Negative symptoms have also been found to correlate with measures of neuropathology, especially those measures of frontal lobe function or the volume of cerebral tissue.

Table 12.2–2.
Symptoms Assessed in the Brief Negative Symptom Scale

1. Intensity pleasure during activities
2. Frequency pleasurable activities
3. Intensity expected pleasure future activities
4. Lack of normal distress
5. Asociality: Behavior
6. Asociality: Inernal experience
7. Avolition: Behavior
8. Avolition: Internal experience
9. Facial expression
10. Vocal expression
11. Expressive gestures
12. Quantity of speech
13. Spontaneous elaboration

Categories of Negative Symptoms. The MATRICS consensus conference on negative symptoms, convened under the auspices of the National Institutes of Mental Health (NIMH) in 2005, suggested that there are five general categories of negative symptoms: avolition, anhedonia, social withdrawal (asociality), affective blunting, and alogia. New rating scales were developed to more carefully assess these categories, in the Clinical Assessment Interview for Negative Symptoms (CAINS) and the Brief Negative Symptom Scale (BNSS) (Table 12.2–2); the BNSS was designed for both research and clinical settings, and might be useful for clinicians who deal with large numbers of patients with psychotic disorders.

Multiple exploratory factor analytic studies have found negative symptoms to be subdivided into two main groups–avolition symptoms, with avolition, anhedonia, and asociality, and the affective blunting symptoms, including affective blunting and alogia. These two groups are the basis for the inclusion of avolition and affective blunting in DSM-5 TR as the representative negative symptoms in Criteria A. The first of these subdivisions—the avolition group—is assessed with interview, while

affective blunting and alogia are signs observed by the clinician. This division of negative symptoms into disturbances of volition and displayed social communication, while conceptually useful for clinicians, has been shown by Gregory Strauss and colleagues to be less accurate than considering each of the five categories of negative symptoms as discrete; at present, this difference is most important for investigators examining the underlying biology of negative symptoms.

The most common negative symptoms are *avolition* and *anhedonia.* Avolition is the loss of will or drive (in neurology sometimes referred to as *abulia*). In psychiatry, the loss of will or drive is sometimes considered to be a manifestation of anhedonia, but in fact, these refer to separate kinds of pathology. Avolition is similar to apathy, and these are considered closely related, with avolition identifying a deficit in the ability to initiate action and apathy a loss of concern for an idea or task. The definition of avolition in the DSM-5 glossary is “an inability to initiate and persist in goal-directed activities” and specifies subsequent deficits in work, intellectual pursuits, and self-care as resulting from avolition. Avolition seems associated with deficits in grooming and hygiene, and it seriously impairs educational and vocational progress. Although often overlooked, this loss of will or drive is the most significant driver of the disability associated with negative symptoms.

Anhedonia is a loss of the ability to find or derive pleasure from experiences, activities, or relationships, and is likely the most persistent of the negative symptoms. In DSM-5, anhedonia is “lack of enjoyment from, engagement in, or energy for life’s experiences; deficits in the capacity to feel pleasure and take interest in things.” Estimates of the prevalence of anhedonia vary widely, but probably half of patients experience considerable anhedonia. Although present in depressive disorders, when anhedonia is present as part of a negative syndrome it is not a manifestation of depression. Evidence available at the time of the last edition of this text suggested that there was not a deficit in the ability to feel pleasure or reward at the moment, but instead, an inability to anticipate future hedonic capacities that were experienced by patients. Recent studies have convincingly shown that people with schizophrenia have a generally diminished hedonic experience, but there is no differential deficit in anticipated versus current hedonic capacity.

Social withdrawal is sometimes referred to as “passive or apathetic social withdrawal” and includes indifference to social relationships and

decreases in the drive to socialize. This includes a decrease in the desire for relationships with family or friends, a decrease in sexual interests, constricted relationships with family and friends, and an inability to feel intimacy or closeness. Patients with social withdrawal have deficits in *theory of mind,* which refers to the ability to understand how another person might be thinking when there is common knowledge of their current circumstance.

Affective *blunting* is a reduction or inability to express emotion and is an important predictor of functional impairment in schizophrenia. The blunting of expression includes deficits in production, facial expression, prosody, and gestures, and there is a link to social cognition through a parallel deficit in understanding these social signals. In the DSM-5 glossary, it is termed “blunted affect” and defined as a “reduction in the intensity of emotional expression,” and “flat affect” the “absence or near absence of affective expression.” It is more common in men, in people with an early onset illness, and in people with poor premorbid function, and it predicts lower scores on quality-of-life measures.

Alogia is a decrease in verbal communication, or “poverty of speech,” and it is found in up to 25% of people with schizophrenia. Initially conceptualized as both the loss of production and a paucity of content with a normal volume of words, it is only the loss of production of speech that is a negative symptom. The lack of speech production is considered to result from a decreased rate of verbal cognition, and alogia is conceived of as a “negative thought disorder.” This loss of production includes an increased latency to response, short verbal responses, extended pauses, and a paucity or complete lack of spontaneous production. In DSM-5, it is “impoverishment in thinking that is inferred from observing speech and language behavior. There may be brief and concrete replies to questions and restriction in the amount of spontaneous speech.” A paucity of meaningful content in the presence of a normal amount of speech was considered a component of alogia but is actually an expression of a disorganization of thought and properly included with the disorganization symptoms. Affective blunting and alogia are two measures of communication, and some authors have labeled these symptoms as “disorders of relating.”

Course and Associated Features of Negative Symptoms. Although the prototype of a patient with negative symptoms is someone with years

of illness, residing in a group home, and passive and indifferent to the events around them, negative symptoms can precede the onset of illness. Anhedonia and social isolation can predict schizophrenia in high-risk populations. These symptoms may be obscured by the drama around fear, agitation, and psychosis in first-break patients, but a broader range of negative symptoms can be found early in overt illness, with most patients having some negative symptoms. Anhedonia is most common, present in about half of patients at onset, and avolition and affective blunting are also common. If recognizable *akinesia* (obvious difficulty in initiating motor activity) is present at the first admission there is an increased risk of subsequent significant negative symptoms. All of the negative symptoms can progress during the first years of illness and alogia in particular can increase from relatively low rates at onset. About 25% of patients will have significant negative symptoms within 2 years of onset of the illness. There is no course of illness that any particular patient can be expected to follow, and for many, there is a variable course for their negative symptoms, with significant expression at some points, and subsiding of symptoms at other times. But prominent negative symptoms at onset are better predictors of the future course of illness than are levels of psychotic or disorganization symptoms.

Negative symptoms arise from multiple sources, including iatrogenic causes. Long-term institutional care or subsistence-level existence on the streets and in shelters removes normal, expectable pleasures and reinforcing activities and will narrow the number of relationships someone with schizophrenia can have. People with schizophrenia may lose the capacity to experience drives and social relationships and reward simply because circumstances eliminate them. A frequent and frequently unrecognized cause of negative symptoms is treatment with antipsychotic medications. Medications for the treatment of schizophrenia can cause a phenocopy of primary negative symptoms that can be distinguished only with a full history of illness or empiric trials of medication adjustment. Reports of excessive doses of antipsychotic medications causing blunting of affect, diminution of motor activity, impairments in grooming and hygiene, and anhedonia have existed since the introduction of neuroleptics, but for many patients overtreatment with medications remains the rule and not the exception. Extrapyramidal symptoms should not be a proxy measure for the presence of medication-induced negative

symptoms, as extrapyramidal rating scales may remain stable even when dose changes sufficient to reduce negative symptoms have been made.

Negative symptoms can also arise from the presence of other psychiatric symptoms. Positive symptoms are a common cause of apparent apathy, social withdrawal, and alogia. Persecutory delusions can engender fear of human contact leading to social withdrawal, and prominent hallucinations can reinforce these fears. Frequent and intrusive hallucinations can lead directly to withdrawal and inaction, strictly through their effects on attention. Depression is common in schizophrenia, and with inattention or perfunctory clinical interviews it can be overlooked, and the appearance of apathy and affective blunting are then attributed to the disease processes intrinsic to schizophrenia instead of a treatable mood disorder. Secondary causes of negative symptoms, with the exception of medication effects, will often remit within a year of their onset, and sometimes the passage of time can help distinguish primary from secondary negative symptoms; symptoms that do not diminish over the course of a year and do not remit with manipulation of the medication regimen should lead to consideration of primary negative symptoms.

Negative symptoms are frequently part of the clinical picture associated with exacerbations of symptoms. As is the case with depression in schizophrenia, an increase in negative symptoms may parallel an increase in psychotic symptoms, and these symptoms may remit when the psychotic symptoms remit. In these cases, use of antipsychotic medications would be expected to decrease the severity of negative symptoms. This, in fact, is found in studies of medication treatment of recently admitted patients where antipsychotic medication does reliably reduce the severity of negative symptoms.

Table 12.2–3.
The Schedule for the Deficit Syndrome

The Schedule for the Deficit Syndrome requires at least 2 negative symptoms be present in the preceding year. The symptoms are not better attributed to other symptoms of schizophrenia, or to symptoms of another psychiatric illness, and are not due to effects of a medication.

Signs and symptoms assessed in the Schedule for the Deficit Syndrome:

1. Restricted affect
2. Diminished emotional range
3. Poverty of speech
4. Curbing of interests
5. Diminished sense of purpose
6. Diminished social drive

Primary Negative Symptoms. Primary negative symptoms are those negative symptoms that appear intrinsic to the disease process. Primary negative symptoms are the least variable of the symptoms of schizophrenia, so that a person with prominent primary negative symptoms is likely to continue to have significant manifestation of these symptoms throughout the course of their illness. This persistence of negative symptoms predicts future disability. According to Bleuler, “It has been known since the early years of modern psychiatry that an “acute curable” psychosis became “chronic” when the affects began to disappear.” When there are multiple negative symptoms and a careful history suggests that these are enduring and not due to secondary causes, the deficit syndrome (Table 12.2–3) is established.

People with schizophrenia and deficit syndrome have a very poor prognosis regarding the possibility of a full functional recovery. They will tend to have a lower clinician-rated quality of life, more time in a hospital, an increased frequency of symptomatic periods, and more social and physical anhedonia. They will generally have lower intelligence quotients, less education, and worse work histories, and they are less likely to be married and more likely to be men than people with schizophrenia who do not have the deficit syndrome. There is a more insidious onset, with a progression of negative symptoms, and more disorganization of behavior, and the negative symptoms in a person with the deficit syndrome are

likely to respond poorly to medication treatment or social skills training. Not all symptoms and prognostic factors are worse in people with the deficit syndrome; they have no more delusions or hallucinations than nondeficit groups, they are less likely to have severe delusions around social themes and tend to have less severe suspiciousness, they are less likely to endorse prominent dysphoria, and they are less likely to have suicidal ideation or suicide attempts than nondeficit populations. Negative symptoms are associated with impairments in insight, and patients with significant negative symptoms rate themselves higher on subjective assessments of quality of life, despite lower scores on scales of function. There are profound implications for treatment and function for a patient with the diagnosis of the deficit syndrome, but reliable assessment has been found to depend on special training and the use of the Schedule for the Deficit Syndrome Scale.

The deficit syndrome affects a minority of people with schizophrenia, but it is a sizable minority. The estimated rates of the deficit syndrome in schizophrenia vary widely, with rates that are lower early in course of illness and progress for the first 5 years. A meta-analysis of 23 studies calculated a rate of almost 30%. Demographic associations for the deficit syndrome include an increase in summer births, reversing the usual pattern of risk for schizophrenia. It has been proposed and is generally accepted that the deficit syndrome is the result of a separate disease process within schizophrenia, and is not just the manifestation of particularly severe illness.

The deficit syndrome is clearly of great importance in clinical populations, but in usual treatment settings, time constraints and insufficient resources might make it impossible to differentiate long-standing and problematic negative symptom from true deficit symptoms. For many patients, a regular sequenced trial of medications and medication doses, attendance in psychosocial rehabilitation programs, or changes in living situations, which all might help tease out a secondary versus primary cause for negative symptoms, is not possible. So the distinction between deficit and nondeficit symptoms can be difficult for the practicing clinician. Robert Buchanan suggested the idea of “persistent negative symptoms” where possible secondary negative symptoms fail to respond to usual remediation methods. The persistent negative symptom criteria requires the presence of a diagnosis of schizophrenia and at least two negative symptoms, for at least 12 months, present during periods of

clinical stability and not due to psychiatric comorbidities or medication effects. The potential for extrapyramidal symptoms to cause negative symptoms is emphasized. If widely adopted, these simple-to-apply criteria might help focus increasing clinical resources on what is currently an under-recognized problem.

Disorganization

The disorganization syndrome has been part of the conception of schizophrenia since Kraepelin included hebephrenia in dementia praecox, but the behaviors, experiences, and associated pathology have been subject to less investigation than the psychotic and negative symptoms. Consequently, the boundaries of the disorganization syndrome are less clear than those of the psychosis and negative syndromes. However, the disorganization syndrome might be the most heritable of the subsyndromes of schizophrenia. Family and twin studies show an association between degrees of relatedness and the presence of prominent disorganization. This evidence parallels the finding that the old classification hebephrenia is the most heritable of the traditional subtypes of schizophrenia.

The disorganization symptoms certainly include the formal thought disorders, bizarre and catatonic behaviors, and inappropriate affect. Factor analytic studies also consistently find that impairment of attention and poverty of content of speech fit best in the disorganization symptoms. Disorganization symptoms can affect almost any kind of behavior and disrupt almost any form of thought. The disruptions of behavior can be marked, with wildly inappropriate expressions of affect including odd or exaggerated gestures, singsong or childlike changes in prosody, silly or inappropriately bright affects, or alternatively, grimacing and wide-eyed expressions of surprise or anger. This disruption of affect can be socially disabling and unfortunately seems to respond more poorly to treatment than other symptoms in the disorganization subsyndrome. During acute episodes, approximately 20% of patients exhibit an inappropriate affect. The motor manifestations of disorganization may change with time; first-episode patients have only a modest relationship between disorganized motor behavior and disorganization of speech but there are strong correlations in chronic populations.

Disorganization can also include erratic behaviors such as broad movements of arms or the trunk as the patient ambulates, jerking the

head or the neck, or posturing that can resemble aggressive stances. Hygiene is frequently poor, and as a group those with disorganized schizophrenia are more indifferent to routine activities of daily living, including health care and health care maintenance, than are other patients with schizophrenia. Attire can be simply unusual or inappropriate (e.g., adults squeezing into adolescents' clothing, multiple layers of clothes during hot summer days, or light-weight attire in the middle of winter), or sometimes dramatically eccentric.

Prominent disorganization symptoms at first episode, especially with an early onset of illness, are associated with a decrease in general levels of function. Although disorganization symptoms follow a variable course for most patients, there are a small number of patients who have multiple persistent disorganization symptoms throughout the course of their illness, and in some cases, these symptoms can be progressive. This group constitutes the traditional hebephrenic subtype of schizophrenia and is less prevalent than the group of patients with enduring primary negative symptoms or the deficit syndrome. These people are also markedly and persistently disabled and should be the subject of a greater research focus.

Motor Symptoms. Motor behaviors can include subtle repetitive hand movements or broad, complex, and purposeless movements that involve the limbs and the trunk. These movements can occur when speaking and seem to be the gestural equivalent of a neologism or can involve multiple movements of a limb or limbs, as though the person were performing some complex but undecipherable manual task. Patients may sometimes mimic the motor behaviors of others, which is referred to as *echopraxia.* Rocking when sitting down or standing is common, as is patients hugging themselves, wringing their hands, or toying with their clothing, hair, or small objects around them. More complex motor behaviors, odd but apparently purposeful, have been described. There can be repetitive directed behaviors such as gestures and hugging others, or patients might have periods of appearing to read materials over and over–even if the text is upside down, or stare for protracted periods into the mirror. An early onset of prominent motor symptoms has been associated with significant thought disorder and may predict greater disability and a deteriorating course.

Symptoms of catatonia are included in the disorganization symptom, although it is important to note that catatonia is more common in psychotic mood disorders and in cases with brain injury and encephalopathies than schizophrenia. This is made explicit in DSM-5 TR, where catatonia can be a diagnostic specifier for other mental illnesses. The DSM-5 defines catatonia as “a marked decrease in reactivity to the environment” and its essential feature as a “psychomotor disturbance that may involve decreased motor activity, decreased engagement during interview or physical examination, or excessive and peculiar motor activity.” In its appearance, it is as though central motor programs are engaged without direction from frontal areas engaged in higher-level planning. The diagnostic criteria require at least three of 12 motor signs: stupor, catalepsy, waxy flexibility, mutism, negativism, posturing, mannerism, stereotypy, agitation, grimacing, echolalia, and echopraxia.

There is a long history of description of catatonic symptoms, and many general classes have been identified. *Catatonic excitement,* with constant purposeless motor activity, might be the most common type seen in psychiatric settings in the Western world; this is sometimes referred to as “agitated catatonia.” Catatonic *rigidity* is similar but refers to patients holding simple, fixed, rigid postures. DSM-5 clarifies some definitions—*negativism* refers to lack of response or automatic resistance to instructions or stimuli, catatonic *posturing* refers to spontaneous and active maintenance of a posture, and *mannerisms* are an “odd, circumstantial caricature” of normal motor behaviors. Some people with *catatonic stupor* can be obviously awake but immobile without rigidity and will sit or lay in these postures until moved. *Catalepsy* is holding a posture held against gravity and is differentiated from waxy flexibility or *cerea flexibilitas,* which is in DSM-5 a tendency to pose modest resistance to repositioning of limbs; in the past, catalepsy and waxy flexibility were often used as synonyms. *Echopraxia* and *echolalia* retain their familiar meanings of unconscious mimicking action or speech, respectively.

Catatonia is less prevalent in the Western world than it was before the introduction of convulsive therapies and antipsychotic medications. In old photographs or films of state hospitals, odd postures and gestures, grimacing, or patients immobile and slumped in chairs are ubiquitous. In the first edition of this textbook, this description was given:

Until the middle 1930s, mental hospitals were filled with stuporous catatonics, many of whom would lie motionless for weeks or months, unresponsive to almost every stimulus,

their eyelids flickering, saliva drooling from their mouths. Since they would not take any nourishment, they had to be fed by stomach tube twice a day as long as they remained stuporous.

Despite its decreasing prevalence in schizophrenia, some signs of catatonia are present in a large minority of patients during some phase of their illness. One estimate puts catatonia at 8% lifetime prevalence in schizophrenia, and DSM-5 suggests up to a 35% rate in inpatient settings. Unlike other markers of severity of illness in schizophrenia, the prevalence is essentially equal across genders. The risk may increase with increasing maternal age, and there is an increased risk of suicide in the absence of an increase in the prevalence of mood disorders.

The experience of catatonia is often difficult to elicit from patients after an episode has resolved. Patients often have little recall or will describe disjointed and impressionistic memories, like those of patients who have recovered from a prolonged delirium. Recollections of motivation or understanding the cognitive sequence that led to their behaviors are particularly hard to obtain. Other patients have recovered to report an awareness of activity outside of their control, without an ability to respond to others or organize any meaningful communication.

In the developing world, catatonia and other marked disturbances of behavior are more common among those with schizophrenia, and this may be particularly true in Africa. It may be that even the infrequent or inconsistent treatment with antipsychotic medications that patients are exposed to in industrialized societies has a prophylactic benefit for catatonia.

Thought Disorder. Thought disorder is the most studied form of the disorganization symptoms. It is referred to as “formal thought disorder,” or “conceptual disorganization,” in studies that examine cognition or subsyndromes in schizophrenia. It has been said that the thought disorder of schizophrenia expressed in speech is easy to recognize but hard to define, but that has not limited attempts to define it. As a primary care physician uses the fundoscopic examination as a way to visualize the vasculature of the central nervous system, in psychiatry speech is examined as a means to understand the central processes of a patient’s verbal cognition. “Thought disorder” here refers to disorganization of the form of thought and not content. An older use of the term “thought disorder” included the phenomena of delusions and sometimes

hallucinations, but this is confusing and ignores the clear differences in the relationships between symptoms that have become apparent over the past 35 years. Thought disorder should be taken to mean formal thought disorders or a disorder of verbal cognition.

In its milder manifestations, thought disorders do not preclude essential communication. Speech is frequently stilted or vague, and sentences may be incomplete. Speech may be persistently vague and have a *paucity of content*, or *tangential,* so that the associative chain moves obliquely off-topic. With the progression of time, or an increased severity of illness, speech can further deteriorate, and inappropriate content can intrude. *Loosening of associations* refers to changes in topic without identifiable links between the subjects and indicates a lack of internal structure for thought expressed as speech. The DSM-5 glossary distinguishes *derailment* as a shift in topics between clauses, where *incoherence* is a shift within clauses. Patients with prominent thought disorders have more confabulation and engage in more symbolic speech. In its most severe form, patients can present with *neologisms* (novel words, and in schizophrenia, taken to indicate that the word has an idiosyncratic or nonsense meaning), *echolalia* (in DSM-5 “pathologic, parrot-like, and apparently senseless repetition [echoing] of a word or phrase”), and incomprehensible speech without meaning or logical internal connections —*word salad.*

There is a recurrent or persistent identifiable thought disorder identified in 20% to 50% of subjects across a variety of studies, and this number goes up to approximately 75% of patients when they present with first episode or acute exacerbations of their illness. Of those subjects who do present with a thought disorder, many will have only mild or moderate disruption, and this can respond to treatment. The possibility that there is a secondary thought disorder, similar to secondary negative symptoms, due to distraction or anxiety that arises during psychotic exacerbations has been poorly explored but may account for some of the improvement seen following these episodes.

There are disturbances of thought or language found in many psychiatric disorders, but the thought disorder in schizophrenia is distinctive. When compared to subjects with bipolar disorders, siblings, and controls, those with schizophrenia are found to be more impaired in comprehension, attention, semantic organization, and fluency and complexity of speech. Prominent thought disorder at illness onset predicts

a worse prognosis. It is associated with an earlier onset of illness, increased risk of hospitalization, decreased functional outcomes, higher rates of disability, and more inappropriate social behaviors. Verbal production tends to be less complex in patients with thought disorder. Thought disorder that does not respond well to treatment also predicts a worse course. In one study, only 20% of those subjects with a severe thought disorder at a posthospital follow-up regained a high level of function at a subsequent follow-up visit. There is a modest but consistent association with some measures of formal cognition, including deficits in abstracting ability, mental flexibility, planning, and both response initiation and inhibition. The thought disorders found in schizophrenia tend to be more stable in their severity than hallucinations and delusions, and when prominent, they seem less likely to attenuate in middle age than psychotic symptoms.

Depression and Anxiety

Depression. Most people with schizophrenia will experience significant depression and anxiety during the course of their illness, and this frequency has provoked a discussion about whether these symptoms are comorbidities, or if they should be considered as intrinsic parts of schizophrenia-like psychotic, disorganization, and negative symptoms. Depression is likely not a unitary phenomenon in schizophrenia, and it has been proposed that for some patients it is intrinsic to schizophrenia and for some, it is a reaction to the illness. People with schizophrenia frequently have the experience of simultaneous positive and negative emotional responses to experiences that are viewed as positive by others, and this plausibly initiates and maintains depression. Awareness of depression in schizophrenia is not universal; clinicians and families may not notice depression and anxiety in patients with schizophrenia, or maybe too distracted by patients' psychotic and disorganization symptoms to notice. Anxiety and depression contribute to the disability associated with schizophrenia, and anxiety and depression symptoms can worsen the other core symptoms of schizophrenia. Clinicians should attempt to rule in or rule out these conditions so that if present they can be properly treated.

Depression can be confused with negative symptoms and vice versa, though there is almost no concordance between negative symptoms and depression in schizophrenia. In DSM-5 the diagnosis of major depression

is neither specifically excluded nor endorsed, though the reality of depression in schizophrenia is acknowledged in the presence of a depression dimension in the Clinician Rated Dimensions of Psychosis Symptom Severity. Despite the uncertain role for depression symptoms in diagnostic schemes for schizophrenia, when patients are asked about the experience of depression they are usually fully capable of acknowledging its presence. In fact, patients are more likely to endorse their past experiences of depression than their past psychotic experiences. Depression clearly adds to the burden of the illness and impairs functional recovery, is associated with increased relapses, and decreased adherence to treatment. However, the presence of significant depression might also be an indicator of the absence of the deficit syndrome and the long-term disability associated with primary negative symptoms.

Depression is a common symptom in the early course of illness, with one-half or more of all patients experiencing a significant depressed mood during the prodrome and first break. In cross-sectional studies, the prevalence of major depression is fairly low, with rates of around 10%. When symptoms are assessed, instead of a complete depressive syndrome, patients followed long-term after first hospitalization reveal rates of some depressive symptoms of up to 75% or 80%. In one group of patients followed from their first episode, follow-up visits showed depression present in about one-quarter of visits when the subjects were also psychotic; in almost all cases, this depression resolved in parallel with resolution of the psychotic exacerbation. Estimates of the lifetime rates of depression vary widely and are often based on point prevalence studies. Studies with prolonged ascertainment periods find significant depression or a full depressive syndrome in up to 80% of patients.

The presentation of depression in schizophrenia may be masked by the frequent focus in clinical settings on the vegetative symptoms of depression. Disturbances of sleep, appetite, energy, and concentration can be so common in schizophrenia that they become useless in screening for depression in these patients. Also, antipsychotic medications can produce a syndrome that appears identical to major depression, and an increasing emphasis on mood symptoms, poor self-esteem, guilt, and nihilism may be necessary to differentiate a primary mood state from medication effects. The Calgary Depression Scale (Table 12.2–4) emphasizes the psychic symptoms of depression, has good reliability, and has the very clinically useful attributes of reliably

distinguishing depression from negative symptoms and detecting mood changes in schizophrenia across the varying phases of illness. This scale should be the first choice for monitoring depression and treatment of depression in schizophrenia.

Table 12.2–4.
Symptoms Assessed in the Calgary Depression Scale for Schizophrenia

1. Depression
2. Hopelessness
3. Self-depreciation
4. Guilty ideas of reference
5. Pathologic guilt
6. Morning depression
7. Early wakening
8. Suicide
9. Observed depression

There has been a common focus on postpsychotic depression in studies of mood disorders in schizophrenia. Postpsychotic depression has been attributed to demoralization and increasing insight following resolution of exacerbations of psychotic symptoms, with patients' increasing insight revealing to them the severity of their illness and the likelihood of a future disability and relapse. Although periods of depression that follow acute exacerbations of symptoms are periods of increased risk of suicide, there is little else to distinguish them from depression that arises during periods of relative stability. At any time in the illness, the combination of depression symptoms and increased insight predicts an increasing sense of distress among patients.

Anxiety. Systematic reviews and meta-analyses of existing studies confirm a high frequency of anxiety disorders in schizophrenia. The presentation of frequent anxiety complaints by patients with schizophrenia is well-known to most clinicians, but the frequency of full syndromes fulfilling diagnostic criteria for specific disorders is probably not as well-known. Anxiety is not surprisingly associated with increases in psychotic symptoms and disorganization of speech and an increase in service utilization. Anxiety disorder diagnoses are not excluded in schizophrenia

by DSM-5 criteria, though there is a suggestion that specific phobias are sometimes better explained by delusions, and if generalized worry occurs only during the course of schizophrenia generalized anxiety disorder should not be diagnosed.

Social phobia, panic attacks and panic disorder, and generalized anxiety disorder are common in schizophrenia. Studies of the prevalence of anxiety disorders in schizophrenia find social phobia to be the most common anxiety disorder, with a prevalence of 15%. Life histories of patients with schizophrenia find frequent premorbid social anxiety that continues through the prodrome and first stages of illness and adds considerably to the social, educational, and vocational deficits associated with the illness. There is evidence of increased suicidality, decreased functional recovery, and decreased self-esteem in patients with social phobia, but there is a relative paucity of research about social phobia in schizophrenia as compared to studies of panic.

Panic attacks are more common than panic disorder, and in some patients, the frequency of panic attacks peaks at around the onset of psychotic symptoms. Although there is a wide range reported for the prevalence of panic attacks in schizophrenia, estimates of 30% to 45% of patients experiencing panic at some point in their illness are reasonable. There is also a broad range of estimates of the frequency of panic disorder in schizophrenia, but a recent meta-analysis finds a rate of 11%, as compared to rates of 2% or 3% in the general population. In schizophrenia, panic seems especially related to psychotic symptoms, and there might be feed-forward cycles of persecutory delusions and related hallucinations precipitating panic, which then can worsen psychosis. Unaffected relatives of patients with schizophrenia and panic have increased risks of panic, raising the possibility of a neurobiologic link between panic and schizophrenia.

Generalized anxiety disorder and agoraphobia are also present at higher rates in people with schizophrenia, and in the case of agoraphobia, the rates are markedly higher. There is no increase in the rates of specific phobias, and the rates in schizophrenia might be lower when compared to rates in the general population found in the National Comorbidity Study.

Trauma

There is a high prevalence of post-traumatic stress disorder (PTSD) in schizophrenia, but the relationship between the two diagnoses makes it

difficult to tease out causation versus shared risks and increased vulnerability. Adverse events including but not limited to traumatic stress during childhood and adolescence increase the risk of developing schizophrenia, but it is also true that the difficult life situations for many people with schizophrenia put them at an increased risk of experiencing traumatic stressors. It has become clear that psychotic experiences themselves can be traumatic stresses and lead to a diagnosis of PTSD. The circumstances surrounding treatment, especially in the first episode, including forced medication and involuntary treatment, can also act as traumatic stressors. Inpatients and outpatients in public mental health facilities in the Eastern United States were found to have a PTSD rate of about 30% in schizophrenia and related diagnoses in male and female patients; the rates of physical and sexual assault experienced by patients of both genders in this study were very high. A meta-analysis found a rate of PTSD in schizophrenia of 12%, which is higher than the prevalence in the general population. In the Recovery After an Initial Schizophrenia Episode (RAISE) study, which by design was limited to patients with first-episode psychotic disorders, there was a very high rate of trauma found in patients, but rates of actual PTSD were about 5%. Symptoms of PTSD that persist but do not meet full criteria for the diagnosis have been found in up to 80% of patients. The comorbidities that attend PTSD are already increased in schizophrenia, and the combination of PTSD and schizophrenia further amplifies their severity and effect. The core symptoms of schizophrenia are more severe in patients with comorbid PTSD, depression is more common, suicidal ideation and suicide attempts are increased, patients require more care (including requiring more hospitalizations), and it is likely that substance abuse rates are higher in this population.

Obsessions and Compulsions

Possibly because of the relatively well-defined neural circuitry in obsessive-compulsive disorder (OCD) and the overlap in these circuits with some of those implicated in schizophrenia, there has been informed speculation about potential overlap in the underlying pathology of schizophrenia and OCD. It does appear that the prevalence of obsessive-compulsive symptoms (OCS) and OCD in schizophrenia exceed the prevalence in the general population, with estimates of about 25% of people with schizophrenia having comorbid symptoms of OCD, and

around 10% qualifying for the diagnosis of OCD. An analysis of CATIE data found about 5% of the patients enrolled had OCD. Ascertainment of OCD can be difficult, with a special difficulty separating delusions and ruminative concern about these delusions from true obsessions.

Comorbid OCD was once considered a good prognostic factor in schizophrenia, but this is clearly not the case. OCS are associated with an earlier age of onset, and OCS or OCD often precedes the onset of psychosis. The presence of OCS or OCD is associated with more severe psychotic symptoms, more depression, more disability, increased hospitalizations, and an increased risk for suicide attempts. As with panic, there is an increased risk for OCD in the relatives of patients with schizophrenia and OCD as compared to relatives with schizophrenia alone. A considerable body of literature has been developed that suggests that for a subset of patients with schizophrenia a real “schizo-obsessive” form of the illness might exist.

Agitation and Hostility

The clinical features of agitation, irritability or frank hostility, uncooperativeness, and impulsivity are familiar to those who deal with clinical populations with schizophrenia, and these symptoms segregate together independent from the influence of culture. These features are associated with increased severity of psychotic symptoms, rehospitalization, and use of high doses of medications. The symptoms are found more commonly in male patients and in those with substantial cognitive impairments. Comorbidities and treatment variables can increase the risk for agitation, with substance abuse particularly prominent. There are other treatment-specific risks, including poor medication adherence, exacerbations of psychosis, akathisia, and other extrapyramidal symptoms (including tardive dyskinesia), that increase the risk of agitation and hostility. Unfortunately, beyond this, little progress has been made in understanding agitation in schizophrenia. The link between agitation and mania has not been adequately explored; intuitively it seems that this might be a subsyndrome, such as psychosis, in which some of the genetic overlaps between schizophrenia and bipolar disorders are expressed. The evidence base that would clarify whether agitation and mania are variable manifestations of a similar underlying process or analogous manifestations of unrelated causes does not exist. Over the

last decade, the predominant focus in research into agitation has concerned its links to violence.

Violence. The topic of violence in schizophrenia is contentious. In the mind of the general public schizophrenia is sometimes synonymous with unreasoned violence. For people with schizophrenia, and for their families and advocates, the real problem is that people with schizophrenia are far more likely to be the victims of violence than the perpetrators. This is true, and although there are studies with negative findings, it also remains true that a small minority of people with schizophrenia will commit a disproportionate amount of violence and even murder. Recent systematic reviews and meta-analyses have led to some downward revision in the estimated rates of violence among those with schizophrenia, especially in the absence of psychiatric comorbidities, but the finding of an increased rate remains. Large cohort studies and smaller diagnosis-specific studies, conducted in a variety of countries that have varying baseline rates of violence, show that the presence of a diagnosis of schizophrenia increases the risks of committing violence or being arrested.

No single variable associated with schizophrenia accounts for the increased rates of violence. A series of factors increase risks, though these factors are so prevalent in the population that the predictive power of any one feature is very small. Some demographic and premorbid features are associated with violence, including gender, with men committing the majority of violent acts. Some people with schizophrenia will exhibit a premorbid conduct disorder in childhood and will move into more serious antisocial behaviors as they age. This group is particularly likely to engage in severe violence and to calculate and plan their violent acts. It has been suggested that most of the violence perpetrated by people with schizophrenia arises in those with premorbid conduct disorder or histories of delinquency and premorbid aggression. Paul Appelbaum has asserted that “only a small proportion of violence appears to be directly due” to the symptoms of mental illness. At present, there are no figures for what proportion of the risk of violence is due to antisocial personality disorder, and how much can be attributed to schizophrenia, but clearly, this is not solely a problem attributable to a psychotic disorder.

Recent careful examination of populations with schizophrenia has made it clear that acute stressors, most prominently violent victimization including abuse during childhood or adolescence, increases rates of

violence in adults with schizophrenia. A study of a large population in Sweden found that victimization and other acute stressors increased the risks of aggression. This included violent victimization but also stressors like parental bereavement, traumatic brain injuries, and accidental injuries. The effects were clearly more pronounced in people with schizophrenia than in the general population or people with bipolar disorder. Hopefully, the effect was most prominent in the week after the stressor, and the risk was briskly attenuated after that.

Some factors intrinsic to schizophrenia also increase the risks of violence. Poor impulse control and cognitive deficits can predate the onset of the illness but can also arise with the expression of the illness. Insight is variable in schizophrenia but those with significant impairments have an increased risk of violence; prominent disorganization symptoms can also increase risks. Not surprisingly, threat delusions, especially those that provoke negative affects, increase risks of violence, and the deficits in interpreting social and emotional communication common in schizophrenia also increase risks. As reviewed in the discussion of auditory hallucinations, the congruence of the content of hallucinations with a delusional structure that focuses on threat and the benefit of compliance increases the likelihood of following the commands; command hallucinations without this delusional structure pose less threat. Delusions in the absence of hallucinations are often sufficient to provoke violence. For many people with schizophrenia, the persecutory delusions that make them believe their lives are at risk are significant contributors to their violent behaviors, and for those suffering from the delusions violence is an act of self-defense. The influence of paranoid delusions on an increased rate of violence persists even when the results are controlled for the effects of demographic factors and substance abuse. In particular, systematized persecutory delusions that suggest that the person is a particular target, with co-occurring delusions of control, may increase the rates of violence. In this group, the increase in the rate of violence perpetrated by women is greater than the increase in rates among men, and in inpatient psychiatric units the rates of assault by men and women may be equivalent. It has been suggested that confusion, frequently seen in emergency and inpatient settings, contributes to a significant percentage of assaults in these settings. Acute exacerbations of illness are usually times of a higher burden of all symptoms, which also increases the risk of violence.

A broad range of comorbidities also increases the risk of violence. The effects of substance abuse, in particular, the effects of alcohol abuse or dependence parallel the effects of substance abuse in the general population. A widely reported meta-analysis found an odds ratio for violence of almost 9 with comorbid schizophrenia and substance abuse diagnoses, and an odds ratio of 2 with schizophrenia alone. Reporting at the time emphasized the dramatic increase in risk with substance abuse, but the study also clearly showed that there is an increase without the presence of substance abuse, and it poses a clinical and societal problem. Frequently co-occurring with substance abuse, nonadherence with medication treatment is associated with increased rates of violence in people with schizophrenia. Suicide threats and attempts, and neurologic comorbidities, each increases rates of violence.

In chronically ill and disabled patients, there are often less severe acts of violence, frequently directed against family, friends, caregivers, and health care providers. This may be the most common type of assault in treatment settings and frequently occurs as medical staff members attempt to modify patient behavior. These incidents seem more likely related to the effects of impoverished and constricted lives, where there is difficulty for patients to gain experience modulating affect and impulses. Impulsivity and poorly moderated affect can lead to transient displays of aggression, and the effects of substance abuse frequently exacerbate these.

People with schizophrenia are overrepresented in the numbers of people who commit homicide. One estimate puts the percentage of homicide offenders with schizophrenia at greater than 6%; a common estimate is that the risk of homicide is 10 to 20 times higher in schizophrenia. In any location, the risks reflect the community rate of homicide, so that areas with low homicide rates see smaller rates of people with schizophrenia, and the rates rise in areas with higher community rates. The MacArthur study found that violence was more likely to be directed at family members than people outside the family or strangers. Other lines of evidence suggest that there is a considerable risk of stranger homicide by people with schizophrenia. The large majority of these individuals were men; many were in the early stages of their illness with a recent exacerbation of their illness and had a recent change in the quality of their delusions. Homelessness, a lack of psychiatric treatment,

conduct disorder, or a history of antisocial behaviors are also associated with stranger homicide.

Suicide

Suicide accounts for a good part of the excess mortality that is usually found in schizophrenia. A commonly cited figure for suicide rate in schizophrenia was 10%, but there is little contemporary evidence to support this figure. Meta-analyses suggest that 5% of people with schizophrenia will commit suicide, with increased risk early in the course of illness–including during the prodrome, in patients with frequent relapses, and at around the time of admission or immediately following discharge from a psychiatric facility. Also, periods of increased psychosis, especially when paranoid delusions are prominent, preserved or emerging insight, and a fear of mental deterioration increase risk. Suicide attempts and suicidal ideation are much more common, with rates of attempts reported to approach 50%. Nonspecific factors such as youth, depression, hopelessness, motor restlessness and agitation, impulsivity, substance abuse, and anxiety, increase the risk for suicide in schizophrenia, as they do in other psychiatric illnesses. People with schizophrenia who attempt suicide tend to use more lethal means in their attempts, have a strong intent to die, and make multiple attempts. The rates of suicide in schizophrenia may be increasing; a review of asylum records from around the turn of the 19th to 20th century found a rate of suicide of about one-twentieth of that in the late 20th century. As noted previously, patients with significant and persistent primary negative symptoms seem to have a lower risk for suicide.

Insight

Lack of insight was the most common symptom of schizophrenia in the IPSS studies of symptoms and course of schizophrenia, and subsequent studies across a wide variety of populations find rates of 50% to 80% of patients with some degree of impairment of insight. Impaired insight has long been recognized as associated with poor social and functional outcomes, lowered quality of life, decreased treatment adherence, increased levels of psychopathology, and recurrent exacerbations of illness and hospitalization. It is clear that better understanding of insight has the potential to generate treatment strategies that significantly improve outcomes—though there is evidence that better insight is

associated with increased suicidality, neuroticism and depression, and self-reported distress. For decades, the primary investigators of insight into schizophrenia came from the philosophic tradition of phenomenology, where the aim is to understand as completely as possible the subjective experience of a person; in schizophrenia, the major focus has been on the psychotic symptoms and the nature of the perception and understanding in psychosis. The functional consequences of impaired insight or the neurobiology behind the impairments are less easily appreciated in this approach.

A lack of self-reflection is frequent in schizophrenia, and as is seen in delusions there can be an undue certainty in judgments that are based on insufficient evidence. Splits in insight are often observed in patients, and it is common for chronically ill patients to find someone who accepts that treatment helps to function and prevents worsening of symptoms but who deny illness and the idea that psychotic symptoms are mental phenomena. Poor insight is correlated with negative symptoms, inappropriate affect and thought disorder, and delusions, although the strength of the correlations is fairly weak. Over the last 20 years there has been a broad surge of interest in insight into schizophrenia, continuing the phenomenologic approach but also driven in part by broad emphasis on understanding the neuropsychological underpinnings of schizophrenia, attributable to an emphasis on outcomes over symptoms and also due to the interest of cognitive therapists.

Insight is not a unitary phenomenon and impaired insight is not due to any single underlying process. There is a continuum of insight, from complete understanding of illness and effects of illness on function and production of symptoms, to understanding that auditory hallucinations are associated with illness but nonetheless feeling that the voices are by some external agent, to total denial of illness and symptoms and dysfunction. Cognitive mechanisms certainly play a part, and there are relationships between cognition as measured with neuropsychological testing and the severity of impairment of insight, but results are inconsistent and taken together the relationships are modest. A separate approach addresses “clinical insight” and focuses on those aspects of insight that effect care or are observed in clinical settings. One useful scheme for conceptualizing insight in schizophrenia suggests four dimensions: awareness of illness, awareness of symptoms and attribution of symptoms to illness, awareness of the need for treatment, and

awareness of the consequences of the illness. There is separately a recent focus on “cognitive insight,” which actually refers to the metacognitive processes that underlie the ability to reflect on conscious cognition and the certainty underlying cognitive processes. Presumably, there will soon be an elaboration of cognitive therapy techniques to address this aspect of insight.

Illustrative Case

A 37-year-old man presents for assessment. He has a chief complaint of “don’t like my medicine,” though a review of his medication profile shows only irregular refills of the atypical antipsychotic agents and serotonin reuptake inhibitors he has been prescribed over the last year. There are notes by two other psychiatrists in the electronic record, but this record includes only a handful of notes and a pattern of infrequent visits and missed appointments over the last 4 years.

As the appointment proceeds, he explains that he feels as though his current medication “makes me too tired” and “makes me fat” but also acknowledges that he has not been taking the medication “for a while” and that current complaints of an altered sleep–wake cycle, daytime fatigue, increased appetite, and lack of self-initiated hobbies or social activities cannot be attributed to medication effects. He denies depressed mood, but blunted responses of affect and little investment in ideas or hopes for his future are observed. He discloses regular but brief verbal auditory hallucinations of a male and female voice that are familiar to him but he does not know the identity of either voice. He feels as though the voices are entities controlled by some unknown group “who have been watching me for a long time” with cameras, microphones, and airplanes. He feels “they used to want to get me” and do physical harm, but for years they have been focused just on monitoring his whereabouts and “what I’m thinking.” Mild perioral and lingual dyskinetic movements and occasional grimacing are evident, but he is also seen to shift to awkward postures and there are occasional complex repetitive movements of his fingers that are judged to be mannerisms. Hygiene is adequate, but he has not recently shaved, and his hair and clothing are unkempt. Speech is very terse and frequently lacking in pertinent detail, with occasional allusions to ideas that are not clear and cannot be explained. He is aware of the clinical setting, his living situation, and the month and the year but cannot recall the day of the month or the week. After some extensive prodding, he agrees to work with his uncle to get his antipsychotic medications refilled and to follow-up within a month.

On his return visit, there is a dramatic decrease in the rate of ambulation, few spontaneous directed movements, and he has a flat, slack-jawed appearance. There is a clear low-frequency tremor in his hands, more prominent in the right than in the left, and significant stiffness in the elbows bilaterally, but the oral dyskinesias are now

absent. Speech production is generally reduced to one- or two-word answers, but he does say that his auditory hallucinations are gone. His uncle accompanies him and confirms good adherence to medication treatment, but although the patient is much slower, his temper seems worse. The patient says that he feels “real bad” and wants to discontinue his medications and wishes he could “go away,” which he indicates means to escape the experience of existence, but he does not want to die or kill himself. He nods assent when asked whether he is depressed. He is prescribed a lower dose of antipsychotic medication and as-needed anticholinergic medications, with follow-up in 2 weeks.

In the interval, copies of his old paper-based chart are retrieved, and there is a more thorough review of his care. He was first seen in a child clinic for presumed depression at 16 years of age, with significant social withdrawal and declining academic performance, along with decreased participation in sports and music classes, disrupted sleep–wake cycle, and frequent irritability. His developmental history indicated no serious medical illnesses, but he tended to be isolative and never more than an adequate student. Social and educational performance deteriorated as his parents went through periods of unemployment and the family frequently moved to stay with various relatives for periods of months to several years. He was treated with antidepressant medications and brief individual and family therapy. His school performance improved slightly, but he remained withdrawn from former friends and interests. After 15 months, he was discharged from care.

He was next seen in the hospital system at 20 years of age. He had graduated from high school but then held a series of entry-level jobs for very short periods and was frequently fired after an inability to get to work on time or inadequate job performance. His parents suspected substance abuse but never found any evidence of illicit drug use. After a half year of getting hired and fired from a series of jobs, he stopped looking for jobs and stayed at home. He was occasionally incomprehensible when explaining his online interests to his parents and became more and more cryptic and more and more irritable with them while his daily rhythms and relationships fragmented. His return to the mental health system was precipitated by an arrest, and then

transfer from jail, after he threatened his parents with some broken glass while arguing that they were “helping to poison me.”

During his first admission, he explained that his parents were trying to poison him so that they could steal his ideas; he knew this based on information from people who were simultaneously plotting with his parents and trying to protect him, who communicated with him through radio waves. He was very agitated, and there were also infrequent but odd motor movements in gait, posture, and gesture. He had a slow initial response to a high dose of an atypical antipsychotic agent, and the slow pace of his response prompted an extensive medical workup by his team. The only significant findings were of mild obesity, a modest elevation in fasting glucose, and a magnetic resonance image of the head that showed lateral ventricles judged to be “minimally enlarged for patient’s age.” After 18 days in the inpatient unit, he was discharged from the clinic.

Because of resistance on the part of the patient, follow-up was erratic through most of his twenties. He was seen in several of the other community hospitals in the same city and treated with a variety of antipsychotic, mood-stabilizing, and antidepressant medications. Several years after his first admission and after a period of medication nonadherence and increasing psychosis, he was transferred to an inpatient unit from an intensive care unit, following admission for injuries he suffered from stabbing himself in the neck. Through his twenties, there were two other suicide attempts, the onset of alcohol abuse and heavy cigarette smoking, an inability to find employment, and variable periods of treatment adherence and nonadherence. During one stretch of almost 2 years in his late twenties, he went to a day hospital program and then to a psychosocial rehabilitation program where he made friendly acquaintances with whom he would sometimes go out to eat or go to a movie. Despite these activities, he still spent most of his time at home, watching television, eating, and smoking cigarettes. For some reason he could not explain, he discontinued the medication he had been taking, became progressively more psychotic, complained of recurrent depressed mood, and had delusions of persecution reinforced by the content of his auditory hallucinations. He was again threatening his parents and had his last psychiatric admission. After discharge from this hospital stay, his parents were unwilling to take him back home, and he moved

in with his uncle. He has been treated in the same system since the last hospitalization, with tobacco use, obesity, and hyperlipidemia as comorbidities.

At subsequent follow-up visits, a low dose of an antipsychotic is found that causes minimal stiffness and no other perceptible extrapyramidal symptoms. The patient and his uncle are educated on sleep hygiene, and his sleep–wake cycle stabilizes. The depressed mood and wish to not exist expressed at the second visit quickly diminish in parallel with the resolution of his extrapyramidal symptoms. His auditory hallucinations returned, but with discussion, it becomes clear that he usually finds the content of the voices helpful, and that they provide companionship that he likes; he is reluctant to consider trials of other medications because it might silence his voices. His dyskinetic movements return, but the odd postures and gestures are alleviated. Despite urging from family and his psychiatrist, his paucity of external activities and lack of exercise only slowly improve, though his better mood allows him to go out to eat or see movies with a variety of family members. Efforts to return him to a psychosocial rehabilitation program are ongoing.

RESEARCH IMPLICATIONS

Since the last edition of this text, there has been a general adoption of either established factor analytic structures (e.g., the consensus five-factor model of Wallwork and colleagues), or incorporation of study-specific factor analysis in the methodology of studies of symptom associations and novel therapeutics. There remains a relative paucity of research investigation into the nature of some symptoms, particularly in the disorganization and agitation factors, that lags behind efforts in psychosis and negative symptoms. The nomenclature assigned to factors has become progressively more confused as the number of investigators increases. In many cases, factors appear to be labeled with one name or another in order to lay claim to the symptoms as supporting a particular hypothesis. Disorganization symptoms have been called “cognitive” symptoms and general cognition labeled “neurocognition”; but now “neurocognition” has been applied to the disorganization factor. The excitement factor is variably hostility, agitation or “manic” though none of the symptoms included in the factor is specific to mania–and the symptom

of grandiosity generally loads on the psychosis factor. As noted earlier, there is a continued use of “positive symptoms” in an undefined fashion–sometimes as the PANSS Positive Factor, sometimes for agitation and confusion in conjunction with psychotic symptoms, and sometimes as a synonym for psychotic symptoms. For clinicians who look to research to enhance their understanding of the illnesses they treat, the nomenclature can make the literature so confusing as to be useless.

In the years immediately before the preparation of this chapter, novel analytic strategies including confirmatory factor analysis, network analysis, and machine learning techniques, have been applied to the assessment of relationships between symptoms and to the relationships of symptoms and other markers of disease. There is not a sufficient number of such studies to make any kind of prediction about the importance of any particular method, but these investigations open the possibility of more detailed dissection of the structure of schizophrenia and schizophrenia’s relationship to other mental illnesses. The opportunities to use phenomenologic approaches to better define the relationship between schizophrenia and bipolar disorders, especially in psychosis and agitation symptoms, and to carry out parallel investigations into concordant (or discordant) nature of negative and disorganization symptoms in schizophrenia and the symptoms of autism spectrum illness have not been exhausted.

12.3 Global Burden of Schizophrenia

DANIEL MAMAH, M.D., M.P.E.

The global burden of disease (GBD) study was initiated by the World Health Organization (WHO) in the early 1990s, in collaboration with the World Bank and the Harvard School of Public Health. GBD 1990, as it was termed, produced prevalence estimates from 107 diseases and injuries over eight world regions and introduced for the first time a new integrated unit of disease burden measurement, the disability-adjusted life year (DALY). One DALY corresponds to one year of healthy life lost in a given population due to the combined effects of disability and premature mortality resulting from disease. Thus, for any given disease:

$$\text{DALY} = \text{YLL} + \text{YLD}$$

Where YLL refers to the years of life lost to mortality and YLD is the years of (healthy) life lost to disability.

Updated GBD studies were conducted by the WHO over the next two decades. Since 2010, subsequent iterations of the GBD study have been done through the Institute of Health Metrics and Evaluation (IHME) based at the University of Washington, expanding the number of disorders included and using an improved methodology. The GBD 2019 study estimated metrics due to 369 diseases and injuries for 204 countries and territories. Worldwide, several psychiatric conditions, including self-harm, depressive disorders, anxiety disorders, conduct disorder, and drug use disorders, were among the top 20 conditions accounting for total DALYs across all ages combined. Among 25 49-year-olds, schizophrenia ranked 22nd in global DALYs, accounting for 1.5% of the total. The findings on

schizophrenia reflect the burden of morbidity and disability that the disorder inflicts on individuals, families, and communities worldwide and underestimates the burden of premature mortality, which is difficult to ascertain. Global DALYs have remained largely stable from 1990 to 2019, and with correcting for population growth and aging, there has been a noticeable improvement in general health. Global disease burden has also continued to shift away from communicable to noncommunicable diseases and injury, and from premature death to years lived with disability. For most diseases, changes in rates of death and disability have been relatively stable or slow; however, regarding behavioral disorders, it is notable that death from drug use disorders has risen significantly since the last decade. Over half of the global deaths from a drug overdose in 2019 occurred in the United States. The prevalence of depressive or other mental disorders has appeared largely stable over the last three decades; however, self-harm had a significant decline of 28.4% during this time period.

This chapter reviews evidence from past and present research, bearing on the individual components that jointly make up the aggregate burden of disease and disability associated with schizophrenia—the variations in its incidence and prevalence, course and outcome, comorbidity and mortality, and socioeconomic costs. In evaluating the evidence, it is important to bear in mind that schizophrenia still remains a broad clinical syndrome (rather than a “disease”) and that the neurobiology and genetics underlying its manifestations are not yet fully understood.

However, research into the genetic underpinnings of schizophrenia recently reached a new milestone with the genome-wide association study (GWAS) of the largest sample to date of patients and healthy controls (36,989 cases and 113,075 controls), which identified 108 associated genomic loci significantly associated with schizophrenia risk. The study, by an international consortium of about 80 research groups, found robust associations of the disorder with the dopamine receptor DRD2, as well as with molecules involved in glutamatergic neurotransmission, suggesting plausible pathogenetic pathways. A surprising novel discovery was the strongest association of schizophrenia risk with the major histocompatibility complex on chromosome 6, pointing to an important, yet poorly understood, role of the immune system in the pathophysiology of the disorder. However, these findings still explain a relatively small fraction (~30%) of the estimated heritability of schizophrenia and can be seen as

the prelude to the next-generation whole-genome sequencing studies. Such studies will have the potential to identify rare genomic variants (mutations present in less than 2% to 5% of the population) that may contribute to familial and individual risk of the disorder.

The clinical concept underlying the present diagnostic classifications of schizophrenia does not indicate whether one or several pathologic processes are involved or whether the causes of schizophrenia are the same in all cases. These gaps in the biologic characterization of schizophrenia reflect its complexity, as well as the currently incomplete understanding of the basic neurobiology underpinning key psychological functions that are impaired in schizophrenia, such as memory, multimodal sensory integration, self-monitoring, and intentionality of behavior.

This chapter builds on text from earlier editions of this textbook, authored by Assen Jablensky. Throughout the chapter, the terms *developing countries* and *developed countries* are used to refer to a broad (and somewhat fluid) grouping of societies still characterized by traditional community structures, beliefs and values, and a relatively recent transition to industrialization and large-scale urbanization, and societies that have undergone the transition to "modernity" much earlier, with all the consequences for community life, family support patterns, and systems of care for the sick and disabled.

SCHIZOPHRENIA BEFORE AND AFTER KRAEPELIN

Since its early formulation in 1896 by Emil Kraepelin (1856 to 1926), the concept of *dementia praecox,* later renamed schizophrenia by Eugen Bleuler (1857 to 1939), has been a hotly disputed diagnostic entity, raising, among other things, the question of its applicability to different populations and cultures. Although the Western medical literature before the 18th century contains unequivocal descriptions of depressive, manic, hysterical, and organic-dementing clinical pictures, it provides hardly any explicit reference to what later became known as schizophrenia. A plausible early description of schizophrenia can be attributed to Philippe Pinel (1745 to 1826), who described "frequent or continual appearance of unconnected ideas and shallow dissociated emotions; disorganized movements and extravagant actions…a kind of automatic existence." However, for most of the 19th century, such occasional descriptions of schizophrenic disorders were completely overshadowed by the all-

embracing notions of “melancholia” and “mania.” There are at least two possible explanations for the underestimation of schizophrenic disorders. One, less likely, is that until the second half of the 19th century, schizophrenia indeed was a rare disease and that the significant increase of the share of schizophrenia in treated psychiatric morbidity did not occur until the last decades of the 19th century. Statistics on patients admitted to the University Psychiatric Clinic in Munich in 1908—some of them diagnosed personally by Kraepelin—indicate that as late as 10 years after the establishment of the diagnostic category of *dementia praecox,* the frequency of this diagnosis among all first admissions was as low as 9.1% in men and 7.3% in women. However, little was known at that time about the prevalence of untreated cases in the community. A second possible explanation is that schizophrenia did exist and was frequent, but for most of the 19th century, it was assimilated with other syndromes, “mania” and “melancholia” in particular. There was no phenomenologic description of schizophrenia as such because the concept did not exist, although all the symptoms and signs that were to be integrated later into the diagnostic category had been present all the time. Social factors likely also played a role. Diminishing tolerance in growing urban communities to bizarre behavior and deviance, and the commitment of increasing numbers of “insane” persons to the mental hospital where “scientific” diagnosis and treatment were believed to be practiced, may have facilitated the nosographic description of new clinical entities. According to statistics from Austria, the community census of “insane persons” rose slightly from 0.94 per to 1.35 per 1,000 population between 1873 and 1905, while the proportion of such persons institutionalized in hospitals during the same period increased from 32.5% to 61.9%. Such unprecedented concentration of psychotic persons in medical institutions undoubtedly made it easier for clinicians to identify syndromes, subtypes, and other varieties of mental disorders.

Comparative Psychiatry and Ethnopsychiatry

During the same period, there was a growing interest in the manifestations and frequency of mental disorders, primarily psychoses, in non-Western cultures. British, Dutch, and French colonial administrations imported into their overseas dependencies the asylum model of care for the mentally ill and built mental hospitals for patients with intractable chronic illness, in particular, including “dangerous” psychotics. In 1903,

Kraepelin traveled to Java and spent several weeks at the Buitenzorg (now Bogor) Hospital. He came to the conclusion that the basic forms of *dementia praecox* and *manic-depressive insanity* in the Javanese were essentially the same as those in Europe, though “racial characteristics, religion, and customs” modified their clinical manifestations. Kraepelin anticipated “rich rewards” from the capacity of cross-cultural studies to “throw light on the causes of mental disorder” and proposed *comparative psychiatry* as the systematic study of mental disorders and personality traits across cultures. However, for decades, the epidemiology of schizophrenia and other psychotic disorders in non-European cultures remained restricted to mental hospital statistics or rudimentary field surveys undertaken by colonial public health administrators. His conclusion was that “true” schizophrenia and depression were rare among indigenous peoples and that chronically ill psychotic people were well tolerated in the community. The ideologic framework in which such early *ethnopsychiatric* observations were embedded varied between benign paternalism and overt racism. In a 1953 monograph, John Carothers (1903 to 1989) claimed that the paucity of structured delusional contents and the lack of systematization of delusions in “the African” could be explained by congenital underdevelopment of the frontal lobes of the brain. Similar assumptions led other authors to conclude that depression was rare in sub-Saharan Africa or in Asia because of the lack of Judaeo-Christian cultural values that made the experience of guilt possible.

The sketchy and often distorted picture of the epidemiology of psychoses in developing countries began to change in the postcolonial era when locally born psychiatrists, educated in the West, entered practice and teaching in their countries. Although trained in the colonial metropolis, they were keen to understand the nature of mental disorders in their own cultures and to introduce culturally appropriate alternatives to the colonial mental hospital, such as the model “psychiatric village” in Ibadan, Nigeria, founded by Thomas A. Lambo (1923 to 2004), the first Western-trained psychiatrist in Africa. In Asia, Pow Meng Yap (1921 to 1971) systematically charted the so-called *culture-bound syndromes,* highlighting their differentiation from schizophrenia. Epidemiologic surveys providing data on the incidence and prevalence of schizophrenia were carried out in Mauritius, Nigeria, India, Taiwan, and mainland China. Since the 1960s, such studies expanded to include a variety of populations in

Africa, Asia, and South America, about which little had been known previously.

The comparative study of schizophrenia across populations and cultures gained in scope and momentum with the research program initiated by WHO in the 1960s. Two multicenter collaborative studies, the International Pilot Study of Schizophrenia (IPSS) and the Ten-Country Study (Determinants of Outcome of Severe Mental Disorders) generated cross-sectional and follow-up data on more than 3,000 cases of schizophrenia in 16 geographical areas in 12 countries in Africa, the Americas, Asia, and Europe. These studies introduced standardized assessment instruments, research procedures, and explicit diagnostic criteria in data collection at community and hospital facilities by local psychiatrists and mental health workers who had been trained to use such research tools and participated in their development. The WHO studies enabled for the first time direct comparisons of the population rates, psychopathology, and burden of disease associated with schizophrenia across various cultures.

DIAGNOSTIC COMPARABILITY OF THE SCHIZOPHRENIA PHENOTYPE ACROSS POPULATIONS

There is, as yet, no validated biomarker that could assist in the diagnosis of schizophrenia. Neuroimaging and EEG can only help in ruling out other psychosis secondary to other medical conditions, such as head injury, seizures, or mass-occupying lesions. The paradigm-transformative DSM-III and subsequently ICD-10, DSM-IV, and DSM-5 are descendants of the Kraepelinian nosology and research work at Washington University developing criterion-based diagnostic criteria for mental disorders, determined using specific clinical description and exclusion from other disorders, as well as outcome and family studies. However, there is little evidence that most currently diagnosed mental disorders, including psychoses, are separated by natural boundaries. There is a growing understanding that the syndromal spectrum of schizophrenia is the end-point for heterogeneous gene networks, pathophysiologic pathways, and environmental modifiers. Increasing experimentation with research-oriented models and cross-disciplinary methodologies linked to the

emerging Research Domain Criteria (RDoC) may eventually reshape diagnostic classification, but this is a long-term project.

Despite the wide acceptance of the DSM and ICD criteria that promote reliable diagnostic identification, the question of whether cases diagnosed as schizophrenia in different populations and cultures are phenotypically homologous is of critical importance, considering that the biologic basis of the disorder is largely unknown and no objective diagnostic test is currently available. Phenotypic comparability implies that the constellation of symptoms is coherent and replicable and that course, outcome, and response to treatment are broadly predictable.

In the past, the belief was widespread that schizophrenia was a “Western” disease and had no counterpart in indigenous populations untouched by modern technology and lifestyles. That this belief was mistaken is demonstrated by the fact that no human community has yet been found to be free of schizophrenia, diagnosable by commonly accepted criteria. Although no single symptom is *pathognomonic* of the disorder, the overall clinical presentation of schizophrenia is similar across cultures. Acutely ill patients in different cultural settings describe the same characteristic symptoms, such as hallucinatory voices commenting in the third person on their thoughts and actions, thoughts being broadcast or taken away, or their surroundings being imbued with special meaning. Negative symptoms, such as psychomotor poverty, social withdrawal, and amotivation, are common, irrespective of the cultural setting. The conclusion that patients diagnosed with schizophrenia in different cultures suffer from the same disorder is further supported by similar age- and sex-specific distribution of the onset of symptoms, which tends to peak in early adulthood. Similarities being present despite the variety of social norms and beliefs about illness across cultures suggests some commonalities in the underlying neurobiology. Nevertheless, variations exist that may affect the recognition and treatment of schizophrenia. For example, Nigerian psychiatrists have described in patients with schizophrenia a characteristic symptom complex consisting of anxiety, depression, vague hypochondriacal symptoms, bizarre magicomystical ideas, episodic twilight or confusional states, atypical depersonalization, emotional liability, and retrospective falsification of memory based on hallucinations or delusions. Certain variants of the schizophrenia syndrome, such as an acute onset form and a catatonic subtype, appear to be more common in traditional rural communities. Research conducted within the WHO

program of cross-cultural schizophrenia studies has confirmed the existence of population differences in the mode of presentation of the disorder. For instance, acute onset was found to characterize in 40.3% and marked catatonic symptoms in 10.3% of cases assessed at research centers in India and Nigeria, compared to 10.9% and 1.2% at European and North American centers.

Differentiation from Other Disorders

A common clinical problem in developing countries is the differentiation of schizophrenia from psychoses due to infectious or parasitic diseases. African trypanosomiasis often results in a symptomatic psychosis that has a slow, insidious onset and may mimic schizophrenia. Since a variety of infectious, parasitic, and nutritional diseases are endemic in the developing world, it has been suggested that a large proportion of the cases of schizophrenia in those populations may, in fact, be symptomatic psychoses associated with tropical communicable diseases. Another brain pathology known to contribute to psychoses with schizophrenia-like features is temporal lobe epilepsy. The association between epilepsy and a chronic, interictal psychosis that is difficult to distinguish from schizophrenia has been well documented clinically. Studies in Europe and North America suggest a nearly 10-fold increase in the risk of schizophrenia-like psychosis among people suffering from epilepsy. Considering that epilepsy is highly prevalent in many regions, undiagnosed and untreated epilepsy may account for a proportion of the cases of schizophrenia-like psychoses. It is unlikely, however, that either communicable diseases or organic brain disorders such as epilepsy account for more than a small fraction of the cases presenting as schizophrenia. Among some 5,000 individuals with psychotic illnesses who were screened in India and Nigeria for inclusion in the WHO Ten-Country Study, only 11.7% were excluded on the grounds of having a physical disease that might explain their psychotic symptoms. Thus, problems of differential diagnosis in respect of organic brain diseases may arise in individual cases, but the majority of schizophrenic disorders in the Third World cannot be attributed to somatic disease or gross brain pathology. Considering all available evidence, schizophrenic disorders in non-Western populations can be reliably distinguished from acute transient psychoses, culture-bound syndromes, and probably affective disorders, although the boundary with the latter has not been adequately

explored, and symptomatic overlap may exist. Family morbidity data for developing countries are still scarce, but where such information is available, it suggests that genetic factors appear to contribute to the transmission of schizophrenia in the same way as in developed countries.

VARIATIONS IN THE INCIDENCE AND PREVALENCE OF SCHIZOPHRENIA

No population or culture has been identified to date in which schizophrenia does not occur. The rates of its occurrence are broadly comparable, provided that the populations being compared are large enough to minimize the effects of small-area variation. This certainly does not imply that the incidence of the disorder is uniform across all populations but rather that the range of variation is modest in comparison with other complex or multifactorial diseases, such as noninsulin-dependent diabetes, ischemic heart disease, or multiple sclerosis, in which 10- to 30-fold differences among populations are not uncommon.

Prevalence

The prevalence of a disease is the estimated number of cases per 1,000 persons at risk present in a population at a given time (point prevalence) or over a defined period (period prevalence). Since schizophrenia cases in prolonged remission are likely to be missed in point prevalence surveys, it is useful to estimate the lifetime prevalence by supplementing the assessment of the present mental state with data about past episodes of the disorder. An overview of selected general population prevalence studies of schizophrenia and related disorders is presented in Table 12.3–1. These studies differ in many aspects of methodology but are generally characterized by a high intensity of case-finding. A systematic review of 188 studies in 46 countries, published between 1965 and 2002, estimated the median value for point prevalence at 4.6 per 1,000 persons, period prevalence at 3.0 per 1,000 persons, and lifetime prevalence at 7.2 per 1,000. The median combined prevalence estimates were also lower in developing nations (2.6 per 1,000) compared to developed countries (3.3 per 1,000) or emerging economy countries (4.7 per 1,000) in this review. Estimates from the GBD 2016 study, which used a Bayesian meta-regression tool to derive prevalence estimates for 195 countries and territories, reported a global age-standardized point prevalence of

schizophrenia to be 0.28%, which did not vary widely across countries. However, China showed the highest age-standardized prevalence estimates of schizophrenia (0.42%), and the Netherlands is the highest in Europe (0.36%). The lowest mean prevalence rates were found across Africa and the Middle East (0.16% to 0.22%). Estimates, however, are less reliable considering the very limited high-quality epidemiologic data from low- and middle-income countries.

The 2010 Australian National Survey of psychosis covered a population of 1,464,923 people aged 18 to 64 years, which was about 10% of all Australians in that age range. The study employed a two-phase design: a psychosis screen of all users of mental health services was followed by a random selection of 1,825 people who were interviewed using a standardized schedule. In addition, two cognitive tests were employed, and all participants provided blood samples for a screen of metabolic abnormalities. The study found the 1-month prevalence of schizophrenia to be 3.10 cases per 1,000 population at risk and the estimated lifetime morbid risk at 3.45 per 1,000. The mean cognitive ability of the participants was 1.6 SD below the population average, but higher scores on the cognitive tests were significantly associated with better independent functioning. A striking finding was the high prevalence of the metabolic syndrome, affecting 60.8% of participants (65.9% were current smokers; 47.4% were obese; 32.4% were sedentary; 50.8% had a lifetime history of cannabis dependence; and 49.8% were chronic alcohol users). These alarming findings pointed to an urgent need for physical health interventions, cognitive remediation therapies, and workforce planning focusing on supported employment.

Incidence

The incidence rate is the estimated annual number of first-onset cases in a defined population per 1,000 persons. Incidence is of greater interest for risk-factor epidemiology than prevalence since it is interpretable in terms of the probability of disease occurrence in a given population and is temporally closer to the antecedents of the disease or its precipitating factors. However, its estimation depends critically on the capacity to determine the point of the disorder reliably—a requirement that is difficult to meet for schizophrenia due to its often long prodromal period and the fuzzy boundary between premorbid state and psychosis onset. Since objective biomarkers of the disease process are still lacking, onset is

usually defined as the point when clinical manifestations become recognizable and can be diagnosed according to specified criteria. The first hospital admission, which has been used as a proxy for disease onset in many studies, is not a robust indicator because of the variable time lag that may exist in treatment facilities between the earliest appearance of symptoms and hospitalization (and many cases do not get hospitalized). A better approximation is provided by the time point of the person's *first contact* with any psychiatric, general medical, or alternative aid agency for reasons likely related to emerging psychosis. Such estimates are less reliable in developing countries with limited access to mental health care. Clearly, both first-admission and first-contact studies share the limitation of measuring "treated" incidence and risk omitting cases that do not present for assessment or treatment. This limitation can be overcome by periodically repeated door-to-door surveys of the same population or by longitudinal cohort studies (though both are difficult to mount for reasons of cost and logistics).

A systematic review of incidence data from some 160 studies from 33 countries, published between 1965 and 2001, yielded a median value of 0.15 and mean value of 0.24 per 1,000, with a fivefold range of the rates and a tendency for recent studies to report lower rates. A more recent systematic review and meta-analysis of studies published between 2002 and 2017 found a median incidence of schizophrenia to be 0.22 per 1,000, with high variation across studies. The same study indicated a pooled incidence of 0.27 per 1,000 for psychotic disorders. A significant portion of the variation highlighted can be attributed to methodologic differences and confounders, including the type of study sample and design, coverage of case findings (hospital-based, field surveys, case registers, birth cohorts), diagnostic practices, sample size, statistical power, and methods of data analysis. For example, birth cohort studies and case registers tend to produce higher rates than cross-sectional community surveys and hospital admission studies. Larger studies often estimate higher incidence rates compared to smaller studies. Furthermore, first-contact studies often lead to lower incidence rates as they include standardized diagnostic assessments, which can reduce the number of false positive results. Notwithstanding such limitations, real variation is undoubtedly present in schizophrenia (as in any human disease). The interesting question concerns the extent and sources of this

variation and whether its study adds any clues to the understanding of schizophrenia etiology.

Table 12.3–1. Selected General Population Prevalence Studies of Schizophrenia

Region	Authors, Publication Year	Diagnosis	Method	Sample Size	Sample Age	Region	Prevalence Per 1,000	Prevalence Type

[a]Age-standardized rates.
Adapted from He H, Liu Q, Li N, et al. Trends in the incidence and DALYs of schizophrenia at the global, regional and national levels: results from the Global Burden of Disease Study 2017. *Epidemiol Psychiatr Sci*. 2020;29(e91):1–11. doi:10.1017/S2045796019000891. License: https://creativecommons.org/licenses/by/4.0/.

Table 12.3–2 presents the age-standardized incidence rates (ASIR) and accompanying age-standardized DALY rates (ASDR) across world regions in 1990 and 2017, based on the GBD 2017 study. The global ASIR (per 100,000) decreased only slightly from 14.98 in 1990 to 14.39 in 2017, while the ASDR (per 100,000) remained largely stable from 157.01 to 156.45. ASIR estimates were lowest in Eastern Europe and sub-Saharan Africa and highest in East Asia. ASDR estimates were lowest in sub-Saharan Africa and highest in East Asia. Figures 12.3–1 and 12.3–2 show the ASIR and ASDR global estimates, respectively, based on the GBD 2017 study. The ASIR and ASDR were highest in China, the Netherlands, and Australia.

The WHO Ten-Country Study

Inferring a more general perspective on the comparative incidence or prevalence of schizophrenia in different populations from individual studies conducted at different times and with different methods or from pooled data from multiple studies is beset with difficulties. The WHO Ten-Country Study, published in 1992, remains to date the only investigation that has applied a uniform design and common research tools to generate directly comparable incidence data for different populations. Incidence counts in the study were based on first-in-lifetime contacts with any aid agency within defined areas (including traditional healers in developing countries), which were monitored over a 2-year period. Potential cases and key informants were interviewed by clinicians using standardized instruments, and the timing of onset was reliably ascertained for the majority of the patients. In 86% of the 1,022 patients, the onset of diagnostic symptoms of schizophrenia was within the year preceding their first contact, and, therefore, the first-contact incidence rate was adopted as a reasonable approximation to the "true" onset rate. Two definitions of *caseness,* differing in the degree of sensitivity and specificity, were used: a "broad" clinical definition comprising ICD-9 schizophrenia and paranoid psychoses and a more restrictive definition of "nuclear" schizophrenia with Schneiderian *first-rank symptoms* of "nuclear" schizophrenia. Intersite reliability of case classification was ensured by applying a computerized diagnostic algorithm. The rates for eight of the catchment areas in which a nearly complete case finding was achieved are shown in Table 12.3–3. The differences between the area rates for "broadly" defined schizophrenia (0.16 to 0.42 per 1,000) were significant ($P < .001$), but those for "nuclear" schizophrenia were not, suggesting that the frequency of the latter subgroup varies less across different populations. No differences were found between the "broad" and "nuclear" cases with regard to age at onset or 2-year course and outcome. Therefore, it is unlikely that "nuclear" and "broad" schizophrenia identify different clinical disorders. Several replications of the WHO design, including its research procedures and instruments, have been carried out with very similar findings in India, the Caribbean, and the United Kingdom.

Table 12.3–3.
Incidence Rates per 1,000 Population, Ages 15 to 54 Years, for a "Broad" and a "Narrow" Case Definition of Schizophrenia (WHO Ten-Country Study, 1992)

		"Broad" Definition (IDC-9)			"Narrow" Definition (CATEGO S+)		
Country	Area	Male	Female	All	Male	Female	All
Denmark	Aarhus	0.18	0.13	0.16	0.09	0.05	0.07
India	Chandigarh (rural area)	0.37	0.48	0.42	0.13	0.09	0.11

USA	Honolulu	0.18	0.14	0.16	0.10	0.08	0.09

Small Area Variations

Since schizophrenia is a low-incidence disorder, variations in its prevalence are more prominent in comparisons of rates obtained from small geographical areas and communities. In a study of an ethnically and socioeconomically homogeneous rural region in Ireland, the overall prevalence of schizophrenia at 3.9 per 1,000 was well within the modal range, but analysis by small district electoral divisions revealed significant variation in rates, ranging from 0.0 to 29.4 per 1,000. Such variation stands in contrast to the more similar rates typically found in studies of large urban areas or at a national level. Local variation can be attributed to several factors, for example, spatial clustering of cases due to shared genetic vulnerability within extended pedigrees, differential mobility and mortality, and, possibly, differential exposure to risk factors influencing intrauterine growth and early neurodevelopment. Such effects may give rise to outlier pockets of high or low incidence and prevalence that tend to cancel each other in larger population agglomerations.

Migrant Populations

Multiple observational studies have found that migration is a significant factor in increasing the risk of developing psychotic disorders. Schizophrenia risk in migrants is typically found to be 2 to 4 times that of the nonimmigrant population, but rates up to 10-fold have also been reported in some groups. A meta-analysis of studies of first- and second-generation immigrants (SGI) (largely in Europe, but also in Israel, Australia, and North America) found that a mean weighted incident rate ratios (IRR) for schizophrenia of 2.3 for first-generation immigrants (FGI) and 2.1 for SGI. The mean-weighted IRR for black FGI was higher (4.0)

than for white FGI (1.8) or another ethnicity FGI (2.0). Black SGI also had IRR rates that were higher (5.4) than that of black FGI, a finding that was not seen among white or other immigrant groups. The persistence of schizophrenia risk in the second generation of immigrants suggests that postmigration factors play a significant role in increasing risk.

The highest IRRs of immigrants have been reported in studies in the United Kingdom, the Netherlands, and Scandinavian countries. An exceptionally high incidence rate of schizophrenia has been found in the African–Caribbean population in the United Kingdom, with a ninefold increase, compared to the native white British population in the 2006 AESOP study, compared to an IRR of 5.8 in black Africans, and 1.4 in South Asians. Similarly, a nearly fourfold excess over the general population rate has been reported for the Dutch Antillean, Moroccan, and Surinamese immigrants in the Netherlands. The causes of the phenomenon remain obscure. Incidence studies do not indicate any excess schizophrenia morbidity in the indigenous populations from which migrants are recruited. Explanations in terms of biologic risk factors have found little support. Misdiagnosis of psychotic disorders in immigrant groups has been debated but is unlikely to fully account for the large disparities in schizophrenia rates found across groups in multiple studies. With an absence of evidence from source countries of elevated schizophrenia rates, the social environment is believed to be the key factor underlying high rates in immigrants. Adverse social experiences involving being marginalized or perceptions of discrimination could be uniquely stressful, particularly when paired with limited social or family support. This is further suggested by findings from several studies showing that the incidence of schizophrenia in a group increases as they represent a smaller share of the host population.

Ethnic Minorities

Almost all empirical studies of psychotic disorder or schizophrenia have described disproportionate effects of race on the diagnosis. In a systematic review and meta-analysis of papers between 2002 and 2017, ethnic minorities had an increased risk of all psychotic disorders, which included nonaffective psychotic disorders. Race has also been related to diagnosis after using standardized diagnostic criteria and structured interviews.

Most empirical studies involving ethnicity or race and psychotic disorders have been conducted in the United States. These studies also include more indigenous ethnic minority populations and fewer immigrants than those conducted in other countries. In clinical settings, African Americans are disproportionately diagnosed with schizophrenia, typically 3 to 5 times compared to White Americans, and when admitted to state hospitals, are up to five times as likely to receive a schizophrenia diagnosis. They are also more likely to be diagnosed as having a psychotic disorder than Latino Americans. A meta-analysis of racial comparison studies in schizophrenia diagnosis found that African Americans had the disorder at a rate 2.4 times higher than White Americans, and odds ratios were slightly higher for studies using unstructured (2.4) than for those using structured (1.8) diagnostic assessments. African Americans and Latin American children and adolescents who present to psychiatric emergency rooms are also twice as likely to receive a diagnosis of a psychotic disorder than White Americans. When lifetime psychotic symptoms were assessed, its prevalence was 15% in African Americans, 13% in Latin Americans, 9% in Asian Americans, and 9% in White Americans. In addition, Blacks are associated with higher doses of antipsychotics, more frequent prescription of long-acting injections, more frequent use of first- compared to second-generation antipsychotics, lower quality of life, and worse outcomes after the first psychotic episode.

There is also a strong effect of ethnicity on diagnosis in other international studies. Black inpatients in Portugal are more likely to be diagnosed with schizophrenia and psychosis than white inpatients, and Black citizens in Sweden receive a psychotic disorder at an increased rate compared to those of other ethnic backgrounds. In the Netherlands, black and minority ethnic groups and whites from other western groups are over twice as likely to receive mandated hospital admissions than Dutch natives.

There are several potential reasons for disproportionately increased diagnosis of schizophrenia in African Americans, though no single empirically proven explanation appears to be sufficient. Unconscious clinical bias based on stereotypes can result in misdiagnosing African Americans at higher rates of schizophrenia, even among people of the same race as the patient. Clinicians may associate symptoms in African Americans with disruptive and socially deviant behaviors to a greater

degree, influencing diagnostic choices. They may also use inappropriate cultural context or misinterpret normative guardedness as paranoid symptoms. In addition, a pattern of less access to healthcare, more distrust in mental health professionals, the higher social stigma of mental illness, and culture-specific methods of dealing with distress among many ethnic minority groups could lead to patients being more symptomatic when they present to treatment settings. Increased rates of schizophrenia in African Americans compared to lower rates in native Africans living in their continent is suggestive of the role of underlying environmental risk factors. Urbanicity is related to the increased incidence of schizophrenia and may be a mediating factor for race relationship to diagnosis, considering ethnic minorities tend to live in urban areas. Migrant studies conducted internationally have attributed perceived discrimination, social marginalization, and low social capital as factors driving factors toward increased psychotic disorder diagnosis. Such social factors are likely also relevant to ethnic minorities such as African Americans and may drive increased schizophrenia diagnosis rates. Differences in substance use rates across ethnic groups have also been hypothesized to contribute to diagnostic disparities. Data from the 2005 to 2013 National Surveys of Drug Use and Health involving 340,456 U.S. adults found that cannabis use disorder (CUD) rates were higher among native Americans (4.2%) and Blacks (2.4%) compared to Whites (1.3%). While specific substance use disparities may contribute to higher schizophrenia rates among African Americans, it is unlikely to be the primary factor. Black FGIs to Europe typically have low substance use rates, despite a relatively high prevalence of psychotic disorders.

Genetic Isolates

Isolated populations provide another source of incidence and prevalence variation. Isolates are characterized by common descent from a small number of *founder* ancestors, a degree of endogamy or inbreeding, and a restricted admixture of immigrants, due to geographical or cultural seclusion over multiple generations, often ranging over hundreds of years. Such populations may vary considerably in size but are likely to be less heterogeneous with regard to genetic makeup and environmental exposures than the outbred (panmictic) populations constituting the world's majority, in which theoretically all individuals are potentially mating partners. The so-called young isolates comprise up to 20 to 30

generations and typically have arisen following drastic population size reductions (bottlenecks) due to wars, famine, epidemics, religious persecution, or other cataclysms. Subsequent population expansion results in a more uniform genetic background, including wider intervals of linkage disequilibrium, a more uniform environment and lifestyle, and a significantly higher or lower prevalence of certain diseases, including psychiatric disorders. If coupled with the availability of genealogic memory or records, such isolates present unique opportunities for genetic linkage and association studies of Mendelian (monogenic) diseases and, hopefully, of complex traits such as schizophrenia, bipolar disorder, and other psychiatric syndromes.

A number of isolated populations in different parts of the world, including Finland, Iceland, and northern Sweden; the Pima Indians; the Bedouins; the people of the Central Valley of Costa Rica, several areas in Quebec, as well as religious communities, such as the Old Order Amish, the Hutterites, and the Mennonites, have been studied by epidemiologists and geneticists with a view to identifying large pedigrees, informative for diseases ranging from asthma and diabetes to schizophrenia and bipolar disorder. High rates of psychoses (two to three times the national or regional rate) have been reported for population isolates in northern Sweden and several areas in Finland. Although the whole population of Finland shares some features of an old isolate (approximately 2,000 years), the northern and eastern regions of Finland have been settled relatively recently (in the 16th and 17th centuries), and one particular subregion with a current population of 18,000 has been founded by 40 families at the end of the 17th century, that is only 12 generations back. Genetic–epidemiologic studies in this isolate estimate the lifetime risk of schizophrenia at 2.2%, compared to 1.2% for the whole of Finland. A case register-based study of a birth cohort (14,817 individuals) from this region established a lifetime prevalence of 1.5% for schizophrenia spectrum psychotic disorders.

Daghestan in the Northern Caucasus (Russian Federation) is a region that has been inhabited for more than 3,000 years by some 26 small ethnic groups constituting together at least five genetically distinct populations, varying considerably in their morbidity patterns. Possibly, the highest-ever lifetime prevalence estimate for schizophrenia (4.9%) has been reported from one such highland subisolate (3,000 members).

The population of the Palau islands (Micronesia), currently 20,470 people, has been geographically and ethnically isolated from other Pacific populations for nearly 2,000 years. A genetic epidemiologic study of treated cases estimated the lifetime prevalence of schizophrenia at 2.77% in males and 1.99% in females, that is, high in excess of the modal risk of about 1% usually reported for large outbred populations. All of the 160 Palau cases were concentrated in 59 families, each traceable to a single common founder, with 11 of them having 5 to 11 affected members each.

At the other extreme, the lowest known prevalence rate of schizophrenia in any population (and a very low rate of bipolar disorder) has been found among the Hutterites in South Dakota, a Protestant sect of European descent (founded in the 16th century) whose members live since the 1870s in closely knit, endogamous rural communities in Manitoba (Canada) and South Dakota (United States). According to preserved pedigree records, all of the present 45,000 Hutterites are descendants of fewer than 90 ancestors who lived in the 18th and early 19th centuries. Reduced genetic heterogeneity and communal lifestyle with minimum variation in environmental exposures make this population an attractive laboratory for a variety of disease studies, including psychiatric disorders. An early epidemiologic study in which the entire population of several Hutterite communities was screened resulted in a schizophrenia lifetime prevalence of only 1.1 per 1,000. Subsequent reanalysis of the data using DSM-III-R criteria, and a repeat survey, replicated the original finding. Both genetic (low frequency of psychosis-predisposing alleles) and lifestyle factors (protective community support) have been proposed as an explanation for the unusually low rate of psychosis. Negative selection for individuals with schizoid traits who fail to adjust to the communal lifestyle and eventually outmigrate without leaving progeny has also been suggested but not definitively proven.

VARIATION IN THE COURSE AND OUTCOME OF SCHIZOPHRENIA

Systematic investigations into the course and outcome of schizophrenia were initiated by Kraepelin, who believed that the natural history of the disorder could provide a provisional validation of the disease concept until final verification by brain pathology and understanding of etiology. However, contrary to Kraepelin postulate of “mental weakness” as the

ultimate outcome of *dementia praecox,* it is precisely the long-term course of schizophrenia that reveals the greatest extent of variation across populations and cultures. The course and outcome of schizophrenia exhibit striking heterogeneity and variability, both across and within populations. Patients with similar clinical and diagnostic characteristics at baseline assessment develop a broad spectrum of outcomes ranging from stable clinical and social recovery after a single psychotic episode to chronic unremitting psychosis and severe impairment. Long-term follow-up studies lend credibility to the conclusion that a high proportion (more than 30%) of patients meeting the diagnostic criteria for schizophrenia may achieve relatively favorable outcomes.

Untreated Schizophrenia

Since the great majority of schizophrenic patients in developed countries are today receiving pharmacologic treatment, one could assume that current research does not reflect the "natural" course and outcome of untreated schizophrenia. However, several studies in an urban area in Scotland and in remote rural areas in India and China have succeeded in detecting and assessing *never hospitalized* patients with schizophrenia. About half of the Scottish patients had been prescribed antipsychotic medications by their general practitioners, while the Indian and Chinese patients were virtually untreated. In all three settings, the outcomes of these samples were heterogeneous, but, except for a larger proportion of Chinese patients having marked psychotic symptoms, they did not differ much from the outcomes in the treated groups. In a historical study of 70 Swedish patients with first admissions in 1925, lifetime records were retrieved and rediagnosed in accordance with DSM-III. None of these patients had received antipsychotics. The final outcome was rated as "good" in 33%, as "profoundly deteriorated" in 43%, and as "intermediate" in 24%.

Secular Trends in the Outcome of Schizophrenia

A long-term perspective on the course of schizophrenia over successive generations is provided by a meta-analysis of 320 outcome studies on schizophrenia or *dementia praecox* published between 1895 and 1992, which comprise a total of 51,800 subjects. Overall, about 40% of the patients have been described as "improved" after an average length of follow-up of 5.6 years. There was a significant increase in the rate of

improvement from 1956 to 1985 compared to 1895 to 1955, clearly related to the introduction of antipsychotic medications, but a secular trend toward better outcomes with every successive decade had been present for much longer. Coupled with the virtual disappearance of the most malignant or “catastrophic” forms of schizophrenia that tended to result in a profound “defect state” after a single psychotic episode or in death (*lethal catatonia*), these observations suggest that a transition to a less deteriorating course of schizophrenia had been taking place prior to the advent of modern pharmacologic treatment. Among the factors that might explain this shift are improvements in general care, progressive changes in attitudes and hospital regimes that occurred in a number of institutions on both sides of the Atlantic in the 1930s and 1940s, and the expectation that psychosocial measures such as psychotherapy or rehabilitation could result in a cure or remission of the disorder.

Concurrently, with the above trends in Europe and North America, reports from developing countries, usually based on small clinical samples, pointed to a less disabling course and a high rate of recovery from schizophrenic psychoses in traditional societies such as Mauritius and Sri Lanka. Good outcome cases included patients who would be expected to have a poor outcome if “Western” prognostic criteria had been applied. However, selection bias could not be excluded, as these studies were based on hospital admissions only. In addition, clinical improvement could have been confounded with the social adjustment many patients achieve in a comparatively undemanding environment. Thus, the room was left for doubts concerning the validity of the early observations of a better prognosis of schizophrenia in non-Western settings.

Table 12.3–4.
Two-Year Course and Outcome Features of 1,070 Patients With Schizophrenia in the WHO Ten-Country Study

Course and Outcome Descriptor	Percent Patients in Developing Countries[a] (*n* = 467)	Percent Patients in Developed Countries[b] (*n* = 603)
Remitting, complete remissions	62.7	36.8
Continuous or episodic, no complete remission	35.7	60.9
Psychotic <5% of the follow-up	18.4	18.7
Psychotic >75% of the follow-up	15.1	20.2
No complete remission during follow-up	24.1	57.2
Complete remission for >75% of the follow-up	38.3	22.3
On antipsychotic medication >75% of the follow-up	15.9	60.8
No antipsychotic medication during follow-up	5.9	2.5
Hospitalized for >75% of follow-up	0.3	2.3
Never hospitalized during follow-up	55.5	8.1
Impaired social functioning throughout follow-up	15.7	41.6
Unimpaired social functioning >75% of	42.9	31.6

follow-up

[a]Study areas in Colombia, India, and Nigeria.

[b]Study areas in Czech Republic, Denmark, Ireland, Japan, Russia, the United Kingdom, and the United States.

Many of the methodologic issues attending such research were later addressed by the WHO multicenter studies that employed standardized assessment, recruitment of homogeneous, incidence-based samples, and more refined, dimensional measures of course and outcome. These studies included a total of 2,736 patients in 16 countries diagnosed with schizophrenia according to strict criteria.

Course and Outcome in the WHO Studies

The earliest WHO investigation, the IPSS, found that higher proportions of patients in India, Colombia, and Nigeria had better outcomes on most dimensions than patients in the developed countries at 2- and 5-year follow-up assessments. However, the IPSS was not free of bias since patients were recruited from hospitals, where admission policies could have led to the overinclusion of chronic cases in the developed countries and of recent onset, acute cases in the developing countries.

Such confounding factors were largely eliminated in the subsequent WHO Ten-Country Study, in which epidemiologic cohorts of first-episode cases were uniformly assessed upon their first contact with community or hospital services. Diagnostic misclassification due to the potential admixture of transient psychotic episodes of good prognosis or of psychoses due to acute physical illness was excluded, as such cases were carefully screened out. The follow-up of these incidence cohorts provided ample confirmation of the finding that the outcome of schizophrenia was generally better in developing than in developed countries (Table 12.3–4). The better course and outcome in the developing country areas could not be attributed to any particular clinical subtype of the disorder. The main outcome difference across the study areas was in the average length of symptom-free remissions. Analysis of the data revealed that the better overall pattern of course and the less disabling outcome in the study areas in developing countries was mainly attributable to a significantly greater percentage of patients remaining in a remission of symptoms over longer periods after an acute psychotic episode, rather than to milder or shorter psychotic episodes. Statistically,

this pattern was significantly predicted by the setting (developing versus developed country), acute onset, being married or cohabiting with a partner, and having access to a supportive network (family or friends). The length of remission was unrelated to antipsychotic treatment, which generally was administered for much shorter periods of time to patients in developing countries.

Table 12.3–5.
Long-Term (15- and 25-Year) Outcome in Patient Cohorts Assessed in the International Study of Schizophrenia (ISoS, 2007)

Outcome Variable	Incidence Cohorts (*n* = 1,171, Including 15-year Follow-up of the WHO 10-Country Cohort)	Prevalence Cohorts (*n* = 462, Including 25-year Follow-up of 373 Cases from the WHO IPSS)
Recovered at follow-up (Bleuler criteria)	48.1	53.5
Not psychotic in the past 2 years	42.8	40.8
GAF-S >60	54.0	56.7
Working most of past 2 years	56.8	73.9
GAF-D >60	50.7	60.3
SMR (range)	0.00–5.71[a]	1.04–8.88[b]

GAF-S, Global Assessment of Functioning–Symptoms Scale; GAF-D, Global Assessment of Functioning–Disability Scale; SMR, standard mortality ratio.

[a]Rochester (0.000), Moscow (1.41), Chandigarh urban (1.88), Prague (2.53), Chandigarh rural (3.02), Honolulu (3.13), Nottingham (3.31), Dublin (4.10), and Nagasaki (5.71).

[b]Sofia (1.04), Cali (1.31), Madras (1.90), Agra (1.86), Beijing (2.97), Prague IPSS (3.84), Mannheim (5.55), Hong Kong (5.76), and Groningen (8.88).

A subsequent long-term follow-up investigation, the International Study of Schizophrenia (ISoS), involving 18 research centers in 14 countries, traced 75% of cases assessed in the earlier WHO studies referred to previously, as well as additional cohorts from China, Hong Kong, and India. Follow-up data were collected on a total of 1,633 cases (surviving or dead), and 890 patients were reinterviewed at either 15- or 25-year follow-up since their first assessment. Key findings from this study are presented in Table 12.3–5.

Several general conclusions can be drawn from the WHO studies. The frequencies of both relapses and remissions tend to increase over time. However, regardless of the increased relapse rate, the cumulative proportion of follow-up time during which patients have psychotic symptoms (as a percentage of the total follow-up time) tends to remain stable or even decrease. At the end of the 5-year follow-up, 57% of the patients had experienced a total of fewer than 9 months of active psychosis; only 22% had been psychotic for 45 to 60 months. At 15-year and 25-year follow-up, 43% and 41%, respectively, have been free of active psychotic symptoms for the past 2 years. The levels of social impairment assessed at 2 years changed little during the subsequent years of follow-up. Overall, most of the observed changes in the clinical state and social functioning of patients between the 2-year follow-up and the 5-year follow-up were toward improvement rather than deterioration. This was congruent with the findings at 15-year and 25-year follow-up. Independently of the WHO studies, similar findings of better outcomes of schizophrenia in developing countries have been reported by other investigators.

Factors Influencing the Variations in Outcome

The differences in outcome between patients in developing countries and patients in developed countries remain insufficiently understood but are unlikely to be reducible to a single variable or to a small number of explanatory variables. The variation in course and outcome may result from additive or interactive effects of genetic differences between populations; from lower incidence in traditional societies of the type of chronic stress to which people with schizophrenia are particularly vulnerable; or from higher odds of an individual–environment fit in traditional communities that minimize social isolation. While genetic differences undoubtedly exist (e.g., in the allelic structure of genes coding

for key neurotransmitter receptors), nothing more specific can at present be said as to their role in the course and outcome of schizophrenia. Worse schizophrenia outcomes in migrants and ethnic minorities compared to that observed in their source countries suggests that genetic differences may be less determinative than environmental influences. A strong modifying influence of the psychosocial environment on the course of schizophrenia is plausible, considering the differences between developing and developed countries with regard to social support systems, kinship networks, and beliefs about mental disease. As regards psychosocial stress, the WHO studies found that the index of *expressed emotion* (EE), a short-range predictor of psychotic relapse, was as effective in Indian families as in European and North American families, but that high-EE families were much rarer in India than in Denmark or the United Kingdom. If this finding could be replicated in other settings in developing countries, the relative rarity of at least one type of pathogenic stress in the daily environment of schizophrenic individuals in such communities could be demonstrated. However, EE may not be the only type of stress to which schizophrenic individuals respond with psychotic exacerbation. Ethnopsychiatrist Henry Murphy (1915 to 1987) proposed four criteria for schizophrenia-evoking stress: (i) a situation demanding action or decision; (ii) complexity or ambiguity of the information supplied to deal with the task; (iii) unless resolved, the situation demanding action or decision persists; (iv) the person has no “escape route” available. Each component of this model may occur at different frequencies in traditional and industrialized societies, a proposition that should be testable epidemiologically or experimentally. For example, important differences exist between traditional cultures and Western societies regarding the perception of the sick role and the beliefs and practices related to mental illness. Shared magical–mystic explanations of mental illness and traditional healing practices, still prevalent in traditional rural communities, certainly provide no cure for schizophrenia, but they may play a role in lowering the barriers to recovery and reintegration into the community. Substance use likely also plays a role in influencing outcomes, particularly cannabis use, which has been associated with triggering psychosis. According to the GBD study, the United States has the highest age-standardized prevalence of cannabis, opioid, and cocaine use disorders. CUDs are next highest in Australia and Western Europe, while Eastern Europe leads the world in alcohol use disorders. In contrast, the continent

of Africa, the Middle East, Central America, and South Asia have relatively low rates of substance use disorders. The findings of a better outcome for schizophrenia in traditional societies are compelling enough to set a research agenda that may lead to important insights concerning the management and treatment of schizophrenia in both developing and developed countries.

To sum up, the most striking finding from long-term follow-up studies is the high proportion of patients who recover completely or with mild residual abnormalities after decades of severe illness. This contrasts with the ingrained image of schizophrenia as an intractable, deteriorating illness that many clinicians tend to adopt on the basis of a limited follow-up horizon and patient samples selected for their unfavorable course and treatment response. It is unlikely that the high percentage of recoveries in the long-term studies could be explained by affective illness or brief transient psychoses being misdiagnosed as schizophrenia. Similarly, unlikely is the attribution of all the good outcomes to antipsychotic treatment since comparable proportions of improvement of recovery had been reported for patients who never received antipsychotic medications. A tentative conclusion is that schizophrenia is not an invariably chronic deteriorating disorder. It should be noted, however, that some studies suggest a recent trend of worsening clinical and social outcomes in patients with schizophrenia in both developed countries and developing countries. People with schizophrenia are profoundly sensitive to their immediate social environment. Increasing social and economic stresses experienced by both rural and urban communities in many developing countries in the last two decades may be eroding the traditional support systems, thus resulting in worse outcomes.

THE BURDEN OF COMORBIDITY

Physical Disease

There is significant medical comorbidity in schizophrenia, comprising mainly common diseases that affect patients with schizophrenia more frequently than attributable to chance, as well as certain rare conditions or abnormalities that tend to co-occur with the disorder. Physical disease in patients with schizophrenia tends to be seriously undetected and underdiagnosed. Between 46% and 80% of inpatients with schizophrenia and between 20% and 43% of outpatients have been found in different

surveys to have concurrent medical illnesses. Persons with schizophrenia, and especially those who are homeless or injection drug users, are at increased risk for potentially life-threatening communicable diseases, such as HIV/AIDS, hepatitis C, and tuberculosis.

However, it is the chronic noncommunicable diseases, that in the past decades, are taking an increasingly heavy toll on people with schizophrenia. Cardiovascular disease (CVD) and the associated premature mortality are significantly increased in schizophrenia. A recent comprehensive meta-analysis of mortality in schizophrenia reported a standardized mortality ratio (SMR) of 2.54. It has been estimated that the high prevalence of CVD impacts the life expectancy of people with schizophrenia by an average reduction of 18.7 years for men and 16.3 for women and that the gap between those affected with the disorder and the general population is increasing. Although suicide rates in schizophrenia are high and equal to those for major depression, recent studies suggest that CVD is at present the main cause of premature death, already evident in early or middle adulthood. The contribution of “atypical” antipsychotic medication to weight gain and hence to metabolic imbalance and type II diabetes is likely, but its effects are collinear with other modifiable lifestyle risk factors, including nutrition, smoking, and lack of physical activity. Obesity and the concomitant metabolic syndrome involving insulin resistance and type II diabetes are at present common problems in patients with schizophrenia.

Certain rare genetic or idiopathic disorders, such as metachromatic leucodystrophy, acute intermittent porphyria and coeliac disease, and dysmorphic features such as high-steepled palate, malformed ears, and other minor physical anomalies, also tend to co-occur with schizophrenia. The genetic syndrome that involves a chromosome 22q11.2 deletion (DiGeorge Syndrome) involves schizophrenia in about 25% of individuals. There are typical associated physical features with 22q11.2 deletion syndrome, including mild facial dysmorphia and congenital anomalies, as well as congenital heart defects, velopharyngeal insufficiency, and submucosal cleft palate in some cases.

Recently, studies have also found that schizophrenia patients infected with the novel coronavirus, COVID-19, caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) are twice as likely to be hospitalized for this infection (OR = 2.15) and remained significant even after controlling for sociodemographic and smoking, obesity, diabetes,

hyperlipidemia, chronic obstructive pulmonary disease, and ischemic heart disease (OR = 1.88). In addition, compared to healthy controls, schizophrenia patients were about three times as likely to have infection mortality (OR = 3.27), and this remained significant after adjusting for sociodemographic (OR = 2.79) and clinical factors (OR = 2.77).

Substance Abuse

Substance abuse is, at present, by far the most common associated health problem among patients with schizophrenia and may involve any drug of abuse or a polydrug combination. The addictive use of cannabis, stimulants, and nicotine is disproportionately high among patients with schizophrenia and may be related to the underlying neurobiology of the disorder. Reasons for the comorbidity of substance use disorders and schizophrenia are unclear, and several theories have been proposed to explain this, including common genetic vulnerabilities and neural networks, cumulative risk and environmental stressors, or attempts at self-medication.

Alcohol and illicit drug use in schizophrenia patients are relevant clinically, as they worsen the overall course of the illness and increase morbidity and mortality. Affected individuals are more likely to get hospitalized or become homeless, violent, suicidal, or incarcerated. It is also linked with decreased treatment compliance and risk of relapse. In a systemic review and meta-analysis of 123 studies on substance use disorders in schizophrenia in community and clinical settings between 1990 and 2017, the overall prevalence was 0.417. The overall prevalence of alcohol use disorder was 0.243, with the prevalence in Asia being lower (0.077) than that in other countries. Illicit drug use disorder use in schizophrenia patients was 0.275 and higher in those with first-episode psychosis (0.362) compared to those with schizophrenia (0.197). The highest prevalence of illicit drug use disorder was found among patients in North America and Australia. The point estimate for prevalence for stimulant use disorder in schizophrenia patients was 0.073, while that for opioid use disorder was 0.051. Male patients also have a two to three times greater risk of substance use disorders than females.

About 3.9% of the global adult population uses cannabis, which is higher than all the other illicit substances combined. Cannabis use has particular relevance to schizophrenia as it has been directly linked to an increased risk of developing psychosis. Cannabis has been extensively

reported to induce psychotic experiences (PEs), and active cannabis users report higher ratings of positive symptoms. Previous meta-analyses indicate that the risk of developing psychotic disorders is increased twofold in those with schizophrenia. A systematic meta-analysis of 10 selected studies involving 66,816 individuals showed that among the heaviest cannabis users, the risk of schizophrenia and other psychotic disorders was even higher (OR = 3.90). In addition to the degree of cannabis exposure, existing evidence indicates that the use of high-potency cannabis and early onset of use are stronger risk factors for developing psychotic disorders. A systematic review of published data on cannabis exposure and the onset of schizophrenia concluded that early use increased the risk of psychosis in a dose-related manner, especially in persons at high genetic risk of schizophrenia. The point estimate for prevalence for studies of subjects with current or lifetime CUD was 0.262. First-episode patients had higher prevalence rates (0.356) of CUD compared to chronic schizophrenia patients (0.208). The highest CUD prevalence in schizophrenia patients was found in the United States, Australia, and Western Europe. The lowest rates of CUD globally are seen in sub-Saharan Africa and North Africa/Middle East, and South Asia.

VARIATIONS IN MORTALITY

In both developing and developed countries, schizophrenia is associated with excess mortality, well documented by epidemiologic studies on large cohorts over extended periods. Those with schizophrenia have been known to have higher rates of somatic disorders, including cardiovascular and diabetes, compared to control populations, as well as increased tobacco, alcohol, and illicit substances use. In addition, increased sedentary behavior, poor dietary habits, and poor health-seeking behavior negatively influence health outcomes. Finally, schizophrenia patients have an increased suicide risk by as much as 22 times compared to the general population, particularly early after symptom onset. A meta-analysis of studies involving 247,603 patients across Africa (n = 1; Ethiopia), Asia (n = 1; Taiwan), Australia (n = 1), Europe (n = 7), and North America (n = 3) found that, on average, those with schizophrenia had 14.5 years of potential life lost. Men lost about two years of potential more than women with schizophrenia, and life expectancy was about 8 years lower for men than women patients, and the difference was primarily due to a male

excess in suicides and accidents. Globally, the loss was the least in Asia and the greatest in Africa. Overall weighted life expectancy was 65.7 years in schizophrenia patients and was lowest in Asia and Africa.

Population-based data from Norway, 1926 to 1941 and 1950 to 1974 indicate that while the total mortality of psychiatric patients had been decreasing, the relative mortality of patients with schizophrenia remained unchanged at a level higher than twice that of the general population. Similar findings have been reported from other European countries and North America, with an SMR of 2.6 or higher for patients with schizophrenia, which corresponds to about a 20% reduction in life expectancy. In Taiwan, data collected over a 15-year period indicate that of all mental disorders followed up, schizophrenia was associated with the highest mortality, representing an 80% increase over the mortality of the general population. Data from successive patient cohorts in Denmark, the United Kingdom, and Australia suggest a trend of increasing mortality in the early stages of the disorder. In Denmark, the 5-year cumulated SMR increased from 5.30 (males) and 2.27 (females) for the period 1971 to 1973 to 7.79 (males) and 4.52 (females) for the period 1980 to 1982 (56). Particularly striking was the SMR of 16.4 for males in the first year after a diagnosis of schizophrenia.

Whereas in the past, the excess mortality among individuals with schizophrenia was due mainly to communicable diseases such as tuberculosis, the leading causes of premature death among patients with schizophrenia at present are CVD, suicide, accidents, and common physical diseases. Suicide accounts for 28% of the excess mortality in schizophrenia, with aggregated SMR of 9.6 for males and 6.8 for females. In developed countries, the suicide risk associated with schizophrenia is now nearly as high as that associated with major depression. In China, the *relative risk* (RR) of suicide in individuals with schizophrenia, compared to those without the disorder, has been estimated at 23.8. Suicide in schizophrenia may occur at any stage of the disorder, but the risk is particularly high in the first 6 months after the first psychotic episode, as well as following periods of frequent hospital admission and discharge. Several risk factors relatively specific to schizophrenia have been suggested: being young and male, experiencing multiple relapses and remissions, comorbid substance abuse, awareness of the deteriorating course of the condition, and a sense of hopelessness with loss of faith in treatment. In the Australian study, suicide risk was highest

in the first 7 days after discharge from inpatient care. The trend seems to parallel the significant reduction in the number of psychiatric beds. Whether the increased suicide mortality is associated with the shift in the management of schizophrenia from hospital to community care remains to be established.

Unnatural causes of death apart, in both developed and developing countries, schizophrenia is associated with excess mortality from common diseases, caused or exacerbated by poor self-care, inadequate nutrition, heavy smoking, and medical neglect. At least part of this excess mortality is preventable.

CRIMINAL OFFENDING AND VICTIMIZATION

Much remains to be understood about the risk of offending by individuals with schizophrenia and related psychotic disorders. Inconsistent research findings have been attributed to the use of varied and sometimes flawed methodologies and biased samples, such as inpatient and prison populations. The risk of violent offending has been estimated to be much higher in people with severe mental illness than that in the general population, partly attributable to the presence of substance abuse. In a large-scale Western Australian study of a cohort of all people born (1955 to 1969), arrest history was documented for the period 1985 to 1996 and cross-linked with the psychiatric case register. The prevalence of mental illness among offenders was 11.1%; 6.5% of offenders had substance use disorders, but only 1.7% had schizophrenia. Notably, for the majority of offenders with schizophrenia, the first arrest preceded first contact with mental health services. Given a large proportion of schizophrenia offenders being arrested prior to their first contact with psychiatric services, there are important implications for mental health and criminal justice policy and practice. Very similar findings were reported from a meta-analysis of nine studies, indicating that a substantial proportion of first-episode psychosis individuals commit offenses before presenting for treatment. Another aspect of the problem is victimization—violent assaults on people with severe mental illness. Among adults with psychotic disorders, especially women, the annual prevalence of any victimization was 38.6%, and of violent victimization 16.4%—nearly five times higher than the general population rate.

CLINICAL HIGH-RISK FOR PSYCHOSIS AND SUBTHRESHOLD PSYCHOTIC EXPERIENCES

Over the past three decades, the study of prepsychotic states has become a rapidly expanding area of research, often coupled with intervention programs and dedicated services. Clinical constructs have evolved to capture potential prodromal syndromes, with terms such as the "clinical high-risk (CHR)" or "ultra-high-risk (UHR)" states. Recognizing these diagnostic syndromes can facilitate early intervention, which can improve long-term outcomes and potentially the progression of symptoms to full-blown psychotic disorders. The role of these syndromes as a diagnosis, however, is being debated, and a related condition has been included as a condition for future study in the DSM-5.

The CHR criteria for the psychosis-risk state are based on either attenuated psychotic symptoms (APS), brief intermittent psychotic episodes (BIPS), or having genetic risk with a marked deterioration in psychosocial functioning (GRD). CHR individuals also tend to have small-to-medium neurocognitive impairments, intermediate between healthy controls and those with schizophrenia. The most commonly used interview measures used to assess CHR features are the Comprehensive Assessment of At-Risk Mental State (CAARMS), widely used in Australia, Asia, and Europe, and the Structured Assessment of Psychosis-Risk Syndromes (SIPS), most commonly used in North America. Basic symptom (BS) criteria have been proposed as symptoms that may identify an earlier prodromal state than the CHR criteria and involve subjectively experienced disturbances in mental processes, including thinking, speech, attention, perception, drive and stress tolerance. While psychosis-risk states are less severe than psychotic disorders, they often are associated with distress and poor functioning. In one study, 89% of adolescents meeting APS were reported to be distressed by the experienced symptoms.

Putative prodromal symptoms are pleiotropic and often do not convert to psychotic disorders like schizophrenia, although the risk of developing psychosis in those in the CHR state is substantially greater than in the general population. Most individuals meeting CHR criteria do not convert to a psychotic disorder over time. In a recent meta-analysis of 9,222 meeting CHR criteria, the cumulative conversion risk for psychosis was 0.09 at 6 months, 0.15 at 12 months, 0.20 at 18 months, 0.19 at 24

months, 0.25 at 30 months, 0.25 at 36 months, 0.27 at 48 months, and 0.28 at more than 48 months. The nonconverting group typically shows improvement in symptoms and functioning, though on average, they remain at a lower level of functioning than the population controls. Compared to those in the general population who meet CHR criteria, help-seeking CHR individuals have a higher conversion risk and are also more likely to exhibit distress and impairment.

Population-based studies have found that a history of subthreshold PEs is not uncommon in the general population, and these can potentially impact everyday functioning. The estimated prevalence of these PEs has varied widely across communities and is influenced by the method of data collection or screening questionnaire used. Screening instruments that probe a larger number of PEs can result in higher prevalence estimates than instruments with fewer questions. In addition, dichotomous (i.e., yes/no) psychosis questionnaires often underestimate prevalence rates compared to dimensional questionnaires, which probe symptom frequency. Past PE estimates in community samples have ranged from 4% to over 70%. A replication study of the National Comorbidity Study found that 9.1% of the U.S. population reported at least one PE. The NEMESIS study found a 17.5% rate of at least one PE in a general population in the Netherlands. PE rates are generally found to be higher among women than in men, in stark contrast to sex differences typically found in psychotic disorders.

The WHO's World Health Survey, composed of 256,445 subjects across 52 countries, found that 12.5% of the overall population responded positively to having had at least one PE over the last year. However, weighted and sex-age standardized PE prevalence estimates varied highly across the countries surveyed, from 0.66 in Vietnam and 1.5 in Bosnia and Herzegovina to 45.8 in Nepal and 32.0 in Brazil. Average standardized prevalence estimates for PEs were 8.83 for high and medium-high-income countries and 12.90 for low- and low-medium-income countries. A subsequent cross-national survey examined data from 31,261 subjects across 18 countries as part of the WHO World Mental Health Survey and reported mean lifetime PE rates of 5.8%. Lifetime PE rates in this study were significantly higher among those from high-income (6.8%) and upper–middle-income (7.2%) countries than among those from low- and low–middle-income countries (3.2%). Overall health status inversely correlates with the number of PEs. PE severity

correlates with increased anxiety, depression, and perceived stress, and may reflect a vulnerability to psychotic, anxiety, mood, and substance use disorders.

SOCIAL AND ECONOMIC COSTS

The health, social and economic costs of schizophrenia are high. In Western countries, the estimated direct costs of schizophrenia, according to the WHO, are between 1.6% and 2.6% of the total health care expenditures. This accounts for 7% to 12% of the gross national product. A systematic review of 56 economic burden studies in schizophrenia up till 2014 found that annual costs ranged from $95 million in Puerto Rico to $102 billion in the United States. The economic burden of schizophrenia as a function of the country's gross domestic product varied between 0.02% in the United Kingdom to 1.65% in Sweden. Most of the cost of schizophrenia is due to productivity losses, indirect costs contributing to 45% to 85% of the overall costs associated with schizophrenia across most national studies. A study in the Netherlands, however, reported indirect costs of only 8%, while two studies in Nigeria reported indirect costs of 12% and 27% respectively. The accuracy of indirect costs, however, depends on the cost estimation method used. Indirect costs refer to productivity losses due to morbidity and premature mortality and include absenteeism or sick leave, decreased work productivity, unemployment, permanent disability, or early retirement for individuals with schizophrenia or caregivers. Direct medical costs refer to costs of hospital and physician visits, long-term institutional care, and other health professionals' care, as well as medication, diagnostic tests, or medical supplies. Direct nonmedical costs include costs of transportation, food and lodging associated with health visits, and social services.

Although the generic cost-driving factors associated with schizophrenia are likely to be similar around the world (management of the chronic or relapsing symptoms and impairments, provision of inpatient and outpatient care and medication, mortality, lost productivity and unemployability, impact on the family, and impact on the community), their relative weights and, hence, the structure of the direct and indirect costs of the illness is likely to vary considerably. Hospital or other residential care, which accounts for more than 75% of the direct costs of schizophrenia in high-income countries, is likely to account for a smaller

fraction in developing countries because of lower staffing and equipment costs. On the contrary, the proportion of direct costs attributable to the dispensing of antipsychotic medication, which is less than 5% of the total direct costs in developed countries, is likely to be higher in developing countries.

It is difficult to estimate the economic impact of schizophrenia on families in developing countries. A study conducted in Nigeria revealed that caregiver *opportunity costs* (e.g., family members' lost productivity or income) were not of a different order from those in the developed world. Yet, the aggregate family costs in developing countries may, in fact, be substantially higher since a larger proportion of schizophrenic patients live with their families, as compared with patients in Western societies, and the family is likely to be the first line of treatment and management of psychotic episodes. The cost of purchasing prescribed maintenance medication is usually borne by the family. Additional direct costs may be incurred by the necessity to travel, often long distances, to the nearest hospital or clinic, as well as by payment for the services of traditional healers. In many traditional communities, the stigma associated with mental illness may affect the family as a whole and restrict, for instance, marital opportunities for younger family members. While lost educational opportunities are likely to be a problem, lost paid employment is more difficult to quantify, and therefore, less likely to appear prominently in estimates of the indirect illness burden in developing countries. On the contrary, reintegration of a family member who has suffered a psychotic episode into the domestic economy may be much easier to achieve than formal employment, and this may be one factor in the better and longer remissions of patients with schizophrenia observed in developing countries.

Notwithstanding the variations in the course and outcome discussed previously, schizophrenia is associated with a greater burden of chronic disability than any other mental disorder. Both the positive and negative symptoms of the disease interfere seriously with a person's capacity to cope with the demands of daily living. Patients with schizophrenia experience particular difficulty in dealing with complex demands and environments, especially those that involve social interaction and decoding of social communication. Moreover, the onset is usually at a developmental stage of incomplete social maturation, educational attainment, and acquisition of occupational skills. The intrusion of

psychosis at this stage results in a severely truncated repertoire of social skills and lifelong socioeconomic disadvantage. These factors are exacerbated by the societal reaction to individuals manifesting behaviors associated with “insanity,” which generally involves stigma and social exclusion.

These adverse factors interact to cause the *social breakdown syndrome,* a term introduced by Ernest Gruenberg (1915 to 1991) to designate the cluster of secondary impairments in schizophrenia resulting in a loss of social support networks and a greatly diminished quality of life for a substantial proportion of patients. Many patients with schizophrenia end up on the streets or in the criminal justice system and are exposed to abuse, even in psychiatric hospitals. Such outcomes are not uncommon in either developed or developing countries, although, in the latter settings, traditional family and community structures are still capable of providing a protective environment, and probably fewer patients are marginalized by society.

An important aspect of the economics of schizophrenia is the so-called *funding imbalance effect:* studies indicate that 97% of the total lifetime costs of schizophrenia are incurred by fewer than 50% of the patients diagnosed with the disorder. While this finding points to a hardcore subset of cases with severe chronic illness, multiple disabilities, and excessive dependence on services and other support, it also suggests that in more than 50% of those with schizophrenia, the disorder is less disabling or treatment more effective.

Another aspect of the social and economic costs of schizophrenia is the commonly perceived association between the disease and criminal behavior. Offenses committed by persons with schizophrenia tend to receive wide media coverage and reinforce popular ideas about the dangerousness associated with mental illness. It is important to dispel such prejudicial attitudes. Carefully designed studies in Europe and elsewhere indicate that a small proportion of patients with schizophrenia tend to be overrepresented among the perpetrators of violent offenses, including homicide. However, the *population-attributable fraction* of such offenses committed by persons with schizophrenia is negligible compared with the total number of offenses in the community. Moreover, the rate of arrest and incarceration is likely to be high among patients with schizophrenia because of their conspicuous behavior and appearance rather than the seriousness of the offense. Issues of protecting patients’

rights must, therefore, be an important part of antistigma campaigns in both developing and developed countries.

FUTURE DIRECTIONS

Important insights into the nature and causes of schizophrenia have been gained from population-based studies, although essential questions still remain unanswered. The clinical syndrome of schizophrenia appears to be robust and identifiable reliably in diverse populations and cultures, suggesting that a common pathophysiology, and possibly, a common genetic predisposition may underlie its manifestations. At the level of large population aggregates, no major differences in incidence and morbid risk have to date been detected, though small geographical area variations exist and appear to be related to a mix of locally operating risk factors whose effects may be attenuated in large, heterogeneous populations.

The study of “atypical” populations, such as genetic isolates or minority groups, may be capable of detecting unusual variations in the incidence of schizophrenia that could provide novel clues to the etiology and pathogenesis of the disorder. Notwithstanding the difficulties in the genetic dissection of complex disorders, emerging powerful methods of genomic analysis will eventually identify polymorphisms and haplotypes associated with schizophrenia risk. The majority are likely to be in genes of small effect, although one cannot rule out the possibility that rare mutations of moderate or major effect will also be found, especially in isolated populations or at the level of neurocognitive and neurophysiologic abnormalities associated with the disorder. Establishing their population frequency and associations with a variety of phenotypes, including premorbid personality traits, will be a major task for comparative epidemiology.

Current epidemiologic research is increasingly making use of existing large databases, such as cumulative case registers or birth cohorts, to test hypotheses about risk factors in case-control designs. Methods of genetic epidemiology are being integrated into population-based studies. These trends predict an important future role for epidemiology in the unraveling of gene-environment interactions that are likely to be the key to the understanding of the etiology of schizophrenia. In this context, research into psychotic disorders in non-Western populations can provide valuable information on genetic heterogeneity, the impact of the

environment, and the course and outcome of schizophrenia. Both traditional communities and societies undergoing a transition in their social and economic organization can contribute to a better understanding of the relationships between culture and mental disorder and the variety of human experiences in coping with mental illness.

The vast majority of people whose lives are profoundly affected by schizophrenia reside in developing countries. As indicated previously, the incidence and prevalence of schizophrenia in developing countries are not different from what is being found in the developed world or may even be lower. Although a greater proportion of people with schizophrenia in developing countries experience longer periods of symptomatic recovery than patients in the West, the burden of illness is severe and affects the productivity and quality of life of many families. The predicament of patients and families is likely to worsen as many of these countries are experiencing the pressures of economic restructuring, increasing income inequality, unemployment, and cuts in public spending on health care. The traditional economic and psychosocial resources of the family, which in the past have been capable of absorbing much of the impact of severe mental illness, may quickly become eroded.

Considering the challenges in managing the impact of established psychotic disorders, fostering a preventive approach is becoming increasingly popular. Long-term outcomes in those with schizophrenia are known to improve with earlier treatment and shorter durations of untreated psychosis (DUP). The median DUP in the United States is estimated at 1 to 3 years, much higher than is recommended by the WHO of 12 weeks or lower. Long DUP is associated with worse symptomatic and social outcomes, decreased chance of remission, underemployment, and quality of life. DUP in schizophrenia is determined by delays in accessing mental health services, and earlier recognition shows the most promise in lessening the global burden of the disease. Universal preventive approaches, such as clinical trials of dietary phosphatidylcholine supplementation in healthy pregnant women beginning in the second trimester, may reduce the likelihood of abnormal fetal brain development. Other candidate universal interventions for primary prevention of schizophrenia may include school-based interventions, e.g., targeting victimization and substance abuse. In particular, minimizing cannabis use early in developing and reducing use frequency may improve mental health literacy in those who are at high risk for schizophrenia and can help

facilitate earlier intervention and engagement with services. The establishment of first-episode psychosis or CHR services has burgeoned around the world, but primarily in North America, Australia, and Europe. These coordinated specialty care (CSC) services generally involve psychotherapy, psychopharmacology, family education and support, case management, and vocational and educational support tailored to early psychosis youth. Individuals who later develop psychosis after engaging with CHR-P services demonstrate a significant decrease in DUP compared to those who do not get these services. CSC services for first-episode psychosis have led to improved quality of life, reduced psychotic symptoms, and greater involvement in work and school compared to community care after 2 years compared to usual care.

A common denominator in the great variety of situations and systems of care for people afflicted with psychotic illnesses in the developing world is that the modest successes achieved in some of these countries are vulnerable to the local repercussions of economic globalization. In all societies, the stigma surrounding mental illness is likely to mean that people with severe mental disorders are among the first to be disadvantaged by shrinking government health expenditures. It is, therefore, imperative to initiate proactive measures on an international scale to forestall such developments.

12.4 Genetics of Schizophrenia

Kimberley M. Kendall, B.Sc. (Hons.), M.B.B.Ch., Ph.D., M.R.C.Psych., Elliott Rees, B.Sc. (Hons.), Ph.D., and Michael J. Owen, B.Sc. (Hons.), M.B., Ch.B., Ph.D., F.R.C.P.Sych.

It has long been recognized that schizophrenia tends to run in families. Systematic attempts to examine the genetic basis of schizophrenia began in the early 1900s but started to gain traction in the latter half of the century.

FAMILY, TWIN, AND ADOPTION STUDIES

Attempts to establish that a disorder has a genetic susceptibility often begin with the demonstration that relatives of probands have an increased risk of developing the disorder (Fig. 12.4–1). Family studies demonstrated that schizophrenia has a high degree of familial loading. For example, siblings have around an 8- to 10-fold increased risk of developing the disorder compared to the general population. For many years, evidence from family studies was interpreted as showing that psychiatric disorders largely “breed true.” That is to say that relatives of an index case are at increased risk only of the index disorder. However, in recent years, as data from better-powered family studies have accumulated, it has become clear that there is evidence for shared as well as independent genetic risk between schizophrenia and other adult psychiatric disorders, particularly bipolar disorder, and between schizophrenia and childhood neurodevelopmental disorders (NDDs).

FIGURE 12.4–1. Morbidity risk for schizophrenia in the relatives of probands with schizophrenia. (The numbers are based on the study data from Gottesman II, Shields J. *Schizophrenia: The Epigenetic Puzzle*. Cambridge University Press; 1982.)

Family studies are unable to distinguish between risks conferred by genetic factors and environmental factors. In order to understand the basis of increased familial risk for schizophrenia, researchers turned to twin studies. Twins brought up in the same household share many aspects of their environment but different proportions of their DNA sequence depending on the nature of their twin relationship. Monozygotic (MZ) twins share all of their variable DNA sequence, whereas dizygotic (DZ) twins share, on average, 50%. Twin studies examine the proportion of twin pairs where both twins are affected or the proportion of cotwins who are also affected by a trait. This is expressed as the concordance rate. If MZ and DZ twins share their environments approximately equally (the shared environment assumption), a higher concordance rate in MZ twins implies that the disorder is, at least partly, genetic. If the concordance rate in MZ

twins is less than 100%, this suggests that environmental factors also play a role. Meta-analyses of twin studies have estimated that the heritability of schizophrenia, the proportion of the phenotypic variance attributable to genetic factors, is around 81%.

The equal environment assumption has been called into question by the suggestion that MZ twins tend to share their environments to a greater extent than DZ twins. The separation of contributory factors in families is difficult because children share both genes and environment with their parents and siblings. Adoption studies provide an opportunity to investigate the genetic basis of a disorder while controlling for environmental factors. In these studies, adopted children, their biologic parents, and adoptive parents are studied. If there is a genetic component to a disorder, there should be a greater similarity between adopted children and their biologic parents than between adopted children and their adoptive parents. Adoption studies in schizophrenia established that children of biologic parents with schizophrenia have at least a 10% risk of developing the disorder or a related disorder. This risk is very similar to that reported in family studies, suggesting that most of the familial transmission of the disorder is genetic.

ADVANCES IN THE MOLECULAR GENETICS OF SCHIZOPHRENIA

Family, twin, and adoption studies successfully demonstrated that genetic factors play an important role in conferring the risk of schizophrenia. However, identification of risk at the level of DNA variation initially proved challenging, slow to advance, and difficult to replicate. The advent of more advanced techniques, including genome-wide association (GWA) studies, copy number variant (CNV) analysis, and next-generation sequencing, has resulted in greater success and optimism for the future.

Genome-Wide Association Studies

GWA studies examine common alleles, defined as variants observed in >1% of the general population, throughout the genome for association with a particular trait. The HapMap Project annotation of millions of single nucleotide polymorphisms (SNPs) demonstrated that many SNPs are highly correlated with neighboring SNPs. Therefore, it is not necessary to genotype all of them in order to gain nearly complete coverage of common variations in the genome. Furthermore, array-based technology has made it possible to genotype millions of SNPs on a single array, making the

examination of common genetic variation across the whole genome in large samples a much less daunting prospect.

The earliest GWA studies were not particularly fruitful, but they did provide some useful lessons, in particular, the need to study extremely large samples due to the requirement to correct for the enormous multiple testing involved and the small odds ratios for risk conferred by common variants. It was estimated that GWA studies require a *P* value of $<5 \times 10^{-8}$ to achieve significance at a genome-wide level. This requires sample sizes in the order of tens of thousands, which could only be reached via collaboration between multiple research groups. The largest and most successful schizophrenia GWA studies to date were conducted by the Psychiatric Genomics Consortium (PGC), a collaboration bringing together data from research groups around the world. Studies by the PGC aggregate the most available schizophrenia samples with GWA genotypes into a single analysis and thus provide the most powerful studies of common alleles in schizophrenia.

The most recent PGC study analyzed SNP genotype data from 90 ancestry-matched, nonoverlapping case-control samples (67,390 cases and 94,015 controls; ~80% of the samples were of European ancestry, and ~20% were of East Asian ancestry). After a cohort association analysis, 7,858,078 common SNPs were meta-analyzed for association with schizophrenia. The results from this discovery analysis are depicted in Figure 12.4–2.

The PGC then meta-analyzed SNPs achieving a *P* value of $<1 \times 10^{-5}$ in this discovery sample with independent data from the deCODE genetics sample (1,979 cases and 142,627). This meta-analysis, which consisted of 69,369 cases and 236,642 controls, discovered 342 linkage-disequilibrium independent common allele associations that exceeded genome-wide significance ($P <5 \times 10^{-8}$). These significant associations mapped to 287 distinct genomic loci.

Schizophrenia common risk alleles are overrepresented among genes that are highly expressed in the brain, with many different brain regions showing evidence for association. However, when considering specific brain cell types and tissues, schizophrenia common risk alleles are concentrated among genes expressed in excitatory and inhibitory neurons, with the strongest enrichment observed for genes expressed in glutamatergic neurons in deep layers of the cortex, amygdala, and hippocampus. Genes related to particular biologic processes are also enriched for schizophrenia common alleles, such as neuronal excitability, development, and structure.

Moreover, schizophrenia common risk alleles have provided strong evidence for synaptic dysfunction in schizophrenia pathogenesis, with associations reported in genes with pre- and postsynaptic locations.

FIGURE 12.4–2. Manhattan plot showing the discovery results from the most recent GWAS of schizophrenia. x-axis–chromosomal position; y-axis–significance of the association (−log10[P]); horizontal line–genome-wide level of significance (5×10^{-8}).

Some genomic loci harboring schizophrenia common allele associations contain genes thought to be related to the etiology and treatment of schizophrenia, including the dopamine receptor D2 (*DRD2*), glutamatergic neurotransmission, and synaptic plasticity (*GRM3*, *GRIN2A*, and *SRR*), and calcium signaling (*CACNA1C*, *CACNB2*, and *CACNA1I*). However, due to the complex linkage disequilibrium structure surrounding associated SNPs, the causal variant or gene is not usually known. The PGC study used a method called fine mapping, which, together with functional genomic data, helped to prioritize 120 genes within associated loci as being the most likely causal gene. These prioritized genes were indeed enriched for characteristics known to be pathogenic for neuropsychiatric disorders, such as brain expression and intolerance to highly damaging classes of mutation, such as loss-of-function variants. Thirteen of the prioritized genes had either pre- or postsynaptic locations and functions related to voltage-gated calcium and chloride channels (*CACNA1C*, *CLCN3*), metabotropic receptors (glutamate and GABA), the ligand-gated NMDA receptor subunit (*GRIN2A*),

synaptic organization and differentiation (*ADGRB3*, *LRRC4B*, *GPM6A*, *IL1RAPL1*), the trans-synaptic signaling complex (*IL1RAPL1*, *SNAP91),* and modulation of chemical transmission (*MAPK3*, *DCC*, *CLCN3*).

It seems likely that the number of genome-wide significant common allele associations identified in schizophrenia will continue to increase as larger samples are analyzed. This has become apparent with the development of methods, such as the polygenic risk score, which quantify the *en masse* effects of common risk alleles, including those risk alleles that are not individually supported at genome-wide levels of significance. These methods have estimated that relatively common, small-effect alleles (odds ratios <1.3) account for at least 25% of the total liability to schizophrenia (about 33% of genetic liability). However, current polygenic risk scores for schizophrenia explain only 7.7% of the variance in liability and thus are unable to accurately predict schizophrenia diagnosis in the general population (Area Under the Receiver Operating Characteristic Curve of 0.71). Nevertheless, polygenic risk scores show great promise in research settings for stratifying patients and may most rapidly find clinical application in groups at elevated risk of schizophrenia, for example, in helping predict which individuals in psychosis high-risk groups will later develop the disorder.

GWA studies have also established that other psychiatric disorders, such as bipolar disorder, attention-deficit hyperactivity disorder, and major depression, have a highly polygenic genetic basis. By comparing the results from GWA studies across psychiatric disorders, it has become increasingly apparent that some common risk alleles for schizophrenia also confer risk for other psychiatric disorders. In particular, common risk alleles for schizophrenia are highly correlated with those for bipolar disorder. Schizophrenia common risk alleles are also correlated, but to a lesser extent, with childhood-onset neuropsychiatric disorders, such as attention-deficit hyperactivity disorder, autism spectrum disorder (ASD), and developmental disorders. Moreover, studies that combine GWA data across schizophrenia and bipolar disorder have identified both shared and divergent common allele associations across these disorders. These findings suggest that, in part, the pathophysiologic mechanisms underlying schizophrenia are shared with other psychiatric disorders.

CNVs and Schizophrenia

CNVs are the deletion or duplication of segments of DNA greater than 1 kb in size. The earliest report of an association between a rare CNV and the

risk of schizophrenia was for a deletion of around 2.5 Mb in size on the long arm of chromosome 22. The 22q11.2 deletion had long been known to cause a severe congenital disorder variously called DiGeorge syndrome, velocardiofacial syndrome, or Sphrintzen syndrome. Carriers of this CNV were shown to have up to 30% risk of developing schizophrenia or another psychotic disorder.

Subsequently, the development of high-resolution and high throughput microarray technologies allowed researchers to interrogate the whole genome and to find other CNVs also associated with an increased risk of schizophrenia. The first new CNV locus to be identified was a single gene–*NRXN1* (neurexin 1) on chromosome 2. Deletions in this region are of variable size and can affect different sections of the gene. In 2009, Rujescu et al. showed that it is deletion CNVs that intersect the exons of *NRXN1* that increase the risk of schizophrenia. *NRXN1* encodes a cell adhesion molecule, which is specific to synapses in the brain. It mediates interactions between pre- and postsynaptic structures and plays an important role in the formation, maintenance, and release of neurotransmitters.

FIGURE 12.4–3. The genetic architecture of schizophrenia. This diagram shows significant genetic associations for schizophrenia from the most recent GWAS, CNV, and sequencing studies. y-axis–odds ratio; x-axis–minor allele frequency in the general population. (See eBook for color images.)

Additional CNV loci have since been identified as conferring an increased risk of schizophrenia (Fig. 12.4–3). To date, a total of 12 CNVs at 11 individual loci have been identified as associated with the disorder at genome-wide levels of statistical significance ($P < 4.1 \times 10^{-4}$)–deletions at 1q21.1, *NRXN1* (exonic), 3q29, 15q11.2, 15q13.3, 16p12.1, and 22q11.2, and duplications at 1q21.1, the Williams–Beuren syndrome locus at 7q11.23, the Angelman/Prader Willi syndrome locus at 15q11-q13, 16p13.11, and 16p11.2. Many schizophrenia-associated CNVs share certain features. They are rare and therefore require very large samples to confirm their role. Many disrupt multiple genes, which likely explains their high levels of pathogenicity. Many are flanked by large stretches of homologous DNA called low-copy repeats that can misalign during meiosis or mitosis and cause the DNA between them to be deleted or duplicated. Therefore, they are usually of the same size in different individuals, and their mutation rates are high compared to other CNV loci. Finally, all CNVs associated with schizophrenia have also been implicated in autism and intellectual disability (ID).

Large studies of rare CNVs in schizophrenia have confirmed the role of previously implicated loci in schizophrenia risk. However, when these were excluded, there remained a residual burden of rare CNVs in schizophrenia, suggesting there are further risk loci yet to be implicated. CNVs at these additional loci may be very rare, requiring even larger samples to confirm their role. The largest schizophrenia CNV study to date examined the effects, on schizophrenia risk, of 51 CNVs previously implicated in ID (excluding 11 known schizophrenia loci). ID CNVs were enriched in schizophrenia cases, and this study implicated the novel locus 16p12.1 deletion in the risk of schizophrenia.

Penetrance of CNVs. All of the individual CNVs described confer high odds ratios for schizophrenia, in the range of 3 to 58 (Fig. 12.4–3). However, each of these CNVs has also been implicated in the risk of other developmental disorders such as developmental delay, ASD, or congenital malformations. When considering the penetrance of CNVs, for example, for the purposes of genetic counseling, one should take into account the risk of developing any serious disorder, not just schizophrenia. A study of the penetrance of rare CNVs found estimates for developmental delay/ASD/congenital malformations to be higher than that for schizophrenia. Taken together, the penetrance for any serious

developmental disorder is substantial, averaging just over 40%, and is accounted for mostly by nonpsychotic disorders.

Sequencing Studies

When examining association with disease, GWA studies are used to detect common variations, particularly SNPs, and the genotyping platforms used can also detect CNVs. However, these platforms will not detect rare single nucleotide variants (SNVs) and small insertions and deletions (indels). Exome-sequencing, which involves sequencing the protein-coding regions in the genome, is now widely used to identify rare SNVs and indels (collectively termed rare coding variants [RCVs]) and test them for association with disease.

Early exome sequencing studies of schizophrenia were underpowered to identify individual genes enriched for RCVs with genome-wide levels of significance, but they were able to demonstrate that people with schizophrenia have an elevated burden of RCVs within specific groups of genes. For example, RCVs in people with schizophrenia were found to be enriched among genes related to glutamatergic postsynaptic proteins, as well as more broadly among ~3,500 genes for which damaging mutations are known to be subjected to strong levels of purifying selection in the general population.

In 2016, an analysis of exome-sequencing data from 4,264 schizophrenia cases, 9,343 controls, and 1,077 schizophrenia trios identified RCVs in *SETD1A* to confer substantial risk for schizophrenia odds ratio = 37.6 (95% CI = 8 – 353). This finding represented the first gene associated with RCVs in schizophrenia with genome-wide levels of significance. Rare mutations in *SETD1A* were also shown to increase the risk for severe developmental disorders, and several schizophrenia carriers of *SETD1A* mutations also had a comorbid ID. *SETD1A* encodes a methyltransferase that catalyzes the methylation of lysine residues in histone H3 and is known to influence the transcriptional regulation of genes important for aspects of cell cycle regulation. Association between *SETD1A* and schizophrenia, therefore, suggests disrupted epigenetic modification as a potential mechanism underlying schizophrenia.

To advance the discovery of individual genes associated with RCVs in schizophrenia, the Schizophrenia Exome Sequencing Meta-analysis (SCHEMA) consortium was established in 2017 to amalgamate new and existing sequencing data sets collected from diverse global populations. After quality control, the SCHEMA study evaluated RCVs in 24,248 cases

and 97,322 controls, and de novo variants from 3,402 trios. This analysis identified 32 genes enriched for RCVs at a false-discovery rate <5%, of which 10 genes surpassed genome-wide levels of significance (i.e., Bonferroni correction for 22,833 tests). RCVs within the 10 genome-wide significant genes conferred substantial risks of schizophrenia, with estimated odds ratios ranging between 3 and 50. The functions of the proteins encoded by these 10 genes are diverse and include ion transport (*CACNA1G*, *GRIN2A*, *GRIA3*), neuronal migration and growth (*TRIO*), transcriptional regulation (*SP4*, *RB1CC1*, *SETD1A*), nuclear transport (*XPO7*), and ubiquitin ligation (*CUL1*, *HERC1*). The findings from the SCHEMA study provide strong support for specific mechanistic hypotheses for schizophrenia; for example, an association of *GRIN2A*, which encodes an NMDA receptor subunit, and *GRIA3*, which encodes an AMPA receptor subunit, support dysregulation of the glutamatergic system in schizophrenia pathophysiology.

Sequencing studies have provided further evidence that schizophrenia and early onset NDDs, such as ASD and ID, share specific risk genes. Groups of genes affected by de novo mutations in people with NDDs are enriched for similar types of mutation in schizophrenia, and there is emerging evidence that within shared risk genes, the same mutation can sometimes confer the risk of schizophrenia and NDDs. However, a small number of genes have been reported to be enriched for different types of mutation in schizophrenia and NDDs; for example, while *TRIO*, *GRIN2A,* and *CACNA1G* are enriched primarily for protein-truncating variants in schizophrenia, only missense variants in these genes are enriched in NDDs. This suggests that within some shared risk genes, different changes in the gene's function can confer risk to different disorders.

CONVERGENCE ONTO BIOLOGIC MECHANISMS

As indicated, despite the undoubted complexity of the genetic picture that is emerging, work using different approaches is beginning to reveal some convergence onto a coherent set of biologic processes. Results from GWA studies, CNV, and sequencing studies all point to a functionally related set of synaptic proteins involved in synaptic plasticity, learning, and memory. Among the gene sets implicated are the ARC and NMDAR complexes, targets of FMRP, and voltage-gated calcium channels. Genes more widely expressed in brain tissues, as well as genes expressed in both excitatory and inhibitory neurons, are associated with both common and rare variants

in schizophrenia. Genes prioritized by the fine-mapping approaches used in the PGC analysis of common alleles are enriched for rare variants in the SCHEMA analysis, and two of the top 10 most significant SCHEMA genes (*GRIN2A* and *SP4*) have robust common allele associations in the PGC study. These findings demonstrate that a wide spectrum of risk alleles disrupt specific biologic processes in people with schizophrenia and that insights into disease pathology can be gained by integrating findings from sequencing and SNP genotype data. Although it seems highly likely that there are other systems and mechanisms involved, including the dopamine system, and that these can be expected to emerge with further and larger GWA studies and sequencing studies, the current findings offer numerous entry points for neuroscientists to probe the biologic basis of schizophrenia.

THE EMERGING GENETIC ARCHITECTURE OF SCHIZOPHRENIA

While much genetic risk is still unexplained at the level of individual risk variants, the findings to date support a general framework for the genetic architecture of schizophrenia. As expected from genetic epidemiology and population genetics, there is now empirical evidence for a spectrum of allelic risk. There is a marked inverse relationship between effect size and frequency, as predicted from the effects of natural selection in a disorder associated with marked reductions in fecundity. There are contributions from alleles that are common in the population. The effect sizes of these are small, enabling them to escape the effects of natural selection, but as a group, they probably account for about a third of genetic liability. There is also a contribution from rare alleles, some of which have large effects on individual risk of disease pending their removal from the population by selection. The relationship between effect size and allele frequency is illustrated in Figure 12.4–3. The relative contribution of alleles of different effect sizes and frequencies is unclear, but this should be clarified as the larger whole exome and whole genome sequencing studies are conducted. However, it seems likely that alleles across the risk spectrum will be found with their effect sizes constrained by natural selection.

It has been shown that people with schizophrenia who carry rare risk CNVs still have an elevated burden of common risk alleles compared with controls, which suggests that cases who carry rare high penetrant mutations and those who do not have overlapping etiologies. However, among people with schizophrenia, those who carry a rare, highly penetrant variant have a

lower burden of common risk alleles compared to cases without a rare mutation. This is consistent with a liability threshold model, where both common and rare mutations act additively to confer the risk of schizophrenia.

NEURODEVELOPMENTAL SPECTRUM

An important implication of recent studies is that genetic risk does not recognize our current definitions of disease. Extensive pleiotropy with respect to diagnosis has been demonstrated for common alleles at the level of individual SNPs, genes, and the *en masse* effects of multiple common risk alleles and for rare variants, including both CNVs and SNVs. These findings, combined with the recognition of the phenotypic similarities between some disorders, led to the development of the neurodevelopmental spectrum. This model proposes the conceptualization of schizophrenia and disorders considered to have a neurodevelopmental etiology, such as ID and ASD, as lying on an etiologic and phenotypic spectrum. The greatest level of neurodevelopmental impairment is observed in ID, and this corresponds to a greater loading of deleterious genetic variants. As one moves across the spectrum, the level of neurodevelopmental impairment and the rate of deleterious genetic variants decreases. Taken together, the existing evidence brings into question whether current diagnostic categories are the most appropriate for future genetic studies, for research aiming to understand relationships between genetic risk and clinical outcome, and to best understand pathophysiology.

CLINICAL IMPLICATIONS

As the body of evidence for the genetic basis of schizophrenia and related disorders increases, so do the clinical implications for individuals with these disorders and their relatives. Interpreting and communicating these findings is not straightforward but is of vital importance.

In the case of schizophrenia, one may inherit an increased susceptibility to developing the disorder. This does not make it inevitable that the disorder will develop, as even MZ twins are concordant for the disorder in only around half of cases. Genetic counseling may be appropriate to enable individuals to develop a greater understanding of the nature of their disorder and its familial basis. However, the complex genetic architecture of schizophrenia means that genetic testing is unlikely to be appropriate for all

individuals with the disorder. The exception is for carriers of specific CNVs, for which reasonably accurate estimates of penetrance are available. Importantly, while these CNVs increase the risk of disorders across the neurodevelopmental spectrum, they also increase the risk of cognitive impairment and physical health phenotypes with implications for morbidity and mortality. Establishing CNV carrier status may inform clinical care by providing information on the potential physical conditions for which monitoring should be instigated. A key piece of work will be developing criteria for which CNV, and other genetic testing, should be offered. In the future, it may also be possible to use polygenic risk scoring to stratify individuals and tailor medication regimes in a biologically informed manner.

12.5 The Clinical Epidemiology of Psychosis Spectrum Disorder

Jim van Os, M.D., Ph.D., and Ulrich Reininghaus, Ph.D.

WHAT IS CLINICAL EPIDEMIOLOGY?

Clinical epidemiology is the basic science of preventive medicine. It examines the variation in susceptibility, onset, course, and outcome of a disease and the reasons behind this variation within defined populations. It is the science of making predictions about the emergence (onset) and persistence (prognosis) of disease through the systematic identification and evaluation of inherited and acquired characteristics, attributes, behaviors, and exposures, known as risk factors (determinants). These risk factors increase an individual's likelihood of developing (1) a precursor of the clinical disorder (a condition or state preceding the recognized onset of a disease), (2) a clinical disease, or (3) a particular course and outcome trajectory for the disease process. Determinants rarely act in isolation to increase risk; rather, their effects are cumulative. Such complementary actions can be additive (the linear sum of the individual effects) or synergistic (interaction of effects) when individual risk factor effects are modified by particular environmental conditions, biologic stochastic events, or other known risk factors. Further, there is no reason to assume that the risk factors for the emergence of a clinical disorder and those influencing persistence are congruent. Evidence that the same risk factor is implicated in both onset and persistence of a disease (discrete major effect) could aid our understanding of etiologic mechanisms. However, the lack of discrete effects suggests the course of a disease is not predetermined and is potentially modifiable after onset.

Clinical epidemiology attempts to harness the heterogeneity observed in risk factor profiles, course, and outcomes and uses this variation to generate hypotheses and develop empirically based conceptual frameworks (models) of mental health as well as public mental health services, including mental health promotion, primary, secondary, and tertiary prevention strategies. Identifying the risk factors operating prior to the onset of the disease is fundamental to effective evidence-based primary (universal) prevention, while the risk factors predicting course and outcome help identify patients at higher risk of poor outcome, so guiding the development of secondary (selective) and tertiary (indicated) preventative strategies and interventions tailored for specific individuals in clinical settings.

Extensive heterogeneity is the hallmark of psychosis spectrum disorder, with manifest variation in (sensitivity for) risk factors for onset, symptomatology, course, and outcome. Predictive power is typically low and attributable fractions are small. Recent years have seen a transformation in our understanding of psychosis spectrum disorder. Based on evidence on shared aetiologic factors as well as a transdiagnostic symptom dimension

that cuts across diagnostic boundaries of nonaffective and affective psychotic disorders in the bipolar-psychosis network on intermediate phenotypes (B-SNIP) and European Network of National Networks studying Gene-Environment Interactions in Psychosis (EU-GEI) consortia, it has been proposed to reconceptualize these disorders as “psychosis spectrum disorder” or, in the Hierarchical Taxonomy of Psychopathology (HiTOP), as “psychosis super spectrum.” The median age of onset of disorders in the psychosis spectrum is 25, with an IQR of 20 to 34. The total lifetime prevalence of disorders in the psychosis spectrum is 3.5%, of which less than a third meets criteria for “schizophrenia.” It has been proposed that for the purpose of clinical epidemiology, the diagnosis of the “psychosis spectrum” is best approached from the perspective of clinical characterization. Clinical characterization is focused on specifically increasing patient value by combining or replacing categorical ICD/DSM diagnosis with transdiagnostic, personalized, and contextual information on symptoms, clinical severity, clinical staging, and antecedent and concomitant variables. These efforts, taken together, are ultimately geared to produce new evidence on the interface between transdiagnostic risk factors, mechanisms, and phenotypic constructs as a means of connecting process and structure in understanding more fully what underpins psychotic disorders. A central tenet of modern risk factor epidemiology is that virtually all diseases are a consequence of the interplay between genetics and environmental characteristics. Therefore, recent studies investigate how differences in genetic endowment moderate the effect of environmental risk factors (gene–environment interactions) across the psychosis spectrum.

RISK FACTORS FOR THE ONSET OF PSYCHOSIS SPECTRUM DISORDER

Genetic Risk: Indirect Evidence from Epidemiologic Studies

Family Studies: Family studies compare the morbidity risk (the proportion of affected to unaffected relatives, usually adjusted for variation in nonaffected participants time at risk) for probands with the diagnosis of schizophrenia or psychosis spectrum disorder, to the morbidity risk in the general population or demographically matched control groups. Results from a systematic review of the studies published during the period 1980 to 2003 found the first-degree relatives of probands to have a higher morbidity risk for psychosis spectrum disorder as compared to the relatives of controls.

Estimates ranged from 2% to 9% (in studies that adjusted for time at risk using Weinberg, Strömgren, or Kaplan–Meier methods) compared to a morbidity risk in the relatives of controls at about 0.5%. The effect varied according to the diagnostic classification employed in the study, with broader definitions of the diagnosis of schizophrenia, such as Research Diagnostic Criteria, tending to show larger estimated effects than the narrower definitions employed in post-third editions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM). Similarly, studies using control groups unscreened for mental disorders showed more conservative estimates. There was also evidence of clinical heterogeneity, with the relatives of early-onset cases having a higher morbidity risk compared to the relatives of late-onset cases. Further studies have examined familiar aggregation for categorical subtypes, symptom dimensions derived from factor analysis, and individual symptoms. The findings are inconsistent and show significant methodologic heterogeneity. Most family studies have investigated morbidity risk in first-degree relatives; the few studies of second- and third-degree relatives suggest an increase in risk with increasing relationship closeness, the structural form of which may not be linear.

Adoption Studies: Most children inherit their genetic characteristics as well as their early rearing environment from their biologic parents. Adoption provides an opportunity to disentangle these genetic and rearing effects. Evidence from adoption studies have primarily come from a small group of studies. An adoptee's family study, using the Danish national linked data set, compared rates of the diagnosis of schizophrenia in the adoptive and biologic families of adoptees with a diagnosis of schizophrenia. Results reported over the past 30 years (using different diagnostic criteria) consistently show the biologic relatives to be at a higher risk of a diagnosis of schizophrenia than the adoptive relatives, who have a similar estimated risk to the rest of the general population. The second strategy compares the rates of a diagnosis of schizophrenia in adopted children for parents with and without a diagnosis of schizophrenia. Early studies using this methodologic approach consistently demonstrated higher rates of schizophrenia in the adopted offspring of affected mothers, compared to the rates in the offspring of the unaffected controls. A recent Finnish study has improved on these earlier methodologies by identifying larger samples, using standardized interviews with home assessments and DSM operationalized diagnostic criteria. Its results support the early findings, showing a morbidity risk in the adopted offspring of mothers with a

diagnosis of schizophrenia of 5.1%, as compared with 1.6% in the adopted offspring of control mothers, a finding that has been replicated in a recent, large Swedish registry study.

Twin Studies: There are some studies that compare the concordance rates for monozygotic (identical) twins (assumed to inherit all their genes in common) with those of dizygotic (nonidentical) twins (who on average share around 50% of their genes). Such studies further assume that twin pairs are equally exposed to environmental risk factors for psychosis spectrum disorder. Statistical combination of the published studies that used DSM-III-R criteria to define caseness estimated pooled concordance rates of 50% in monozygotic twins and 4.1% in the dizygotic pairs; the pooled estimates of concordance for studies using different diagnostic classification systems are actually very similar. The concordance rate for monozygotic twins was higher in twins with an early, rather than a late, onset of psychosis spectrum disorder. Twin studies investigating classical schizophrenia subtypes show higher monozygotic concordance rates for the hebephrenic subtype compared to the paranoid type but this may not be a conclusive finding. Combination twin and family studies find the risk for a diagnosis of schizophrenia in the offspring of the identical and unaffected twin to be the same as that seen for the offspring of the affected twin.

SPECIFICITY OF HERITABILITY

Relationship to Attenuated Psychosis Phenotypes

Clinicians have long recognized that some close relatives of patients with psychosis spectrum disorder, although never frankly psychotic, display symptoms and signs similar to the pathologic experiences seen in the clinical disorder. Some are attenuated forms of the positive/disorganized symptoms of psychotic disorder (odd behavior, odd speech, muddled thinking, loose associations, ideas of reference, magical thinking, suspiciousness, and illusions), while others resemble the negative symptoms (social withdrawal, aloofness, guardedness, poor rapport). The DSM classification system has combined these quasipsychotic (schizotypic) features under the diagnostic category of schizotypal personality disorder. As schizotypal, schizoid, and paranoid personality disorders are found to co-occur, they have been grouped together under the rubric Cluster A personality disorder within the manual. Family studies measuring lifetime prevalence for DSM Cluster A personality disorders (some studies have also included avoidant personality disorder) in first-degree relatives of

patients with schizophrenia (and other psychotic disorders including psychotic bipolar disorder) find rates in the relatives of the probands (range: lifetime prevalence 2.8% to 8.2%) that are two to four times the rates found in the control families. The significant heterogeneity in estimated lifetime prevalence is primarily due to methodologic differences. Adoption and twin studies confirm this familiar aggregation. The familiar coaggregation of pathologic and attenuated schizotypal symptoms suggests that there may be a single continuum of liability across the schizotypic features and pathologic psychotic symptoms.

A recent systematic review of genome-wide association studies (GWAS) of attenuated psychotic symptoms and negative symptom (PENS) showed that in the most recent and well-powered studies, polygenic risk score (PRS) for schizophrenia was associated with all types of psychotic experience and negative symptom traits and that negative symptom traits also share genetic influences with major depression.

Relationship of Schizophrenia to Other Psychotic Disorders and Bipolar Disorder

Family and adoption studies of schizophrenia have generally shown an excess of risk in biologic relatives, not only for schizophrenia, but also for a broad range of psychotic disorders, such as schizophreniform, schizoaffective, delusional, and atypical delusional disorders. Biologic relatives also have higher rates of nonpsychotic disorders. A large, recent registry study of Swedish families reported evidence that schizophrenia and bipolar disorder partly share common genetic determinants. An extended adoption and cross-generational study form the same country showed that cross-generational transmission between bipolar disorder and broad schizophrenia appears to be entirely genetic with a moderate genetic correlation.

These studies do not help us elucidate the nature of this shared liability. A possible explanation would be an underlying continuous common liability for all psychotic disorders including bipolar disorder. Findings from GWAS such as those conducted by the Cross-Disorder Group of the Psychiatric Genomics Consortium indicate highly significant polygenic overlap between schizophrenia and not only bipolar but also major depressive disorder. These findings are complemented by evidence on shared intermediate and clinical phenotypes of schizophrenia, schizoaffective, and bipolar disorder from the EU-GEI and B-SNIP consortia. The Brainstorm Consortium quantified the genetic sharing of 25 brain disorders from GWAS of 265,218

patients and 784,643 control participants and assessed their relationship to 17 phenotypes from 1,191,588 individuals. The results showed that psychiatric disorders (psychotic and nonpsychotic) share common variant risk, whereas neurologic disorders appear more distinct from one another and from the psychiatric disorders. Overall, around two-thirds of genetic associations are common to schizophrenia, bipolar disorder, and major depressive disorder and overlaps also exist with genetic variants contributing to autism, attention-deficit/hyperactivity disorder, and intellectual disabilities. These findings suggest that PRS for mental disorders to a large extent represents transdiagnostic risk for mental suffering. PRS for schizophrenia in particular is associated with a variety of disorders, quality-of-life, and subclinical multidimensional phenotypes. Indeed, investigation of electronic health records from the United States reveals that PRS for schizophrenia is associated with not only a diagnosis of schizophrenia, but also diagnoses of other related psychiatric and medical conditions. Overall, the current evidence points toward a model of liability, which incorporates a common (shared) genetic susceptibility for psychosis spectrum disorder and many other mental disorders and traits.

GENETIC MODEL OF LIABILITY FOR PSYCHOSIS SPECTRUM DISORDER

The family, adoption, and twin studies provide irrevocable evidence for the involvement of a major genetic component in the liability for psychosis spectrum disorder. However, the familiar distributions are inconsistent with simple Mendelian modes of inheritance (single major locus) and are more compatible with a polygenetic mode of inheritance. One possible model is the *polygenetic threshold model*, which assumes most of the risk of psychosis spectrum disorder is due to additive effects of multiple small genes at different loci, and only a small amount of risk is associated with rare variants and copy number variants. However, the polygenetic threshold model does not adequately account for the exponential rise in the risk of psychosis spectrum disorder observed with increasing familiar closeness, which is more consistent with (at least some) epistatic gene–gene interaction. Nonetheless, the monozygotic/dizygotic twin correlations are significantly lower than would be expected with a full epistatic model. Recent years have seen rapid advances through large-scale collaboration in GWAS, which has generated replicated findings on a number of common risk alleles. However, the common variants identified to date explain not all

of the genetic risks of psychosis spectrum disorder as established in family and twin studies. Molecular genetic analysis allows the estimation of a model that predicts trait values from genotype data expressed as a PRS. The amount of phenotypic variance explained by PRS is typically much lower than the amount of additive genetic variance estimated across twin studies. For arguably the most investigated mental disorder, schizophrenia, with an estimated twin heritability of 80%, tens of thousands of markers explain only 7% of the variance on the liability scale and around 24% of the variance on the observed 0 to 1 scale derived from the logistic regression model. Thus, a considerable “heritability gap” remains; the origin of which may represent environmental effects, indirect genetic effects within the family, rare genetic variants, gene-environment interplay, assortative mating, or other factors. It is likely that both genetic and environmental factors contribute to the development of psychosis spectrum disorder. The mechanisms by which these factors interact to influence risk remain unclear but will probably involve the complex interplay of both additive and interacting genes, environmental factors, gene-environment interactions (genetic moderation of environmental factors and environmental moderation of gene expression), as well as neural, cognitive, and affective mechanisms underlying the interplay of genetic and environmental factors. These are likely to be continuously distributed within the population. This model of risk may vary within and across individuals, families, or clinically defined subgroups of the disease, depending on the specific risk factors active within the person at different stages of development. If this probabilistic model of risk transmission is accepted, then environmental risk factors appear to be necessary complementary components in the development of psychosis spectrum disorder in many, if not all, cases.

Table 12.5–1.
Causal Criteria for the Onset of Psychosis

1. **Strength of the association**
   The argument states that strong associations are more likely to be causal because if they could be explained by another factor, the effect of the confounder would have to be even stronger than the observed association. While weaker associations are more likely due to noise and bias, it is important to remember that measures of association (e.g., the relative risk for odds ratios) are characteristic of the sample under study and depend on the relative prevalence of other causal factors.
2. **Dose-response relationship (biologic gradient)**
   Defines a unidirectional trend in disease frequency with increasing levels of exposure; however, this is neither necessary nor sufficient for causality as the presence of an unadjusted confounder will also show a gradient. Further, some causal relationships show single jumps (thresholds).
3. **Temporal association**
   This is a *sine qua non* for causality. Requires that for a factor to be considered causal, it must precede the disease. This is irrefutable; however, it does not provide evidence for or against causation when the cause is present prior to the onset of the disorder.
4. **Consistency of findings**
   Is the repeated observation of an association in different populations under different circumstances? However, lack of consistency does not rule out a causal association because some risk factors only produce effects under certain situations where a complement of causes is present (or has been present). Consistency can only really be assessed after the relevant details of the causal mechanism are understood.
5. **Specificity of effect**
   This is still emphasized in psychiatric epidemiology, perhaps due to the continual nosologic debates regarding the classification of disorders. However, there are no good grounds to refute a causal interpretation of an exposure because it is related to multiple effects or disease outcomes.
6. **Biologic plausibility**
   Plausibility is important; however, biologically plausible hypotheses can be constructed that are later found to be erroneous, and vice versa, causal associations can be dismissed due to current knowledge or belief systems.
7. **Coherence**
   Related to biologic plausibility and, therefore, similar problems, the

association should not conflict with what is known about the natural history and biology of the disease.

8. **Experimental evidence**
   Commentators are unclear about what is meant by experimental evidence, whether it is evidence coming from laboratory work or human experiments such as the removal of an exposure. However, this is a test for causality rather than a criterion.
9. **Analogy**
   Analogy may provide a source for more elaborate hypotheses about the associations but does not falsify a hypothesis.

Critique of the Causal Criterion

With the exception of temporality, none of the above situations can be viewed as necessary or sufficient criteria for determining whether an observed association is causal. Causal inference cannot be deduced with certainty.

Environmental Risk Factors for the Onset of Psychosis Spectrum Disorder

A number of environmental factors are statistically associated with an increased risk for onset of psychosis spectrum disorder. Evidence of association, however, does not equate to causality. Decisions regarding causation require deductive judgments. In order to aid this logic, causal criteria have been developed (Table 12.5–1). This section uses the most frequently applied criteria to structure the review of the current evidence for the risk factors for the onset of psychosis spectrum disorder. However, it is important to stress that these criteria should not be used in a mechanistic fashion, as all have exceptions and are useful at best as a framework for thought.

Table 12.5–2.
Commonalities in Patterns of Environmental Risk in Psychosis

The developmental window of exposure	The best-established risk factors impact the postnatal period of childhood–adolescence
Pleiotropy	The same risk factor impacts nonspecifically both psychotic and nonpsychotic disorder
Aetiologic heterogeneity	The same disorder is nonspecifically associated with a range of different risk factors
Operates across the severity spectrum	Environmental risks are associated with both attenuated psychotic symptoms and the clinical psychotic syndrome
Effects are additive	Effects of different environmental risk factors are independent and add to each other
More exposure is more symptom admixture and more severe psychopathology	The more severe the psychopathology (i.e., the more symptom domains involved), the greater the level of environmental exposure
Evidence of differential genetic sensitivity	There is emerging evidence that genetic factors make individuals differentially sensitive to the risk-increasing effect of environmental factors
Evidence of dose-response	Many risk factors have established evidence of a dose-response relationship in association with a psychotic disorder
Evidence of a degree of genetic confounding	There is some evidence that risk factors are, in part, driven by genetic factors. However, even so, they likely remain causally associated with a psychotic disorder.

Although there is a wide range of different risk factors, they have a number of commonalities that are highlighted below (Table 12.5–2).

Risk and Protective Factors Operating During Early Development

Early signals in relation to the later development of psychotic disorder have been studied extensively, and although there is some evidence for association, interpretation is difficult due to the long period between

exposure and outcome and the many possible confounders, particularly genetic confounding.

A recent systematic review covering 152 studies and 98 risk or protective factors estimated that the following early exposures may be associated with psychotic disorder: maternal age younger than 20 years (OR 1.17) and 30 to 34 years (OR 1.05); paternal age younger than 20 years (OR 1.31) and older than 35 years (OR 1.28); any maternal (OR 4.60) or paternal (OR 2.73) psychopathology; maternal psychosis (OR 7.61) and affective disorder (OR 2.26); three or more pregnancies (OR 1.30); herpes simplex 2 (OR 1.35); maternal infections not otherwise specified (NOS; OR 1.27); suboptimal number of antenatal visits (OR 1.83); winter (OR 1.05) and winter to spring (OR 1.05) season of birth in the northern hemisphere; maternal stress (NOS; OR 2.40); famine (OR 1.61); any famine or nutritional deficits in pregnancy (OR 1.40); maternal hypertension (OR 1.40); hypoxia (OR 1.63); ruptured (OR 1.86) and premature rupture (OR 2.29) of membranes; polyhydramnios (OR 3.05); definite obstetric complications (NOS; OR 1.83); birth weights of less than 2,000 g (OR 1.84), less than 2,500 g (OR 1.53), or 2,500 to 2,999 g (OR 1.23); birth length less than 49 cm (OR 1.17); small for gestational age (OR 1.40); premature birth (OR 1.35), and congenital malformations (OR 2.35). Significant protective factors were maternal ages 20 to 24 years (OR 0.93) and 25 to 29 years (OR 0.92), nulliparity (OR 0.91), and birth weights 3,500 to 3,999 g (OR 0.90) or more than 4,000 g (OR 0.86).

Although the results were corrected for publication biases and sensitivity and metaregression analyses confirmed the robustness of these findings for most factors, interpretation is difficult. It is likely that at least some of the factors anticipate unmeasured environmental risks associated with other, later risk factors such as childhood adversity, tobacco smoking, minority group, urban environment, and drug use. The factors may also generally reflect current—and later—severe social adversity and inequality, contributing to high levels of allostatic load and increased risk for psychotic disorder. It is also likely that some of the reported risks are mediated by genetic risk for psychotic disorder. For example, maternal mental ill health may reflect psychotic disorder genetic risk and have no direct causal impact on the risk of psychotic disorder in the offspring. Other factors may also apply. For example, a large Danish study suggested that the association with higher paternal age may be due simply to selection into late fatherhood accompanying a predisposition to psychosis spectrum disorder.

Winter birth may be a proxy indicator for some seasonally fluctuating environmental factors. The most popular hypotheses relate to seasonal variation in exposure to intrauterine viral infections around the time of birth or variation in light, temperature/weather, or external toxins. For a dose-response relationship, the effect size increases with latitude (although there are fewer studies from the lower latitudes of the northern hemisphere in the pooled analyses) until about 50 degrees latitude, where it then starts to fall, suggesting a nonlinear inverted U-shaped association, which may in part be explained by methodologic heterogeneity across studies. For temporal association, exposure clearly predates the diagnosis of psychosis spectrum disorder. Studies from northern hemisphere countries consistently show excess winter births in people with psychosis spectrum disorder; however, the effect seems to be greater for those born in urban as compared to rural settings. A meta-analysis of studies carried out in the southern hemisphere did not find an effect for the season of birth (pooled odds ratio 1.04; 95% CI, 0.99 to 1.08). Studies examining season of birth association with other psychiatric conditions are small, and their findings are inconsistent. The largest and most robust study carried out in Denmark, did not find an association between the season of birth and the development of a bipolar disorder, suggesting some specificity of effect for schizophrenia (spectrum) disorder as compared with bipolar disorder. Few studies have looked at the age of onset in relation to the seasonality of birth in people with a psychotic spectrum disorder. The largest study to date found higher rates of winter births in patients who developed psychosis spectrum disorder later in life; however, most studies are underpowered to investigate this issue.

The listed pregnancy and birth complications cover a broad range of pre- and perinatal events, but even a large systematic review of prospective population-based studies (period 1995 to 2001) was unable to identify one individual complication or unifying mechanism. Taken together, findings may implicate an increased risk of hypoxia.

Studies to date have mostly been underpowered to uncover variation in effect size (odds ratio) across groups ordered by degree of exposure to pregnancy and birth complications. One population-based cohort study from Helsinki used continuous measures and found an effective gradient of increasing risk with decreasing birth weight, length at birth, and placental weight (controlled for family history of psychosis); and the National Collaborative Perinatal Project found risk increased when multiple hypoxia-associated complications were present. However, it is difficult to interpret these gradients while the underlying mechanism remains elusive. Exposure

clearly predates diagnosis of psychosis spectrum disorder, although fetal growth retardation may be an early indicator of aberrant neurodevelopment. The associations for individual obstetric complications with the later development of psychosis spectrum disorder are mostly negative and inconsistent; however, statistically pooled estimations suggest a modest effect with the broad category of pregnancy and birth complications.

Pregnancy, birth, and neonatal complications do not act independently of one another; however, current studies are underpowered to detect interaction effects. There have been only a few small studies examining the differential effects of pregnancy and birth complications and symptom dimensions or subtypes of psychotic disorder. A recent systematic review of pregnancy and birth complications and bipolar disorder estimated the pooled odds ratio for exposure to pregnancy and birth complications and later development of bipolar disorder to be 1.01 (95% CI, 0.76 to 1.35) compared with controls and 0.61 (95% CI, 0.39 to 0.95) compared with people who later developed schizophrenia. Furthermore, a Danish National Register study did not find fetal growth indicators to be associated with the development of bipolar disorder. This suggests some specificity for schizophrenia (spectrum) disorder among psychiatric conditions. Indirect evidence of gene–environment interactions comes from a population-based cohort study in Helsinki that found that a history of fetal hypoxia was associated with increased structural brain abnormalities (reduced gray matter and increased ventricular size) among patients with psychotic disorder and their nonaffected siblings but not among controls at lower genetic risk for the disorder. Moreover, the effect size was greater for these patients compared to the unaffected siblings, suggesting that while they show some sensitivity to the psychosis-promoting effects of hypoxia, there is a quantitative difference in this sensitivity. Evidence of gene–environment correlation from a meta-analytic study of pregnancy and birth complications in children born to parents with psychotic disorder suggests individuals with psychotic disorder have an increased risk of obstetric complications, low birth weight, and poor neonatal condition. The risk is greater for mothers with psychotic disorder, but is not confined to mothers with onset prior to delivery or to the births of the children who develop psychosis spectrum disorder themselves later in life. These findings possibly reflect a gene-environment correlation whereby the genetic liability for psychosis in the parent increases the likelihood of social adversity that is associated with obstetric complications.

RISK FACTORS OPERATING DURING CHILDHOOD AND ADOLESCENCE

Urban Birth and Upbringing

Numerous studies to date have investigated variations in the incidence of psychotic disorders in terms of place. The latest and largest international incidence study from the EU-GEI consortium thoroughly documented marked geographic variation in the incidence of psychosis spectrum disorder across 17 catchment areas and six countries. Over 20 studies have demonstrated an association between urban living and rates of psychosis spectrum disorder in countries from the Global North. Generally, studies show a twofold increase in the risk of psychosis spectrum disorder in urban as compared to rural settings, as evidenced by a recent meta-analysis. Further, the weight of evidence supports a risk gradient, with unidirectional increasing rates of psychosis spectrum disorder with increasing levels of urbanicity. There is compelling evidence suggesting that elevated rates of psychosis spectrum disorder in urban areas are not due to social drift during the prodrome (reverse causation). There is some evidence; however, that part of the association between urban environment and psychosis spectrum disorder may be due to genetic confounding (genetic variation predisposing to psychosis spectrum disorder also influencing urban residence). It is urban exposure prior to the onset of the disorder that seems to be more important, rather than the level of exposure at the time of illness onset. A case register study from the Netherlands demonstrated an increased risk of psychosis spectrum disorder for people born in urban areas, irrespective of where they were living at the time of presentation, while those living in urban areas were only at increased risk if they had also been born within an urban area. Furthermore, a Danish study measured the effect of cumulative urban exposure on the risk of psychosis spectrum disorder and found the first 15 years of life were the most critical, as well as evidence of a dose-response relationship. Analyses from the same cohort further suggest that people conceived (including the period of gestational development) in urban areas but reared in less urban areas may be at higher risk of psychosis spectrum disorder. This phenomenon of increased risk seen when there is a mismatch between in-utero developmental environments versus the environment in adult life is recognized in other chronic complex diseases, such as cardiovascular disease. The findings are consistent with similar effect sizes seen across studies from different geographical areas. The

effect is not confounded by other known risks, such as pregnancy and birth complications, and is present after controlling for sociodemographic variables. Most analyses have examined the association of urban living within the broad psychosis category rather than specific diagnoses. Studies that have compared across diagnostic categories have found the risk to be relatively specific for schizophrenia (spectrum) disorders compared to bipolar disorder. Studies investigating the family history and urban exposure support a possible interaction with genetic liability. For example, in the Danish cohort, those *without* a family history of psychosis spectrum disorder had a much smaller risk of psychosis spectrum disorder (0.054% increased risk per unit change of urbanicity) compared to those with a family history (0.22% increased risk, per unit change of urbanicity). New evidence shows that urbanicity effects may be context-specific, as indicated by absent or reversed effects for psychosis spectrum disorder in southern European countries. Similarly, more recent evidence on the prevalence of attenuated psychotic symptoms from the World Health Survey (WHS) conducted in countries from the Global South does not show a consistent pattern of higher prevalence estimates in urban areas. Therefore, urban-rural differences may vary in pattern across the globe and it would be ill-advised to assume city living has the same meaning worldwide. The contrasting findings highlight the strong need for adopting a global perspective in investigating geographic variation in the incidence and prevalence of psychosis spectrum disorder, such as in the INTREPID ("India, Nigeria, Trinidad: Researching Psychosis in Diverse Settings") research program.

Could group-level social processes account for the urban upbringing effect? Growing up in an urban environment in a country of the Global North is a proxy environmental risk factor. Recent research has started to examine the social and economic structure of neighborhoods as a possible explanation for this effect. The social environment varies widely and systematically across dimensions of material deprivation, neighborhood organization (social fragmentation), and ethnic composition. Studies have consistently found a relationship (not necessarily linear) between material deprivation and risk of psychosis spectrum disorder, although study design has generally been cross-sectional, precluding assessment of the direction of the relationship, and could be accounted for by people drifting into more deprived areas before presenting to clinical services. Ecologic studies have consistently shown area-level social fragmentation to influence strongly the rates of psychosis spectrum disorder. A small number of recent studies have examined levels of social cohesion and found neighborhoods richly

endowed with stocks of social capital (interpersonal trust, norms of reciprocity, mutual aid) to have reduced rates of psychosis independent of material deprivation. Ethnic density is an area-level characteristic, defined as the percentage of composition (in a particular geographical area) of people with a given ethnicity, and it has been found to be protective. That is, the higher the area's ethnic density, the lower the rates of psychosis spectrum disorder for the ethnic group under study, independent of area measures of deprivation, a finding that has been consistently reported in a number of studies. Taken together, these reports suggest a possible neighborhood-level social process influencing the risk of psychosis spectrum disorder and emphasize the important role of social context in pathways to psychosis, which will require further elaboration and replication.

Minority Position and Migration

Many studies have reported increased rates of affective and nonaffective psychosis in migrants, especially among the second generation born in the new homeland. Increased risk is found among black Caribbean and Black African immigrants to the United Kingdom; Surinamese, Dutch Antillean, and Moroccan immigrants to the Netherlands; Australian, African, and Greenland immigrants to Denmark; and Greek immigrants to Belgium. Meta-analyses of incidence studies found a higher risk of psychosis spectrum disorder in almost all immigrant groups compared with the majority population. Although the pooled effect sizes suggest a threefold increase in risk, there was evidence of systematic heterogeneity across studies that could not be accounted for by variation in study design. Analyzing first- and second-generation migrants separately results in a pooled relative risk of around 2.5 for the first generation and a higher pooled relative risk for the second generation. However, there is no conclusive evidence that the risk in second-generation migrants is higher than in first-generation migrants. There is also a higher risk of psychosis spectrum disorder in migrants from developing countries; however, the most conspicuous finding was the increased risk associated with being Black, with a pooled relative risk of around 5. Migrant status is a binary exposure; one is either a migrant or one is not. Therefore, a dose-response association will only be testable after the underlying mechanism operating to increase the risk is established.

Meta-analysis of suitable studies has suggested that migration prior to age 18 is associated with a greater risk of psychotic disorder compared to migration in early adulthood.

The selective migration of people at increased risk of psychosis is possible (reverse causation). However, this does not explain the increased risk apparent in groups who migrated *en masse*, such as the Surinamese mass migration to the Netherlands. Further, it cannot explain the increased risk found in second-generation immigrants. Increased risk of psychosis spectrum disorder in migrant groups is a replicated and consistent finding. The validity of this finding has been intensely debated, however. Increased rates do not appear to be explained by psychiatrists diagnosing psychosis spectrum disorder differently in migrant groups, differential service use, or under enumeration, which may have hampered some of the earlier studies. Poor obstetric care in migrant mothers has also been suggested as an explanation, but there is no evidence to support this view. While there has been only a limited amount of research on candidate explanatory factors of the high rates of psychosis spectrum disorder in migrant and ethnic minority groups, the evidence reported to date by investigations such as the etiology and ethnicity in psychosis and other psychoses (AESOP) study; a large epidemiologic incidence and case-control study of first episode psychosis conducted in the United Kingdom suggests that it is a broad range of social adverse experiences in both childhood and adulthood that may combine and interact in complex ways to increase risk in some groups. Finally, studies mostly from the United Kingdom have found the risk of psychosis spectrum disorder to vary across different ethnic groups. The Black Caribbean and Black African groups in the United Kingdom are at higher risk than the Asian group, as are the Surinamese and Moroccan groups compared to the Turkish group in the Netherlands. The association of effect is not specific to schizophrenia, with rates of nonaffective and bipolar disorder also higher in migrants. For instance, the AESOP study found a sevenfold increase in mania among the Black Caribbean and Black African groups compared to the majority group and a twofold increase in mania among other migrant groups. There is no difference in the age of onset in migrant groups as compared to the majority population.

Use of Cannabis, Tobacco, and Other Drugs

There is little doubt that cannabis intoxication is associated with transient psychotic symptoms in some individuals. Furthermore, case-control studies have consistently demonstrated higher rates of cannabis use among patients with psychosis spectrum disorder as compared with controls. Prospective studies additionally have found higher rates of psychosis spectrum disorder in users of cannabis. The pooled analysis of the

association between cannabis and psychosis indicates approximately a fourfold increase in risk for the heaviest users and a twofold increase for the average cannabis user in comparison to nonusers.

Studies examining cannabis use and the subsequent development of other psychiatric conditions are small and their findings are inconsistent, but they may indicate an impact on anxiety, depression, and mania. The association between prior cannabis use and subsequent psychosis spectrum disorder is a consistent finding across studies. Adjusting for other drug abuse, known risk factors of psychosis spectrum disorder, and sociodemographic variables attenuates the effect, but it remains statistically significant. A family study of adolescents with acute psychosis found a tenfold increase in the morbidity risk for psychosis in relatives of probands who tested positive for cannabis use compared to the relatives of probands who tested negative for cannabis, suggesting gene-environment interaction.

Observational studies on the association between cannabis use and psychosis outcomes commonly suffer from so-called omitted variable bias. This refers to the possibility that the observed link is due to any of a range of plausible confounders beyond simple demographics and direct confounders that can never be measured precisely in combination such as genetic vulnerabilities, cognitive abilities, fetal exposures, early development, and parental rearing practices. One way of comprehensively addressing omitted variable bias is to study within-person associations of cannabis and psychosis outcomes using panel data. Panel data (the same subjects measured at two or more points in time) consist of repeated measures that are nested within individuals. The repeated measures are referred to as the within-person level or level 1 units, whereas the persons are referred to as the between-person level or level 2 units. Studies on the association between cannabis use and psychosis over time are usually analyzed at the between-person level or the mixed within-person and between-person level. However, the relationship between cannabis use and psychosis may well differ across levels (i.e., between-person versus within-person levels). A classic example involves the relationship between physical exercise and heart rate: the within-person analysis will reveal a positive association in that more strenuous exercise leads to a higher heart rate. However, in contrast, this association is likely to be reversed at the between-person level, as people who exercise a lot, on average, tend to have a lower heart rate due to their overall better fitness. Panel data of individuals measured repeatedly over time allow control for fixed characteristics, including full nongenetic and genetic risk, whether they are

measured/measurable or not. Three studies applied this within-person paradigm to cannabis and clinical and attenuated psychosis outcomes. All three found strong evidence for an association between cannabis and psychosis, and one additionally found no evidence for the self-medication hypothesis.

Another plausible epidemiologic paradigm to examine the causality of the association between cannabis and psychosis is to demonstrate an association between the level of use in the general population and the rate of psychotic disorder in that population. Using this paradigm, researchers in the EU-GEI consortium showed differences in the frequency of daily cannabis use and in the use of high-potency cannabis contributed to striking variation in the incidence of psychotic disorder across 11 studied sites in six countries.

Cannabis use is reliably associated with an earlier age of onset. Research suggests that the association between cannabis use and earlier onset of psychosis spectrum disorder is robust and is not the result either of tobacco smoking by cannabis-using patients or the other potentially confounding factors. This supports the hypothesis that, in some patients, cannabis use plays a causal role in the development of psychotic disorder.

Use of Tobacco and Other Drugs: Accumulating evidence suggests that tobacco use may be associated with schizophrenia, with findings from Mendelian randomization studies suggesting a possible causal link. A major challenge of studying tobacco use is confounding other smoking-based drugs such as cannabis. Tobacco smoking, unlike cannabis use, is not associated with differences in age at onset.

It is likely that stimulants as a class contribute to the overall burden of psychosis. The available evidence indicates a consistent relationship between methamphetamine use and psychosis, as well as depression and an increased risk of mortality due to suicide and overdose. Both lifetime and current cocaine users show a high prevalence of cocaine-induced psychosis, the prevalence of cocaine-induced psychotic symptoms being higher than the prevalence of the cocaine-induced psychotic disorder.

STRESSFUL LIFE EVENTS AND EARLY CHILDHOOD ADVERSITY

Many studies report an excess of stressful life events in the few weeks prior to the onset of psychotic and affective disorders. A recent systematic review and meta-analysis of studies published during the period 1968 to 2012

suggest a more than threefold increased risk of psychosis spectrum disorder in those exposed to adult life events. However, the authors noted several methodologic limitations of included studies, such as small sample sizes and the use of checklist measures. Although these life events may precipitate the disorder, there is some evidence to suggest they reflect a concatenation of stressful life events over a more sustained period before the onset of psychosis spectrum disorder. However, it is difficult to establish whether increased stress is a cause or a consequence of the development of the psychotic disorder. This is difficult to disentangle with traditional risk factor methodologies; gene-environmental interaction designs may be a more fruitful way of exploring the effect of stress.

Early childhood adversity studies describe a range of clustered adverse experiences, including sexual, physical, and emotional abuse and neglect. There are now a modest number of population-based studies that were recently combined into a meta-analysis (covering the period from 1980 to 2012), suggesting that the risk of attenuated psychotic symptoms and psychotic disorder is increased almost threefold in those exposed to early childhood adversity. There is evidence that childhood adversity-related psychosis is associated with more severe psychopathology as indicated by higher levels of dimensional admixture of different symptom domains. There is also some evidence that childhood adversity is associated with cognitive impairment and, therefore, with some of the childhood neurodevelopmental factors associated with an adult psychotic disorder. A meta-analysis of possible mediating psychological mechanisms found mediating roles of dissociation, emotional dysregulation, and post-traumatic stress disorder symptoms (avoidance, numbing, and hyperarousal) between developmental trauma and hallucinations.

Gene-Environment Interaction

Traditional epidemiologic risk factor methodologies measure the linear association of environmental exposures to risk for the onset and persistence of psychosis. Such studies demonstrate that people respond differently to the same environmental exposure. Some individuals seem to have a low risk of developing the disorder as a result of environmental exposure, while others are more vulnerable; in some circumstances, persons with increased liability for a disorder seem to have a higher exposure frequency to noxious environmental agents, as compared with the general population. Variation in genotype may, in part, account for this heterogeneity. There are two most often studied gene-environment relationships. *Gene-environment*

correlation occurs when a genotype could increase the likelihood of a person becoming exposed to an environmental risk factor. For example, biologic parents not only determine a child's genotype but also provide their early rearing environment; or a child's temperament (at least partially genetically determined) influences how they select and/or shapes their environment. Some studies have suggested, for example, that the association between urban environment and psychosis may be due, at least in part, to gene-environment correlation. However, gene-environment correlation does not preclude the environmental factor from still having a causal impact. For example, in the Environmental Risk (E-Risk) Longitudinal Twin Study, a nationally-representative cohort of 2,232 British twins born in 1994 to 1995 and followed to age 18 (93% retention), socioenvironmental risks (urbanicity, air pollution, neighborhood deprivation, neighborhood crime, neighborhood disorder, social cohesion, residential mobility, family poverty) were associated with molecular genetic PRS for schizophrenia and depression, but the associations between socioenvironmental risk and adolescent attenuated psychotic symptoms existed above and beyond this gene-environment correlation. *Gene-environment interaction (synergism)* (G × E) posits that instead of inheriting a disease state per se, a person actually inherits a set of genetic susceptibility factors that act to moderate the effects of (causal) environmental exposures. If this assumption is correct, integrated epidemiologic approaches which examine the joint influence of genes and environment on the risk for psychosis spectrum disorder, will improve the accuracy and precision of the measured risk estimates and the predictive power of environmental risk factors.

G × E is notoriously difficult to study. However, with the advent of direct molecular measures of genetic risk, some progress has been made. Initially, studies modeled interactions between (functional) variants in a candidate gene and a measure of the environment. This resulted in some early results on, for example, the interaction between cannabis use and genetic variation in AKT1. However, these results likely represent false positives. A more robust approach involves the use of summary measures of polygenic risk and environmental risk. Thus, the utilization of PRS as a single metric of molecular genetic risk has considerably increased the power to detect associations with phenotypes as well as gene-environment interactions. Currently, PRS for schizophrenia of an individual can be estimated by summing the log odds ratios of individual single nucleotide polymorphisms multiplied by the number of risk alleles present at the corresponding loci. Similarly, recent work on the exposome paradigm has shown that it is

possible to investigate the sum of nongenetic “risk” and apply predictive modeling approaches to construct an exposome score (ES; an aggregated score of nongenetic exposures) for schizophrenia. Evidence was found in the EU-GEI consortium and replicated in another study for additive interaction of molecular genetic risk state for schizophrenia with ES and, separately, the presence of lifetime regular cannabis use and exposure to early-life adversities. The results suggest that the etiopathogenesis of schizophrenia involves genetic underpinnings that act by making individuals more sensitive to the effects of some environmental exposures.

PREMORBID VULNERABILITY INDICATORS/MARKERS

Premorbid Indicators: Early Developmental Abnormalities

As a group, individuals who develop psychosis spectrum disorder as adults are more likely to manifest subtle motor/language and cognitive abnormalities during childhood and adolescence compared with individuals who do not develop psychosis spectrum disorder. There does not appear to be any association between developmental abnormalities and prenatal insults, suggesting they may be indicators of genetic liability. A series of large birth cohort studies have consistently found evidence for delays in the attainment of developmental milestones for children who later develop psychosis spectrum disorder. A meta-analysis focusing on motor milestones found that walking unsupported, standing unsupported, and sitting unsupported were significantly associated with adult schizophrenia risk. Abnormalities in motor milestones are most conspicuous before the age of 2, while receptive language abnormalities are most prominent between the ages of 5 and 15. The relationship between the age of acquiring motor/language milestones and the risk of psychosis spectrum disorder appears to be linear, making a possible developmental subgroup unlikely. Furthermore, severe motor/language abnormalities tend to predict an earlier age of onset for psychosis spectrum disorder. A study from Philadelphia found increased rates of motor and language abnormalities, not only in the children who later developed psychosis spectrum disorder but also in their siblings who remained unaffected, suggesting manifest motor abnormalities may be markers of underlying genetic liability. The early emerging motor and language deficits appear to be relatively specific for psychosis spectrum disorder. As a group, children who later develop psychosis spectrum

disorder score lower on standardized measures of intelligence compared to their unaffected counterparts throughout childhood. However, the difference widens around the ages of about 4 to 7. Studies that compared affected and unaffected siblings found that the children who later developed psychosis spectrum disorder had a lower intelligence quotient compared to their unaffected siblings. This deviance in cognitive impairment seems to be relatively specific to schizophrenia (spectrum) disorder and is not present in bipolar disorder. Twin and family studies have shown that the alterations in adult cognitive performance seen in patients and their first-degree relatives are markers for schizophrenia genetic liability. It is likely that the developmental cognitive alterations similarly reflect the influence of genetic factors associated with schizophrenia.

As a group, the children who later develop psychosis spectrum disorder are more likely to show signs of subtle social maladjustment, for example, poor relationships with other children, social isolation, lone play, and social anxiety as compared to their peers. However, these subtle social markers are common among children who later develop a broad range of different psychiatric disorders. Although developmental abnormalities are common in children who later develop psychosis spectrum disorder, many of them have normal developmental histories, which results in low sensitivity (the ability to predict children who will later develop psychosis spectrum disorder correctly). Furthermore, they are relatively prevalent in the general population (estimated at around 15%), which consequently reduces their specificity (the ability to correctly predict children who will not develop psychosis spectrum disorder) and, in turn, makes them poor predictors of future psychosis spectrum disorder (positive predictive power estimates range from 3% to 5%). Developmental abnormalities may be most useful as a possible measurable indicator of genetic liability for psychosis spectrum disorder.

Premorbid Indicators: Psychopathology

Childhood psychiatric disorders: Longitudinal research from Israel and Denmark shows that a diagnosis of psychotic disorder is commonly preceded, sometimes by decades, by almost any other mental disorder suggesting the pathway from early psychopathology to schizophrenia is heterotypic. This was confirmed by the Dunedin Multidisciplinary Health and Development study, a longitudinal follow-up of a representative birth cohort of 1,037 children born in Dunedin, New Zealand, during the year 1972 to 1973. Its strength lies in the fact that it has sequentially assessed not only

childhood developmental indices but also serially collected self-reported psychopathology (ages 11, 13, 15, 18, and 21 years), with further psychiatric interviews carried out at ages 11 and 26 years. The study found that generally, there was child-to-adulthood syndrome homotypic continuity found for anxiety, depression, and antisocial disorders. However, no such syndrome continuity was evident for adult schizophreniform disorder, which was heterotypically preceded by a range of different childhood disorders, including anxiety, depression, conduct/oppositional disorder, and attention-deficit hyperactivity disorder (ADHD). This group of juvenile diagnoses did not specifically predict adult psychotic disorder but were, in fact, the harbinger of many different adulthood psychiatric illnesses. Such findings clearly demonstrate significant heterotypic psychopathology prior to adult-onset psychosis spectrum disorder. However, the juvenile categorical diagnoses are demonstrably poor discriminators for what adult psychiatric disorder a child is likely to develop in the future.

Attenuated psychotic symptoms: Many studies have reported on the homotypic association between childhood attenuated psychotic symptoms and later psychotic disorder. For example, in the Dunedin Multidisciplinary Health and Development study, attenuated psychotic symptoms at age 11 were associated with increased rates of a psychometrically defined psychotic disorder outcome by age 38. More severe childhood psychotic symptoms carried higher risk than less severe expression of psychosis. Replication of this transition over time from attenuated psychotic symptoms to full-blown psychotic disorder, with evidence for dose-response, comes from longitudinal studies in the Netherlands (NEMESIS and NEMESIS-2), Germany (EDSP), Turkey (TURK-SCH), and the United Kingdom (ALSPAC). A limitation of these studies is the use of a nonclinical, variably, and rather arbitrary defined psychometric definition of psychotic disorder. The exception was a longitudinal study in Israel, which relied on the outcome of a registry-based clinical diagnosis of psychotic disorder requiring hospital admission. A stratified full probability sample of 4,914 persons aged 25 to 34 years who were screened for psychopathology in the 1980s. Subsequent psychiatric hospitalization was ascertained using the psychiatric hospitalization registry, with a mean follow-up of 24 years. Early attenuated psychotic symptoms predicted risk of later hospitalization for nonaffective psychotic disorders, mostly during the 5 years after baseline (adjusted odds ratio = 4.31; 95% CI, 2.21 to 8.41; positive-predictive value = 1.27%; population attributable risk fraction = 33%). Also, attenuated psychotic symptoms increased the risk of later hospitalization for other

psychiatric disorders (adjusted odds ratio = 2.21; 95% CI, 1.02 to 4.82). Early negative symptoms (five interviewer-rated items assessing speech deficits, flat affect, and poor hygiene) were also associated with an increased risk of later schizophrenia only in the presence of attenuated psychotic symptoms (OR = 13.0, 9% CI, 2.1 to 79.4).

HIGH-RISK MODELS OF PSYCHOSIS ONSET

Strong heterotypic associations between prior psychopathology and later psychotic disorder outcomes may indicate a possibility for prevention. As a result, there is interest in advancing research on the predictive modeling of psychosis, similar to other areas of medicine such as cardiovascular medicine, oncology, and dementia care. Finding ways to understand and predict important health transitions and the factors causally impacting these represent a growing part of health expenditure at the interface of clinical medicine and public health.

Table 12.5–3.
High-Risk Strategies to Study the Onset of Psychosis and Develop Early Intervention

	Clinical high-risk studies	Population-based cohort studies of attenuated psychotic symptoms	Follow-back samples of patients with a psychotic disorder
Sampling	Opportunistic samples through selected searches and advertising, sometimes part of special “prodromal service”	Representative population-based samples	Representative samples of patients
Sample risk enrichment strategy	Yes	No	No
Risk predictors used	Almost entirely based on the construct of attenuated psychotic symptoms, based on clinical interview	Attenuated psychotic symptoms and other measures of psychopathology based on self-report or clinical interview	Measures of psychopathology elicited through follow-back clinical interview
Role prediction nonpsychotic psychopathology	Exclusion variable (attenuated psychotic symptoms are not “better explained” by another DSM disorder)	Included as an essential mechanistic factor of psychosis onset	Included as an essential mechanistic factor of psychosis onset

Prediction paradigm	Homotopic (psychosis → psychosis)	Homotypic and heterotypic (nonpsychotic → psychosis)	Homotopic and heterotypic
Baseline mental health status	The great majority are already ill with anxiety disorder, depression, substance use disorder	Illness rate representative of the general population	All diagnosed with a psychotic disorder
Psychotic disorder outcome	Arbitrary psychometric, typically based on an increase in a continuous positive psychotic symptom scale	Mostly arbitrary psychometric, typically based on composite measures of psychosis and functioning, need for care or care use	Natural clinical psychotic disorder
Transition rates	Less than 10% per year	Less than 1% per year	100% (per definition)
The main factor driving a transition	Sample risk enrichment strategy	Risk over time	Risk over time
Length of follow-up	Mostly 1–3 years	Mostly 5–20 years	NA (follow-back)

Psychosis research has been slow to develop strong links with public health approaches. One reason is that the incidence of psychosis spectrum disorder is low and the latency long. Much of the risk contributing to adult mental ill health is developmental. To conduct decades-long cohort studies to study the relationship between developmental risk and the onset of adult psychopathology is impractical and expensive. Although some impressive work has been carried out in, for example, the U.K. MRC birth cohort

studies, the New Zealand Dunedin cohort study, the Israeli draft board studies, and the Scandinavian birth cohort studies, there is an urgent need for data on the clinical ontogenesis and prediction in the psychosis spectrum.

To this end, three types of approaches have been developed in recent years. These include the selected *clinical high-risk approach*, the representative *population-based attenuated symptom approach,* and the *clinical sample follow-back approach*, depicted in the table (Table 12.5–3).

The clinical high-risk approach can bypass the problem of low incidence and long latency inherent to population-based approaches to psychosis. It has been extensively piloted, resulting in a burgeoning literature on prognostic prediction in so-called "ultra–high-risk" or "clinical high-risk" samples. The results of these, however, cannot be translated to psychosis incidence in the general population—and clinical practice—as they are based on nonepidemiologic opportunity sampling of selected help-seeking individuals who majorly already have a nonpsychotic disorder (anxiety, depression, substance use), yielding sample-specific results that are unlikely to be either representative or generalizable. In addition, the outcome of "transition" in clinical high-risk studies is not clinical but psychometric, typically based on an arbitrary increase in positive psychotic symptoms on a 5- or 6-point scale. Also, the relatively high rate of transitions in these individuals (10% to 15% over a period of 2 years) largely arises as a function of risk enrichment strategies embedded in specific sampling procedures, further limiting their use as a model of the onset of psychosis in the general population. Finally, risk and transition are modeled as a homotypic process (attenuated psychosis gives rise to psychotic disorder), whereas population-based epidemiologic evidence discussed above indicates that more clinical psychosis is attributable heterotypically (i.e., nonpsychotic symptoms give rise to psychotic disorder) to prior affective and other nonpsychotic dysregulation than to prior subthreshold psychosis.

Another way to study the development of psychotic disorder, developed in parallel to the development of the "clinical high-risk" or "ultra–high-risk approach," is the prospective population-based cohort approach, focusing on psychopathology risk factors for mental health outcomes, including psychotic disorder. The exposure used in these studies typically involves attenuated psychotic symptoms (also referred to as "psychotic experiences") in combination with other nonpsychotic psychopathologic predictors. For example, the German EDSP and the Dutch NEMESIS-2

studies managed to follow representative cohorts of around respectively 3,000 and 6,600 individuals over a period of approximately 10 years, conducting four extensive structured interviews over that period. While these cohort studies yield interesting findings about the ontogenesis of psychosis (typically at much lower yearly transition rates than clinical high-risk/ultra–high-risk studies), early-risk states typically are described at the level of attenuated psychotic symptoms, which can be difficult to measure in general population settings. Some studies, however, like the Dutch NEMESIS-2 and German EDSP studies, used clinical interviews to assess attenuated psychotic symptoms. Nevertheless, although rare transitions to full psychotic disorder in these cohort studies can be used to study real population-based transitions, analyses are often hampered by low power and difficulties accurately pinpointing transitions, given the low frequency of interviews over the follow-up period.

Despite limitations inherent to the population-based approaches of psychosis prediction, a consistent finding is the importance of nonpsychotic psychopathology. The actual emergence of psychosis is not an isolated "onset" of a specific phenotype with homotypic progression, as in the "clinical high-risk" or "ultra–high-risk" paradigm, but rather is an indicator of increasing severity/complexity of an underlying heterotypic progression of mixed psychopathology, particularly affective dysregulation, giving rise to psychosis (Fig. 12.5–1). These findings echo the increasing awareness that genetic and environmental risk and the clinical manifestation of early psychopathology, including psychosis, to a large degree is "transdiagnostic." The broader, transpsychopathological, and heterotypic approaches have conceptual and statistical advantages over a more narrow focus on psychosis in clinical high-risk and population-based approaches.

FIGURE 12.5–1. Conceptual and practical contrast between the heterotypic and homotypic prediction of psychosis onset. The figure shows the relative "blindness" of the homotypic clinical high-risk (CHR)/transition paradigm for the heterotypic development of psychotic disorder. On the **left** is the natural development of multidimensional psychopathology over time (five phases) as established in recent prospective population-based cohort studies and retrospective follow-back studies. *Black circles* indicate (attenuated) positive psychotic symptoms. Other gray-scale circles indicate other psychopathology (e.g., anxiety, depression, obsessions, somatic concern). As the CHR paradigm ignores multidimensional nonpsychotic psychopathology, it remains "blind" and only "sees" homotypic psychotic phenomena as precursors of schizophrenia-"transition" (i.e., more severe psychosis; below on the **right**), while these phenomena are, in fact, a marker of relative poor outcome of heterotypic multidimensional psychopathology, diagnosable as a psychotic disorder in DSM-5 (below on the **left**). The restricted focus on positive symptoms in the CHR paradigm means that considerable potential for prevention in phases 1 to 4 is missed.

Recently, researchers have resurrected a time-honored method addressing the issue of studying psychosis onset and early intervention; the epidemiologic follow-back study. In a recent study in Canada, an intensive follow-back methodology was used to study the onset of psychosis in an

epidemiologically representative incidence sample (n = 430), similar to the seminal work of Heinz Häfner in Germany, but modernizing it to fit the research framework of the current early intervention era. The authors found that individuals experiencing a first episode psychotic disorder could be traced back to the group with the most complex nonpsychotic syndromes, indexed as the number of preonset nonpsychotic symptoms identified. They established that (i) initial attenuated psychotic symptoms were preceded in time by nonpsychotic symptoms, (ii) nonpsychotic symptoms were more frequent and complex in those with attenuated psychotic symptoms, and (iii) higher levels of nonpsychotic symptoms were predictive of more subthreshold psychotic symptoms. The authors thus suggest that what is commonly considered the onset of a "psychotic disorder" may, in fact, represent an outcome of a prior nonpsychotic state.

These findings were confirmed in another prospective population-based cohort study, which showed that the risk in "psychosis high-risk" states was mediated not by attenuated psychosis per se but specifically by the combination of attenuated psychosis and nonpsychotic disorder. Psychosis high-risk research, therefore, may benefit from a reconceptualization from a focus on attenuated psychotic symptoms, with the exclusion of nonpsychotic DSM disorders providing a "better explanation" of the psychotic state, toward a focus on poor-outcome nonpsychotic disorders, characterized by a degree of psychosis admixture, on the pathway to psychotic disorder outcomes.

THE COURSE AND OUTCOME OF PSYCHOSIS SPECTRUM DISORDER

Prognostic Pessimism and Psychosis: Does the Evidence Stack Up?

Origins of prognostic pessimism: The pervading clinical and societal view of the diagnosis of schizophrenia is one of a uniformly "debilitating" and "deteriorating" disorder of poor outcome, the basis of which probably stems from clinically biased observations and a degree of conceptual confusion. For example, a carefully conducted Finnish study showed that the prevalence of the group of highly related (affective and nonaffective) psychotic disorders, that is, the psychosis spectrum, is as high as 3.5%, of which less than a third had a diagnosis of schizophrenia. As the different psychotic disorders share aetiologic factors, symptoms, and treatments, with no "point of rarity" separating them in these domains, schizophrenia

may be considered the (relatively) poor outcome subgroup of a general broader psychosis spectrum syndrome. As schizophrenia is much more studied than other psychotic syndromes, the relatively poor outcome of schizophrenia has affected expectations of psychosis prognosis across the range of psychosis expression. The idea that a diagnosis of schizophrenia refers to a deteriorating disorder originates directly from the work of Kraepelin, who systematically investigated the course of psychoses in patients admitted to a large custodial institution in Germany during the late 19th century. He combined a number of clinical syndromes into a single disease entity (dementia praecox) because they appeared to share a poor longitudinal course (estimated range of permanent cure: 2.6% to 16.0%). However, the asylum provided long-term residential care for people with the most severe, complex, and debilitating conditions (i.e., a biased sample, skewed toward the worst outcomes—a mechanism known as “hospital bias” or “Berkson bias”), indicating that Kraepelin seminal description is unlikely to fully reflect the complete range of outcomes for the diagnosis of schizophrenia.

Table 12.5–4.
Methodologic Heterogeneity: Limiting Comparability between Studies of Course and Outcome of Psychosis

1. ***Variation in the populations from which patients are selected.*** Many studies have relied on in-patient samples only. However, approximately 20–40% (depending on the country and region) of patients with psychosis are never admitted to a hospital, and they may differ from those admitted in important variables associated with outcome.
2. ***Variation in diagnostic criteria.*** Lack of reliability between different classification systems may result in different samples being identified. Also, if broad concepts of psychosis are employed, the results tend to be more favorable than studies using narrow definitions.
3. ***Variation in the length of illness before entry into the follow-up study.*** If this varies, then subjects with an admixture of follow-up epochs and levels of chronicity are being examined.
4. ***Variation in length of follow-up*****.**
5. ***Variability of attrition rates.*** In any follow-up study, a proportion of participants will be lost to follow-up due to death, migration, or refusal or are untraceable for other reasons. Many published studies have high rates of attrition (greater than 20%); further, if the analyses were done at a time when the researcher was unable to take into account this attrition (using imputation methods or other latent variable methods), loss to follow-up is likely to be related to particular patterns of course and outcome, which will bias the outcome.
6. ***Variation in methods used to assess course and outcome*****.** There is no single measure of course and outcome for complex disorders, and qualitative summary terms (e.g., recovery, improvement, or deterioration) are likely to obfuscate intraindividual variability over time, and the terms are used inconsistently in the literature. The outcome is multidimensional (at least four domains should be considered, namely, symptom severity, functional impairment, disability in social and occupational roles, and existential recovery). There is very little work on the domain of existential recovery (recovery of perspective and the experience of a meaningful life despite problems) over time. The four domains are likely to be related, and few studies have used data reduction techniques to deal with the problems of multiple analyses. Further, few studies examine serial follow-up measures, and a single outcome measure will be less representative of a longitudinal course the longer the follow-up period is.
7. ***Variation in the characteristics of the general population*****.** For example, social outcomes (e.g., unemployment) will be influenced by

the general unemployment rates in the area. Low and Middle Income Countries (LAMIC) countries may differ in the structure of mental health care and social care, as well as social cohesion and family structure, possibly impacting outcomes in many ways.

8. ***Variation in statistical techniques and adjustment of confounding.*** Statistical methods, which deal with multiple comparisons made at different time points, were not available or not utilized at the time of publication of the study. Further studies have often not had the resources to collect adequate data on potential confounding variables when assessing potential predictors (or prognostic indicators).
9. ***Variation in long-term management of psychosis spectrum disorder.*** Treatment may vary across time and place, which may differentially modify the natural history of the disorder. LAMIC countries may differ in structure of mental health care and social care, possibly impacting outcome in many ways.

Although most clinicians no longer work in long-term custodial settings, clinical caseloads remain Berkson-biased toward patients who require sustained contact with mental health services and have a continued need for care, rather than the representative sample of all persons ever diagnosed with psychosis spectrum disorder; therefore perpetuating the clinical illusion of the diagnosis of schizophrenia referring to an *invariably* chronic and deteriorating disorder. During the past century, many studies have attempted to examine the outcome of psychosis spectrum disorder yet, despite this effort, the data on longitudinal course remain weak, primarily due to the inherent and complex methodologic difficulties associated with carrying out follow-up studies, which are especially sensitive to confounding, bias and diagnostic selection (i.e., narrow schizophrenia vs. broad psychosis spectrum disorder) at baseline (Table 12.5–4). There is actually little information regarding the natural history of psychosis spectrum disorder in the literature, as, throughout history, psychosis has tended to result in custodial care or other medical, religious, or cultural interventions, which could potentially modify the longitudinal trajectory of the disorder. Since the 1950s, the vast majority of individuals diagnosed with psychosis have received antipsychotic treatment, so it is unlikely that contemporary studies actually reflect natural history. A study from India was able to examine outcomes in individuals who had never received treatment for psychotic disorder (a closer approximation to natural history, notwithstanding the potential influence of cultural context).

The course for the untreated group was heterogeneous and rather similar to the course of those who had received treatment.

Most descriptions of the longitudinal (symptom) pattern of psychosis have to date, been derived from systematic clinical observation (rather than statistical modeling techniques). Clinical researchers working during the early part of the 20th century followed patients with psychotic disorders over the long term and noted that the significant variability in the course of treatment could be usefully described by a number of course typologies (European researchers recognizing eight categories, while American observers described 12). These longitudinal patterns (slightly modified) have been incorporated into the current diagnostic classification systems as additional descriptors. The World Health Organization has described operationalized (symptom) descriptors for the course (Table 12.5–5) that are useful and reliable in clinical and research settings. The outcome is a multidimensional construct that, at minimum, requires a description of domains for (1) clinical (symptoms and treatment), (2) social (e.g., independent living, maintenance of social relationships, and employment), and (3) existential (meaningful life despite mental health problems). Such domains are likely, in part, to overlap. However, studies examining risk factors for the persistence of psychosis and disease-environment interactions should measure symptom course and social and existential domains independently, as the different domains probably do not covary directly but are more likely to be the result of different influences, at least in part (Tables 12.5–6 and 12.5–7).

Table 12.5–5.
World Health Organization Life Chart Description of Clinical Symptom Course

1. Single-psychotic episode followed by complete remission
2. Single-psychotic episode followed by incomplete remission
3. Two or more psychotic episodes with complete remission between episodes
4. Two or more episodes, with incomplete remission between episodes
5. Continuous (unremitting) chronic psychosis

Based on World Health Organization. *WHO Coordinated Multi-Centre Study on the Course and Outcome of Schizophrenia*. World Health Organization; 1992.

There is a small body of literature comparing the patterns and frequencies of outcomes using different perspectives, but few studies have examined

multiple perspectives in the same sample. One such study carried out in South Verona's community care service, found a distinction between objective indicators and patient-reported outcomes. Patients were especially troubled by persistent unmet social, existential (help in the recovery of perspective), and functional needs. This may have important implications for the clinical management of people with psychosis, particularly since mental health services currently emphasize pharmacologic and psychological treatments while de-emphasizing social, existential, and functional interventions, yet social and existential unmet needs seem to influence disability over the longitudinal course.

Table 12.5–6.
Variation in Proportion of Good Outcome due to Variation in Outcome

Study	*N*	Period	Event Rate	Upper Limit	Lower Limit	Definition of Good Symptom Outcome
Muller, 1951 (Germany)	200	30	0.33	0.26	0.40	Recovered or substantially improved at the time of discharge (residual symptoms)
Bland, 1978 (Alberta)	43	14	0.21	0.09	0.33	Symptomatic recovery with no social or intellectual deficit through follow-up
Stephens, 1978 (Baltimore)	349	>5	0.24	0.20	0.29	"Recovered" included patients with symptoms but no social impairment
Ciompi, 1980 (Switzerland)	289	37	0.27	0.22	0.32	Remitted completely or had only mild residual symptoms
Salokangas, 1983 (Finland)	161	8	0.55	0.47	0.62	Complete recovery or occasional mild psychotic symptoms
Rabiner, 1986 (New York)	36	1	0.56	0.39	0.72	Symptomatic remission for at least 3 months prior to assessment
Sartorius, 1986 (Multinational)	1,352	2	0.39	0.36	0.42	One episode with no or minimal symptoms at follow-up
Shepherd, 1989 (United Kingdom)	107	5	0.22	0.15	0.30	Had no relapse during follow-up period
McCreadie, 1989 (Scotland)	49	2	0.37	0.23	0.50	Asymptomatic and functioning adequately at the time of follow-up
Marneros, 1992 (Germany)	355	25	0.07	0.04	0.10	Full remission after first episode
Thara, 1994 (India)	76	10	0.17	0.09	0.26	Complete recovery without relapse during follow-up period
an der Heiden, 1995 (Germany)	56	14	0.25	0.14	0.36	Full recovery over follow-up period
Mason, 1996 (United Kingdom)	58	13	0.52	0.39	0.65	Full remission in 2 years prior to outcome assessment
Wieselgren, 1996 (Sweden)	101	5	0.30	0.21	0.39	Dichotomized variable "good outcome" versus "poor outcome"
Ganev, 1998 (Bulgaria)	55	16	0.38	0.25	0.51	Complete remission in 2 years prior to follow-up assessment
Wiersma, 1998 (Netherlands)	82	15	0.27	0.17	0.36	Complete remission never readmitted

Broad Pattern of Course and Outcome

The first 5 to 10 years of psychosis spectrum disorder are considered "critical," referring to the, to date, nonconfirmed hypothesis that early energetic treatment may causally impact the later course of the syndrome. After the first episode, around 90% of patients will experience a rapid remission of symptoms. After 5 years, however, 80% will have experienced one or more relapses. With each episode, a small proportion of patients will develop a continuous illness course, displaying a mix of persistent positive symptoms, severe negative symptoms, cognitive difficulties, catatonia, and a state of demoralization and internalized stigma. After the first 10 years after onset, the illness course tends to plateau. However, cross-sectional outcome measures of psychopathology do not differ substantially according to study duration, suggesting that there is no clear pattern of deterioration or

“progression,” although this may occur in a subgroup of patients. A systematic review of prospectively designed studies examining the outcome of first episode psychosis (and other psychosis) published during the period 1966 to 2003 found good clinical outcomes in 42%, intermediate outcomes in 35%, and poor outcomes in 27% of the samples with a diagnosis of psychosis. In a recent 10-year follow-up of the AESOP first-episode psychosis cohort, 23% of cases did not experience a remission, 13% remitted and remained symptom-free, with an intermediate group of 44% having had at least one remission of 6 months or longer, and at least one episode of 6 months or longer. Moreover, using growth mixture modeling to identify latent trajectory classes that accounted for heterogeneity in the patterns of change in psychotic symptoms over time, four trajectories of psychotic symptoms were empirically identified in the AESOP study: (1) remitting-improving (58.5%); (2) late decline (5.6%); (3) late improvement (5.4%); and (4) persistent (30.6%). In addition, although recently, life expectancy in the general population has risen, there was further evidence from this study that the excess mortality, which has been repeatedly reported in people with psychosis, remains high. The absence of a uniform definition for outcome across studies makes direct comparison difficult. This frequency distribution is comparable with the findings from an earlier meta-analysis of long-term follow-up studies (published between the turn of the 20th century and 1998 with a follow-up period greater than 1 year). The evidence from recent systematic reviews is summarized in Table 12.5–8.

Table 12.5–8.
Summary of Findings from Follow-Up Studies on Course and Outcome of Psychosis Spectrum Disorder

1. The course of psychosis is highly variable both *within* and *between* patients, even after taking account of methodologic heterogeneity across studies. There is a broad range of possible course patterns ranging from complete recovery to continuous unremitting psychopathology, cognitive performance, and social functioning. Between such extremes, a substantial number of patients present with multiple episodes of psychosis interspersed with partial remission.
2. Less than half of patients diagnosed with psychosis show substantial clinical improvement after follow-up time averaging 6 years. Although these estimates are more optimistic than the earlier reports based on observations in institutional settings, they importantly emphasize the fact that psychosis is more often associated with persistent chronic disability that profoundly affects a person's development and quality of life.
3. Examining the trends in course and outcome over the past century revealed substantial gains in favorable outcome from the 1920s until the 1970s, after which time the gradient seemed to reverse (slightly). This biphasic trend may reflect developments in treatment, changes in diagnostic criteria across the decades, as well as possible sampling bias. Moreover, a secular trend (benign metamorphosis) toward better outcome and the virtual disappearance of the most lethal forms of catatonia was evident prior to the introduction of antipsychotics. The reasons for this trend are unclear, but commentators have speculated that they reflect changes in care and expectations within health service settings, or the development of psychological, social, and rehabilitation approaches to treatment. Unfortunately, the current cannon of outcome studies (as published) does not lend itself to easily disentangling direct disease effects from environmental factors that may influence the persistence of the disorder.
4. Course descriptors vary as a function of the length of follow-up, with the greatest variability being in the first 5 years, after which time the course tends to plateau. However, cross-sectional outcome measures of psychopathology do not differ greatly according to study duration, suggesting there is no clear pattern of deterioration.
5. On average, patients with a diagnosis of schizophrenia have the poorest outcome, with schizoaffective patients occupying an intermediate position between schizophrenia and affective psychosis; however, diagnostic categories of psychosis poorly predict outcome. Further, course and outcome estimates vary depending on the

diagnostic classification used. Patients diagnosed using broadly defined schizophrenia have generally better outcomes compared to the narrowly defined (post-DSM-III) schizophrenia.

6. There is no reliable set of predictors yet identified for course and outcome. Furthermore, the predictive value of putative prognostic indicators is generally poor and likely to depend on the duration of illness (stage) and the projection time. Significant methodologic differences in the definition of predictor variables, adjustments for other known risk factors, differential attrition rates (loss to follow-up), and variation in outcome measurement reduce the comparability of studies on the prediction of prognosis and make exploratory subgroup analyses difficult, despite a large number of published studies. Best estimates to date suggest that all known prognostic factors or psychopathology explain only a small amount of the total variance in outcome (estimates at around 30%, depending on the outcome domain under study), which translates into low predictive power.
7. Very little is known about outcomes of existential recovery (recovery of perspective and experience of a meaningful life despite difficulties), despite growing evidence that existential recovery can be attained by many patients.

Risk Factor for the Persistence of Psychosis (5 Years' Follow-Up)

Although there have been considerable advances and concerted research efforts into the determinants of the onset of psychosis, there has been a paucity of studies examining the determinants of persistence over the past decade. The body of research evidence reflects this neglect. Many early studies of family risk and outcome of psychosis found an association between the good outcome in psychosis and a family history of affective disorders. However, the findings were inconsistent and, at times, contradictory. There was significant methodologic heterogeneity that could potentially bias the results, such as retrospective design, insufficient adjustment for potential confounders (family size, age, and sex of the relatives), the use of global unidimensional outcome measures, and mixed samples (recent onset and chronic disorders studied together).

There have been few recent studies examining the effect of family risk on the course of psychosis. The largest study to date examined outcome and family history in a sample of 253 DSM-III patients with psychosis and 723 first-degree relatives. There was a higher morbidity risk of psychosis (spectrum) disorder in the relatives of probands with poor outcome

disorders, although this did not reach statistical significance. However, there was a (statistically significant) higher morbidity risk of affective disorder in the relatives of probands with good outcome disorder. A study from Camberwell examined the associations between 4-year outcomes and familiar loading for a range of psychotic disorders in a sample of 150 consecutively admitted patients with recent onset disorder. Higher familiar loading for psychosis predicted higher rates of persistent negative symptoms (estimated odds ratio 1.5), more time in the hospital, and poorer social functioning at follow-up. The effect of familiar loading was greatest in the group of patients with a diagnosis of schizophrenia compared to other psychotic disorders. These findings suggest poor outcome disorders, with higher levels of negative symptoms that may “breed true” within families. However, recent studies using molecular measures of PRS for schizophrenia did not find clinically meaningful associations with measures of course and outcome. There are relatively few studies examining the relationship between pregnancy and birth complications, and psychosis, and results are mixed.

There is evidence that childhood cognitive ability is associated with the outcome; lower intelligence has been shown to predict unfavorable clinical and functional outcomes at follow-up. There is interest in the question of to what degree any association between cognitive ability and outcome may be mediated by metacognition (referring to the cognitive processes involved in thinking about thinking) and by factors that may confound cognitive ability measurement in patients with a psychotic disorder such as motivation, effort, defeatist performance beliefs, stress, anxiety, and physical inactivity. Studies also have found that subtle social premorbid adjustment is associated with a less remitting course and poorer functional outcomes. There are now a number of relatively small- to medium-term (2 to 5 years) follow-up studies comparing the course and outcome of patients with psychosis exposed to cannabis versus nonexposed patients. They are methodologically heterogeneous, but some consistency across studies is evident. The cannabis-exposed patients have more positive symptoms (but not negative symptoms), and the course tends to be relatively unremitting. A poorer outcome in the domains of work and education has been demonstrated, which are most likely reflecting factors that independently increase the likelihood of early cannabis use and later education and labor difficulties. A review of reviews concluded that cannabis use was associated with increased relapse rates, more hospitalizations, and more pronounced positive symptoms in patients with a psychotic disorder. By contrast,

psychosis that follows stressful life events may have a better outcome. The risk factors for the persistence of psychosis have been less intensively and comprehensively studied than the risk factors for the onset of psychosis. Further research is required to draw any firm conclusions that risk factors for onset may also be determinants influencing outcome (discrete effect models) but is worthy of further investigation. Discrete effects can be broadly grouped into two groups: (1) early developmental abnormalities and premorbid cognitive alterations, which may be more strongly associated with a clinical symptom profile characterized by cognitive alterations, negative symptoms, insidious onset, unremitting course, and functional deterioration, which are linked to the neurodevelopment model of psychosis; (2) adverse life events and migrant status, which may have a less specific association with the schizophrenia syndrome and whose clinical correlates suggest less prominent negative symptoms, acute onset, remitting course, and better functional outcomes, which may be linked to a mechanism of social stress sensitivity.

TOWARD AN EMPIRICALLY BASED MODEL OF PSYCHOSIS SPECTRUM DISORDER: A WORK IN PROGRESS

Understanding cause is fundamental to the development of scientific knowledge and the development of empirically based models of disease. Modern medicine has developed a deductive system for evaluating causation based on Koch postulates and Hill criteria (and their elaborations). The integrated interpretation of epidemiologic, clinical, and experimental research aided by such causal criteria has resulted in the successful identification of important risk factors for some leading causes of morbidity and mortality (e.g., cardiovascular disease), some forms of cancer, and infectious diseases. Why has this type of research, which has been reasonably successful for other diseases, been less successful for psychosis spectrum disorder? At least three (interrelated) factors may be impeding progress: (1) the lack of a sufficiently validated operational definition for psychosis outcomes (caseness definition). (2) The disorder has a spectrum-like distribution with a complex time course and a broad range of ages of onset. The most common course pattern is episodic (single or multiple), with delusions and hallucinations being prominent symptoms; however, mounting evidence from population studies suggests that these symptoms are also relatively prevalent in the general population and other

psychiatric disorders. A more transdiagnostic approach toward research may be required. Furthermore, risk factors for psychosis probably operate throughout the life course, perhaps even prior to birth. (3) Classical epidemiologic strategies assume a static unidirectional cause–effect linear association, which may be of limited usefulness if psychosis is better conceptualized as a dynamic transitional process of small iterations of phenotypic change mediated by the complex interplay and coevolution of environmental, mental, and biologic risk factors that are continuously distributed in the general population. While the most widely accepted contemporary model of psychosis is based on a neurodevelopmental process, in recent years, there has been a substantial move toward an integrated model of psychosis based on consistent and strong evidence that implicates socioenvironmental and attenuated psychosis risk factors in the development of psychosis.

Neurodevelopmental Model of Psychosis Spectrum Disorder

The broad neurodevelopmental hypothesis posits that psychosis is the behavioral outcome of subtle deviances in early brain development, the full effect of which is not manifest until adolescence or early childhood. There is some evidence for the broad neurodevelopmental model, in agreement with the developmental abnormalities and possible prenatal risk factors reviewed in this section. Further evidence is the absence of inflammatory reactions in the brains of people with a diagnosis of psychosis. Ultrastructural refinement at the synapse is shaped by patterns of environmental input that occur across the lifespan and seems to have functional significance. Such plasticity in the connectivity of neurons is thought to underlie new learning and the development of new schemata and mental skills. There is generally a long latency period between exposure (before adulthood) to known risk factors and the onset of psychosis. Such a delayed effect may be consistent with a causal model where the environmental risk factor increases a person’s liability, but the full manifestation of the disorder, beyond attenuated symptoms, requires the addition or interaction of other complementary (gene or environmental) causal components.

Epidemiologic Psychosis Proneness—Persistence—Impairment Model

Emerging evidence from general population studies shows that attenuated psychotic symptoms are relatively common (prevalence of around 8%, based on a recent meta-analysis). However, most are brief, self-limiting developmental phenomena. The reason why approximately 15% of children

have attenuated psychotic symptoms during development is not fully established, but it may, in part, reflect the shared genetic liability for psychosis continuously distributed in the general population. In two large independent general population samples, NEMESIS and the German Early Developmental Stages of Psychopathology Study (EDSD), investigators examined the hypothesis that these relatively common, developmental attenuated psychotic symptoms could become abnormally persistent when synergistically combined with known risk factors for the onset of psychotic disorders (the study used cannabis, urban upbringing, and developmental trauma). Over a follow-up period of 3 years, the studies found the rates of attenuated psychotic symptoms that *persisted* in being relatively low, 26% (NEMESIS) and 31% (EDSP). However, rates of persistence increased progressively with higher baseline doses of exposure to known risk factors. A systematic review established that childhood trauma was associated with a greater degree of persistence of attenuated psychotic symptoms over time. In addition, over a 10-year follow-up in the EDSP study, it was established that the greater the risk of persistence of attenuated psychotic symptoms over time, the greater the risk of eventual transition to clinical psychotic disorder. This suggests that environmental determinants of psychotic disorders may, in part, operate by driving up the rates of affective dysregulation and, if severe enough, attenuated psychotic symptoms, which become persistent in individuals with a genetic liability for psychosis. A dynamic model of psychosis evolution or proneness-persistence-impairment model may best conceptualize this trajectory from a developmental expression of affective dysregulation and psychosis liability (transitory subclinical psychotic symptoms) to more intrusive persistent subclinical psychotic symptoms to significant impairment and dysfunction and the eventual onset of psychotic disorder (Fig. 12.5–2). Such a model is supported by recent meta-analytic evidence and provides a framework for the further investigation of the ontogenesis of psychotic disorders. The psychosis–proneness—persistence–impairment model of psychosis offers a possible epidemiologic insight into the underlying mechanism for the development of psychosis.

Integrated Model of Psychosis Spectrum Disorder

The strong and consistent evidence that implicates socioenvironmental risk factors in the etiology of psychosis and the evidence suggesting a progression from psychosis proneness to persistence and, finally, full-blown psychosis, reviewed in this section, has recently led investigators to posit an

integrated model of psychosis. In this model, the neurodevelopmental model is extended to and combined with other hypotheses, including sociodevelopmental, experiential, cognitive, neurobiologic, and G × E/epigenetic. Given the variation in incidence and expression of psychosis across different social contexts, this model introduces a level of explanation focusing on the impact of the environment, in interaction with genetic risk, on cognitive schemata as well as on brain neurobiologic mechanisms across the life course. So, for example, exposure to trauma during childhood may lead to the development of subtle developmental delays, cognitive alterations, and affective dysregulation and, thereby, predispose individuals to a paranoid way of thinking, which, when coupled with a sensitized dopamine system, may manifest as psychosis proneness which, in combination with further environmental impact, may result in persistence over time and increase liability to psychotic disorder. Given that every human being has thousands of genetic risk variants for psychosis, suggesting implication in natural processes like the ability to distill signals and meaning from environmental noise, psychosis susceptibility genes may interact with environmental factors to affect signal-to-noise ratio across the life course, an effect which may be mediated by an (epigenetically) sensitized dopamine system.

FIGURE 12.5–2. Epidemiologic psychosis—proneness–persistence–impairment model of psychosis onset. Person A has "normal" developmental expression of subclinical psychotic experiences (*psychosis proneness*) that are transient. Person B has similar expression but longer *persistence* due to additional but mild environmental exposure. Person C has longer persistence due to severe, repeated environmental exposure and transition to clinical psychotic disorder with significant *impairment*.

12.6 Cellular and Molecular Neuropathology of Schizophrenia

Ali S. Imami, M.B.B.S., M.S., Nicholas D. Henkel, Ph.D., Justin F. Creeden, Ph.D., and Robert E. Mccullumsmith, M.D., Ph.D.

Schizophrenia is a chronic and debilitating brain disease. Despite concerted efforts, fully understanding the pathophysiology of the illness has been a challenge to the field. A factor in this has been the scarcity of reliable direct data, as direct observation of anatomical and molecular characterization is only possible with postmortem human brains. It was not until the 1980s, with the emergence of more sophisticated tools and techniques, that there was a deeper interest in the characterization of the pathophysiology of schizophrenia.

While there is no obvious, identifiable neuropathologic lesion that causes schizophrenia, there is a slew of subtle pathologies that underlie the illness. Over the past 40 years, many postmortem studies have been published, examining the various angles of the pathology at the tissue and molecular level. However, due to incomplete guiding hypotheses, the postmortem literature on schizophrenia is very broad and, at times, fragmented. Nonetheless, a consensus has emerged that suggests localization to

specific brain regions such as the prefrontal cortical regions, thalamus, and limbic structures in the brain.

MORPHOMETRIC STUDIES AND CYTOARCHITECTURAL CHANGES

Gross anatomical and histologic changes have been a consistent feature of schizophrenia. There have been several studies that imply changes in the architecture of frontal lobe regions and their gross structure.

Whole Brain

The most consistent observation in schizophrenia is the normal macroscopic appearance of the postmortem brain. However, over the course of the past three decades, postmortem brain tissue studies have begun to provide clues into anatomical and histologic correlates of schizophrenia pathology. It should be noted that their findings are disparate, sometimes discrepant, or even conflicting. This may be due to disease heterogeneity, methodologic issues such as quality of postmortem tissue, sample size, or confounders of postmortem research such as tissue quality. Nonetheless, a coherent picture supported by converging data is beginning to emerge.

A meta-analysis looking at postmortem brain weight found a small but significant reduction in schizophrenia that inversely correlates with the age of onset. Consistent with this finding, structural imaging studies demonstrate that brain volumes are smaller in the prodrome, at the time of first break psychosis, and in the chronically ill. A recent longitudinal study reported reduced prefrontal and temporal lobe volumes in individuals with a high genetic load for developing schizophrenia. Those individuals who did go on to develop schizophrenia showed even greater reductions in prefrontal volumes. Furthermore, there is evidence that gray matter volume reductions may be progressive in the initial stages of the illness. Regional postmortem studies have identified evidence of subtle changes in cellular morphology, with regions most often implicated being the prefrontal cortex (PFC), thalamus, and medial temporal lobe (Table 12.6–1). An initial study in 1982 found that a large proportion of patients with schizophrenia showed evidence of gliosis. While several studies since then have not supported this finding, more recent studies suggest that the different types of glia may play roles in schizophrenia pathology. The absence of other classical attributes of neurodegenerative diseases, such as obvious neuron loss or

neurofibrillary tangles, has led to the belief that schizophrenia is not a degenerative disease. Rather, the reported glia-related changes raise the possibility of an immunologic or inflammatory component to disease pathophysiology. A landmark study in 1976 reported ventricular dilatation in subjects with chronic schizophrenia. Since then, numerous studies have replicated this observation, primarily enlargement of the third and lateral ventricles in subjects with schizophrenia. This observation, however, lacks diagnostic specificity, as it can occur in numerous other brain disorders, such as Alzheimer disease and hydrocephalus. In addition, high-risk and family studies show that enlarged ventricular volume is also found in unaffected relatives who share genetic material (and, by extension, genetic risk for schizophrenia).

Table 12.6–1.
Summary of Golgi Studies Examining Dendritic Spine Density in Schizophrenia

Region	Reported Finding	Observations
Prefrontal cortex	Lower	In layer 3
Temporal cortex	Lower	In layer 3
Visual cortex	Unchanged	In layer 3
Hippocampus		
Subiculum	Lower	Apical dendrites
CA3	Higher	Apical dendrites

A more recent observation is related to the laterality of the brain's hemispheres. There has been evidence that there is loss of laterality in the schizophrenia brain in patients with earlier onset. This observation may interact with other variables like sex, disease severity, and duration of illness. In addition, abnormal gyrification has been frequently observed in schizophrenia.

Prefrontal Cortex

The PFC has been hypothesized as a major site of dysfunction in schizophrenia. There is reduced task-related prefrontal activation in patients with the illness and prominent deficits in certain PFC-dependent cognitive functions. Structural imaging studies have provided evidence that frontal

lobe volume is reduced in schizophrenia. Stereologic analysis of postmortem brain samples has refined this observation by ascribing this volume deficit primarily to a 3% to 12% reduction in the gray matter of schizophrenia subjects compared to controls. Gray matter is composed of neurons, glial cells, and neuropil that include neuronal processes such as dendritic trees and axonal arbors. Initial studies using a two-dimensional stereologic approach detected neuronal loss in the PFC with no evidence of change in glial numbers.

FIGURE 12.6–1. Perturbed neurotransmitter systems in schizophrenia. From top, moving counterclockwise: the biochemical evidence for increased dopaminergic neurotransmission has been limited to the D2 receptor. Hyperdopinamergia, on the other hand, has been well supported in live-human, imaging studies. Adenosine signaling inhibits the release of dopamine and glutamate. The canonical adenosine receptors, A1 and A2, transcript expression is decreased in schizophrenia. These receptors may modulate glutamate and dopamine release and signaling at the pre- and postsynapse, respectively. Though further work is required, adenosine receptor expression changes may be attributed to faulty bioenergetic function in the disease. Further, while changes in adenosine modulate glutamatergic neurotransmission, glutamate receptor changes also have been reported in the AMPA receptor and in the GluN1 subunit of the NMDA receptor. GABA levels may be altered as the enzyme GAD67, which converts glutamate to GABA, is decreased in the prefrontal cortex. Of all the neurotransmission systems, the muscarinic and nicotinic acetylcholine receptor changes are the consistently reported in postmortem brain and in preclinical models of schizophrenia.

More recent studies have employed a three-dimensional stereologic approach that considers cell size and number per unit volume. These studies have not found changes in neuron numbers, suggesting that the volume decrease is not attributed to neuronal loss but rather reductions in neuropil. Indeed, quantitative analyses of neuron number and density in the PFC (Brodmann areas 9 and 46) demonstrated increases in neuronal density, smaller pyramidal somal cell volumes, and reduced neuropil in

schizophrenia in layer 3 (Fig. 12.6–1) but not in layer 5 or 6. The reductions in neuropil suggest that schizophrenia is associated with a quantitative deficit in neuronal connections. Several studies have examined dendritic spine density in schizophrenia (Table 12.6–1) and consistently find reductions in spine density in layer 3 of the PFC. The layer 3 pyramidal neurons serve as a major site for the integration of information from other intrinsic cortical neurons and input from the thalamus, implicating these neural pathways in schizophrenia pathophysiology.

The issue of the influence of long-term antipsychotic treatment and its possible effect on these cellular measures has been examined. Exposure of nonhuman primates to chronic antipsychotic medication does not appear to alter the cortical neuronal density, suggesting that the elevated neuronal density found in schizophrenia is not a medication effect. Interestingly, in these chronically treated animals, the numbers of glia increased as much as 33% in certain cortical layers. The implication of this is not yet clear but may suggest a role for glia in terms of antipsychotic response.

Hippocampal Formation

Magnetic resonance imaging (MRI) studies find consistent reductions in hippocampal or amygdala–hippocampal volumes in schizophrenia that may be lateralized to the left side. Meta-analyses report hippocampal reductions of the magnitude of 4% in schizophrenia. Smaller hippocampal volumes are present at the time of disease onset and in those with high genetic loading for the illness. Human postmortem studies suggest an anteroposterior gradient of the neuropathologic findings, with the anterior part putatively more affected than the posterior part. If the volume decrease holds true, what causes it is still a matter of debate. The current consensus is that there are no significant differences in neuronal density in the hippocampus in schizophrenia, although it remains a possibility that there are cell-type–specific differences in subregions of the hippocampus. Studies of neuronal size have demonstrated somewhat more consistent results. As in the PFC, smaller pyramidal neurons have been reported in the hippocampus, but with normal-sized neurons in the visual and motor cortex in schizophrenia. A question that remains to be answered pertains to the timeline of changes. Although reduced hippocampal volumes can be identified at the beginning of the illness, imaging data attest to a progressive course (i.e., hippocampal volumes continue to decrease with disease advancement), which may suggest a potential toxic effect of the ongoing disease or drug treatment, particularly first-generation antipsychotic medications. Two Golgi

impregnation studies have examined spine density in hippocampal pathways. One reported a reduction in spine density, while another recent study reported a specific increase in spine density on CA3 pyramidal cell apical dendrites postulated to reflect an increase in CA3 basal activity, thereby raising the possibility of subregional changes within the hippocampus. In the entorhinal cortex, early studies showed neurons in aberrant and poorly formed clusters. Since the spatial arrangement of cells is largely determined during brain development in utero, a disruption in this arrangement could reflect a developmental abnormality. Well-designed follow-up studies considering the rostrocaudal heterogeneity of the entorhinal cortex have not replicated these findings, and the results remain controversial. Similarly, initial reports of reduced number and smaller size of neurons in the entorhinal cortex have not held up to replication.

Thalamus

The thalamus, because of its pivotal position in relationship to afferent sensory information and as a station in the cortical–subcortical circuits, is a brain region of interest. The volume, cell number, and cell densities have been investigated in several thalamic nuclei, including the mediodorsal (MDL) and anterior thalamic nuclei, where the main efferent connections to the PFC and limbic regions arise. In the MDL nuclei, total neuronal counts are decreased, although not in all studies. These reductions in neuron number are reported to be in the parvocellular and densocellular parts of the MDL, which project primarily to the dorsolateral PFC (DLPFC). More recent studies with larger sample sizes have not, however, replicated these findings of reduced neuronal number.

Table 12.6–2.
Summary of Main Morphologic Findings in Human Postmortem Studies in Schizophrenia Compared to Control Cases

Region	Major Macroscopic Finding	Neuronal Cell Size	Neuronal Cell Number	Observations
Ventricles	Enlargement			Present at onset
Prefrontal cortex	Slight cortical thinning	Smaller	Unchanged	Increased neuronal density in Brodmann areas 9 and 46. Reduction in dendritic spines
Anterior cingulate cortex	Unchanged	Unchanged	Unchanged	
Hippocampal formation	Decreased volume	Smaller	Unchanged	Some evidence of laterality (L < R) Maybe due to partial volume effect
Thalamus	Unchanged	Unchanged	Unchanged	Earlier studies showing reduced neuronal size and number in certain nuclei have not been replicated in recent larger studies
Basal ganglia (enlargement of caudate)	Mixed findings			Increased number of synapses. Possible medication effect.

Basal Ganglia

Postmortem and in vivo imaging studies have reported volumetric increases in the caudate–putamen complex in patients with schizophrenia. Although animal and human studies initially suggested that the volumetric increase could be explained by antipsychotic medications, electron microscopic studies suggest an increase in the number of synapses in the caudate and putamen, suggesting increased neuronal activity in the basal ganglia. Whether this is disease related or a medication effect is not yet conclusive.

Table 12.6–2 summarizes the morphologic findings seen in schizophrenia.

NEUROTRANSMITTER SYSTEMS

Neurochemical studies began in schizophrenia at a time when scientists were anticipating a single neurobiologic defect. Although no single defect has been found, investigators interpret studies in a broader systems context. Nonetheless, findings are often still organized by neurotransmitter system.

Dopamine

In the 1960s, it was proposed that hyperdopaminergic activity may be responsible for the positive psychotic symptoms in schizophrenia. This was based on the pharmacologic observation that blockade of dopamine receptor subtype 2 (D_2) reduced positive psychotic symptoms. A series of studies in the nonhuman primate showed that a reduction in dopamine transmission in the PFC was associated with cognitive deficits such as those found in schizophrenia. This led to a modification of the dopamine hypothesis to the presence of an imbalance of dopamine transmission in schizophrenia, with dopaminergic hyperactivity in subcortical regions but hypoactivity in prefrontal cortical regions. These findings served as the compelling impetus to study biochemical measures of dopamine neurotransmission in the human postmortem brain in schizophrenia.

Although the dopamine hypothesis has been the prevailing hypothesis for decades, evidence of dopamine dysfunction in human postmortem studies has not been forthcoming.

Studies examining D_1 expression in the PFC and striatum have been largely negative. Increases in D_2 receptors are a consistent finding in several postmortem studies, but since chronic antipsychotic treatment is known to upregulate D_2 receptors, these findings have been largely

attributed to a medication effect. Consistent with this notion, the density of D_2 receptors is increased in schizophrenia, while the density of D_1 receptors is not changed. D_3 receptor expression was increased in the ventral striatum of medication-free cases of schizophrenia but normal in subjects treated with antipsychotics. D_3 messenger RNA levels are, however, reported to be normal in the accumbens. There was considerable interest in the D_4 receptor, fueled in part by the high affinity of clozapine for D_4 receptors, but neither genetic nor postmortem studies have been able to provide conclusive associations between this receptor and schizophrenia. In addition, ligand-binding studies specifically targeting the D_4 have not been efficacious in mitigating psychosis. Finally, dopamine active transporter (DAT) expression in the striatum has been examined by several research groups, the majority finding that levels are unaltered in schizophrenia.

On the other hand, studies with living schizophrenia subjects have yielded support for hyperdopaminergia. In vivo imaging studies have demonstrated pronounced differences in dopamine neurotransmission in schizophrenia subjects. Schizophrenia subjects exhibit increased nascent dopamine synthesis, have higher subcortical dopamine content, and, when exposed to amphetamines, release more dopamine. Increased dopamine synthesis and synaptic content are not only highly correlated with the presence of positive symptoms but are also associated with the resolution of positive symptoms when antipsychotic treatment is initiated. However, the measurement of dopamine and metabolites in lumbar cerebrospinal fluid (CSF) as a reflection of neurotransmitter activity in the brain has not contributed to the understanding of schizophrenia pathophysiology.

Glutamate

The glutamate hypothesis of schizophrenia is centered on the clinical observation that N-methyl-D-aspartate (NMDA) receptor antagonists, such as phencyclidine (PCP) and ketamine produce a syndrome that is indistinguishable from schizophrenia.

Glutamate is the major excitatory amino acid neurotransmitter in the brain and is known to activate both ionotropic and metabotropic glutamate receptors (mGluRs).

The ionotropic receptors, α-amino-3-hydroxyl-5-methyl-4-isoxazolepropionic acid (AMPA), kainite (KA), and NMDA receptors, have been extensively studied at the mRNA, protein, and ligand-binding level in the cortex, striatum, thalamus, and limbic regions in schizophrenia.

In schizophrenia, hippocampal AMPA receptor subunit transcript and protein expression are consistently decreased. Likewise, the NMDA GluN1 subunit is downregulated in the temporal cortex, hippocampus, and thalamus. However, the NMDA GluN2B subunit is upregulated in the temporal cortex and the hippocampus. Among the mGluRs, mGluR2 and 3 have been implicated in both patients with and animal models of schizophrenia.

Studies showing a hypoactive NMDA Receptors are supported by further studies showing reduced expression of the protein complexes that mediate their downstream signaling, such as PSD-95, neurofilament light, and SAP102 in the PFC. There is emerging evidence that hypofunction of NMDARs may also be attributed to epigenetic changes that occur early in development. Such changes may impact other neurotransmitter systems.

γ-Aminobutyric Acid

γ-Aminobutyric acid (GABA) is synthesized from glutamate by glutamic acid decarboxylase (GAD). There are two isoforms of this enzyme, GAD_{65} and GAD_{67}, which are encoded by the genes *Gad1* and *Gad2,* respectively. A consistent finding in schizophrenia is the reduction in GAD_{67} mRNA levels in the PFC in schizophrenia. Since neuronal numbers are unchanged in the PFC, the decrease in GAD67 is likely due to decreased expression per neuron. Interestingly, the reduction in GAD67 found in the PFC is associated with reductions of GABA transporters in parvalbumin (PV)-positive interneurons. This effect, reportedly, is not due to antipsychotic treatment. With respect to interneuron subtypes, somatostatin interneurons, as well as the expression of somatostatin, are decreased. Broadly, GABA is modulated by several genes implicated in schizophrenia, such as *BDNF*, *DISC1*, and *NRG1*, which impact the migration of PV+ interneurons to the cerebral cortex, GAD67 expression, and development of GABA circuitry.

These changes suggest reduced synthesis and reuptake of GABA in these neurons and, thereby, altered GABAergic transmission. Dysfunction of GABAergic neurotransmission correlates with cognitive dysfunction in schizophrenia.

Acetylcholine

Cholinergic neurotransmission is integral to normal cognition and memory processing, functions disrupted in schizophrenia. Postmortem evidence for abnormalities in this system has shown decreased levels of the nicotinic

(both the α7- and the α4β2-nACHR subtypes) and muscarinic receptors (namely the M_1 and M_4 receptors) in the hippocampus, frontal cortex, thalamus, and striatum in schizophrenia subjects. Moreover, genetic polymorphisms in the M_5 (*Chrm5*) and the α7-nACHR (*Chrna7*) genes are linked to a higher risk of developing schizophrenia.

While there is a substantial body of preclinical evidence suggesting the procognitive effects of modulating α7-nACHRs in rodent models of schizophrenia, human trials have often been unsuccessful. Recent evidence suggests that positive allosteric modulation of M1 receptors is impaired in schizophrenia, which may account for some of these failures. Reconciling the differences will require close examination of the study variables, including frequency, duration, and route of administration, as well as patient populations.

Further research is needed to confirm how these biochemical and genomic changes contribute to schizophrenia.

Adenosine

Adenosine is a neuromodulator of both the glutamate and dopamine neurotransmitter systems. Adenosine acts on purinergic receptors (e.g., A1 and A2A receptors) in the brain. Presynaptic activation of adenosine A1 receptors inhibits the release of glutamate, while postsynaptic activation reduces NMDA-receptor functioning. In addition, adenosine signaling through postsynaptic A2A receptors inhibits D2 receptor signaling through a heteromeric complex. For this reason, dysfunction of the adenosine system may play a role in the hyperdopaminergic and hypoglutamatergic states in schizophrenia.

Changes in the expression of the transcript and protein levels of enzymes that regulate extracellular adenosine levels as well as adenosine (i.e., purinergic) receptors have been consistently reported in postmortem schizophrenia studies.

Ectonucleoside triphosphate diphosphohydrolase (ENTPD)-1, the enzyme responsible for hydrolyzing adenosine triphosphate (ATP) to adenosine monophosphate (AMP) and adenosine diphosphate (ADP), transcript expression was decreased in the striatum. Transcript expression of both ENTPD-1 and -2 was decreased in astrocytes, but not neurons, isolated from the DLPFC. Interestingly, adenosine deaminase (ADA), which breaks adenosine down to inosine, is increased specifically in DLPFC neurons.

While no changes were found in A1 receptor protein expression in the striatum of schizophrenia subjects, A1 receptor transcript was reduced in an enriched population of pyramidal neurons from the DLPFC. In the striatum, a reduction in the transcript and the protein levels of A2A receptor was attributed to hypermethylation of the A2A coding region. However, the density of these A2A receptors was 70% higher in schizophrenia patients, possibly to compensate for low adenosine levels.

Conclusion

In summary, molecular abnormalities are found in several anatomic regions and in several neurotransmitter systems in schizophrenia. Identification of primary pathology from epiphenomenon is essential. For example, neurotransmitter systems are dynamic, and disruption of one system would lead to compensatory mechanisms in other relevant pathways. A sound strategy to adopt once an abnormality is discovered is to first confirm the finding by replication in a second cohort and then determine whether the molecular abnormality is part of the primary pathology. Converging data from in vivo human studies, human postmortem studies, and animal model studies would provide clues to the primary pathology.

BIOENERGETIC DYSFUNCTION

A substantial and diverse body of literature suggests that the pathophysiology of schizophrenia is related to dysregulation of bioenergetic function. Perturbations of various metabolic pathways across different brain regions have been reported in relation to the symptomology of schizophrenia. While a whole body of literature exists regarding the changes in several bioenergetic subprocesses, changes in glucose metabolism and mitochondrial oxidative phosphorylation are the best documented in the postmortem brain, especially in the DLPFC.

Glycolysis

Glucose enters neurons and astrocytes via glucose transporters (GLUTs). Decreases in the transcripts of GLUT1 and GLUT3 in pyramidal DLPFC neurons of schizophrenia subjects have been reported. In these cells, glucose is phosphorylated by hexokinase. In schizophrenia, the cytosolic to mitochondrial hexokinase ratio is increased in the DLPFC, suggesting an uncoupling of bioenergetic processes that produce ATP. Consistent with these findings, transcript expression of other regulatory glycolytic enzymes,

namely hexokinase, phosphofructokinase, and glucophosphoisomerase, is decreased in schizophrenia. Hexokinase activity was also decreased, which suggests a decrease in glycolytic capacity. Evidence suggests that this finding was not secondary to antipsychotic treatment.

Beyond these biochemical findings, genes for key regulatory glycolytic enzymes, such as the rate-limiting enzyme complex, phosphofructo-2-kinase/fructose-2,6-bisphosphatase (PFKFB), hexokinase, and pyruvate kinase, fall within schizophrenia “risk” genomic regions in individuals of European decent.

Tricarboxylic Acid Cycle

The tricarboxylic acid (TCA) cycle is the final shared pathway for the aerobic oxidation of molecules to produce energy in cells. These enzymes have been extensively studied in the schizophrenia brain.

Transcriptomic studies have consistently reported significant decreases in the expression of TCA cycle genes in the DLPFC in schizophrenia. A report comparing the DLPFC in 13 pairs of schizophrenia and healthy controls showed alterations of several critical enzymes in the TCA cycles. The activities of enzymes in the first half of the TCA cycle (namely, aconitase, ketoglutarate dehydrogenase complex, and succinate thiokinase) were reduced in schizophrenia subjects. In contrast, enzymes in the second half of the cycle (succinate dehydrogenase and malate dehydrogenase [MDH]) were increased. Interestingly, pyruvate dehydrogenase complex (PDHC), citrate synthase (CS), isocitrate dehydrogenase (ICDH), and fumarase activities remained the same. Aside from the DLPFC, protein expression of the β-subunit of the PDHC was decreased in the schizophrenia striatum.

Oxidative Phosphorylation

Numerous studies suggest that oxidative phosphorylation is dysregulated in schizophrenia. Decreases in transcript levels of electron transport chain (ETC) complexes and ATP-synthase have been found in the PFC of subjects with schizophrenia. Concordant with these findings, decreases in transcripts for mitochondrial pathways were also reported in DLPFC layers III and V in schizophrenia isolated by laser capture microdissection. Proteomic analyses by Liquid Chromatography with Tandem Mass Spectrometry (LC-MS/MS) found a decrease in complexes I and III of the ETC. However, the activity of complex IV, but not complex I, is changed in the schizophrenia DLPFC. However, perturbation of ETC complexes has been reported in other brain regions. Complex I and III activities are

reduced in the temporal cortices and in the basal ganglia. Complex IV activity was also reduced in the temporal cortices. Finally, in the dentate gyrus of the hippocampus, transcript expression of ATP synthase, cytochrome c, succinate dehydrogenase, and reduced nicotinamide adenine dinucleotide (NADH) dehydrogenase are all decreased.

Mitochondria

Abnormalities in the mitochondria and mitochondrial function are commonly reported in schizophrenia research across various substrates: postmortem brain, cell lines, and animal models. While there is a plethora of evidence suggesting dysfunction of both the TCA and oxidative phosphorylation, which take place in the mitochondria, there is variability in reporting morphologic and structural mitochondrial data. Due to the breadth and the diversity of the methodologies, brain regions studied, cell lines used, and subject diversity, reconciling the findings to draw a definitive conclusion is a challenge to the field.

In general, there appears to be a decrease in the number and the size of mitochondria across brain regions and cell types (both neurons and glia). However, this evidence is challenged by studies that have reported equal mitochondria, size, and density in the schizophrenia brain compared to controls.

Conclusion

The evidence for bioenergetic dysfunction in schizophrenia is accumulating. Further work is required to delineate the cellular specificity (i.e., interneuron, pyramidal neuron, glial, or global deficits) or the regional changes (i.e., frontal cortex, striatum, temporal lobes, etc.) of these perturbations and characterize the causative metabolic pathways (i.e., glycolysis, oxidative phosphorylation, or other metabolic pathways, etc.). How these deficits manifest in the behavioral and symptomology of schizophrenia has yet to be fully detailed.

SCHIZOPHRENIA AS A NEURODEVELOPMENTAL DISORDER

The development of the brain is a complex process that involves an intricate sequence of events marked by sensitive or critical time periods when neural circuits are maximally plastic. This plasticity allows essential developmental

changes to occur but also confers vulnerability. Disruptions to essential neurodevelopmental processes can cause permanent alterations in brain circuitry and behavior. Schizophrenia demonstrates approximately 79% heritability, while proband concordance rates are reported as 33% for monozygotic twins and 7% for dizygotic twins. Although the etiology of schizophrenia remains unknown, these data suggest that most schizophrenia cases are the result of neurodevelopmental interactions between genetic predispositions and environmental factors.

Genetic Predisposition and Environmental Factors

Schizophrenia is a highly heritable and polygenic illness. Genome-wide association studies (GWAS) and copy number variation (CNV) studies have implicated many common alleles of small effect size as well as rare CNVs of large effect size in the development of schizophrenia. Polygenic risk scores (PRS) aggregate the risk scores of gene variants to estimate overall genetic predisposition. Expression profiles for some of these putative risk genes, including neuregulin 1 (*NRG1*), dystrobrevin-binding protein 1 (*DTNBP1*), disrupted in schizophrenia 1 scaffold protein (*DISC1*), and regulator of G-protein signaling 4 (*RGS4*) have been characterized in human postmortem tissue. The human postmortem brain remains an invaluable resource for schizophrenia research. In addition to gene expression profiles and variations in copy number, human postmortem tissue studies have identified single nucleotide polymorphisms (SNPs) risk variants for schizophrenia, such as rs1344706 (A/C) in the zinc finger protein 804A gene (*ZNF804A).* In addition to risk estimates, genetic studies are also beginning to inform schizophrenia diagnosis and treatment. By leveraging genetic findings with biomarker identification, neurobiologic strata are beginning to emerge. Understanding neurodevelopmental abnormalities within the context of neurobiologic subtypes (biotypes) provides insight into schizophrenia as a neurodevelopmental disorder driven, in part, by patient-specific genetic variations. Environmental contributions are also well described. Socioeconomic factors, fetal and perinatal infections, nutritional deficiencies, birth complications, and cannabis exposure are epidemiologically associated with neurodevelopmental abnormalities and schizophrenia. The development of the brain is a protracted process. As such, environmental factors span childhood, adolescence, and adulthood.

Functionally, schizophrenia symptoms derive from neurotransmitter imbalances within the brain. Genetic studies suggest that inherited or de novo mutations associated with synaptic dysfunction play an etiologic role in

the disease mechanisms of schizophrenia. Many recent efforts to identify genetic risk factors for schizophrenia converge upon the salience of excitatory phenotypes.

Epigenetic Factors

Epigenetic processes dynamically regulate gene expression independently of DNA sequence variation and can regulate key neurobiologic processes. Modification of the chromatin structure of DNA (chromatin remodeling) is associated with reversible modifications of DNA rather than with inherited variability within the DNA sequences and is, therefore, called epigenetic modification. This important process is tightly regulated by histones that control how tightly DNA is bound and whether the copy machinery will have access to individual genes. Epigenetic regulation of chromatin can occur via several mechanisms such as DNA methylation and posttranslational modifications of histones. There appear to be periods during development when epigenomic changes take place in the human brain. For example, DNA methylation patterns show a unique temporal pattern across the lifespan, with the greatest changes occurring during the prenatal period, slowing after birth, and gradual slowing with aging. DNA methyltransferases (*DNMTs*), which mediate DNA methylation, are highly expressed in the brain and are overexpressed in GABAergic neurons in the PFC of schizophrenia subjects. A differential DNA methylation profile has been reported in leukocytes and postmortem brains in schizophrenia. One genome-wide methylation study using human postmortem schizophrenia tissue identified 2,929 unique genes that were differentially methylated, many of which were also identified in prior studies using leukocytes. Environmental factors can also influence epigenetic changes. Maternal malnutrition, certain intrauterine conditions, and viral infections can lead to hypermethylation of DNA. The epigenome might serve as a substrate that links environmental exposures, genetic variants, and psychopathology.

Brain Regions

Since the first study over a decade ago, several transcriptome studies have been conducted using postmortem tissue. Gene expression changes are found in several brain regions, including the PFC, hippocampus, and temporal cortices. Correlation networks are increasingly being used in bioinformatics applications. Weighted gene co-expression network analysis (WGCNA) is a method used to describe the correlation patterns among genes across microarray samples. This approach, successfully used in

other biologic contexts such as cancer, can be used to find clusters (modules) of highly correlated genes and to relate modules to one another. Pathways identified in the schizophrenia PFC include oxidative phosphorylation, myelination, synaptic transmission, and immune function, while data from the hippocampus show deficits in immune response and inflammation, transcriptional regulation, and epigenetic control in PV-containing interneurons.

Neuronal Migration and Neurogenesis

During the second trimester of fetal development, neurons migrate upward from the ventricular wall to their target cortical layer. Initial postmortem studies in cortical tissue from individuals with schizophrenia found ectopic neurons and abnormal cytoarchitecture in the PFC and entorhinal cortex. These data were consistent with an impairment of neuronal migration of these cells into the cortex during their critical developmental period (second trimester) in schizophrenia and have been interpreted as evidence of schizophrenia as a developmental disorder. While intriguing, precise and carefully designed follow-up studies have not been able to replicate or confirm these initial findings. With recent advances in the field of adult neurogenesis, modern tools have become available that support the study of the proliferation and differentiation of stem cells in the brain. The use of antibodies previously used in cancer research has recently been applied in histologic studies of the postmortem human hippocampus, including Ki-67 and proliferating cell nuclear antigen. There are initial observations that suggest a reduction in cell division in the hippocampus in schizophrenia. Although provocative and interesting, replication studies are ongoing.

Spinogenesis and Pruning

Adult schizophrenia subjects have fewer synaptic connections in specific brain regions, and there is some evidence, although divergent and inconsistent, that synaptic proteins such as synaptophysin (*SYP*), growth-associated protein 43 (*GAP43*), complexin 1/2 (*CPLX1/2*), and synaptosome-associated protein 25 (*SNAP25*) are reduced in these individuals. Prior electron microscopy studies show that cortical synaptic density reaches maximum levels at 2 to 4 years of age—at which time, density is approximately double normal adult levels—with a reduction in the number of synapses (i.e., synaptic pruning) occurring mainly during adolescence. This prompts the suggestion of schizophrenia as a defect of excessive pruning during adolescence. However, data collected from

subjects with ages ranging from newborn to 91 years old suggest that synaptic elimination may be a more extended process, continuing throughout the third decade of life before synaptic density stabilizes at adult levels. While the hypothesis of excessive pruning may still hold true, these new studies suggest pruning may occur over a broader time course. Excessive synaptic pruning caused by hyperactivity of the complement system has also been proposed. Another possible explanation for reduced spine density in certain brain regions in schizophrenia could be related to altered development and stabilization of dendritic spines.

Myelination

Myelination is critical for the proper axonal conductance and communication between brain regions. The first 2 years of life see the rapid myelination of axonal fibers that continue into adulthood following a region-specific course. In the PFC, for example, myelination occurs well into the second decade of life. Abnormalities in myelin-related genes are observed in schizophrenia. The protracted development course provides opportunities for genetic and environmental exposures to interfere with normal myelin maturation in the brain.

Neurologic Soft Signs

Neurologic soft signs (NSS) are clinically observable deficits in sensory integration, motor coordination, developmental reflexes, and other central nervous system functions. While not specific to schizophrenia, NSS suggest developmental abnormalities in schizophrenia patients. Subtle physical deviations indicative of abnormal prenatal development also exist. Patients with high CNVs of schizophrenia-associated genes can also present minor physical anomalies.

THE INFLAMMATION HYPOTHESIS

There is gradually accumulating evidence that hints toward the role of inflammation in the pathogenesis of schizophrenia. While the inflammation hypothesis is not new for schizophrenia and psychiatric disorders in general, the evidence now hints at a strong relationship.

The CNS Inflammatory machinery includes cellular components like microglia, astrocytes, and immune cells from the peripheral immune system and active components like C-reactive proteins (CRP) and cytokines. The exact role of inflammatory markers like CRP and cytokines is still unclear. A

2019 epidemiologic study found evidence that CRP has a protective effect against schizophrenia. There is also evidence of an increase in proinflammatory cytokines in patients with psychosis. This is supplemented by evidence of increased functioning and decreased positive symptoms in animal models. Finally, some of the SNPs associated with the highest risk for schizophrenia are found in or near genes that are immune system constituents.

The role of inflammation in schizophrenia is rapidly evolving and has significant therapeutic implications. Accounting for inflammation may allow identification of better treatments for schizophrenia.

INTEGRATIVE PATHOPHYSIOLOGY OF SCHIZOPHRENIA

There has been progress over the past decades that has led to landmark discoveries in the pathophysiology and treatment of the disease. There is neither a single brain region nor a single neurochemical alteration, but several associated with schizophrenia.

The PFC, hippocampus, and thalamus are most often implicated, perhaps in part because these are the most studied. At the cellular level, reduced gray matter volumes, reduced size of neurons but without cell loss, and reduced dendritic arborization and spines are the main observations seen in schizophrenia. White matter changes also contribute to connectivity deficits between brain regions implicated in schizophrenia. The true cause remains unknown, but the implication of these findings is one of reduced connectivity in the brain in schizophrenia.

Neurochemical deficits in neurotransmitter systems indicate abnormal synaptic communication between neurons. There may be specific neurotransmitter systems involved in certain cortical regions, with deficits in the GABAergic system being the most consistent. A plausible formulation is that schizophrenia is a disease of abnormal connectivity, one that may occur at the cellular level, synaptic level, or circuit level.

The nature, location, and timing of pathology seem to be key factors in the development of schizophrenia and warrant further exploration. The advent of next-generation sequencing (NGS) allows for the rapid sequencing of entire genomes, transcriptomes, and epigenomes from specific brain regions, specific cell types, and specific time points in development. The collaborative use of modern translational research

methodologies and tools will be critical to the successful pursuit of understanding the pathophysiology of schizophrenia.

12.7 Structural Brain Imaging in Schizophrenia

Amanda E. Lyall, Ph.D., Marek Kubicki, M.D., Ph.D., and Martha E. Shenton, Ph.D.

THE BRAIN AND SCHIZOPHRENIA: HISTORICAL PERSPECTIVE

After more than 100 years of research, the neuropathology of schizophrenia still remains unknown. This is despite the fact that both Eugen Bleuler and Emil Kraepelin, who first described “dementia praecox” and “the schizophrenias,” postulated that brain abnormalities would ultimately be linked to the etiology of schizophrenia. The conviction that serious psychiatric illness was likely the result of an unhealthy brain was further fueled by critically important inroads into Huntington chorea, some forms of epilepsy, Pick’s disease, tertiary syphilis, and Alzheimer’s disease that were being made during this same time period. Alois Alzheimer, in fact, was one of the first to investigate the neuropathology of schizophrenia, although he later went on to investigate other illnesses that he believed were more tractable brain disorders.

Researchers at the end of the 19th and beginning of the 20th centuries were nevertheless hopeful that they would succeed in identifying neuropathologic features of schizophrenia. Results from postmortem studies, however, were ultimately disappointing, often leading to conflicting findings due in part to the crude measurement tools available and, in part, due to the high expectations, researchers had that they would observe more remarkable abnormalities. This state of affairs led to a waning interest in the neuropathology of schizophrenia, and although a small number of researchers continued to investigate the brain and its role in schizophrenia, the general consensus, as clearly articulated by the eminent neurologist Fred Plum, was that “schizophrenia is a graveyard of neuropathologists.” Consequently, research investigating brain abnormalities using histologic methods in schizophrenia lost favor.

Early Applications of Neuroimaging to the Study of Schizophrenia

It was not until 1976 that interest in investigating brain abnormalities in schizophrenia was renewed with the first computer-assisted tomography (CT) study of schizophrenia by Johnstone and colleagues. These investigators observed enlarged lateral ventricles in individuals with schizophrenia compared to healthy control (HC) subjects. This single study led to a proliferation of CT studies as well as a reinvigoration of postmortem studies investigating schizophrenia, with the overwhelming majority confirming the original finding of enlarged lateral ventricles. This early study was the impetus for later investigations of structural brain anomalies in schizophrenia where the goal was to identify markers of pathologic processes in the brain. This interest has continued to the present day.

Following the introduction of CT, nuclear magnetic resonance (NMR) was developed in the 1970s, based on the seminal work of Peter Mansfield and Paul Lauterbur. These two scientists shared the Nobel Prize in Medicine in 2003 for their independent contributions to the theory that led to the development of magnetic resonance imaging (MRI). MRI was then introduced and soon became the most powerful tool for visualizing soft tissue contrast in the brain (e.g., gray and white matter). Moreover, and in contrast to CT that uses ionizing radiation x-rays, MRI uses magnetic field and radio waves, which have no known adverse effects, and only a small number of contraindications. MRI can thus be used as a research tool in at-risk populations, such as children and pregnant women, and it can be repeated as needed, thereby opening the door to longitudinal studies to investigate brain changes over time, or to monitor more precisely treatment efficacy.

MR scanners were first built and clinically used in the 1980s, and today they are used routinely to visualize the anatomy and morphology of the body and the brain. The use of MRI in clinical research made it possible to evaluate specific brain regions *in vivo.* The promise of what MRI offered the field led to a proliferation of studies in schizophrenia. MRI studies conducted between 1988 and 2000 led to compelling evidence that brain abnormalities were present in individuals with schizophrenia. These studies also observed, not surprisingly, that most abnormalities were small and subtle, rather than large and dramatic, suggesting still further that more advanced and accurate measurements were needed to detect and understand such brain abnormalities. As will be detailed below, a number of novel imaging technologies have since become available that make possible even more precise identification and characterization of subtle structural abnormalities in schizophrenia.

The time period between 1988 and 2000 also witnessed a burgeoning of neuroimaging studies in schizophrenia “that have led to more definitive findings of brain abnormalities than in any other time period in the history of schizophrenia research” (see review by Shenton and colleagues in 2001). Combined with the wider application of MRI methodologies, there were also unparalleled advances in MR image acquisition protocols. For example, image acquisition paradigms evolved from evaluating a single 1-cm slice in the brain on MR scanners with low field strength (0.5 Tesla [T]) to acquiring 1-mm or thinner slices throughout the entire brain on MR scanners with higher field strengths (specifically 1.5 T and 3 T). This change in technology made it possible to evaluate the entire brain using thin, contiguous slices,

thereby resulting in greater anatomical detail. Developments of novel sequences, such as those utilized for diffusion magnetic resonance imaging (dMRI), a technique most known for its ability to indirectly interrogate white matter microstructure through the detection and measurement of water diffusion in the brain, were significant accomplishments that furthered the imaging field. Likewise, the subsequent expansion of cutting-edge image analysis tools for both MRI and dMRI acquisitions led to an unprecedented number of novel findings in schizophrenia. For example, the introduction of semiautomated segmentation algorithms to classify different brain tissues into gray matter, white matter, and cerebrospinal fluid (CSF) and the development of newer automated atlas-based parcellation methods have made it possible to conduct larger studies with increased accuracy, greater speed, and higher reliability when compared to previous studies that employed manual tracing methods (i.e., manual region of interest-ROI methods). Figure 12.7–1 shows a coronal slice through the brain where the temporal lobe, amygdala, parahippocampal gyrus, and superior temporal gyrus have been manually drawn. Figure 12.7–2 shows a lateral view of the brain where the surface shows the different lobes of the brain. Such parcellations are now commonly done using automated procedures, with manual editing only being conducted when necessary.

Recent advances in imaging technology during this period also made it possible to associate gray matter and white matter abnormalities with genetic, environmental, behavioral, and neuropsychological measures in those suffering from schizophrenia. Significant efforts are also being made to link multimodal imaging techniques (e.g., structural MRI with functional MRI) within the same cohort of subjects so as to explore more fully the entire brain and its role in schizophrenia. It has also become increasingly clear that inroads to understanding the biologic underpinnings and developmental progression of this disorder are contingent upon more methodologically rigorous studies that will introduce measures with greater sensitivity for detecting changes in both brain structure and function. In summary, the 21st century has been and will continue to be an exciting time for brain imaging studies in schizophrenia, as advances in imaging technology over the past 30 years make new insights into the brain and its processes possible.

FIGURE 12.7–1. Coronal 1.5-mm slice that shows the medial temporal lobe region of the brain, with the temporal lobe delineated in *white* on the **left** side of the image (subject's **right**). Regions delineated in *white* on the right side of the brain (subject's **left**) are the superior temporal gyrus, which borders the Sylvian fissure, the amygdala (the *almond-shaped object*), and the parahippocampal gyrus, inferior to the amygdala. Advances Inspired by Seminal Studies and the Path Forward

As described above, advances in imaging were critical for confirming the presence of structural brain abnormalities in schizophrenia. These early seminal works inspired new studies that include (1) more homogeneous patient groups to explore relationships between structural abnormalities and clinical symptoms; (2) at-risk populations, based on increased clinical or genetic high risk; (3) applications of newer, more sensitive acquisition and analysis methods, such as dMRI to investigate brain microstructure and connectivity; and, (4) multimodal imaging to investigate brain structure and function within the same patient (e.g., fMRI, dMRI, or magnetic resonance spectroscopy [MRS], to name just a few). It is also clear that future investigations are needed to elucidate the natural history of when brain abnormalities first appear and how they may change over time. This includes a shift in the types of clinical populations investigated, with the field showing an increase in the number of studies of first-episode individuals and of those individuals with an increased clinical or genetic high risk for

schizophrenia and other psychiatric illnesses, as opposed to studying individuals with more advanced illness.

The first studies of schizophrenia, as noted earlier, used relatively crude neuroimaging techniques by today's standards. Nonetheless, and as noted above, seminal early studies confirmed that schizophrenia is, in fact, "a brain disease." In 2001, Shenton and colleagues reviewed 193 peer-reviewed sMRI studies of schizophrenia conducted between 1988 and 2000. This review confirmed a number of findings described earlier in CT and postmortem studies. For example, 80% of the studies reviewed reported enlarged lateral ventricles in patients with schizophrenia compared to controls. This was a common finding in early CT studies and has proven to be the most replicated finding in schizophrenia. The second most replicated finding in this review was deficits in the medial temporal lobe, where 74% of studies reported volumetric reductions in medial temporal lobe structures, most notably in the amygdala, hippocampus, parahippocampal gyrus, and proximal neocortical areas, such as the superior temporal gyrus. Other abnormalities included cavum septi pellucidi (92%), third ventricle enlargement (73% of studies), parietal lobe volume reduction (67%), frontal lobe volume reduction (59%), occipital lobe volume reduction (44%), as well as thalamus (42%) and cerebellar volume reduction (31%). Basal ganglia showed abnormalities (68%, however, some increased volume, some decreased volume), as did the corpus callosum (63% showed abnormalities). Work following this time period has led to a further understanding of brain structural abnormalities in schizophrenia, through the incorporation of newer tools, more accurate measurements, and information gleaned from other imaging modalities. As will be made clear in our selective review below, a further appreciation of the importance of how brain circuitry abnormalities and alterations to brain structure occur, and how these aberrations relate to both the development of specific cognitive deficits and the manifestation of the clinical symptoms of schizophrenia, are topics of interest in current research.

The vast majority of studies today are no longer investigating whether schizophrenia is "a brain disease" but are asking instead: "What sort of disease is it?" Researchers are also more interested in posing questions such as: "Are there disease-specific structural abnormalities in schizophrenia compared to other disorders with psychotic features? At what point in brain development do brain abnormalities first appear? Do these brain abnormalities change over time? If brain abnormalities change over time, do they have a neurodevelopmental origin, are they the result of

neurodegenerative processes, or both? Will the early treatment be effective at mitigating or preventing the progression of the disorder? What impact does medication/polypharmacy have on the brain in the short and/or long term? Could early treatment help attenuate cognitive decline? Is schizophrenia truly one illness or a spectrum?" A focus on answering these questions will bring us to a closer understanding of the nature and time course of schizophrenia. One such recent initiative is the Accelerated Medicine Partnership in Schizophrenia (AMP SCZ), "a public-private partnership between the National Institutes of Health (NIH), the U.S. Food and Drug Administration (FDA), the European Medicines Agency, and multiple public and private organizations. The overall aim of the AMP Schizophrenia (SCZ) initiative is to generate tools that will considerably improve success in developing early-stage interventions for patients who are at risk of developing schizophrenia" (https://www.nimh.nih.gov/research/research-funded-by-nimh/research-initiatives/accelerating-medicines-partnership-schizophrenia-amp-scz).

OVERVIEW OF CHAPTER

The goal of this chapter is to review progress in structural imaging findings from studies using T1-based structural MRI (sMRI) and dMRI techniques that further our understanding of schizophrenia. In this chapter, we provide a selective review of what we believe are among the most impactful publications over the last 10 years. We exclude case studies, studies with no control group, studies with small sample sizes ($n < 20$), and studies investigating schizotypal personality disorder or childhood-onset schizophrenia. We include important review articles that appropriately and accurately summarize the state of the field for a given area. In addition, we highlight studies that, in our opinion, will provide critical insights for future neuroimaging investigations into the underlying neuropathophysiology of schizophrenia.

In this chapter, the first section presents findings from studies that focus only on the use of sMRI methodologies, such as cortical gray matter volume and cortical thickness, followed by a section where we discuss studies that have utilized dMRI approaches, such as diffusion tensor imaging (DTI) and tractography. For both imaging modalities, we first present studies where individuals with schizophrenia who are at different stages of illness are collapsed into one larger analysis in an effort to increase sample size and to identify consistent abnormalities that have been found in patients with

schizophrenia compared to healthy controls (HCs) regardless of illness stage. After this, we present studies which focus on discrete illness stages, first describing studies which center on individuals with chronic schizophrenia, then with studies on early course schizophrenia, and then a summary of studies carried out in individuals at risk for developing schizophrenia. To conclude each section, we also present studies that represent cutting-edge advances for each modality. At the end of this chapter, we examine the findings and then provide recommendations for future directions and considerations for brain imaging research in schizophrenia that will bring us closer to understanding, treating, and preventing this serious mental illness.

Structural Magnetic Resonance Imaging Findings in Schizophrenia

As discussed previously, the number of structural neuroimaging studies of schizophrenia has continued to increase at an exponential rate since the early 90s. While initial sMRI studies tended to measure values like cortical volume in small, well-defined populations, advances in computational power and image analysis techniques have provided a wider range of faster, more automated, and more precise measurement tools. This has led to large, multisite prospective and retrospective studies investigating morphometric brain changes in not tens, but thousands of individuals with schizophrenia. These “big data” approaches, which will be discussed at length later in the chapter, are represented by studies from the Enhanced NeuroImaging Genetic through Meta-Analysis (ENIGMA) Consortium. Of further note, several recent meta-analyses from the ENIGMA Consortium confirm widespread gray and white matter volumetric reductions in schizophrenia that were summarized in the earlier review in 2001 by Shenton and colleagues.

In one study, van Erp and colleagues utilized data from 2,028 individuals with schizophrenia and 2,540 HCs to investigate volumetric differences in subcortical structures. In this meta-analysis, those with schizophrenia exhibited reductions in the volume of the hippocampus, amygdala, thalamus, and nucleus accumbens. This study also confirmed prior reports that individuals with schizophrenia have reductions in overall intracranial volume. These individuals also showed increased volumes in the globus pallidus and the lateral ventricles. The majority of these differences exhibited effect sizes ranging from small to medium, with the largest effect being observed in the hippocampus (Cohen’s $d = -0.46$). In a separate 2018 meta-analysis, van Erp and colleagues applied the same approach to

cortical thickness and surface area data from 4,474 subjects with schizophrenia and 5,089 HCs. In this study, the authors observed global reductions in cortical thickness and surface area, though to a lesser degree, in both hemispheres in schizophrenia. After taking into account global cortical thickness and surface area losses, it was found that those individuals showed additional regional changes in cortical thickness (but not the cortical area) of the fusiform gyrus and several temporal regions, in addition to thickness reductions in the ventrolateral prefrontal cortex, insula, and anterior cingulate cortex. Interestingly, those with schizophrenia also showed areas of thicker cortex in the motor, somatosensory, parietal, and rostral anterior cingulate cortex compared to healthy individuals.

Taken together, these findings confirm the presence of subtle but widespread case-control differences in gray matter in the brain in individuals diagnosed with schizophrenia. Smaller intracranial volumes and larger lateral ventricle volumes thus continue to be core features of the illness. Small but replicable reductions in the volume of subcortical structures, such as the hippocampus and thalamus, also continue to be observed. Cortical tissue reduction, compared with HCs, also appears to be more dramatic in frontal and temporal cortices as well as in several limbic areas, specifically the insula and the anterior cingulate cortex. Aberrant cortical thickening appears to be found in several areas, including the primary cortex, such as motor and sensory areas, as well as in the parietal cortex.

The studies reviewed above, however, do not provide a dynamic window into the brain changes along the schizophrenia time course. In the coming section, we introduce several recent studies which have provided insight into stage-specific volumetric changes in schizophrenia.

Chronic Schizophrenia. Chronic schizophrenia represents the most severe end of the clinical spectrum. Most of these individuals have received medications over a long period of time, and have been living with a chronic illness, both factors that may confound structural imaging findings. More recent studies have attempted to disentangle the effects of chronicity, medication, and aging on findings in chronic schizophrenia populations. In addition, in the last decade, there has been support for the idea of “accelerated aging” in schizophrenia. This hypothesis supports the idea that tissue reduction observed in chronic schizophrenia may be the result of exaggerated age-related decline. One example of this approach is a study by Cropley and colleagues, who used sMRI data of 326 subjects with schizophrenia (average duration of illness 15.9 years) and 197 age-

matched HCs. They found that those with schizophrenia exhibit large differences in total gray matter volume when compared to HCs, which begins early in adulthood and extends into middle age. More importantly, the rate of gray matter volume loss was significantly greater compared to matched controls until middle age, with patients between the ages of 20 and 45 showing a 30% to 60% faster rate of gray matter volume loss. Interestingly, after the age of 50, the rate of loss begins to slow, at which time those with schizophrenia appear to age similarly to HCs. When investigating region specific, as opposed to global differences, the authors reported the fastest rate of volume loss in the frontal, temporal, occipital, and cingulate cortices in those individuals who were between 30 and 45 years of age. The authors also found that gray matter volume loss tended to predate pathologic changes in white matter (to be discussed later). Taken together, the results of this study provide evidence for the presence of an accelerated rate of gray matter loss in schizophrenia that the authors argue would normally be associated with healthy aging but at an earlier age.

Another key area of recent interest in chronic schizophrenia research is the investigation of the long-term impact of antipsychotic medication on brain structure. While this is still an area of active debate, recent work by Liu and colleagues provides some key insights. In this study, the authors utilized sMRI data from 35 never-treated individuals with chronic schizophrenia (average duration of illness 20 years), 20 chronic risperidone monotherapy individuals, 20 chronic clozapine monotherapy individuals (both matched to the never treated group for duration of illness), and 55 HCs. In their study, the authors found that compared to controls, both the never-treated and treated individuals exhibited significant gray matter volume loss in the bilateral rostral middle frontal and medial frontal cortex, as well as reductions in the left fusiform gyrus, left pericalcarine, and left banks of the superior temporal sulcus. Of further note, increased gray matter volume was found in the cuneus in both never-treated and treated individuals, but the never-treated individuals also showed an increase in both left and right frontal poles. When comparing the never-treated group to the treated groups, it was revealed that the treated group showed volume reductions in bilateral frontal, prefrontal, and temporal areas, as well as in the left inferior parietal lobule. When comparing individuals receiving risperidone monotherapy to those receiving clozapine monotherapy, it was observed that clozapine individuals had more severe reductions in gray matter volume, predominantly in the prefrontal cortex. In addition, gray matter reductions were shown to be negatively correlated with medication

dosage as well as with the duration of illness and symptom severity in treated individuals, while changes in gray matter were not found to be related to clinical symptoms or duration of illness in the never-treated individuals.

In summary, while all individuals diagnosed with schizophrenia, whether treated or not, exhibit significant gray matter loss compared to HCs, this study showed that those who were treated showed further gray matter loss compared to their never-treated counterparts. As such, the work of Liu and colleagues provides preliminary evidence that cumulative medication exposure may be a potential contributing factor that influences the progression of gray matter deficits in chronic patients, which is consistent with previous animal work, and could partially explain cortical changes observed in the “accelerated aging” experiments described earlier in this section.

Moving forward, research in chronic schizophrenia may benefit from a greater focus on underrepresented groups, such as individuals who are treatment resistant or with a late onset of illness, as this may help to further our knowledge regarding factors that contribute to pathologic features observed in the brain in those in the chronic stages of schizophrenia.

First-Episode and Early-Course Schizophrenia Patients. Since the early 2000s, neuroimaging studies in schizophrenia have shifted from the study of chronic, clinically stable, and medicated individuals to investigating those who are in the early stages of illness, particularly after the onset of the first psychotic episode. Such studies are critical for differentiating between primary and secondary markers of illness. In these studies, confounds commonly observed in chronic populations, such as medication, are minimal, thereby making it possible for researchers to understand better the location or nature of structural abnormalities that are either contributing or present at the transition to illness. These studies tend to focus on those who experienced their first psychotic episode within the last 5 years. Recent work that focuses on the recruitment and longitudinal monitoring of antipsychotic naive subjects has also been critical to understanding the impact of medication on the brain in the early stages of the illness.

One of the seminal publications in clinical neuroimaging is a study carried out by Andreasen and colleagues in 2011, the Iowa Longitudinal Study. This groundbreaking effort was a prospective study of 543 first-episode psychosis subjects who were followed for up to 18 years. The authors included a total of 952 scans from 202 individuals with schizophrenia and

125 HCs to determine whether or not progressive brain changes occur after the onset of the illness. Each participant in this study had a minimum of two scans and a maximum of five scans over a 15-year period. The authors observed significant gray and white matter tissue loss in these individuals compared to controls. While the amount of tissue loss was relatively small, these losses occurred predominantly during the first 2 years after illness onset for nearly all gray and white matter measures. Overall, 34% of those diagnosed with the first episode of schizophrenia exhibited reductions in brain volume at a rate of 0.5% a year, with 14% exhibiting reductions in brain volume at a rate of 1% a year. Frontal gray matter and white matter volumes were most affected, though the white matter was more severely impacted. The authors also reported a significant increase in CSF volume in the first-episode subjects that was concurrent with the early gray and white matter tissue loss. When investigating remission status in the first-episode group, throughout the course of this longitudinal study, the authors reported that those first-episode individuals with the smallest increases in CSF were more likely to have longer periods of remission. This study aligns well with a study by Cropley and colleagues, described earlier, which also showed, albeit in a different type of analysis, progressive reductions in gray matter volume in the early stages of illness. As such, there is converging evidence that the greatest amount of tissue loss occurs in the earlier stages of illness, in the first few years after the emergence of frank psychosis. The authors suggest that this may be a consequence of impaired synaptic plasticity, particularly in the late-developing frontal lobe.

While tissue loss is likely to occur in the early stages of illness, it is still unclear what leads to the sudden loss of gray and white matter at this stage of illness. To address this question, in the last 5 to 10 years, there have been several lines of evidence that implicate immunologic processes in the pathophysiology of schizophrenia. These data range from studies demonstrating high levels of proinflammatory cytokines in the blood and CSF of early-course psychosis to postmortem studies demonstrating evidence for the upregulation of genes related to immune system functioning. While it has yet to be determined if immunologic activation is a cause or an effect of the transition to psychosis in the early course of the illness, accumulating evidence suggests its involvement.

Work by Núñez and coauthors provides evidence in support of the hypothesis linking immune activation to gray matter pathologies in the early course of psychosis. In this study, the authors used structural imaging data from 137 first-episode individuals and 81 HCs, as well as blood samples

that were collected at a baseline visit or at a 2-month follow-up. The number of neutrophils, one of the subtypes of the white blood cells, was significantly higher in first-episode individuals compared to HCs, whereas the number of erythrocytes (i.e., red blood cells) was significantly lower. In the early-psychosis group, a high neutrophil count was also associated with smaller gray matter volumes and larger CSF volumes. Interestingly, none of the blood cell types were related to white matter volume. These relationships were also not observed in the HCs. The authors then performed a voxel-based morphometry analysis to determine whether or not there were specific gray matter areas that were more susceptible to higher neutrophil counts in early-course psychosis individuals. In fact, reductions in gray matter volume within the right anterior insula, right temporal pole, right entorhinal cortex, right middle temporal gyrus, and right inferior temporal gyrus were significantly correlated with the neutrophil count in first-episode individuals. Interestingly, neutrophils were also directly associated with the total score and the positive score from the Positive and Negative Syndrome Scale (PANSS), a clinical inventory of symptoms for psychotic disorders.

This study thus provided preliminary evidence for immune dysregulation as a potential link to tissue loss in the early stages of illness. Given the role of neutrophils in neuroimmune modulation, this study may provide a foundation for the development of novel treatment strategies focusing on the immune system. It is important to note, however, that the immune dysregulation hypothesis is only one of many theories purported to explain the pathologic tissue loss in schizophrenia. Others include oxidative stress and redox dysregulation, glutamatergic dysregulation, dopaminergic dysregulation, excessive synaptic pruning, aberrant neurodevelopment, and maturation, accelerated aging (discussed earlier), and the compromised functional integration of information due to faulty neurocircuitry, also known as the dysconnectivity hypothesis. Unfortunately, a comprehensive discussion of these models is outside the scope of the present chapter.

In summary, reductions in gray matter are already present at the time of the first psychotic episode. After illness onset, the rate of decline in cortical volumes appears to be faster in those with schizophrenia when compared to healthy individuals, at least for the first few years after disease onset. There is also evidence that gray matter reductions may be linked, at least in a subset of subjects, to immune activation that takes place at the onset of illness. However, this should be interpreted with caution, and future studies are needed to determine the functional consequences of immune activation to determine its role in early-course schizophrenia.

High-Risk Populations. An important question to answer in schizophrenia, as noted previously, is whether brain abnormalities are present prior to the onset of illness (i.e., before psychosis begins). To some extent, this question can be addressed by longitudinal studies that begin prior to illness onset, in what is called the *prodrome period*, or "*attenuated psychosis syndrome,*" that latter term proposed by the DSM-5. A further question to be addressed is whether brain abnormalities observed are also observed in family members without psychosis, which could indicate a potential genetic contribution to observed brain abnormalities independent of the presentation of psychotic symptoms. In this section, we first discuss studies that focus on sMRI findings in individuals exhibiting subthreshold symptoms and are deemed clinically at risk for developing schizophrenia. In the second section, we present a brief summary of sMRI studies focusing on unaffected family members who are deemed genetically at risk for developing schizophrenia.

CLINICAL HIGH RISK. There are several large research consortia around the world that focus on those who are at risk for developing psychosis. Due to the relatively low conversion rate to schizophrenia from those at high risk (less than one-third of those at clinical high risk [CHR] will convert), the number of subjects needed to investigate this population is understandably large. Nonetheless, to date, several studies have successfully investigated high-risk populations, including but not limited to the Edinburgh High-Risk Study (EHRS), the Melbourne Personal Assessment and Crisis Evaluation (PACE) study, the North American Prodrome Longitudinal Study (NAPLS) and the Shanghai At-Risk for Psychosis (SHARP) study. One of the main goals of high-risk studies is to identify consistent differences between individuals who convert compared to those who do not. Similarly, when comparing at-risk individuals to HCs allows for the identification of structural changes related to a more generalized risk of psychopathology, as opposed to the specific risk of developing a psychotic disorder. The long-term goal of identifying these structural alterations is that they may be useful early-stage biomarkers to stratify those most in need of treatment or intervention. Early intervention has, in fact, been shown to have significant efficacy in mitigating the severity of the illness and, in the future, could potentially even prevent onset.

In a publication from the NAPLS consortium in 2015, Cannon and coauthors investigated a cohort of 274 clinical high-risk cases, where 35 converted to psychosis. Follow-up scans were performed 12 months after

baseline or after conversion to psychosis. No significant differences were found at baseline for cortical thickness and subcortical or ventricular volumes. However, CHR individuals who converted to psychosis exhibited a significantly faster rate of gray matter loss in right superior frontal, right middle frontal, and right medial frontal gyri, as well as a significantly larger expansion in third ventricular volume compared to nonconverters and HCs. In addition, the authors found that converters with no exposure to antipsychotic medications during the interscan interval actually showed a greater reduction in right prefrontal cortical thickness and greater expansion of third ventricle volume compared to nonconverters (with and without antipsychotic exposure) and HCs. This finding suggests that the differential rate of gray matter loss between converters and nonconverters was not explained by exposure to antipsychotic medications, further suggesting that cortical thinning may be the result of the pathophysiology of the onset of psychosis.

In 2019, Ding and coauthors conducted a meta-analysis of 14 studies that used voxel-based morphometry to study subjects at risk for psychosis (of which the prior study discussed was included), comprised of data from 743 at-risk individuals and 588 HCs. In this meta-analysis, reductions in gray matter volume were found in several frontal regions, including the gyrus rectus, right superior frontal gyrus, and left superior frontal gyrus. Increased gray matter volume was observed in the bilateral cingulate cortex, right fusiform gyrus, left superior temporal gyrus, and right thalamus. The authors also conducted a systematic review of studies that focused on cortical thickness as the measure of interest. Nine studies, comprising a population of 700 at-risk subjects and 469 HCs, were identified. Four studies reported cortical thinning in frontal, temporal, and occipital areas, while three studies found no differences. The remaining two studies reported increased cortical thickness, with one study observing increases in parietal and occipital cortices and the other describing an increase in the right frontal pole (though this finding was observed prior to being corrected for multiple comparisons). Among these nine studies, five included longitudinal scanning paradigms, yet only three employed cortical thickness. When looking at all five studies, individuals who eventually converted to psychosis were reported to have increased gray matter in the right superior, inferior, frontal, and Heschl's gyrus when compared to HCs. Yet, when confined to studies utilizing cortical thickness, two of the three studies showed reduced cortical thickness in the right superior, middle, and medial orbital frontal gyrus and left angular gyrus, precuneus, and temporoparietooccipital

regions in those who converted. In the discussion, the authors highlight several key findings from their work, most notably that many of the regions which were identified as being abnormal in high-risk individuals are also commonly reported in first-episode populations as well, specifically the widespread reductions in frontal gray matter. Despite these findings, the authors further commented on the limited number of longitudinal studies that fail to find differences between converters and nonconverters. This lack of consistency in the findings within the high-risk field can be attributed to methodologic differences (e.g., inclusion/exclusion criteria, different pre- and postprocessing methods across samples), although one of the most compelling reasons for such inconsistencies is the heterogeneity in those who are at risk for psychosis, suggesting the importance of stratifying subjects into more homogeneous groupings.

GENETIC AND FAMILIAL HIGH RISK. Studying unaffected family members of individuals with psychosis is also important. First, these individuals have not been hospitalized for a psychiatric disorder and, therefore, are not suffering from the possible putative or neurotoxic effects of psychosis. Second, unaffected family members are generally not medicated with neuroleptic medications, thus removing the potential confound neuroleptics likely have on structural brain findings. Information acquired by investigating unaffected family members thus likely reflects an increased genetic vulnerability to developing schizophrenia, as opposed to illness-specific features. Importantly, however, this notion needs to be tempered with the knowledge that genetic factors may interact with environmental factors, thus making it difficult to determine with certainty that brain abnormalities observed in family members of patients with schizophrenia are necessarily driven only by genetic factors.

A recent review by Bois and colleagues in 2014 summarizes sMRI findings from multiple familial and genetic high-risk studies and meta-analyses. Cross-sectional analyses found decreased gray matter volume in genetic high-risk subjects in the dorsolateral prefrontal cortex, Broca area, Wernicke area, bilateral anterior cingulate cortex, right superior temporal gyrus, left precuneus, left medial frontal gyrus, right middle frontal gyrus, and bilateral hippocampal/parahippocampal regions. Similar results have been reported in studies employing cortical surface measures, with siblings and unaffected relatives showing decreased cortical thickness and surface area in the cingulate gyrus, superior temporal gyrus, and prefrontal cortex when compared to HCs. Investigations into gyrification patterns in familial

high-risk individuals have proven to be generally inconclusive, with some studies reporting significant differences in cortical gyrification in unaffected relatives and siblings, whereas others have not. Abnormal gyrification patterns are posited to be indicative of aberrant pre- or perinatal neurodevelopment. Equivocal findings in gyrification in familial risk studies may indicate that the unaffected relatives of individuals with schizophrenia might not have experienced a potential early-stage insult, thereby contributing to their resilience against a transition to psychosis despite their genetic predisposition.

Longitudinal familial risk studies, which follow family members over time to determine if familial high-risk individuals convert to psychosis, also provide a powerful neuroimaging paradigm to assess potential neurodevelopmental progression. Despite the generally low conversion rate seen in familial high-risk studies, comparisons by Bois and colleagues in 2014 between high-risk converters and nonconverters have found that subjects that convert to psychosis exhibit different developmental trajectories from nonconverters and matched unaffected controls. Subjects who convert to psychosis tend to show reductions in cortical thickness over time in frontal, temporal, and parietal areas, as well as localized reductions in cortical surface area, while subjects who do not convert and controls exhibit cortical thickening or surface area expansion over time. These studies demonstrate that structural differences in schizophrenia may precede symptom onset and therefore provide researchers and clinicians with an avenue for the identification of structural biomarkers of risk that may be used for targeted therapeutic interventions, which might mitigate or prevent the onset of psychosis.

Looking Forward: Advances in Structural MRI for the Future. The majority of neuroimaging investigations continue to employ case-control comparisons to determine the location and extent of structural changes in the brains of individuals with schizophrenia or those who are at risk of developing the disorder. While this approach continues to be the bedrock of psychiatric neuroimaging studies, this paradigm does not consider the potential importance of the heterogeneity of the clinical presentations for individuals with schizophrenia or the potential heterogeneity of brain changes that could occur. New applications of a technique called normative modeling, an analysis that investigates the individual deviations from a normative range (usually defined by a population of individuals without severe mental illness), allow for the more refined investigation of the extent

to which changes in an individual align with what is observed in a population of healthy individuals. In a study by Lv and coauthors, the investigators applied normative modeling to cortical thickness values derived from structural imaging data from 322 patients with schizophrenia and 195 HCs. When using a case-control approach, significant reductions in cortical thickness were found in 60 of 68 cortical regions examined. However, when applying the normative modeling approach, the majority of individuals with schizophrenia fell within the normative range. In fact, no more than 18% of patients were found to deviate from the normative range. Infranormal (lower than normal) deviations were commonly observed in the temporal and ventromedial prefrontal cortices, but interestingly only 10% to 15% of patients exhibited significant deviations in these areas. Supranormal (higher than normal) deviations were found in the paracentral lobule but only in 3% of the patients. These data provide strong preliminary evidence that there is significant heterogeneity in the location of anatomical differences found in individuals with schizophrenia and that it is likely that case-control comparisons do not appropriately reflect pathologies that would be found in individual patients. Given the results of this study, it is clear that new approaches which aim to refocus research investigations to the study of the individual as opposed to the “average patient” are needed. This has led to the emergence of “precision medicine” approaches, which we discuss in greater detail in the concluding sections.

As we have shown, reductions in gray matter are one of the most consistent findings in sMRI studies of schizophrenia. However, neuroimaging tools remain limited in their ability to probe the underlying cellular and molecular mechanisms that may lead to schizophrenia. Large-scale, genome-wide association studies (GWAS), which can consist of genetic samples of more than 20,000 people, have identified over 100 genes associated with schizophrenia. A greater understanding of the link between schizophrenia risk genes and brain abnormalities would provide much-needed validation of potential neuroimaging biomarkers of psychosis. However, at present, there is no structural imaging sample large enough to conduct a genome-wide neuroimaging association study. In a study by Ji and colleagues, the authors chose to utilize a transcription-neuroimaging association analysis, an approach that does not require extremely large samples. These authors used this approach to determine which schizophrenia-related genes, previously identified by GWAS, were associated with gray matter volume reductions. sMRI data were compiled from five independent samples that were harmonized to generate a

population of 276 patients with schizophrenia and 284 HCs. Gene expression data were derived from six postmortem brains from the Allen Human Brain Atlas (http://human.brain-map.org) and were then correlated with the harmonized imaging data. The authors reported that 98 genes showed significant correlations with changes in gray matter volume between patients with schizophrenia and HCs. The 98 identified genes were implicated in critical functions like synaptic transmission, central nervous system development, and cell projection. For example, the authors found a strong positive correlation between gray matter volume reductions in patients and *GRIA1*, a gene linked to the α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid (AMPA) receptor. In patients, higher levels of *GRIA1* were associated with a greater degree of volume loss, a finding which is consistent with other studies that have observed aberrations in synaptic plasticity and glutamatergic transmission in schizophrenia. While this approach is indirect, as the genetic and imaging data were not obtained from the same individuals, approaches such as this provide significant insights into the molecular mechanisms that may underlie structural pathologies commonly observed in schizophrenia populations and will ultimately help to identify candidate markers for future studies. Interdisciplinary approaches exemplified by this study are increasingly needed and will be discussed in depth later in this chapter.

Summary. In summary, structural MRI has proven to be an extremely powerful tool in identifying structural abnormalities in gray matter in patients with schizophrenia. Differences in cortical and subcortical structures are reported at all stages of the disorder, from onset to chronicity, as well as in individuals who are at increased risk for developing the disorder. In addition, large cross-sectional, as well as longitudinal, studies have begun to chart the complex dynamics of gray matter pathology, with its accelerated trajectory around the psychotic onset and possibly later during early aging. At the same time, the newest studies highlight the heterogeneity of schizophrenia pathology, indicating that there might be more than one path to developing the disorder. This includes the already discussed potential influence of genes and environment (in both risk and resilience to develop schizophrenia), aberrant cellular and/or neuroinflammatory pathways, as well as other factors not discussed here, such as hormonal imbalances or cellular senescence. As the field progresses, structural neuroimaging will continue to move toward larger, longitudinal studies where imaging and nonimaging biomarkers will be combined with sophisticated analytic.

Diffusion Magnetic Resonance Imaging Findings in Schizophrenia

Since the early 2000s, there has been a growing interest in understanding the role that white matter may play in the pathophysiologic of schizophrenia. This has been jointly motivated by the development of imaging modalities specifically targeting white matter, such as dMRI, a method capable of visualizing and quantifying major axonal connections of the brain, and by the observation that the pattern and number of gray matter abnormalities observed in schizophrenia are consistent with a disturbance of connectivity within and between brain regions. In addition, transition to psychosis tends to occur in early adulthood, a period that overlaps with the rapid maturation of the majority of white matter tracts in the brain, while gray matter matures earlier. Moreover, neuropathologic and genetic studies suggest the specific involvement of oligodendrocytes, the neural cells that form myelin and provide protection to axons, as well as improve communication between brain areas in the pathophysiology of schizophrenia. All this evidence warrants further research into evaluating the degree to which the white matter abnormalities may contribute to schizophrenia pathophysiology. Since dMRI is the leading method in evaluating white matter structural pathology in the living human brain, in this section, we will focus on schizophrenia findings using dMRI methodology. To parallel the structure of the preceding section, we will first introduce studies that provide an overview of dMRI findings in schizophrenia. This will be followed by a presentation of stage-specific studies (i.e., chronic, first-episode, and clinical high-risk populations), again following the information provided previously for sMRI findings in schizophrenia.

DMRI methodology was introduced in the early 80s, but the first fully quantitative method used to estimate white matter microstructural integrity, called DTI, was introduced in 1994. The main measure derived from this method, called Fractional Anisotropy (FA), was sensitive to multiple microstructural changes within the white matter tissue, including myelin thickness, axonal number, axonal density, fiber coherence, and extracellular water content. The first DTI studies in schizophrenia evaluated the whole brain in relatively small samples with 20 or fewer subjects. However, even with these small sample sizes, reductions in FA were reported in several brain regions.

Over the last 20 years, there has been a dramatic increase in the number of studies focusing on the use of dMRI to investigate individuals with schizophrenia. More importantly, many of the datasets that were acquired are being made publicly available as part of a large-scale effort to promote

the development of collaborative “big data” approaches. The availability of these datasets has motivated investigators to develop analytic methods that could combine and analyze multisite–multicenter studies that could leverage much greater statistical power than earlier single-site studies.

One of the first such studies was published in 2018. In this study, Kelly and her colleagues within the ENIGMA Consortium published the results from a meta-analysis on diffusion MR data compiled from 29 independent international sites. Their sample consisted of 1,963 patients with schizophrenia and 2,359 HCs. Of the 25 anatomical regions that were included in their meta-analysis, 20 exhibited significantly lower FA in individuals with schizophrenia compared to controls. The largest effect sizes were found for average whole-brain FA (Cohen’s d = –0.42), followed by the anterior corona radiata (Cohen’s d = –0.40) and the corpus callosum (Cohen’s d = –0.40). These findings align well with several previous research reports in smaller samples which have also shown widespread reductions in FA, as well as more specific reductions in key frontal, temporal, and commissural tracts. Larger effect sizes were also observed for FA when compared to the other DTI indices, mean diffusivity (MD), axial diffusivity (AD), and radial diffusivity (RD), though significantly higher MD and RD were reported in the schizophrenia cohort. This study also found no associations between current medication dosage and age of onset, two key clinical variables of interest. In sum, the results of the meta-analysis by Kelly and colleagues provided further evidence for the presence of microstructural white matter pathology in schizophrenia.

Following this study, Cetin-Karayumak and coauthors took a different approach by using diffusion MR harmonization methods, as opposed to a meta-analytic approach, to combine and analyze together extant dMRI schizophrenia datasets. Briefly, the purpose of harmonization methods is to remove the site-, scanner-, and sequence-specific differences that are generated during data acquisition. Since no two scanners are alike, even if diffusion MR data were to come from two sites that use similar hardware (i.e., same scanner), software (e.g., scanner software upgrades, pre- and postprocessing steps), or sequences, there will still be inherent differences in the data that cannot be controlled for statistically (i.e., including “site” as a covariate). Harmonization methods remove these variabilities from the raw diffusion image at the signal level, thereby allowing for imaging data from independent sites to be compiled and analyzed as if they were acquired from the same scanner with the same sequence. This groundbreaking

approach holds significant promise for the future of large-scale data analytics in imaging.

When applying this harmonization method, Cetin-Karayumak and coauthors were able to determine the pattern of global and tract-specific age-related FA differences across the illness course in a sample of 600 patients with schizophrenia and 492 HCs. In whole-brain white matter, FA was significantly reduced in patients across the entire age range studied (14 to 65 years). Reductions in whole-brain FA were greatest in more chronic patients (up to 7% reduction in FA), with smaller differences being observed earlier in the course of illness (minimum reduction: 1.5%). Moreover, individuals diagnosed with schizophrenia were found to reach peak FA (a putative indicator of white matter maturity) 5 years earlier than their healthy counterparts (patient peak FA: 27 years; healthy control peak FA: 33 years). When investigating regional white matter trajectories, the authors observed three distinct patterns of age-related white matter pathologies in schizophrenia. First, neurodevelopmental abnormalities were observed in limbic white matter tracts (e.g., cingulum bundle), manifested as small to medium differences in FA that were stable across all ages. Second, abnormal maturation (i.e., earlier peak) and moderate evidence of accelerated aging were observed in the long-range association fibers (e.g., superior longitudinal fasciculus). Finally, significant deterioration from the onset of illness was observed in commissural tracts (e.g., corpus callosum). One of the strengths of this study is that in addition to showing whole-brain reductions in white matter FA across the entire illness spectrum, this study also demonstrated that there may be significant age-related differences that are tract specific. The use of the diffusion MR harmonization approach was thus critical in being able to model these differences over the illness course because many imaging studies, as we will show and discuss in the subsequent section, tend to focus on the recruitment samples at discrete stages of illness.

In summary, similar to studies using structural MR to study gray matter pathology, the use of diffusion MR has also revealed widespread abnormalities in white matter microstructure in patients with schizophrenia, further suggesting the developmental as well as progressive nature of such abnormalities. Below, we further discuss recently published, and in our opinion, important to the field, dMRI studies investigating discrete schizophrenia populations (chronic, first episode, and CHR) in the context of psychopathology and confounding factors, as well as their potential biologic correlates.

Chronic Patients. Similar to investigations employing sMRI, many of the initial dMRI studies of schizophrenia chose to focus on individuals in the chronic stage of illness. In these studies, the most common index evaluated was FA. A comprehensive review of dMRI findings was compiled in 2014 by Wheeler and colleagues. They report that patients with chronic schizophrenia exhibit decreased FA within the prefrontal and temporal lobes. Specifically, tracts connecting frontal and temporal areas, including the uncinate fasciculus, cingulum bundle, corpus callosum, and internal capsule, were the most consistently reported in the field.

As discussed in several sections of this chapter, one of the prevailing theories regarding structural pathologies in schizophrenia is the idea that those with schizophrenia are experiencing a period of "accelerated aging." In the earlier section focusing on sMRI techniques, we introduced the 2017 study by Cropley and colleagues, which showed evidence of higher rates of gray matter loss in subjects with schizophrenia compared to HCs. The authors also included diffusion MR images in their analysis to investigate white matter FA. Overall, those with schizophrenia exhibited a significantly faster rate of FA decline than controls. In fact, the slope of the line describing the relationship between age and FA was 60% steeper in those with schizophrenia compared to HCs. Significant reductions in FA were observed starting around 35 years of age, after which the reductions continued to increase until the early 60s (maximum difference observed: 3%). Early localized reductions, which also did not emerge until 35 years of age, were primarily found in the genu and body of the corpus callosum and the superior longitudinal fasciculus. With increasing age, localized reductions continued to progress, encompassing more areas until almost all areas of the cortex and the cerebellum exhibited FA reductions. One of the most significant findings of this paper was that in addition to demonstrating that both gray and white matter exhibit evidence of "accelerated aging," gray matter pathologies were present earlier than white matter pathologies. This is significant because it may suggest that white matter pathologies arise as a result of gray matter loss. However, the alternative hypothesis must also be considered—that aberrant processes relating to the development, maturation, and aging of both gray and white matter tissue is just as likely, particularly given that gray matter develops at a younger age than white matter which continues to develop up until the third decade of life. In any case, this study demonstrated that white matter exhibits a deterioration with increasing chronicity, supporting the findings also presented by Cetin-Karayumak, which were reviewed in an earlier section of this chapter.

Aligning with the notion of chronicity-related pathologies, the impact of antipsychotic medication on white matter is also an area of significant interest in the field. While some studies argue that antipsychotic use is detrimental to white matter, others have found evidence that antipsychotic use can ultimately lead to white matter improvements. In contrast to gray matter, which, as noted previously, matures earlier in development, white matter does not mature until the third decade of life. This means that white matter is still actively developing when many individuals are first placed on antipsychotic medications. Neuroimaging studies that have access to chronic, but never-treated patients, while rare, are critical for parsing out the impact of disease processes from those occurring as a result of treatment. In 2018, Xiao and others presented the results of a diffusion dMRI study that sought to determine the extent and location of differences in FA between 31 never-treated patients (average duration of illness: 21.3 years), 46 duration-matched individuals with schizophrenia who were treated with antipsychotics, and 58 HCs. Overall reductions in FA were found in those with schizophrenia compared to HCs. However, greater reductions were observed in the schizophrenia cohort who were never treated compared to those who were treated, specifically in the left anterior thalamic radiation, left cingulum–hippocampal pathway, genu, and splenium of the corpus callosum left superior longitudinal fasciculus and right uncinate fasciculus. In addition, never-treated individuals with schizophrenia exhibited a faster age-related decline compared with the treated the schizophrenia and HC groups. This faster age-related deterioration in FA was primarily observed in the corpus callosum. This report lends further evidence to earlier studies that argue for the beneficial impact of medication on white matter health. Interestingly, this is in opposition to the study presented early in the section on sMRI, which suggested that antipsychotic medication, particularly clozapine, was related to more pronounced gray matter loss. Thus, given the likely interrelatedness of gray and white matter pathologies in schizophrenia, it will be important to fully elucidate the timing and exact biologic nature of medication-induced brain changes in future studies in this area.

In summary, studies using diffusion MR approaches in chronic schizophrenia show reductions in FA in a large proportion of brain regions. Many of the reductions are the result of an exaggerated age-related decline in FA that begins in the commissural tracts and ultimately expands to all parts of the brain. Long-term medication may potentially lead to improvements in white matter in the later stages of illness. However, this is

still being investigated. Future studies in chronic schizophrenia need to include multiple additional factors that likely influence the integrity of white matter and may contribute to the pathology observed in more chronic stages of the disease. These include chronic substance abuse, social isolation, and/or comorbid medical disorders (including metabolic syndrome, which is prevalent in schizophrenia).

First-Episode and Early-Course Patients. Similar to the pattern of gray matter changes, white matter also appears to exhibit widespread but less pronounced changes in the early stages of the illness compared to chronic stages. Studies conducted in the early 2000s, many of which had small sample sizes and relatively low statistical power, have been now replaced by larger multisite mega-analyses, novel analytic approaches which pool raw data from multiple studies conducted under comparable conditions (in contrast to meta-analyses which solely rely on summary statistics). In one such review by Wheeler, authors reported the involvement of white matter tracts (frontotemporal and interhemispheric connections) in the pathology of early course schizophrenia which was also observed in chronic schizophrenia. These investigators, however, noted that the findings in the early stages of the disease are less consistent across studies than those reported in chronic schizophrenia. Based on data from the available studies, the authors also concluded that medication was not likely the direct cause of white matter pathology, as studies with medication-naive subjects also report reductions in FA.

While dMRI is used to characterize the location and the extent of white matter pathology in first-episode and early-course schizophrenia, there are also other metrics used to characterize white matter alterations that contribute to our understanding of schizophrenia pathophysiology. Over the last several years, the focus has also shifted from the leading hypothesis that white matter anomalies in schizophrenia involve myelin pathology to the alternative hypothesis discussed earlier that implicates an immunologic brain response, especially in the early phases of the disorder. Immune activation is purported to negatively affect white matter integrity and lead to neurodegenerative and/or progressive changes in the later stages of the illness. In order to test such hypotheses, new models based on diffusion MR have emerged. One such model is called free water (FW) imaging. In this model, the diffusion signal is broken down into two components. The first component measures the amount of unrestricted or “free” diffusion that is taking place in the extracellular space (FW), while the other measures the

amount and orientation of restricted water diffusion taking place in close proximity to cellular processes (FA of the tissue—FAt). Both the traditional DTI model and the FW model were applied to diffusion MR data from 63 first-episode patients and 70 matched HCs in a study by Lyall and colleagues. When applying the traditional DTI model, FA reductions in individuals with schizophrenia compared to controls were seen in most white matter areas (consistent with Wheeler and other studies). However, when applying the FW model, widespread and significant increases in FW showed a high degree of spatial overlap with the observed FA reductions. In contrast to earlier studies suggesting potential widespread white matter pathology in first-episode populations, the authors only observed small, localized reductions in the tissue-related measure FAt, which were mainly restricted to the body and genu of the corpus callosum, the left and posterior corona radiata, and the left superior longitudinal fasciculus. The results of this study are important because they suggest that there may be two co-occurring pathologies that are present in the brains of individuals who recently converted to psychosis. The first pathology is a widespread increase in extracellular water that may potentially be related to immune activation, while the second may reflect white matter-specific tissue aberrations (possibly related to myelin degeneration). Future studies are needed to understand better the timing and clinical correlates of such changes, but the initial findings discussed here have helped to pave the way for the development of more targeted medical treatment that will be based on biologic, rather than clinical biomarkers of early psychosis.

High-Risk Populations. Over the past few decades, there has been a gradual shift from characterizing actively ill chronic and early-course individuals with schizophrenia to dMRI investigations focusing on individuals at high risk for psychosis. The aim of this research is to understand better potential factors that contribute to the transition to psychosis from those who exhibit evidence of subthreshold clinical symptoms (CHR individuals) or those who have a first-degree relative with a confirmed diagnosis of schizophrenia (genetic and/or familial high risk). By studying the brains of these individuals, researchers hope to identify features that could be helpful for diagnosis, patient stratification, outcome prediction, symptom mitigation, treatment options, and, ultimately, prevention. While this field has grown in size, the application of dMRI has become a useful tool to understand the degree to which structural connectivity changes can confer and/or

contribute to increased risk. Here we present a selection of this emerging field.

CLINICAL HIGH RISK. As highlighted in the preceding section, newer dMRI techniques, such as FW imaging, are being applied in clinical settings. This is particularly true for the investigation of individuals who are at clinically high risk for developing schizophrenia. This is due, in part, to the inconsistent findings in the dMRI literature for CHR populations which, in turn, is likely due to this cohort being highly heterogeneous. As a result, more sophisticated methods are necessary to identify reliable and objective markers for critically important clinical outcomes, such as the likelihood of transitioning to psychosis, functional/cognitive decline, and other adverse outcomes. One example of the application of newer models in CHR populations is a study by Tang and colleagues, where the authors utilized dMRI data from 50 CHR individuals, 40 of whom were not medicated, and 50 matched controls. The group acquired multishell dMRI data, a more advanced acquisition protocol that allows for more complex biophysical models of water diffusion to be applied. The investigators used FW imaging to investigate whole-brain white matter microstructure and observed a reduction in the tissue-related measure FAt but not in the extracellular measure of FW in the CHR group when compared to controls. Reductions in FAt in the CHR group were also associated with lower Global Assessment of Function (GAF). Taken in the context of previous studies which have utilized FW imaging, specifically those studies which focused on the investigation of first-episode psychosis populations, the lack of FW elevations was surprising but led to the conclusion that FW elevations may only be present at the onset of psychosis, but not in the at-risk state. The reductions in FAt (which, as suggested earlier, might reflect myelin pathology) were interpreted as evidence of a potential neurodevelopmental white matter aberration, predisposing individuals to exhibiting subthreshold clinical symptoms.

Recent results from the NAPLS-3 consortium are also consistent with the Tang et al. study cited above. Here, Di Biase and coauthors leveraged a longitudinal multishell dMRI data collection paradigm (dMRI data collected one to five times over the course of 1 year for each participant) from 286 subjects (aged 12 to 32 years). Within this sample, there were 25 CHR individuals who transitioned to psychosis during the follow-up period (CHR-P), 205 CHR individuals who did not transition (CHR-U), and 56 HCs. At baseline, there were no group differences observed between the CHR-P,

CHR-U, and HC for either FAt or FW. However, when investigating the relationships of these measures across the age range, the authors observed that both CHR-P and CHR-U populations exhibited initially higher FAt when compared to controls. After adolescence, FAt gradually decreased for both CHR-P and CHR-U individuals, ultimately falling below their HC counterparts as they entered adulthood (~30 years of age). Interestingly, the rate of FAt decrease was greater in the CHR-P population than in the CHR-U population, suggesting greater developmental deterioration in CHR-P individuals nearing transition. When taken together, these findings provide evidence that the CHR state may be characterized by subtle neurodevelopmental differences in white matter microstructure and, more importantly, that transition to psychosis may not be a period during which dramatic WM structural changes occur. Thus, in contrast to findings of gray matter that were previously discussed, where significant gray matter loss is observed after the transition to illness, this study showed that subtle, developmental differences in white matter maturation may be central to the manifestation of psychosis and further supports the need for well-designed and well-powered longitudinal, multimodal studies.

GENETIC AND FAMILIAL HIGH RISK. Genetic and familial high-risk populations are also critical for the identification or characterization of features more likely to be associated with genetic, trait-related factors as opposed to the presentation of subthreshold symptoms, which would be considered state related. In these studies, dMRI data from unaffected family members are usually compared to control subjects and to their affected family members in order to determine the extent to which white matter displays potential genetically mediated phenotypes.

One recent representative example of this approach is a study by de Leeuw and colleagues. Instead of performing a whole-brain approach, the authors chose to specifically investigate frontostriatal white matter tracts in adolescents (aged 10 to 18 years) who had a parent diagnosed with schizophrenia. The decision to focus on these specific tracts was motivated by prior work performed by the research team, which demonstrated compromised structural connectivity in the tract, which connected the left nucleus accumbens and left dorsolateral prefrontal cortex in individuals with schizophrenia. Imaging data from 27 adolescent offspring of schizophrenia individuals and 32 matched healthy adolescents was investigated using DTI, and findings showed increased FA in the frontostriatal white matter tract in high-risk adolescents relative to controls. In addition, while FA

showed age-related increases in the control subjects in this tract, the same increase was not observed in the genetic high-risk subjects. The greater FA, as well as the abnormal relationship between FA and age in the genetically high-risk individuals, was suggested to represent an acceleration of the maturation of white matter, which may take place in individuals who are at an elevated risk for psychosis. These findings align well with previous studies reviewed in this chapter that implicate abnormal white matter development at the time of the emergence of psychotic symptoms. They further suggest that there is likely a genetically mediated component to these neurodevelopmental aberrations.

Looking Forward: Advances in Diffusion MRI for the Future. While we tended to focus on studies that applied FW imaging in several previous sections, there are several other advanced models for dMRI widely used, which should be recognized. In the interest of brevity, we will only focus on one of these methods: neurite orientation dispersion and density imaging (NODDI). NODDI approaches require the collection of multishell diffusion data. As a result, the NODDI approach cannot be applied to older, legacy datasets. Similar to FW imaging, NODDI models several water compartments that are proposed to represent different biologic processes of the underlying tissue. One example of the NODDI approach in the study of schizophrenia is a study by Rae and colleagues. In this publication, the authors apply both the traditional DTI approach in addition to NODDI in 35 individuals with first-episode psychosis and 19 matched controls. As previously reported, individuals with first-episode psychosis exhibited lower FA in the corticospinal tracts as well as several commissural and association tracts. However, when applied NODDI, the authors found that FA reductions were co-localized with a reduction in neurite density index (NDI), as opposed to fiber arrangement (compartment termed orientation distribution index—ODI). The authors interpreted these differences to be indicative of aberrant processes that would most likley affected axonal fibers number, density and/or myelination as opposed to processes that would affect the spatial organization of fiber tracts. In addition to providing further evidence for a neurodevelopmental origin for schizophrenia white matter pathology, this also demonstrates that the utilization of novel tools can provide an avenue for the generation of new biologic hypotheses for schizophrenia.

Summary. In summary, dMRI has proven to be an extremely powerful tool in identifying white matter abnormalities in patients with schizophrenia.

Differences in white matter axonal connections are reported at all stages of the disorder, from onset to chronicity, as well as in individuals who are at increased risk for developing the disorder. Recent advances in dMRI processing and analysis including novel methods for data aggregation, have allowed for analysis of large, multisite datasets and a greater understanding of the timing of white matter pathology. In addition, the development of novel, biologically sensitive diffusion measures have shed light on the possible biologic nature of those abnormalities. White matter tissue pathology (most likely myelin abnormalities) appears to predate schizophrenia onset and might be a good biomarker for conversion to psychosis in clinical high-risk individuals. White matter tissue pathology also seems to follow that of gray matter, and progress over time, but unlike gray matter, chronic medication does not seem to negatively affect white matter health. In addition, it is suggested from some findings in the literature that the onset of psychosis may be characterized by increased extracellular water, which, in turn, might be linked to possible neuroinflammatory pathways. Finally, findings from familial studies seem to suggest that there might be a factor of white matter resilience in healthy offspring or siblings of schizophrenia patients.

FUTURE DIRECTIONS FOR STRUCTURAL BRAIN IMAGING IN SCHIZOPHRENIA

As noted in the information presented in this chapter, there have been incredible advances gleaned from studies of structural brain imaging in schizophrenia. Since its inception, neuroimaging has proven to be a powerful way to establish schizophrenia more clearly as a “brain disorder,” as well as to interrogate, *in vivo*, both the biologic nature and the trajectory of the illness. However, despite a large number of structural imaging studies, the field has yet to achieve the goal of producing clinically relevant imaging-based “biomarkers of schizophrenia.” This goal is motivated by the fact that within practically all other fields of medicine, a series of diagnostic evaluations can be carried out upon entry into a hospital. Unfortunately, psychiatry still relies on observation or report of symptoms and patient illness history, which can vary significantly between and within individuals. Similarly, many structural imaging research studies continue to rely upon case-control comparisons, many of which can be underpowered and therefore lack generalizability to the entire population. Despite the enormous contributions toward a greater understanding of schizophrenia,

the field of structural imaging has yet to provide a feature or set of features that will yield sufficient diagnostic information that is clinically relevant to a given individual. Thus, while structural imaging tools continue to be valuable in research studies, reliable biomarkers remain elusive, and the field needs to change both conceptually and methodologically with respect to how we approach the study of schizophrenia. Below we present some recommendations for future approaches that may bring the field closer to this overarching goal.

Biologic Classifications for Schizophrenia

It is becoming more widely accepted that the clinically defined disorder known as “schizophrenia” may potentially be an assemblage of subtle biologic changes that present along an illness spectrum. As a result, the acknowledgment of a model in which psychiatric illnesses are characterized as a set of potentially overlapping biologic pathologies instead of discrete entities is shaping pathways forward in the field. Initiatives such as the National Institute of Mental Health’s Research Domain Criteria (RDoC) framework identified the need for more biologically based approaches to the study of psychiatric illnesses. Imaging techniques are uniquely suited to address this need as they are presently the only avenue to investigate human brain structure and function *in vivo.* Along these same lines, there has already been a considerable effort to define, based on imaging and electrophysiologic profiles, the so-called “biotypes” along the psychosis spectrum (e.g., see the work of Clementz et al., 2016). Such efforts should benefit further from including morphometric as well as more biologically sensitive neuroimaging measures discussed in the previous sections of this chapter.

Big Data Meets Precision Medicine

One of the biggest limitations of the clinical neuroimaging field is the recruitment of psychotic populations for research studies. Small samples and the resultant limited power in statistical analyses are recurrent issues in neuroimaging that likely contribute to replicability problems within the field. To overcome such limitations, and as showcased in this chapter, many groups have chosen to employ either meta-analytic or harmonization methods to increase sample size in order to ascertain a greater understanding of the general trends within a specific area of research. These approaches are aiding “big data” analytical approaches, which have garnered significant popularity within the clinical imaging field in the last

decade. In fact, many large-scale databases have already been created, several of which are freely available to the public (e.g., fBIRN, NAPLS, PRONIA, Australian Schizophrenia Research Bank, BSNIP, Human Connectome Project). The compilation of these resources, along with the advancement of image analysis methodologies, has also made it possible for research teams around the world to employ another important emergent group of analysis tools: machine learning.

Due to the current shift in focus toward the identification of biologic constructs underlying psychopathologic features of psychotic illnesses, many researchers have started to embrace a bottom-up, data-driven approach to the stratification and/or classification of patients with psychiatric disorders. In these paradigms, subgroups of individuals can be created based on objective and measurable phenotypes derived from an assortment of modalities, whether it be neuroimaging metrics, physiologic assays, or genetic information. Two classes of approaches exist: (1) supervised methods (e.g., support vector machines) and (2) unsupervised methods (e.g., principal component analysis). Supervised methods are best used for predictions, whereas unsupervised methods are commonly used for clustering, where groups are defined without any *a priori* knowledge (as in the context of the “biotypes” example discussed earlier). With the increased availability of large data repositories, research teams can begin to apply these approaches to search for viable, replicable biomarkers of disease risk, onset, and outcome.

The complementary approach to big data is precision medicine. Here, individual patient information such as illness history, family history, medication history, trauma exposure, genetics, and nutrition, are incorporated into a framework that allows for more detailed and patient-specific questions. The main difference of this approach, compared to a big data approach, is that the individual nature of the illness is recognized, as opposed to an individual serving as a single data point in a larger analysis. Precision medicine also encourages the development of small, well-designed, hypothesis-driven, and, most importantly, patient-centered studies. When successful, many of these studies can have a significantly higher impact on the life of a patient and are much more easily transferred to a clinical setting. The major limitation of precision medicine approaches is the limited generalizability to larger populations of individuals with similar diagnoses.

Interestingly, despite appearing to represent two ends of a methodologic spectrum, “big data” and precision medicine approaches have been shown

to work synergistically. In fact, for many machine learning approaches, a model can be trained on a set of data and then subsequently tested or challenged with the introduction of a new individual's data. These types of approaches are best used in classification paradigms for individuals who may be appropriate for specific types of treatment or for patient stratification. With the imaging community having greater access to larger repositories of high-dimensional data (both imaging and nonimaging), it is becoming possible to develop new hypotheses from the smaller groups of patients, which can then be tested in a larger, more representative samples for that given clinical population, and vice versa.

Studying Schizophrenia as a Lifespan Disorder

Schizophrenia is a chronic and debilitating life-long illness with likely neurodevelopmental origins. As such, it is important to recognize that it is a disorder with pathologies that evolve over time. In order to appropriately use the power of neuroimaging to study the structural changes that are linked to schizophrenia pathophysiology, there need to be concerted and continuous efforts to design effective, well-powered, longitudinal imaging studies. Multimodal acquisitions, such as the collection of both functional and structural imaging data, along with other important nonimaging markers like electrophysiology, blood, genetics, and behavioral inventories, will be critical. Ensuring that these collections occur at multiple points in a patient's illness course (e.g., before and after the onset of illness, before and after initiation or alteration of medication, during periods of high symptom burden vs. low symptom burden) will provide key steps forward in understanding the dynamic interplay that likely takes place between several biologic systems in the brain and body and how they contribute to the structural alterations observed in schizophrenia.

12.8 Functional Brain Imaging in Schizophrenia

Raquel E. Gur, M.D., Ph.D., and Ruben C. Gur, Ph.D.

Functional neuroimaging has become a major translational tool for advancing the understanding of the neurobiology of schizophrenia. Neuroimaging affords dissecting complex mental processes disrupted in schizophrenia to probe the nature and extent of aberrant activity in the underlying brain circuitry. The functional imaging methodology can thus help incorporate cognitive and affective neuroscience paradigms in efforts to understand brain regulation of behavior. The challenge is to harness the power of functional neuroimaging to clarify the neuropsychiatric manifestations of schizophrenia, integrating this knowledge with advances in genomics. Functional neuroimaging, applied in combination with pharmacologic probes, can augment the bridge between basic and clinical neuroscience. Such advances are helping elucidate mechanisms underlying schizophrenia with implications for treatment.

In the years since the previous edition of this textbook, the literature on functional neuroimaging in schizophrenia has continued to grow, especially in the application of functional magnetic resonance imaging (fMRI) methods applied for activation and for examining resting-state connectivity. This chapter will highlight fMRI applications in schizophrenia and clinical risk populations, summarizing main areas of progress, common issues, and potential future directions.

MAGNETIC RESONANCE FUNCTIONAL IMAGING METHODS

The introduction of fMRI was an exciting development in functional imaging research. Functional MRI methods offer multiple advantages over positron emission tomography (PET) for imaging brain function, including higher spatial resolution, higher temporal resolution, noninvasiveness,

lack of ionizing radiation, direct correlation with anatomical imaging, greater repeatability, and economy. Disadvantages of fMRI techniques include the presence of loud background noise generated by the gradients, difficulties in presenting stimuli and performing tasks in the magnet bore, claustrophobia, low signal-to-noise ratios for most methods, and lack of quantitation in physiologic units for most methods. Many of these disadvantages can be overcome through the use of specialized equipment compatible with the MRI environment (Fig. 12.8–1). Considering the costs versus benefits and availability of fMRI, most PET studies in schizophrenia now examine receptor function, whereas brain-behavior research is conducted with fMRI. The most commonly applied methods are blood oxygenation level-dependent (BOLD) and arterial spin–labeled (ASL) imaging of cerebral blood flow rates in physiologic units (mL/100 g/min).

FIGURE 12.8–1. A schematic functional magnetic resonance image setup. fORP, fiber-optic response pad.

Blood Oxygenation Level–Dependent Imaging

The technique relies on the magnetic susceptibility effects of deoxyhemoglobin, which cause regional signal decreases in imaging sequences that are sensitive to susceptibility (e.g., echoplanar or routine gradient echo sequences). With regional brain activation studies, a net

increase in signal intensity is observed in regions activated by the task. The increase in image intensity corresponds to a local decrease in deoxyhemoglobin. This effect is attributed to a greater increase in regional blood flow than in regional oxygen consumption, as indicated by PET measurements of blood flow and oxygen consumption associated with brain activation. A variety of pulse sequences can be used to obtain BOLD measures. Many simple activation paradigms have been tested, and activation has been observed with both fast and slow imaging. A typical response is a 1% to 25% change in regional image intensity that develops over 3 to 8 seconds following task initiation. The susceptibility effects of deoxyhemoglobin are field dependent. Thus, a scanner with 1.5 T field strength would typically record signal changes with functional activation of about 0.25% to 5%, while at 3 T and 7 T, scanning changes even higher than 25% have been observed. The main advantage of novel ultrafast imaging, especially using multiband parallel acquisition, is that the time course of signal change can be observed, and multislice imaging can be carried out in a reasonable time period.

FIGURE 12.8–2. Block analysis results. **A:** Group analysis (n = 17) showing average brain activation for all target emotions and target emotion-sensitive activation in the inferior frontal gyrus. **B:** Mean percentage signal change for inferior frontal gyrus by target emotion. Images are displayed over a Talairach-normalized template in radiological convention (left hemisphere to viewer's right). (Reprinted from Loughead J, Gur RC, Elliott M, Gur RE. Neural circuitry for accurate identification of facial emotions. *Brain Res.* 2008;1194:37–44. Copyright © 2007, with permission from Elsevier. doi: 10.1016/j.brainres.2007.10.105.)

BOLD studies have initially relied primarily on blocked conditions where signal change was integrated over periods ranging from 20 seconds to minutes. In such designs, a sequence of stimuli is presented, and either the type of stimulus changes in blocks or the task may change. The signal is contrasted between different blocks. For example, in a study investigating neural substrates for identifying facial expressions, a sequence of faces is presented, separated by a control stimulus. The face stimuli repeat throughout the study, but the task changes, creating four blocks or conditions: (1) Push button for happy; (2) Push button for sad; (3) Push button for anger; (4) Push button for fear. Comparing signals integrated across face trials to that of the control stimulus will identify brain regions recruited for facial affect identification. Contrasting each

condition with the baseline and with each other would highlight activation specific for each block of a specific target emotion (Fig. 12.8–2).

Event-Related fMRI

This method is a variant of the BOLD technology where, rather than aggregating the tasks into blocks, an estimate of the hemodynamic response is obtained by interspersing the appearance of stimuli and contrasting the signal following stimulus presentation to that following a control stimulus. These contrasts provide information on brain regions whose activation is time-locked to the appearance of the specific stimulus class. For example, if the task is to push the button for a specific emotion such as fear, the question may be asked: Which brain regions activate every time a fearful face appears, compared to when the face is neutral? This is a different question from that posed by the blocked analysis. The condition is the same, searching for fearful expressions that are intermixed with other emotions and with neutral faces. However, the event-related analysis will identify those brain regions within the facial affect–processing network that is specifically engaged when a fearful face appears rather than a neutral face. Furthermore, an event-related analysis can identify brain regions whose activation is associated with correct responses and separate them from brain regions associated with errors. This feature permits a closer link between brain activation with performance. An fMRI study can be done with blocked and event-related paradigms, or, by carefully spacing stimulus classes, hybrid designs can be applied where blocked analysis can identify brain regions engaged in specific tasks, and event-related analysis can be used to establish time-locked components of the hemodynamic response related to specific stimulus classes. For example, in the facial affect identification task, the block design revealed a circuitry engaged in this task that included sensory, limbic, and evaluative components. However, the spacing of the presentation of stimuli within blocks enabled contrasting hemodynamic changes associated with the appearance of fearful faces to those associated with neutral faces, and this contrast showed greater limbic activation associated with the correct identification of fearful and angry faces in healthy people (Fig. 12.8–3).

FIGURE 12.8–3. Event-related results. **A:** Emotion (happy, sad, anger, fear), accuracy (correct vs. incorrect), and interaction effects for whole brain repeated measure ANOVA highlighting mesial temporal lobe regions. **B:** Mean percentage signal change for regions showing main or interaction effects (error bars represent S.E.M. [standard error of the mean]). Images are displayed over a Talairach-normalized template in radiologic convention (left hemisphere to viewer's right), masked by block activation and thresholded P = .05. (Reprinted from Brain Res 1194. Loughead J, Gur RC, Elliott M, Gur RE. Neural circuitry for accurate identification of facial emotions, 37–44. Copyright © 2007, with permission from Elsevier. doi: 10.1016/j.brainres.2007.10.105.)

Arterial Spin Labeling

This technique provides a quantitative perfusion imaging method that uses magnetization tagging of endogenous arterial water to determine perfusion of brain tissue by comparing images obtained with and without labeling of the arterial supply. The method is analogous to steady-state techniques used in PET since the regional signal intensity is dependent on the arterial blood flow, which delivers labeled spins, and the T1 relaxation rate, which causes the labeling to decay. This technique has

the important advantage of providing quantitative cerebral blood flow parameters in physiologic units (milliliter per 100 g of tissue per minute). Furthermore, perfusion is measured in brain parenchyma directly and is thus better localized than measurements obtained using an intravascular tracer, which is most sensitive to venous outflow effects. There may also be less motion sensitivity than BOLD (Fig. 12.8–4).

Analytic Approaches

The application of analytic methods in fMRI has been increasingly standardized and includes motion correction, high-pass filtering, spatial smoothing, and scaling. The resulting translational motion parameters should be examined to ensure that there is no excessive motion. Non-brain areas should be removed and the functional images coregistered to the structural volume. This image is then usually transformed into a standard anatomical space, and transformation parameters are later applied to statistical images after analysis is carried out in the subject's space. A more advanced spatial normalization procedure for fMRI data involves the application of the high-dimensional deformations determined from the anatomic images to the coregistered fMRI images. This provides higher registration accuracy across subjects and, therefore, potentially improves sensitivity in activation detection. This approach also allows correlating brain volumes with fMRI activity voxel-wise, as structural and functional images follow the same transformation to the standard space.

Subject-Level Time Series. This statistical analysis is carried out where condition events are modeled with a canonical hemodynamic response function and, when appropriate, its temporal derivative. Whole brain statistical analysis is completed for each individual in subject space, and resulting contrast maps, obtained through linear contrasts of event types, are spatially normalized.

Group-Level Random Effects. This analysis is performed, including within- and between-group comparisons. Significance thresholds are based on spatial extent (k) and peak height (u). Often, a height threshold corresponding to an uncorrected P value of .005 is used, requiring a minimum cluster $P \leq .05$. This results in a corrected probability of $P < .05$, based on the theory of Gaussian fields.

FIGURE 12.8–4. Map of quantitative blood flow obtained in a healthy individual with arterial spin labeling magnetic resonance imaging. (See eBook for color image.)

In addition to the whole brain analysis, a region-of-interest analysis can be performed to obtain the percentage signal change values for specific nodes in a hypothesized network. Predictor variables are a set of lagged indicators of stimulus type associated with each scan. Convolution with a priori hemodynamic response functions is not required. Resulting regression coefficients (β parameters) represent unbiased estimators of incremental hemodynamic responses at each time point, beginning at stimulus presentation and continuing for 16 seconds poststimulus. These data can be extracted for offline analysis.

Pattern Analysis and Classification. Voxel-by-voxel or region-of-interest-by-region-of-interest analysis of data is not able to capture correlations among structural and functional measurements at different brain locations. Therefore, spatially distributed and complex structural and

functional patterns are better captured with high-dimensional pattern analysis and classification methods.

Connectivity Analysis. Although most fMRI studies have focused on examining brain regions activated by specific tasks, increased attention is being drawn to examining intercorrelations among brain regions. Such "connectivity analyses" can help identify the strength of association among nodes in the network and to establish in clinical populations whether deficits relate to reduced connectivity. Defined as the temporal correlations in neural activity among brain regions, functional connectivity provides a conceptual and methodologic framework for identifying spatially distributed patterns of brain activity and for quantifying inter-regional interactions. Several specific approaches have been implemented, and their relative merits are being investigated. The time series correlation method examines inter-regional correlations within individual subjects over the time course of an experiment and has been effectively applied to measure functional connectivity at a resting "default mode" state as well as across a wide range of cognitive and physiologic states.

More recently, graph theory has been applied to the analysis of functional connectivity. This approach considers the brain as consisting of nodes ("vertices") that communicate with each other, with an index of the strength of connectivity represented by edges. The values determining the significance of edges could be any index of relatedness, such as coordinated fluctuations in activity measured in changes in the BOLD signal time series. Graph theory permits the identification of networks and quantitation of the predominance and strength of within- and between-networks communications. For example, each node may show fluctuations that are synchronous not only with adjacent nodes but also with nodes that are in a homotopic region or nodes that belong to a different region entirely. Graph theory can calculate parameters of "community structure," such as modularity and cohesiveness. Graph theory has helped identify networks such as the default mode, salience, and cognitive control.

The methodologic developments summarized previously for measuring regional brain activation have been embraced by investigators because of the diverse parameters of brain structure and function they offer. Furthermore, MR scanning facilities are available in academic settings

around the world. Consequently, numerous studies have applied neurobehavioral paradigms in fMRI studies aimed at dissecting complex behavior in schizophrenia. This has resulted in a large body of literature, with converging results that are contributing potential biomarkers that can advance the search for dimensional underpinnings of schizophrenia along the continuum of psychosis.

FUNCTIONAL MAGNETIC RESONANCE IMAGING IN SCHIZOPHRENIA

The literature on fMRI studies in schizophrenia has continued to grow with efforts to examine samples early in the course of psychosis and across psychotic disorders. Such efforts have capitalized on functional brain abnormalities identified in schizophrenia, including abnormal activity in response to motor tasks, working memory, attention, word fluency, emotion processing, and medication effects. These functional neuroimaging studies have suggested links between deficits in performance to abnormalities in activation patterns. Before summarizing such findings, it is important to outline some of the special challenges confronting the application of functional neuroimaging in schizophrenia. Although these challenges are not unique to functional imaging studies, they should be addressed systematically as the field matures.

Special Considerations in fMRI Applications in Schizophrenia

In addition to methodologic considerations that are common to all fMRI studies, several factors merit further consideration in the study of schizophrenia. These are likely to affect data interpretation and generalizability and relate broadly to several categories.

Clinical Variables

SAMPLE CHARACTERISTICS. The heterogeneity of schizophrenia can influence fMRI results. Samples vary in age, gender, and clinical status. Regarding sample size, most fMRI studies include relatively small samples that are not sufficiently powered to address pertinent clinical questions. Data on healthy people in fMRI studies are often obtained from university undergraduates, and small samples have sufficient power to detect task effects. However, in the study of schizophrenia, such samples

could be marginally adequate to demonstrate differences between patients and healthy comparison participants but not informative for correlation with important clinical variables or for comparison with other clinical samples. The heterogeneity of schizophrenia may preclude adequate representation of some diagnostic subcategories, which can be further confounded by demographic characteristics. For example, patients are likely to be older than college undergraduates unless they are studied early in the course of the illness or have an early age of onset. Age and gender are important moderating variables in examining the study of brain and behavior, and they are even more so in schizophrenia. The age of onset is earlier in men, and premorbid functioning and outcome are worse. These considerations entail the recruitment of a comparison sample that is sociodemographically balanced to that of patients, and there must be a sufficiently large sample of patients to examine the possible effects of age and chronicity of illness on the measures obtained.

MEDICATIONS. Another relevant potential confound that needs consideration when applying functional neuroimaging in schizophrenia is the medication status of the participants. Unless studied at first presentation, when neuroleptic-naïve, patients are likely to be treated with psychoactive medications that affect brain function, and it is unclear how these effects will be reflected in BOLD signal changes. Short of controlled clinical trials, there are no simple and ethically acceptable ways to study or control potential medication effects. It is important to document medication status and examine, to the extent possible, whether they can account for the differences observed between patients and controls.

SYMPTOM SEVERITY. The clinical status of patients with schizophrenia is a factor that, in addition to influencing the feasibility of participation, may also compound the complexity of data interpretation. This factor is especially relevant when attempting to link imaging data to clinical measures of symptomatology. For example, men are likely to have more prominent negative symptoms than women, and, therefore, samples need to be adequately powered to clarify this potential confound. Obviously, the exclusion of acutely ill patients may limit the generalizability of data to patients who are clinically stable or who have more negative symptoms.

PERFORMANCE. A critical yet often overlooked issue in understanding the results of functional neuroimaging studies that involve neurobehavioral probes is how to deal with performance. The typical goal of tasks in functional imaging studies with healthy people is to activate a specific neural circuitry, and performance is usually required to be perfect or is used as a “nuisance” variable. When the aim is to identify a set of regions that get uniquely activated for a specific behavioral process or domain, making the task difficult will introduce individual differences that can diminish experimental effects and may engage extraneous regions related to frustration, anxiety, or motivation. This methodologic requirement for tasks that do not produce variable performance becomes problematic in studies in which the goal is to examine neural substrates for behavioral deficits. Thus, when comparing patients with schizophrenia to healthy controls on tasks where patients are putatively impaired, should it still be insisted that performance is perfect for patients? Such methodologic considerations have compelled some investigators to seek ways to equate difficulty levels when contrasting activation between patients and controls by making an easier version of the task for patients through titrating performance. This practice, however, may result in comparing activation maps between groups who received different tasks. Other approaches include changing the level of prescanning training to maximize patients’ performance. However, such practices could result in group differences due to habituation.

Arguably, different paradigms are appropriate at different stages of the research. To establish whether the neural system under investigation engages the same regions in patients with schizophrenia as in controls, it would make sense, even when investigating a domain in which impairment is expected in patients, to make the task so easy that patients and controls will perform near perfection. Failure of patients to activate a specific region under these conditions will indicate that they do not recruit the requisite circuitry for that domain, which may explain why they fail when the going gets tough. However, in the next phase of the research, it would be important to make the task harder so that individual differences in activation could be correlated with individual differences in performance both in patients and in control groups.

FIGURE 12.8–5. Regions activated for emotion identification task relative to baseline (block analysis) in controls (*upper row*), patients (*middle row*), and the controls–patients contrast (*bottom row*). No patients–controls contrast survived correction. Significance thresholds are based on spatial extent using a height of $z \geq 3.1$ and a cluster probability of $P \leq .05$. Images are displayed over a Talairach-normalized template in radiological convention (left hemisphere to viewer's right). The *z*-level coordinates are provided. AM, amygdala; IF (47), inferior frontal (Brodmann area 47); HI, hippocampus; IF (45), inferior frontal (Brodmann area 45); TH, thalamus. (Reproduced with permission from Gur RE, Loughead J, Kohler CG, et al. Limbic activation associated with misidentification of fearful faces and flat affect in schizophrenia. *Arch Gen Psychiatry*. 2007;64:1356–1366. Copyright © 2007 American Medical Association. All rights reserved. doi:10.1001/archpsyc.64.12.1356.)

Event-related paradigms can help address this issue to some extent because they enable the separation of correct from incorrect responses, thereby "leveling the playing field" with regard to performance. For example, on the emotion identification task described previously, a blocked analysis showed that patients with schizophrenia activated the same regions as controls but to a lesser degree (Fig. 12.8–5). An event-related analysis, however, showed a more dramatic difference when comparing activation time linked to correct and incorrect responses.

Activation was similar in patients and controls for correct responses. Yet, for threat-related expressions (angry and fearful faces), unlike controls in which greater limbic activation portended correct identification, in patients, greater activation in these regions was associated with incorrect responses (Fig. 12.8–6).

Major Findings in fMRI Studies in Schizophrenia

Cognition. Impaired cognition in schizophrenia has stimulated efforts to examine brain processes related to information processing cascades. Diffuse deficits have been documented, with relatively greater impairment in executive functions and in learning and memory. These deficits have been related to frontotemporal systems. Such impairments are core features of schizophrenia, important for elucidating underlying mechanisms, as buttressed by their prominence at initial illness presentation, limited amelioration with symptomatic relief, link to functional outcome, and utility as endophenotypes or biomarkers (quantitative intermediate phenotypic measures).

Neurobehavioral probes with functional imaging provide a powerful method for exploring the neural circuitry underlying such observed deficits. Abnormal activations in the ventromedial and superior temporal lobe, prefrontal cortices, and limbic structures were documented with memory and executive tasks. These complex processes could be compromised as downstream effects of sensory integration deficits.

Verbal learning deficits are well-established in schizophrenia. They are prominent at early clinical presentation, persist despite therapeutic intervention and amelioration of symptoms, and relate to functional outcomes. The relevance of learning and memory deficits in schizophrenia provides an impetus to integrate well-developed paradigms in cognitive neuroscience to advance the understanding of the neurobiology of these deficits.

FIGURE 12.8–6. Activation maps showing peak amygdala response for anger (**A**) and fear (**B**) conditions for the event-related analysis. Images are displayed over a Talairach-normalized template in radiologic convention and thresholded at $z \geq 3.1$, uncorrected (>25 continuous voxels). Outline shows extent of atlas-derived amygdala regions of interest (Wake Forest University pickatlas) used for percentage of signal change extraction. Inset (**C**) highlights "patients versus controls" incorrect responses superimposed on "controls versus patients" correct responses at $z \geq 1.64$, uncorrected. (Reproduced with permission from Gur RE, Loughead J, Kohler CG, et al. Limbic activation associated with misidentification of fearful faces and flat affect in schizophrenia. *Arch Gen Psychiatry*. 2007;64:1356–1366. Copyright © 2007 American Medical Association. All rights reserved. doi:10.1001/archpsyc.64.12.1356.)

The application of fMRI enables researchers to examine distinct memory processes such as encoding and retrieval. Studies in patients, compared to healthy participants, have consistently demonstrated that during the learning phase, there are frontotemporal abnormalities. Most studies on schizophrenia have reported decreased activation of the frontal cortex, especially the inferior prefrontal region. The data are less consistent with regard to the temporal lobe. Most studies have observed

decreased activation in patients' hippocampus and parahippocampal gyrus, but other studies have noted increased activation. As emphasized earlier, performance may be a contributing factor as the studies differ in task difficulty and their approach to performance variance.

Examining frontal lobe function, event-related fMRI studies have shown deficits in working memory and cognitive control in schizophrenia. Studies that focus on the temporal lobe in schizophrenia have progressed from language-processing tasks to the examination of the hippocampus and parahippocampal gyrus and probes evaluating long-term memory. Such reports noted that hippocampal dysfunction was often concomitant with aberrations in prefrontal function, suggesting that frontotemporal connectivity is disrupted in schizophrenia. As summarized previously, advances in image analysis methods enable researchers to measure the connectivity of distributed brain circuitry and test hypotheses implicating specific network models. Verbal episodic memory is differentially affected in schizophrenia, in part due to the use of inefficient organizational strategies. Indeed, providing a semantic organizational strategy during word encoding normalizes subsequent recognition accuracy in patients. This finding suggests that deficits in verbal memory may result in part from aberrant frontotemporal interactions, a hypothesis that fits well with the prevailing view of schizophrenia as a disorder of disturbed neural and psychological integration.

Supporting this hypothesis, functional neuroimaging studies in schizophrenia have revealed abnormalities in both frontal and temporal activities. Earlier PET studies showed that healthy people, when performing verbal tasks, activated prefrontal regions and deactivated the superior temporal gyrus. In contrast, patients with schizophrenia showed less superior temporal gyrus deactivation and a positive correlation between activity in the prefrontal and superior temporal gyrus regions. Further evidence of reciprocal changes in left frontal and left temporal regions was provided in fMRI studies of word fluency and in studies of word encoding and recognition.

Defined as the temporal correlations in neural activity among brain regions, functional connectivity provides a conceptual and methodologic framework for identifying spatially distributed patterns of brain activity and for quantifying inter-regional interactions. Several specific approaches have been implemented as outlined previously, and their relative merits have not been established. The time series correlation method examines

inter-regional correlations within individual subjects over the time course of an experiment and has been effectively applied to measure functional connectivity across a wide range of cognitive and physiologic states.

In a study examining within-subject correlations of frontal and temporal time series during verbal encoding, aberrant frontotemporal connectivity was noted in schizophrenia, confirming previous reports. The study also identified distinct alterations within the dorsal and ventral prefrontal cortex. Relative to healthy controls, patients with schizophrenia had reduced connectivity between the dorsolateral prefrontal cortex and temporal lobe areas, including the parahippocampus and superior temporal gyrus. Patients, however, showed *increased* connectivity between a region of the ventrolateral prefrontal cortex and these same temporal lobe regions. Higher temporal–dorsolateral prefrontal cortex connectivity during encoding was associated with better subsequent recognition accuracy in healthy participants but not patients. Temporal–ventrolateral prefrontal cortex connectivity was uncorrelated with recognition accuracy in either group. The results suggest that reduced temporal–dorsolateral prefrontal cortex connectivity in schizophrenia could underlie encoding deficits, and increased temporal–ventrolateral prefrontal cortex connectivity may represent an ineffective compensatory effort (Fig. 12.8–7).

Notwithstanding extensive literature applying fMRI in schizophrenia, data on early information processing are more limited. A visual stimulation study demonstrated normal activation of visual, motor, somatosensory, and supplementary motor regions to a flashing checkerboard paradigm with a motor response. However, abnormal activation was reported for more complex sensory conditions, especially when requiring integration. A block design study presented simultaneous visual and auditory stimuli to first-episode neuroleptic-naive patients. Reduced activation in the parietal lobes, right thalamus, and prefrontal cortex, implicated in the dorsal visual processing pathway, was observed in patients. Diminished activation in patients in prefrontal regions implicated in regulating inhibition was reported in a study of the inhibitory P300 for a no-go condition. A three-stimulus auditory oddball task showed diffuse cortical and subcortical hypofunction during target detection and novelty processing in schizophrenia. Individuals with prodromal symptoms demonstrated smaller differential activation in frontal regions between relevant and irrelevant stimuli. In a visual oddball study, patients and healthy participants showed activation patterns specific to targets and novels, and

activation of both neural systems was associated with faster performance. Specifically, reduced activation in regions involved in target and novelty processing in patients was accompanied by increased activation in circuits related to elaborated stimulus processing. For targets, abnormal activation was noted in regions related to ideational and visual association, and for novels, patients overactivated sensory and frontal areas related to visual–spatial processing and working memory (Fig. 12.8–8). Thus, the attenuated electrophysiologic response to targets seen in event-related potential studies may relate to insufficient top-down activation of target circuitry, while the attenuated-evoked response to novel distractors reflects overprocessing of bottom-up events. Notably, abnormal activation in patients was associated with more severe symptoms.

FIGURE 12.8–7. Group differences in left STG–DLPFC (superior temporal gyrus–dorsolateral prefrontal cortex) and STG–VLPFC (superior temporal gyrus–ventrolateral prefrontal cortex) connectivity (*left column*) and in left PHIP–DLPFC (parahippocampal gyrus–dorsolateral prefrontal cortex) and PHIP–VLPFC connectivity (*right column*). **A:** Left column, group-averaged STG time series correlation maps for control group (*left*) and schizophrenia group (*right*), from a representative coronal plane (y = 30). A region of DLPFC shows greater connectivity (measured as average Fisher's Z-transformed correlation coefficients) with STG in controls, while a region in VLPFC shows greater connectivity with STG in patients. **B:** Results of voxel-by-voxel t tests are overlaid on the two prefrontal regions of interests (ROIs) and a standard reference brain (Colin, MNI [Montréal Neurological Institute]), in the same coronal plane. The group differences seen within DLPFC and VLPFC are statistically significant. **A:** Right column, group-averaged PHIP time series correlation maps reveal a region within DLPFC, showing greater connectivity with PHIP in controls, while a region within VLPFC shows greater connectivity with PHIP in patients. **B:** Group differences seen within DLPFC and VLPFC are statistically significant. Emotion. Social cognition, the cognitive processes involved in the perception, interpretation, and processing of social information, is increasingly recognized as a core domain of deficit in schizophrenia. Neurobiologic models of social cognition have confirmed that the processing of social information requires complex and synergistic interactions between several neural regions, which encompass the basic perception of social stimuli and the later evaluation of these stimuli.

The increased interest in affective neuroscience has likewise generated several tasks that probe emotion processing and social cognition. Such tasks may have relevance to schizophrenia, perhaps especially for understanding the intransigence of negative symptoms and poor social

functioning. For example, functional imaging studies have demonstrated the role of limbic response in the identification of facial emotions in healthy people and diminished response in schizophrenia. As can be seen in the middle row of Figure 12.8–2, top-down (task-related) limbic activation is diminished in schizophrenia. However, patients showed abnormally increased limbic activation time-locked to the appearance of threat-related facial emotions of anger and fear. Furthermore, increased amygdala activation for fear was associated in patients both with failure to identify the emotion and with more severe flat affect (Fig. 12.8–9).

FIGURE 12.8–8. Examples of stimuli used in "oddball" studies of attentional processing (*top*) and contrast images of patients with schizophrenia and comparison subjects for target and novel stimuli. Greater activation in patients is depicted by the scale on the right, whereas greater activation in comparison subjects is shown by the scale on the left. Images are in radiological convention (left hemisphere to viewer's right). (See eBook for color image.) (Reprinted with permission from Gur RE, Turetsky BI, Loughead J, et al. Visual attention circuitry in schizophrenia investigated with oddball event-related functional magnetic resonance imaging. *Am J Psychiatry.* 2007;164(3):442–449. (Copyright © 2007). American Psychiatric Association. All Rights Reserved. doi: 10.1176/ajp.2007.164.3.442.)

Impaired emotional functioning is a prominent feature of schizophrenia. Although positive symptoms have traditionally attracted more attention and targeted treatment, negative symptoms, including flat affect, are increasingly recognized as more debilitating and resistant to intervention. Early studies reported impaired identification of facial affect in

schizophrenia, but there was limited information on its relationship to clinical features and cognition.

Although there is growing literature in healthy people elucidating the role of the amygdala in affect processing, fewer functional neuroimaging studies have examined this circuitry in schizophrenia. Consistently in fMRI and PET studies with emotionally valenced pictures, faces, and odors, patients showed diminished activation in limbic and paralimbic regions, especially the amygdala. Abnormal activation of related cortical regions has also been observed. Functional MRI studies with block design report a lack of amygdala activation for sad mood induction, also evident in unaffected siblings. Decreased activation and accuracy in identifying expressions of fear, anger, and disgust contrasted with responses to mild happiness, especially in nonparanoids. Presentation of fearful and neutral faces showed a disconnection between brain activity and arousal in paranoid patients, where increased arousal was associated with decreased amygdala/medial prefrontal activity. In a study using a block design alternating between emotion and age identification, patients showed decreased activation in the left amygdala and bilateral hippocampus for the emotion condition. In a study examining intensity judgment, patients had an *exaggerated* amygdala response: Positive faces induced right amygdala activation in both groups, while negative faces activated only the right amygdala in controls and bilaterally in patients. Picture categorization (pleasant, unpleasant, neutral) produced less activity in amygdaloid–hippocampal and cortical–basal ganglia-thalamic circuitry in patients.

FIGURE 12.8–9. Association between brain activity and clinical measures. **A:** Correlations between event-related activation for the four emotional expressions in activated regions and severity of clinical ratings for flat affect.

B: Scatterplot of the association between percentage of signal change for the appearance of fear expressions and severity of flat affect. MO, midoccipital; FG, fusiform gyrus; TH, thalamus; AM, amygdala; HI, hippocampus; IF, inferior frontal; MF, midfrontal. (Reproduced with permission from Gur RE, Loughead J, Kohler CG, et al. Limbic activation associated with misidentification of fearful faces and flat affect in schizophrenia. *Arch Gen Psychiatry.* 2007;64:1356–1366. Copyright © 2007 American Medical Association. The growing fMRI literature complements PET studies that also showed abnormal cerebral blood flow in patients engaged in emotion-processing tasks. Pictures with aversive and nonaversive content activated the right insula in patients and controls, but patients showed greater activation of the medial prefrontal cortex for aversive stimuli. Furthermore, controls activated bilateral amygdaloid and orbitofrontal regions for nonaversive pictures, but patients activated only the left orbitofrontal cortex. Activity in the left amygdala correlated with positive symptoms. In a subsequent study, emotionally salient pictures produced abnormal activation in patients' ventral striatum and amygdala and increased tonic activation of the amygdala. Notably, a greater abnormality was associated with less severe positive and negative symptoms. The amygdala did not activate in patients for unpleasant pictures during valence categorization. Areas of decreased cerebral blood flow included the prefrontal cortex and subcortical regions such as the thalamus and cerebellum.

These studies of emotion processing in schizophrenia vary in methodology and design. Nonetheless, there seems to be considerable convergence of evidence that patients show abnormal activation in the amygdala and associated regions. It also appears that the abnormalities are more pronounced for negatively valenced stimuli, although no further differentiation for specific emotions has been established. In most studies, patients' performance was carefully examined, and tasks were often constructed so as to minimize performance differences to avoid confounding physiologic measures. In all cases in which performance was evaluated, it did not explain the difference in activation patterns. However, reduced task-related (top-down) activation could reflect bottom-up interference from abnormally increased amygdala activation related to stimulus valence. Thus, if the task is to identify emotions, the sensitivity of the amygdala to specific stimuli may disrupt the cortical processes required for categorization and response. Increased activation associated with incorrect responding was also seen for faces expressing anger. Thus,

it appears that threat-related faces induce greater activation in patients in a way that interferes with the top-down process, thereby producing errors. Whenever this response differed between patients and controls, it indicated more error-associated activation for fear or anger in patients.

Bottom-up interference in cognitive functioning likely operates by disrupting the coordinated activation of regions required for its support. Although there is considerable work on conditions associated with task activation, recent efforts have been aimed at studying inter-regional connectivity. These studies have used structural equation modeling that permits the assessment of whether specific causal models linking activation of one region to another are not rejected by the data. To examine connectivity, it is useful to consider the pattern of correlations among activation parameters obtained from regions recruited for a specific task. These correlations would reflect the extent to which activation in one region is proportional to that in another. Controls have high-specific connectivity for activation to the top-down task and for bottom-up activation associated with correct responding. Patients, by contrast, show abnormally high connectivity associated with activation to threat-related stimuli, leading to incorrect responses. Thus, disrupted operation of a top-down process in schizophrenia could be linked to excessive connectivity for bottom-up amygdala activation related to stimulus valence. Such disruptive activation could not only reduce connectivity among regions participating in the top-down process but also trigger the recruitment of other regions, including cortical ones, that may further disrupt task-related processing. Therefore, abnormal amygdala activation will lead to dysfunctional activation in other regions involved in information processing and disrupt downstream processes involving complex behavior. This will manifest in cognitive deficits.

Ultimately, the importance of abnormal activation depends on whether it relates to disease variables. This question has received less attention, and results diverge. Studies show abnormally increased amygdala activation associated with more severe positive symptoms, both positive and negative symptoms, or less severe symptoms. It may be that the direction of such correlations depends on whether the abnormality is that of over- or underactivation and whether the activation potentiates symptoms or reflects a compensatory process. Although correlations between activation parameters and symptom severity are small or moderate, abnormally increased bottom-up amygdala activation for fearful

faces was correlated highly with increased severity of affective flattening. Determining such correlations could help guide efforts to ameliorate symptoms with knowledge of regions where activation change can be palliative.

A likely specific consequence of abnormal bottom-up activation of the amygdala is the disruption of memory processes. There is considerable evidence that the amygdala interacts closely with the hippocampus in the formation of episodic memory, not only when affective valence is prominent. This area needs further investigation.

The convergence of findings pointing to the amygdala and its connectivity as a likely source for the devastating effects of schizophrenia propels a search for factors that could modulate amygdala response. Fortunately, there is an expansion of rigorous studies with fMRI in healthy people that have attempted to identify such modulators in efforts to construct mechanistic models of affect regulation. Emerging findings from meta-analyses support the notion of a fear-specific response of the amygdala and partially support the laterality hypothesis with increased left amygdala activation across tasks. Potential contributions of modulating processes such as attention, habituation, arousal and anxiety, learning, and extinction have been examined. Overall, while the amygdala response to fearful expressions can be influenced by such factors, the response is quite robust and specific for fear and could be neither explained nor completely extinguished by such manipulations. There is evidence that fear-related stimuli are especially potent activators of the amygdala, although cognitive processing modulates stimulus effects. The amygdala's extensive connections with subcortical regions are likewise essential for its role in affect processing. It has been proposed that rapid visual input from a subcortical thalamic pathway provides an early alarm signal for threat detection, whereas slower input through a geniculostriate pathway enables a more detailed evaluation of environmental input. This slower pathway could explain why amygdala activation seems to habituate rapidly in passive viewing but shows no signs of habituation when the task involves top-down processing where affective valence is relevant.

Studies attempting to elucidate mechanisms underlying fear response have often used faces to link with animal evolutionary approaches. Affective information on the face was systematically manipulated by methods including spatial frequency, binocular suppression, chimeric

faces, masked fearful eye whites, and gaze direction. These methods have suggested that amygdala response can be potentiated or suppressed by such factors. For example, the amygdala response is stronger when information is presented in low rather than high-spatial frequency, and the effect is especially pronounced for fear in the upper part of the face, presumably the eye region. Notably, bilateral amygdala lesions specifically diminish a patient's ability to utilize fear-related information in the eye region and direct the patient to note that the eyes could temporarily reverse this deficit. This finding is encouraging in that rehabilitation could possibly ameliorate deficits.

Gaze direction is another modulator of amygdala response. In healthy people, directed fear and averted anger expressions produced greater amygdala responses than averted fear and directed anger. This effect was interpreted to suggest that the amygdala is especially sensitive to threat-related ambiguity. Since poor eye contact is a major feature of impaired social interactions in schizophrenia, gaze direction, and evaluation of the patient's ability to use information in the eye region seem the most appropriate target for the next phase of the investigation. Although scan path studies reported a restricted range of visual scanning in schizophrenia for happy, sad, and neutral faces, these studies have not indicated a difference between the eyes and the mouth regions. However, fear and anger stimuli have not been used. Because amygdala damage leads to avoidance of the eyes region in fearful faces, and the eyes region is important for distinguishing anger from fear, the difficulty of patients in identifying fear could be related to impairment in recognizing changes in the eyes region, thereby diminishing amygdala response to fear in the eyes relative to the mouth region. As with other bottom-up activation abnormalities, it is expected that the severity of these abnormalities is associated with poorer eye contact and affective flattening.

Pharmacology. The literature on the possible effects of antipsychotic agents on BOLD signal change is limited. Few studies have examined neuroleptic-naive patients, let alone in a repeated measures design. Furthermore, small samples and methodologically limited designs have precluded systematic examination of the possible effects of therapeutics. Nonetheless, the recognition that impaired cognition is a hallmark of schizophrenia and that fMRI enables researchers to examine the brain

systems underlying the aberrant functioning has extended studies of cognition to fMRI.

Examples of studies include a working memory evaluation with an n-back paradigm after patients switched from first-generation antipsychotics to second-generation agents. Increased dorsolateral prefrontal cortex and parietal cortex activity were reported in the patients with the new treatment. Similarly, normalization of brain activity was reported in patients treated with long-acting risperidone (Risperdal) compared to conventional depot medication while performing an n-back task. Normalization of prepulse inhibition, which is impaired in schizophrenia, was also noted in patients treated with olanzapine (Zyprexa) and risperidone compared to those on first-generation antipsychotics. Studies that examined motor control in relation to medications have also noted improved brain activity in patients treated with second-generation agents compared to first-generation antipsychotics.

The well-established literature on the heritability of endophenotypic brain behavior measures in unaffected family members of individuals with schizophrenia can provide a path to investigate the potential effect of psychoactive medications on brain function in unmedicated family members. For example, an abnormally strong alprazolam-induced reduction in amygdala and hippocampus activation during emotion identification was observed in first-degree family members relative to healthy controls, compared to an equal reduction in both groups for the emotion memory task. An aberrant response may be related to unmasking underlying amygdalar and GABAergic abnormalities. Such pharmacologic fMRI paradigms could prove useful for developing drugs targeting specific neural circuits in schizophrenia.

Given the limited number and scope of the available literature, there is no conclusive evidence yet, as double-blind studies are lacking, and most reports consist of cross-sectional design. Thus, it is difficult to conclude that the reported “normalizing” effects of the medications are indeed attributable to specific medication effects and are not part of clinical stabilization or practice effects. Furthermore, as no absolute measures of brain activity are provided with BOLD, the relative change needs to be interpreted with caution. Pharmacologic fMRI is a potentially powerful methodology when integrated with well-designed and informative pharmacologic designs.

Genetics. The genomic architecture of schizophrenia has been investigated in large samples that have relied on the clinical phenotype with more recent efforts, including endophenotypes. As detailed in other chapters, it has become increasingly clear that this heritable, heterogeneous disorder does not have shared genetic contributions of relatively few genes. On the contrary, as more research emerges there seems an ever-growing list of foci, each with a small effect, that is associated with the disorder.

The application of fMRI in genetic paradigms is more limited relative to structural MRI. Initial studies have examined genetic effects indirectly by comparing activation patterns in probands with schizophrenia, unaffected siblings, and healthy comparison subjects with no family history of schizophrenia. Such studies have demonstrated, for example, that there were abnormalities in siblings that were less severe than those seen in affected individuals. Such findings support the application of fMRI as a quantitative phenotypic marker of schizophrenia.

The availability of sequencing of the human genome offers unprecedented opportunities for direct evaluation of the effects of genetic variability on brain activity. Early work exploiting this potential has demonstrated such effects in healthy people by comparing activation patterns between genotypically characterized groups. Studies applying genetic strategies used functional polymorphisms to group individuals for comparisons. For example, a common Val108/158Met substitution in the gene for catechol-O-methyltransferase (COMT) leads to decreased activity of this enzyme in dopamine catabolism and has been linked to decreased prefrontal cortical activity. Studies, therefore, examined val/met polymorphism and prefrontal cortex activation. Individuals homozygous for the met allele had diminished prefrontal and hippocampal engagement while performing episodic memory encoding and retrieval compared to val/val subjects. Notably, however, a recent meta-analysis of fMRI working memory studies in people with schizophrenia and healthy controls did not find evidence for an impact of COMT Val158Met genotype on brain activation. Diverse analytic approaches and small sample sizes are likely to contribute to inconsistent findings.

Using a similar approach, a risk haplotype was examined in *GRM3,* a gene encoding a metabotropic glutamate receptor. The findings were of reduced neuronal function in the prefrontal cortex and impaired activation in the hippocampus during the performance of a verbal memory task. The

risk allele in the promoter region was associated with decreased activation of the prefrontal and temporal lobe cortex.

The incorporation of functional neuroimaging into genomic studies has the potential for constructing mechanistic models for the pathophysiology of schizophrenia but poses additional challenges. Since the expected effects of any single polymorphism are small, it is essential to pay close attention to experimental design in neuroimaging genomics. It is important to use well-characterized neurobehavioral probes to evaluate and control confounding variables such as age, gender, basal abilities, performance, and clinical status. In addition, neuroimaging genomic studies require large samples that can optimally be obtained by multisite studies. Such efforts introduce additional variability related to scanner characteristics and image acquisition. Nonetheless, the field is positioned to make new discoveries that will illuminate neural pathways to specific features of schizophrenia in ways that will lead to novel interventions.

Functional Neuroimaging in Clinical At-Risk Samples

The investigation of schizophrenia as a brain disorder began with studies that evaluated chronic patients, establishing neurocognitive deficits associated with abnormalities in parameters of brain structure and function. With the increased availability of noninvasive neuroimaging methodology, studies of younger patients became feasible, and this work indicated that brain abnormalities and neurocognitive deficits are already evident in first-episode individuals. This work has produced two shifts of emphasis in the study of psychosis that can advance the understanding of the underlying neurobiology. The first is a shift to study even earlier phases of psychosis–the clinical risk stage–the second is a shift from dichotomous symptom categorization to quantitative dimensional endophenotypes, which can be examined across psychosis. This development will benefit genomic investigations because such vulnerability indices are heritable brain and neurobehavioral parameters that are trait markers related to illness.

Functional MRI has been applied to individuals at risk for psychosis, commonly in small samples of people at genetic risk because of family history or help-seeking individuals with attenuated psychosis spectrum symptoms. Neurobehavioral probes applied were those that have shown differences between patients with schizophrenia and controls such as working memory using the n-back paradigm. Overall, psychosis risk

groups show decreased activation in the BOLD response in the dorsolateral and medial prefrontal regions. The pattern of activity is similar to that seen early in the course of schizophrenia, but less pronounced abnormalities are observed. Similar to data obtained from patients with schizophrenia, individuals at risk show *increased* amygdala activation for the identification of threat-related expressions (Fig. 12.8–10).

To evaluate activation changes with disease progression, longitudinal designs are necessary. Such designs have been applied in several fMRI studies. This small literature suggests that individuals who transition to psychosis differ from those who do not, with the latter group showing normalization of brain activity. Thus, the application of fMRI holds promise as a tool that may facilitate elucidating the brain circuitry dysfunction underlying the psychotic process.

Furthermore, prior fMRI studies of psychosis risk have typically examined only categorical effects, lacking adequate power to identify correlates of illness dimensions. Therefore, it remains unclear to what extent the reported abnormalities relate to positive psychotic symptoms that are used to select the samples versus negative symptoms or cognitive deficits that are likely also present.

Dysconnectivity of resting BOLD has been reported in several brain networks in adults with schizophrenia, including the default mode and the cingulo-opercular network. More recently, youth at risk for psychosis showed multifocal dysconnectivity, implicating the bilateral anterior cingulate, frontal pole, medial temporal lobe, opercular cortex, and right orbitofrontal cortex. These results were driven by hyperconnectivity among default mode regions and diminished connectivity among cingulo-opercular regions, as well as diminished coupling between frontal and default mode regions. Thus, functional dysconnectivity in psychosis spectrum youths corresponds to abnormalities reported in adults with established psychotic disorders.

Challenges for Functional Neuroimaging Research in Schizophrenia

Considerable advances with functional neuroimaging technologies have been made in efforts to understand the neurobiology of schizophrenia. fMRI has become the dominant method to examine brain systems because it provides noninvasive measures with good anatomic resolution and increasingly reliable quantitation. Abnormalities in schizophrenia have been documented at many levels of neurobehavioral and

neurophysiologic processing and in multiple neural systems. However, these diffuse abnormalities, which implicate neurodevelopmental aberrations, are not fully expressed as a disorder until after brain development and maturation are largely completed.

FIGURE 12.8–10. Aberrant activation in youth with psychosis spectrum symptoms. Top panel shows the working memory n-back task effect and bottom panel shows effects of emotion identification task. For top panel: **A:** The contrast evaluating the effect of working memory load (2-back greater than 0-back) robustly recruited executive function regions, including dorsal anterior cingulate and bilateral dorsolateral prefrontal cortex, with a qualitatively similar regional pattern in both the psychosis spectrum (PS) and typically developing (TD) groups. **B:** The PS group showed significantly reduced activation in these regions (significant clusters shown in light gray). R indicates right. For bottom panel: **A:** Facial emotion-processing activated amygdala and other regions implicated in emotion and face processing, with a qualitatively similar regional pattern in both the PS and TD groups. **B:** The PS group showed significantly greater activation in bilateral amygdala (significant clusters shown in black). R indicates right. (Reproduced with permission from Wolf DH, Satterthwaite TD, Calkins ME, et al. Functional neuroimaging abnormalities in youth with psychosis spectrum symptoms. *JAMA Psychiatry.* 2015;72(5):456–465. Copyright © 2015 American Medical Association. All rights reserved. doi:10.1001/jamapsychiatry.2014.3169.)

The recognition that the underlying pathologic processes of schizophrenia are present throughout the central nervous system (CNS) suggests that there may be some core defects in neurotransmission whereby the ability of neurons to respond to and process stimuli is curtailed. However, within the context of global abnormalities, some neural systems are differentially affected. Brain regions with greater vulnerability, such as the hippocampus, prefrontal cortex, and olfactory system, are dynamic and maintain a high degree of plasticity during brain maturation and thereafter. Thus, neuronal plasticity, evident in molecular, chemical, morphologic, and physiologic modifiability with neural activity, is abnormal in schizophrenia. This may ultimately be manifested in the array of complex features that characterize schizophrenia. However, functions mediated through other neural systems, where greater plasticity is not required, show subtle abnormalities, and motor abilities, sensation, and autonomic functions are relatively spared.

These challenges are further compounded by the absence of suitable animal models for the disorder as phenotypically defined, buttressing the need to identify endophenotypes that can be studied in both humans and animals. For example, sensorimotor gating and encoding can be characterized in animals and in humans, as can fear conditioning and affiliative behavior. The identification of such quantitative phenotypes in schizophrenia that have their counterparts in rodents enables researchers to investigate the genetic, molecular, biochemical, anatomic, and physiologic aspects of these behaviors in ways not possible in humans. Findings from studies in rodents will provide new information about these behaviors and elucidate the effects of genetic, pharmacologic, and behavioral manipulations, which can then be pursued in humans. This top-down–bottom-up interchange holds great promise for advancing the understanding of the pathophysiology of schizophrenia, where functional neuroimaging provides a bridge between the molecular and the system levels.

12.9 Molecular Brain Imaging in Schizophrenia

Dean F. Wong, M.D., Ph.D., Ganesh B. Chand, Ph.D., Gerhard Gründer, M.D., Jimmy E. Jakobsson, Ph.D., and Albert Gjedde, M.D., D.Sc.

Molecular brain imaging is the visualization of in vivo brain chemistry in humans and animals and has undergone remarkable growth since the first imaging of neuroreceptors in humans four decades ago. Molecular brain imaging uses radiologic techniques that present unique opportunities to study disease mechanisms and therapeutic options in people with schizophrenia (see Table 12.9–1 for a glossary of terms). Additionally, molecular brain imaging is a powerful tool for the documentation of animal models that simulate the symptoms and signs of schizophrenia as part of parallel studies of animals and humans. Furthermore, molecular brain imaging provides the means to determine the effects of therapeutic interventions on variables such as receptor occupancy in animal models, healthy adult human volunteers, and people with schizophrenia.

MOLECULAR BRAIN IMAGING AND THEORIES OF SCHIZOPHRENIA

Arvid Carlsson's *dopamine hypothesis of schizophrenia* focused on the hyperactivity of the subcortical dopamine system as the basis of the pathogenesis and pathophysiology of schizophrenia. The hypothesis is closely associated with the original recognition of the role of dopamine independent of its additional role as a precursor of norepinephrine some 50 years ago. The dopamine hypothesis originated from the finding that traditional neuroleptic drugs such as chlorpromazine (Thorazine) antagonize dopamine activity by blocking postsynaptic D_2-like dopamine receptors. Subsequent research into schizophrenia provided the basis of additional hypotheses, including the serotonin hypothesis of schizophrenia, substantiated by studies of the mechanisms of action of atypical second-generation antipsychotics and, more recently, the glutamate hypothesis of schizophrenia. Molecular imaging provided the means to test these hypotheses directly in living humans with schizophrenia. Consequently, the original dopamine hypothesis that schizophrenia results from excessive dopaminergic activity required expansion to reflect contributions from dysfunction of serotonergic, glutamatergic, and several other neurotransmitter systems.

The study of molecular imaging in schizophrenia has a historical root in the very basis of neuroreceptor imaging with positron emission tomography (PET) and single-photon emission computed tomography (SPECT). Indeed the first imaging study in 1983 of a living human brain used the antipsychotic drug spiperone (Spiroperidol), first labeled with ^{11}C from [^{11}C]iodomethane and later with fluorine-18 (^{18}F). This advance was followed by the isotopic drug [^{11}C]raclopride (no difference of chemical structure or pharmacology), also an antipsychotic as well as a D_2 and D_3 antagonist that had been studied in clinical trials of humans. Although neither antipsychotic remained in use clinically in the United States, the radiolabeled PET analogs both led the way to the study of D_2-like dopamine receptors and the entire field of investigation of neuroreceptors as an essential new subspecialty of neuroimaging with tremendous application in neuropsychiatry. Both radiotracers quickly were shown to be replaceable by labeled versions of common antipsychotics such as haloperidol (Haldol), which ultimately led to occupancy studies and therapeutic drug dose levels now being visualized in the human brain.

The initial dopamine studies raised the interest in the serotonin system which is now held to be important to some aspects of schizophrenia symptomatology and potentially to treatment. Indeed, starting with clozapine (Clozaril) and subsequent later-generation antipsychotics such as risperidone (Risperdal) and olanzapine (Zyprexa), many atypical antipsychotics have both serotonergic and dopaminergic receptor-binding properties. Hence, the development of molecular imaging of the serotonin sites was a natural progression.

More recently, a “glutamate hypothesis” of schizophrenia emerged, as an extension of the dopamine hypothesis. The prevailing theory involves a hypoglutamatergic state of frontal cortical regions in subjects with schizophrenia, leading to a hyperdopaminergic state of the striatum. The glutamate hypothesis helps explain the evidence of psychostimulant (e.g., amphetamine) induced dopamine release (DAR), although substantial evidence for or against it remains lacking. Similarly, the actions of *N*-methyl-D-aspartate (NMDA) antagonists such as ketamine (Ketalar) that affect a phencyclidine (PCP) site (an ion channel) open the possibility of measuring DAR changes in schizophrenia and are now actively pursued.

Thus, neuroreceptor imaging as a technical achievement of neuropsychopharmacology and radioisotope methodology both paralleled and benefitted from research into the pathophysiology and treatment of schizophrenia. Once it is possible to study the glutamate, dopamine, serotonin, and other important systems in the same individuals and similar cohorts, the combined practices of neuroreceptor imaging will continue to help to continue to push forward the frontiers of schizophrenia research.

Synergy has developed among, on one side, the molecular imaging by PET or SPECT of radioisotopes of drugs, as well as by magnetic resonance spectroscopy

(MRS), structural (sMRI), and functional magnetic resonance imaging (fMRI) and, on the other side, our current knowledge of schizophrenia, including its pathophysiology and treatment. The strength of MRS is the ability to quantify amino acids (such as γ-aminobutyric acid [GABA] and glutamate). These magnetic resonance approaches complement the information obtained by the PET and SPECT molecular imaging records of signals from neurotransmitter metabolism and transporter and receptor activity that is evident in the brain, albeit the latter at lower levels of resolution. It is important to consider the contribution of changes in brain structure (sMRI) in the interpretation of neurochemical and functional imaging data methods (fMRI). Thus, the PET, SPECT, and MR methods are unique sources of information applicable to the resolution of specific research questions relevant to the pathophysiology and potential treatment of psychiatric diseases and disorders.

Table 12.9–1.
Glossary of Terms, Abbreviations, and Definitions for Molecular Brain Imaging in Schizophrenia

Term	Abbreviation	Definition
α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid	AMPA	A glutamate agonist
α-methyl-para-tyrosine	AMPT	A pharmacologic agent to deplete presynaptic dopamine by inhibition of tyrosine hydroxylase
β-carbomethoxy-3-β-(4-iodophenyl)-tropane	β-CIT	An agent to bind to dopamine transporters (DATs) and serotonin transporters (SERTs)
Binding affinity	$1/K_D$	Tightness of the attachment between a neurotransmitter and its neuroreceptor
Binding potential	BP	An estimate of the density of the indicated receptors in specific brain regions estimated by the ratio of B_{max} to K_D
[^{11}C]-3-amino-4-[2-(dimethylaminomethylphenylthio)]benzonitrile	[^{11}C]DASB	A radiotracer to bind to serotonin transporters (SERTs)
Dopa-decarboxylase	DDC	The rate-limiting enzyme in the

		presynaptic metabolism of dopamine
Dopamine receptor	D_2/D_3 R	D_2/D_3 R represents the receptors labeled by benzamide PET radiotracers, e.g., [^{11}C]raclopride.
Dopamine release	DAR	The increment in intrasynaptic dopamine following physiologic stress or pharmacologic stimulation by a dopaminergic agent, e.g., amphetamine and methylphenidate
Dopamine transporter	DAT	The reuptake site for dopamine from the synapse into the presynaptic neuron to be packaged again for rerelease into the synapse
(+)-enantiomer of 1,2,3,4a,5,6-hexahydro-9-hydroxy-4-n-propyl- 4H-naphth[1,2-b][1,4]-oxazine	(+)-PHNO	A potent dopamine D_2/D_3 agonist
Equilibrium dissociation constant	K_D	The inverse of the affinity of radioligand binding

Functional magnetic resonance imaging	fMRI	A brain imaging method detecting functional changes using magnetic waves
γ-aminobutyric acid	GABA	An inhibitory neurotransmitter
[^{123}I]iodobenzamide	[^{123}I]IBZM	An iodinated benzamide
Lysergic acid diethylamide	LSD	A hallucinogen
Molecular imaging	MI	The use of molecular-based probes to visualize physiologic process
Magnetic resonance spectroscopy	MRS	The visualization of in vivo brain chemistry using magnetic waves
Maximal binding potential	B_{max}	The theoretical density of the indicated neuroreceptor in portions of the brain
N-methyl-D-aspartic acid	NMDA	An agonist of the NMDA glutamate receptor
3-*N*-methylspiperone	NMSP	The methylated derivative of spiperone, a potent agent to bind to dopamine $D_2/D_3/D_4$ and

		serotonin (5-HT_{2A}) receptors
Positron emission tomography	PET	A technique for the visualization of positrons in an organ after the administration of a radioactive compound
3-quinuclidinyl benzilate	QNB	A potent antagonist of muscarinic receptors
Serotonin	5-HT_{2A}	An excitatory neurotransmitter
Serotonin receptor	5-HT_{2A} R	Molecules on the postsynaptic site to activate the neuron after being stimulated by serotonin
Serotonin transporter	SERT	The reuptake site for serotonin from the synapse into the presynaptic neuron to be packaged again for rerelease into the synapse
Single photon emission computed tomography	SPECT	A technique for visualization of single photons in an organ after the administration of a radioactive compound
2-deoxy-2-[^{18}F]fluoro-D-glucose	[^{18}F]FDG	Radioactive sugar

$H_2[^{15}O]$	$H_2[^{15}O]$	Radioactive water

Molecular Imaging of Cerebral Blood Flow and Cerebral Metabolism

Prior to the first neuroimaging receptor studies in schizophrenia in the mid-1980s, decades of imaging from the late 1940s involved cerebral blood flow measurements with 15% nitrous oxide, krypton ([^{85}Kr]Kr), xenon ([^{133}Xe]Xe), or radioactive water ([^{15}O]H_2O), and from the late 1970s measurements of regional cerebral glucose metabolism using 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) PET. The PET studies with FDG suggested the presence of hypofrontality in patients with schizophrenia, and PET with ([^{15}O]H_2O), demonstrated reduced blood flow to the frontal cortex, anterior cingulate, cerebellum, and thalamus in the left hemisphere, with possible compensatory blood flow increases to the right hemisphere. Nonetheless, the findings were difficult to relate to brain neurochemistry, a correlation that is now possible with molecular imaging studies.

The imaging of receptors began with tracers derived from drugs primarily used as antipsychotics and now extends to other neurotransmitter systems as well as to pre- and intrasynaptic binding sites. The methods of molecular imaging (see Section 1.17 on radiotracer imaging with PET and SPECT) revolutionized the field of central nervous system (CNS) neuroimaging by adopting a common methodology applied to neuropsychiatric disorders in general and, more recently, to drug development. While the initial imaging research primarily focused on schizophrenia, it also led the way to the study of common neuroreceptor systems in other disorders and organs (Table 12.9–2).

Molecular Imaging of D_2-Like Receptors

Historical advances in both molecular imaging and schizophrenia research extend beyond investigations of postmortem autoradiography and tissue samples to include the in vivo imaging of radiolabeled drugs such as [^{11}C]chlorpromazine. The first successful in vivo molecular imaging, a translation of in vitro neurochemistry, began with the imaging of [^{11}C]3-*N*-methylspiperone (NMSP), a methylated derivative of spiperone, one of the highest affinity antipsychotics tested in clinical trials in the 1970s. The methylation of spiperone provided the technical tool applicable to the imaging of D_2-like dopamine receptors with the object of quantifying the density of dopamine receptors in the basal ganglia, as well as serotonin (5-HT_{2A}) receptors in the cortex. Now, more specific D_2 and D_3 ligands exist, such as [^{11}C]raclopride and [^{18}F]fallypride.

Table 12.9–2.
Abbreviated and Chemical Names of Available Nuclear Neuroimaging Radiotracers and the Indicated Neurotransmitter Systems

Target	Abbreviated Name	Chemical Name
Acetylcholinesterase (AChE) activity	[^{11}C]MP4A	*N*-[^{11}C]methylpiperidin-4-yl acetate
Cannabinoid CB_1 receptors	[^{3}H]MePPEP	[^{3}H](3*R*,5*R*)-5-(3-methoxy-phenyl)-3-((*R*)-1-phenyl-ethylamino)-1-(4-trifluoromethyl-phenyl)-pyrrolidin-2-one
Cannabinoid CB_1 receptors	[^{11}C]OMAR	1-(2,4-dichlorophenyl)-4-cyano-[^{11}C]-5-(4methoxyphenyl)-*N*-(piperidin-1-yl)-1*H*-pyrazole-3-carboxamide
Cannabinoid CB_1 receptors	[^{18}F]MK-9470	*N*-[2-(3-cyano-phenyl)-3-(4-(2-[^{18}F]-fluoroethoxy)phenyl)-1-methylpropyl]-2-(5-methyl-2-pyridyloxy)-2-methylproponamide
Dopamine synthesis and storage	6-[^{18}F]DOPA	6-[^{18}F]dihydroxyphenylalanine
Dopamine D_1 receptors	(+)-[^{11}C]NNC112	(+)-8-chloro-5-(7-benzofuranyl)-7-hydroxy-3-[^{11}C]methy1-2,3,4,5-tetrahydro-1H-3-benzazepine
Dopamine D_1 receptors	[^{11}C]SCH23390	(*R*)-(+)-8-chloro-2,3,4,5-tetrahydro-3-[^{11}C]methyl-5-phenyl-1*H*-3-benzazepin-7-ol
Dopamine D_2 receptors	[^{11}C]RAC	[^{11}C]raclopride
Dopamine D_2 receptors	[^{18}F]NMB	[^{18}F](*N*-methyl)benperidol
Dopamine D_2 receptors	[^{123}I]IBZM	(*S*)-*N*-[(1-ethyl 2-pyrrolidinyl)] methyl-2-hydroxy-3-[^{123}I]iodo-6-methoxybenzamide
Extrastriatal dopamine D_2 receptors	[^{11}C]FLB 457	(*S*)-*N*-((1-ethyl-2-pyrrolidinyl)methyl)-5-bromo-[^{11}C]2,3-dimethoxybenzamide
Dopamine D_2/D_3 receptors	[^{18}F]FAL	[^{18}F]fallypride
D_3 receptors	[^{11}C]-(+)-PHNO	[^{11}C]-(+)-4-propyl-3,4,4a,5,6,10b-hexahydro-2H-naphtho[1,2-b][1,4]oxazin-9-ol
Dopamine transporter	[^{123}I]β-CIT	β-CIT2-betacarbomethoxy-3 beta-(4-

		[^{123}I]iodophenyl)tropane
γ-aminobutyric acid (GABA)	[^{18}F]FMZ	[^{18}F]fluoroflumazenil
Glycine transporter type 1 ($GlyT_1$)	[^{11}C]GSK931145	N-((1-([$^{11}CH_3$]dimethylamino)cyclopentyl)(phenyl)methyl)-2,6-dimethylbenzamide
Glycine transporter type 1 ($GlyT_1$)	[^{11}C]R05013853	[5-[^{11}C]methanesulfonyl-2-((*S*)-2,2,2-trifluoro-1-methyl-ethoxy)-phenyl]-[5-(tetrahydro-pyran-4-yl)-1,3-dihydro-isoindol-2-yl]-methanone
Muscarinic acetylcholine receptor (mAChR)	[^{11}C]NMPB	[^{11}C]*N*-methyl-4-piperidyl benzylate
Muscarinic acetylcholine receptor subtype 1 ($mAChR_1$)	[^{11}C]GSK1034702	[^{11}C]4-fluoro-6-methyl-1-(1-(tetrahydro-2H-pyran-4-yl)piperidin-4-yl)-1,3-dihydro-2H-benzo[d]imidazol-2-one
Nicotinic acetylcholine receptor (nAChR) subtype α4β2	[^{18}F]AZAN	(−)-2-(6-[^{18}F]fluoro-2,3'-bipyridin-5'-yl)-7-methyl-7-aza-bicyclo[2.2.1]heptane
Nicotinic acetylcholine receptor (nAChR) subtype α4β2	2-[^{18}F]FA	(*S*)-3-(azetidin-2-ylmethoxy)-2-[^{18}F]fluoropyridine
Nicotinic acetylcholine receptor (nAChR) subtype α4β2	6-[^{18}F]FA	6-[^{18}F]fluoro-3-(2(*S*)-azetidinylmethoxy)pyridine
Nicotinic acetylcholine receptor (nAChR) subtype α4β2	5-[^{123}I]IA	(*S*)-5-[^{123}I]iodo-3-(2-azetidinylmethoxy)pyridine
Nicotinic acetylcholine receptor (nAChR) subtype α7	[^{11}C]CHIBA-1001	4-[^{11}C]methylphenyl 2,5-diazabicyclo[3.2.2]nonane-2-carboxylate
Nicotinic acetylcholine receptor (nAChR) subtype α7	[^{18}F]ASEM	[^{18}F]3-(1,4-diazabicyclo[3.2.2]nonan-4-yl)-6-fluorodibenzo[b,d]thiophene 5,5-dioxide
Opioid receptors	[^{18}F]MK-0911	1-(2-[^{18}F]fluoroethyl)-3-(3-(hydroxymethyl)-1-(spiro[2.5]octan-4-

		ylmethyl)piperidin-4-yl)-1,3-dihydro-2H-benzo[d]imidazol-2-one
Phosphodiesterase 10A (PDE_{10A}) receptors	[^{18}F]JNJ42259152	2-[4-[1-(2-[^{18}F]fluoroethyl)-4-(4-pyridinyl)-1*H*-pyrazol-3-yl]phenoxy]methyl]-3,5-dimethyl-pyridine
Phosphodiesterase 10A (PDE_{10A}) receptors	[^{18}F]MNI-654	2-(2-(3-(1-(2-[^{18}F]fluoroethyl)-1*H*-indazol-6-yl)-7-methyl-4-oxo-3,4-dihydroquinazolin-2-yl)ethyl)-4-isopropoxyisoindoline-1,3-dione
Phosphodiesterase 10A (PDE_{10A}) receptors	[^{18}F]MNI-659	2-(2-(3-(4-(2-[^{18}F]fluoroethoxy)phenyl)-7-methyl-4-oxo-3,4-dihydroquinazolin-2-yl)ethyl)-4-isopropoxyisoindoline-1,3-dione
Serotonin 5-HT2a receptors	[^{11}C]MDL100907	(*R*)-(+)-[3-O-methyl-[^{11}C]-4-(1-hydroxy-1-(2,3-dimethoxyphenyl)methyl)-*N*-2-(4-fluoro-phenylethyl)piperidine
Serotonin 5-HT2a receptor	[^{18}F]altanserin	{3-(2-[4-(4-[^{18}F]fluorobenzoyl)piperidin-1-yl]-ethyl)-1,2-dihydro-2-thioxo-quinazolinone, *1*}
Serotonin (5-HT) transporter	[^{11}C]DASB	[^{11}C]-3-amino-4-(2-dimethylaminomethylphenylsulfanyl)-benzonitrile
Translocator protein (TSPO)	[^{11}C]PK11195	*N*-butan-2-yl-1-(2-[^{11}C]chlorophenyl)-*N*-methylisoquinoline-3-carboxamide
Translocator protein (TSPO)	[^{18}F]FEPPA	N-(2-(2-[^{18}F]fluoroethoxy)benzyl)-N-(4-phenoxypyridin-3-yl)acetamide
Vesicular acetylcholine transporter	[^{123}I]IBVM	[^{123}I]iodobenzovesamicol
Vesicular monoamine transporter type 2 (VMAT-2)	[^{11}C]DTBZ	[^{11}C]dihydrotetrabenazine

FIGURE 12.9–1. High-resolution positron emission tomography (PET) scanner.

TYPES OF MOLECULAR IMAGING

Molecular imaging techniques include PET, SPECT, MRS, and fMRI. They are functional brain imaging techniques that visualize the metabolism and other physiologic processes in the living brain.

Figure 12.9–1 illustrates a state-of-the-art PET device used in these studies. Functional brain imaging seeks to identify and characterize the dynamic chemical and biologic changes of brain work under varying conditions. Functional brain imaging contrasts with structural brain imaging that involves procedures to precisely demarcate anatomical regions of the brain. Thus, molecular brain imaging is a subclass of functional brain imaging.

Indirect Molecular Imaging Estimates

Ideally, concentrations of neurotransmitters would be measured in the living human brain. Unfortunately, procedures to directly measure these molecules are not yet available. Therefore, molecular brain imaging requires indirect techniques to estimate the density and distributions of neurotransmitters in the living brain. For example, there are no noninvasive procedures that directly measure glucose concentration in the living human brain. Instead, PET with [^{18}F]FDG is a technique that yields the density and distribution of [^{18}F]FDG molecules that trace the fate of glucose and its metabolism in the brain. Similarly, the concentrations of dopamine and serotonin cannot be directly measured in the brain. Instead,

radiotracers exist that trace the density and distribution of endogenous substrates of the presynaptic dopamine (DAT) and serotonin (SERT) transporters, the postsynaptic dopamine (D_1–D_5) and serotonin (5-HT) receptors, the latter of which there are at least 14 different subtypes and opiate receptors of the mu subtype. For example, molecular imaging demonstrates the alterations in the density of dopamine D_2 receptors with the menstrual cycle, during which the binding of the dopamine D_2 receptor is reduced in the follicular phase and increased in the periovulatory and luteal phases of the estrous cycle in some early PET studies. Molecular imaging also was used to confirm the dopamine hypothesis that people with schizophrenia have an excess of intrasynaptic dopamine in the brain. The dopamine hypothesis represents a cornerstone of schizophrenia pathophysiology, and drugs that block the binding of dopamine to dopamine receptors remain a fundamental tool of the pharmacology of schizophrenia.

Pharmacologic Challenges

Pharmacologic challenges are experimental tools used to test the effects of the administration of drugs hypothesized to alter the levels of neurotransmitters in regions of the brain. Examples of pharmacologic challenges of the dopaminergic system include the administration of pharmacologic agents to increase, for example, amphetamine (Dexedrine), or decrease, for example, α-methyl-para-tyrosine (AMPT), metyrosine (Demser), intrasynaptic dopamine given before PET scans and to estimate the occupancy of dopamine receptors by endogenous dopamine in the brain. These techniques demonstrate that intrasynaptic dopamine is increased following the administration of amphetamine. After AMPT administration, patients with schizophrenia still have more dopamine available than normal, although both are decreased compared to nontreated AMPT subjects. This is also consistent with elevations of baseline dopamine D_2 receptors in schizophrenia.

Grace (1991) hypothesized that, in contrast to healthy normal controls, people with schizophrenia demonstrate abnormally elevated intrasynaptic levels of dopamine in both (1) the resting, basal, unstimulated, tonic state and (2) the phasic state of maximal arousal like the one induced pharmacologically by amphetamine or another agent as methylphenidate that produces maximal intrasynaptic levels of dopamine. The value of pharmacologic challenges in the molecular imaging of schizophrenia has been demonstrated by studies that have confirmed the hypothesis of Grace that extrasynaptic dopamine is abnormally reduced in the tonic state and intrasynaptic dopamine is abnormally elevated in the phasic states in people with schizophrenia. Pharmacologic challenges also represent tools to evaluate the mechanisms of action of novel agents. For example, agents hypothesized to alter the intrasynaptic concentration of

dopamine can be administered before scans compared with the placebo states to determine the increase or decrease of intrasynaptic dopamine (Table 12.9–3).

MOLECULAR IMAGING IN PATHOPHYSIOLOGY

Molecular Imaging of Dopamine in Schizophrenia

The development of molecular imaging studies resulted from the successful radiolabeling of dopamine receptor antagonists, “typical” antipsychotic drugs (now called “first-generation”), in the mid-1980s, consistent with the investigation of postsynaptic dopamine D_2-like receptors.

Estimation of the Binding Dopamine D_2-Like Receptors. The study of the binding of D_2-like receptors is typically made in a single PET or SPECT imaging session at high specific activity of the tracer (i.e., with low mass of the nonpharmacologic moiety injected) designed to yield the maximum value of the binding potential (BP), equal to the ratio of available receptor density to binding affinity. The BP has been determined with two main classes of radiotracers of dopamine receptors. The first class of radiotracers that visualize D_2 or D_3 receptors in the brain includes butyrophenones such as [^{11}C]NMSP and [^{18}F]spiperone derivatives. The second class of radiotracers that visualize D_2-like receptors in the brain includes radiolabeled benzamides such as [^{11}C]raclopride (Fig. 12.9–2), [^{18}F]fallypride ([^{18}F]FP) (see Fig. 12.9–2), or [^{123}I]iodobenzamide ([^{123}I]IBZM).

Dopaminergic Neuroreceptor Mapping In Schizophrenia. Dopamine belongs to the group of monoamines that arise from the decarboxylation of large neutral and aromatic amino acids in brain tissue. Depending on the specific precursor, they fall into two categories, catecholamines that derive from phenylalanine but in the brain only from tyrosine, and the indoleamines that derive from tryptophan. Neurotransmission is the term applied to the exchange among brain cells of specific information encoded in chemicals known as transmitters. Neurotransmission includes the steps of synthesis, vesicular storage, release, reuptake, and removal or breakdown of neurotransmitters. Extra- or intracellular proteins function as enzymes, receptors, or transporters that implement the individual steps.

Table 12.9–3.
Imaging Studies of Dopamine Neurotransmission in Schizophrenia: Observations and Possible Mechanisms

Site	Observation	Salient and Related Findings	Possible Mechanism
D_2 (striatum)	Elevations with [^{11}C]NMSP (butyrophenone)	Varied postmortem changes, internalization, monomer elevation	Decreased tonic DA
D_2 (striatum)	No change (benzamides) except following AMPT using [^{123}I]IBZM or [^{11}C]raclopride	Due to competition with intrasynaptic DA or dimer configuration, unmasking of D_2 due to intrasynaptic DA removal with AMPT	Increased phasic DA Decreased tonic DA
DDC (striatum)	Elevation with [^{18}F]fluorodopa	Majority of imaging studies	Decreased tonic DA
DA (striatum) release after AMP challenge	Elevation with [^{123}I]IBZM or [^{11}C]raclopride	Majority of imaging studies	Increased phasic DA
DA (striatum) release after ketamine challenge	Elevation with [^{11}C]raclopride Elevation with [^{11}C]FLB457	Glutamate antagonist stimulates hypoglutamatergic state	Increased phasic DA
Prefrontal D_1	Decrease with [^{11}C]SCH23390		Unknown
ACCX D_2	Decrease with [^{11}C]FLB457	Postmortem tyrosine hydroxylase immunoreactive changes	Unknown

[^{11}C]NMSP, (3-*N*-[^{11}C]methyl)spiperone; DDC, dopa decarboxylase; DA, dopamine; AMPT, α-methylparatyrosine; [^{123}I]IBZM, (*S*)-*N*-[(1-ethyl 2-pyrrolidinyl)]methyl-2-hydroxy-3-[^{123}I]iodo-6-methoxybenzamide; AMP, amphetamine; [^{11}C]FLB457, (*S*)-*N*-((1-ethyl-2-pyrrolidinyl)methyl)-5-bromo-2[^{11}C], 3-dimethoxybenzamide; [^{11}C]SCH23390, (*R*)-(+)-8-chloro-2,3,4,5-tetrahydro-3-[^{11}C]methyl-5-phenyl-1*H*-3-benzazepin-7-ol; ACCX, anterior cingulate cortex.

2002;59(5):440. doi:10.1001/archpsyc.59.5.440. Copyright © 2022 American Medical Association. All rights reserved.

Transmitter molecules are ligands because they engage in binding ("ligation") as the first step of a chain of interactions that differs according to the proteins that do the binding. *Receptors* return the ligand to the original pool of unbound molecules after a delay that depends on the affinity of the receptor toward the ligand. *Transporters* relocate the ligand to a different pool of unbound ligands. *Enzymes* release the ligand to the same pool but in a new chemical form. Exogenous or artificial ligands may differ so much from the native ligand that transporters or enzymes fail to carry out their primary function and instead act as receptors by simply returning the ligand to its original pool. Depending on the degree of interference, exogenous or artificial ligands may be antagonists or partial agonists of the action of the native transmitter. We list the main extra- and intracellular sites of binding, reuptake, and metabolism of dopamine in Table 12.9–1 and with the radiotracers in Table 12.9–2.

FIGURE 12.9–2. Structures of typical PET dopamine radiotracers.

The expression of receptors, transporters, and enzymes is highly variable and depends on the intra- and extracellular environments, making the results of PET and SPECT studies contingent upon specific circumstances at the time of the study, as is also true of transporters. When baboons and humans received the first tropane-based PET probes of the dopamine transporters, researchers generally held that the number of transporters remained constant. We now know that the number of dopamine transporters is subject to regulation by intrinsic mechanisms as well as pharmacologic manipulation.

Methods of Dopaminergic Neuroreceptor Mapping. PET studies yield multiple brain images of dopaminergic neurotransmission acquired as dynamic series of tomographic frames, typically 30 to 50 frames obtained as two- or three-dimensional images in sessions of 60 to 120 minutes. Because of the short half-lives, this duration is the limit of most studies with ^{11}C or ^{18}F. In contrast, SPECT studies with ^{123}I may continue for 6 or more hours. In two-dimensional imaging, the tomographic record consists of 15 to 64 or more sections of the brain, depending on the tomograph. Arterial sampling and brain imaging together establish the concentrations of the tracer in the blood and brain as functions of time. The records then form the basis for subsequent kinetic analyses that yield the specifics of dopaminergic neurotransmission (Fig. 12.9–3). The choice of the right tracers is the key to the successful imaging of animals or humans. With PET, the half-life of tracers limits the duration of imaging to the first hour of recording in the case of most of the ^{11}C-labeled (20-minute half-life) tracers. The pharmacology and binding properties of the tracers, in turn, dictate the usefulness of this information in relation to the relevant proteins and not solely to the properties of the ligand.

FIGURE 12.9–3. Typical time activity curves for kinetic modeling of dopamine receptors. Part **A** is arterial input plasma curve (**left**) and caudate and cerebellum time activity curve of PET imaging of [^{11}]CNMSP over 90 minutes (**right**) and is an illustration of irreversible binding to dopamine D_2/D_3 receptors; Part **B** is arterial plasma input curve (**left**) where total is the [^{11}C]raclopride including metabolites and the raclopride is the lower curve where only the parent [^{11}C]raclopride in plasma is shown and caudate and cerebellum time activity curve of PET imaging of [^{11}C]raclopride over 90 minutes (**right**) and is an illustration of reversible binding to dopamine D_2/D_3 receptors. (Data from Wong DF, Wagner Jr. HN, Tune LE, Dannals RF, et al. Positron emission tomography reveals elevated D_2 dopamine receptors in drug-naive schizophrenics. *Science*. 1986;234(4783):1558–1563. https://doi.org/10.1126/science.2878495; Phan JA, Wong DF, Chang NHS, Kumakura Y, Bauer WR, Gjedde A. Transient equilibrium determination of dopamine D_2/D_3 receptor densities and affinities in brain. *Front Nucl Med*. 2022;2:1030387. doi: 10.3389/fnume.2022.1030387.)

An important challenge to PET imaging is the necessary anesthesia of animals used in research. It has been possible in very few places to train nonhuman primates to remain awake while seated comfortably on a horizontally suspended

tomograph. In other places, it is necessary to use a within-subject design of drug studies to reduce the variability of the PET measures. In some preclinical or clinical studies of animals, investigators did not routinely sort out all factors, such as the size of the brain, genotype, age, latent disease states, personality, and adaptation to stress and drugs. Another important factor is the sample size. Typical numbers of humans in PET studies range from 10 to 20, and populations of 30 subjects in single studies are rare. Adequate numbers are necessary to counteract the confounding influence of the tomography's finite power of resolution of recorded radioactivity, known as the "partial volume" effect. The effect is most prominent in small structures that typically are below a diameter of 2 to 3 mm or even 1 cm, depending on the resolution of the PET scanner. Current state-of-the-art PET scanners are now close to 2.5 to 4 mm in the ability to resolve structures without loss of quantification or to resolve two radioactive sites rather than smeared as one.

Tracers of Dopaminergic Neurotransmission. Table 12.9–2 lists a large number of dopaminergic tracers tested with variable success since 1983. Unfortunately, of the hundreds or thousands of compounds developed by the pharmaceutical industry, universities, or governmental institutions, only a tiny fraction reached the stage of successful labeling. Radioligands are useful only when they meet specific requirements of selectivity, affinity, and kinetics of binding, transport, or metabolism. Only when they meet these requirements can reliable estimates of receptor density or neurotransmitter synthesis, release, or metabolism, be obtained noninvasively.

Three tracers illustrate the historical advance of dopaminergic tracer development and the problems associated with the use of the tracers. In 1983, the experimental neuroleptic spiroperidol (spiperone, 8-[4-(4-fluorophenyl)-4-oxo-butyl]-1-phenyl-1,3,8-triazaspiro [4.5]decan-4-one) served as the precursor by methylation of the radioligand [^{11}C]3-*N*-methylspiperone (NMSP), for which the dopamine D_2-like (D_2, D_3, and D_4) receptors have high affinity. The radioligand yielded the very first D_2-like receptor images in the human brain with PET. However, the selectivity was not exclusive for this receptor subtype, as the serotonin 5-HT_{2A} receptors had a significant affinity. In contrast, useful ligands frequently have binding characteristics that include high selectivity but only moderate affinity, commensurate with BPs between unity and as much as approximately 6.

Currently, the most common dopamine receptor ligand used with PET is [^{11}C]raclopride (3,5-Dichloro-*N*-[(2*S*)-1-ethyl-2-pyrrolidinyl]methyl]-2-hydroxy-[^{11}C]6-methoxybenzamide), derived from another class of chemical, the benzamides. Benzamides are derivatives of benzoic acid, and substituted benzamides often serve as neuroleptics or antipsychotics in psychiatric practice. Two active substances from the group of benzamides are in clinical use, sulpiride

and amisulpride (see reference to LB-102 methyl-amisulpride below). Raclopride binds reversibly and selectively to the dopamine D_2 and D_3 receptors, with BPs close to 3 (Gjedde 2003), making it an ideal tracer of dopaminergic binding sites in high-density locations such as the striatum. In the cerebral cortex, the lower density renders the BP too low to be of routine usefulness. Several alternatives with higher affinity are available for this purpose. Tracer [^{18}F]fallypride ([5-(3-[^{18}F]fluoropropyl)-2,3-dimethyl-*N*-[(2*S*)-1-(2-propenyl)-2-pyrrolidinyl]-methyl]-benzamide) is a radioligand with BPs of 0.5 to 1.5 in the cerebral cortex. The higher affinity elevates the retention in the striatum, where the BP is so high that binding is delivery-dependent.

In the case of metabolic substrates, the product must be retained in the brain as an index of the activity of the enzyme, provided the transport across the blood-brain barrier is not rate-limiting for the uptake. The first study with PET of the metabolism of the dopamine precursor tracer [^{18}F]fluorodopa ([^{18}F]FDOPA) was published in 1983 with an uptake that appeared to be irreversible, although the retention may reflect only a fraction of the tracer. This meant that subsequent researchers have attempted a host of different kinetic analyses to solve the issue of the specificity of the signal. It is now clear that the retention primarily reflects the transport of the labeled product fluorodopamine (FDA) into vesicles, and the retention depends on the irreversibility of this transport. Two processes interfere with the retention: FDA is subject to oxidation by monoamine oxidases, and release of FDA from the vesicles exposes the released FDA to renewed metabolism after reuptake into the terminals. Therefore, low retention can reflect both reduced vesicular incorporation due to loss of terminals or loss of dopa decarboxylase (DDC) activity, as well as inhibition of vesicular transporters, or increased release of FDA in response to increased dopaminergic neurotransmission.

As markers of dopaminergic activity in presynaptic terminals, alternatives to FDOPA are tracers of the dopamine reuptake sites, based on the tropane structure known as nortropane (8-azabicyclo[3.2.1]octane). Tropane is a nitrogenous bicyclic organic compound, mainly famous for the large group of alkaloids that derive from it, including, among others, atropine and cocaine. Several potentially irreversible ligands for the cocaine receptor site on the dopamine transporter derive from cocaine. The cocaine analog CFT (2-carboxymethoxy-3-(4-fluorophenyl) tropane or WIN-35,428) first arose as a radiolabeled probe for PET and SPECT by Madras and coworkers and later developed into the PET tracer [^{11}C]WIN-35,428 by Kuhar and coworkers. The tracer binds irreversibly to the cocaine site on the dopamine transporter (DAT) but also to the serotonin (5HTT or SERT) and norepinephrine (NET) transporters. The vesicular monoamine transporter (VMAT2) is located in the membranes of terminal vesicles and can be imaged with the radioligand [^{11}C]D-dihydrotetrabenazine ([^{11}C]DTBZ). However, the imaging of the VMAT2

transporter may not settle the "transporter regulation issue," as VMAT2 also appears to be regulated (see Table 12.9–2).

Estimation of Absolute Dopamine D_2-Like Receptor Density. In contrast to the typical approach to measures the BP of D_2-like receptors, the use of at least two PET scans provides the basis of calculation of the unique ability to measure absolute receptor density (B_{max}). The measurement of absolute B_{max} can be carried out by performing at least two brain imaging sessions with the administration of [^{11}C]raclopride or [^{11}C]NMSP, with at least one after a known potent dose of a cold, nonradioactive D_2-like receptor antagonist such as unlabeled raclopride itself or haloperidol, respectively, to reduce some of the binding. Following some additional mathematical modeling, these results then provide an estimate of the B_{max} and binding affinity (K_D). These results correspond to the results from autoradiography studies or in vitro homogenate studies.

Subsequent simplified studies involved single high-specific activity injections of radiotracer mass of less than 20 μg, carried out in order to estimate the BP, that is, the ratio of the maximum number of receptors B_{max} to the half-saturation concentration K_D. Nonetheless, in order to separate these variables of B_{max} and K_D, it is necessary to carry out receptor saturation studies with varying unlabeled mass injections. In general, the absolute B_{max} studies have tended to show elevations ranging from small to large as much as a threefold increase with [^{11}C]NMSP, a butyrophenone. Although B_{max} elevations have been consistently shown with [^{11}C]NMSP, no changes have been demonstrated with B_{max} using benzamides such as [^{11}C]raclopride or [^{123}I]IBZM. Interestingly, one of the characteristics of these benzamides is that they are also quite susceptible to endogenous dopamine and recently have gained popularity for measuring the effect of pharmacologic challenges or psychological stress that alter endogenous dopamine levels. Some have suggested that the differences in B_{max} between raclopride and NMSP could be attributed to the preferential affinity for a monomer versus a dimer form of the dopamine receptor in the case of the [^{11}C]NMSP and possibly receptor internalization and susceptibility to endogenous neurotransmitter for [^{11}C]raclopride. Regardless of the reasons for the differences, meta-analysis has shown that there is a small 12% significant elevation of striatal D_2 receptors with an effect size of 0.51, and there is an association between increased D_2 receptor density and positive symptoms.

Dopamine Precursor Estimates. Dopamine precursor measures using [^{18}F]FDOPA or [^{11}C]DOPA were among the first markers of dopamine neurotransmission to be studied. When properly quantified, these measurements

reflect DDC rates of activity or represent some measure of dopamine presynaptic function. A number of these studies have demonstrated that the dopa uptake was higher in people with schizophrenia and other psychoses in contrast to healthy matched controls. Elevated [^{18}F]fluorodopamine ([^{18}F]FDOPA) turnover has been shown to coexist with decreased steady-state storage of FDOPA and its decarboxylated metabolites in the caudate nucleus and amygdala of untreated people with schizophrenia. Interestingly, the decreased steady-state storage of FDOPA in the amygdala correlated inversely with positive symptoms of schizophrenia, suggesting a role for this brain structure in the pathophysiology of the disease. Hence, the striatal findings are among the most substantial evidence of a "biomarker" in schizophrenia and are consistent with the concept of decreased tonic dopamine and elevated phasic dopamine proposed by Grace. More recently, in studies by Jauhar with [^{18}F]FDOPA, Ki^{cer} has been shown to be elevated in responders compared to nonresponders and also positively correlated with PANSS positive, negative, and total scores and negatively with Global Assessment of Function (GAF).

Regarding possible effects of antipsychotic medication, Jauhar studied 17 patients with schizophrenia on medication at therapeutic doses. There was no significant effect of treatment on dopamine synthesis capacity in the whole striatum (P = .47), thalamus, or midbrain, nor was there any significant relationship between change in dopamine synthesis capacity and change in positive (r = 0.35, P = .13), negative, or total psychotic symptoms. They concluded that dopamine synthesis capacity is unaltered by antipsychotic treatment and therapeutic effects are not mediated by these dopamine antagonist medications. However, this is contrary to what others found, such as Gründer with a decrease in dopamine synthesis capacity with treatment.

Other Dopamine Subtypes. There is considerable interest in the D_3 receptor as a potential therapeutic target for schizophrenia. Unfortunately, no studies are explicitly able to image the D_3 receptor in vivo without also measuring the much more densely distributed D_2 receptors, for example (^{11}C PHNO). A high-affinity selective D_3 radioligand is needed. Most measures of D_3 are quantified in brain regions of a relatively high density of D_3 as the ventral striatum, substantia nigra, and globus pallidus.

Dopamine D_1 receptors may also play a role in the development and maintenance of the symptoms and signs of schizophrenia. Several studies have shown no significant difference in D_1 receptors in untreated patients with schizophrenia. However, a twin study showed reduced striatal D_1 receptors in the affected twins who were on medications compared to the unaffected cotwins. Two studies have reported associations between D_1 receptor density in the dorsolateral prefrontal cortex and impairments in working memory performance

and negative symptoms. The limitations of these studies of the D_1 receptors are that the radiotracers are not selective for D_1 receptors but also bind to 5-HT_{2A} receptors. Thus, further radiotracer development is needed for the D_1 receptor site. Several years ago, D_4 was considered a serious candidate for antidepressant action, but initial PET ligands and small therapeutic trials for schizophrenia failed. It is still of interest, perhaps in other areas of neuropsychiatry, and is a binding site for [^{11}C]NMSP.

Measuring Intrasynaptic Dopamine. In the past decade, an important property probably unique to radiolabeled benzamides has been found. Specifically, the D_2-like receptor binding of [^{123}I]IBZM and [^{11}C]raclopride (see Fig. 12.9–2) and probably [^{18}F]fallypride (see Fig. 12.9–2) can decline in the presence of a pharmacologic challenge with a pharmacologic agent that induces increased or decreased levels of intrasynaptic dopamine. In the case of increased intrasynaptic dopamine, challenges with dopaminergic agents, including methylphenidate (Ritalin) as well as amphetamines, have been employed. Investigators have shown that these benzamides can have a reduced BP in the presence of an intravenous amphetamine challenge (0.3 mg/kg body weight). Researchers showed significantly greater decreases in BPs in patients with schizophrenia in contrast to healthy normal control volunteers. There is still some controversy about the meaning of these decreases in BP. What is probably most defendable is that there is an increase in occupancy of the D_2-like sites such that the radiolabeled benzamides cannot bind to them. This reduction of occupancy could be due to the increased intrasynaptic dopamine released into the synapse through the use of psychostimulants. However, a change in the affinity state, which might increase with dopamine, could be occurring. These results, however, are not without controversy. Instead of the radiotracer binding returning to baseline as one might expect after a bolus amphetamine challenge, it stays depressed for many hours, sometimes exceeding 6 to 8 hours, which could be consistent with other factors than simply intrasynaptic DAR. Furthermore, at least one study has not demonstrated significant elevations in DAR, which in itself is an interesting finding suggestive of a potential heterogeneity in dopamine response to challenges with stimulants. The heterogeneity may be related to heterogeneity in clinical symptoms, as at least one study has shown that DAR is greater in patients who have more positive symptoms at the time of scanning.

It is interesting to note that one other neuropsychiatric disorder, Tourette syndrome, has shown highly significant elevations of DAR after amphetamine challenge and bolus intravenous [^{11}C]raclopride PET studies. These DAR measures seem to be greater with Tourette syndrome patients with comorbid obsessive-compulsive disorder. Hence, the elevated DAR appears not to be specific to schizophrenia.

Molecular Imaging after Dopamine Depletion. Another procedure used for changing intrasynaptic dopamine is dopamine depletion. This has been typically tried either with reserpine (Serpalan), as is typical with animals, or with AMPT, a drug that is approved in humans for pheochromocytoma. Using such AMPT challenges has allowed the demonstration of elevation in BPs, presumably reflecting the decrease of competition with intrasynaptic dopamine. Such measures have allowed an estimate of baseline or basal dopamine in the synapse. One such study demonstrated that the elevation or change in BP post-AMPT dopamine depletion is greater in people with schizophrenia than in healthy controls. Patients with greater elevations in D_2 receptor binding demonstrated greater improvement in positive symptoms with antipsychotic treatment. This is consistent not only with an increase in basal intrasynaptic dopamine but also with elevated basal densities of elevated D_2 receptors. Thus these findings support the results of a meta-analysis that shows a small but definite elevation of D_2 receptors in schizophrenia.

In schizophrenia, PET reveals increased capacity of dopamine synthesis from DOPA, first shown by increased tonic and phasic DAR, elevated density of dopamine D_2-like receptors, and increased extracellular dopamine. These findings explain how antagonists of dopaminergic neurotransmission can mitigate the worst effects of the disease, at least for some subtypes with positive symptoms. Still, complete reversal did not happen, probably because the primary disorder is cortical. It is likely that the increased synthesis capacity is due to an increase in enzyme activity, with the actual increase of dopamine production depending on the concentration of the precursor DOPA.

Future Molecular Imaging of Agonists of Dopamine and Glutamate. In the future dopamine agonists, such as the ^{11}C-labeled (+)-enantiomer of 1,3,4,6,7,11b-Hexahydro-9,10-dimethoxy-3-(2-methylpropyl)-2*H*-benzo[*a*]quinolizin-2-ol ([^{11}C](+)PHNO), or glutamate agonists, such as [^{11}C]α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate ([^{11}C]AMPA), may help determine whether there is truly intrasynaptic DAR. Dopamine agonists are more reflective of the competition with the intrasynaptic dopamine itself. On the other hand, a recent study with [^{11}C](+)PHNO did not demonstrate a significant change in DAR, probably related to experimental differences.

Extrastriatal Dopamine D_2-Like Receptors. Striatal D_2 radioligands are not ideal for extrastriatal imaging even though they have been examined longitudinally and have shown some limited imaging, such as the thalamus and some cortical regions. With the advent of higher affinity radiotracers of the D_2-like receptors, such as [^{18}F]fallypride and [^{11}C]FLB 457, it has been possible to image extrastriatal dopamine D_2-like receptors in the cortex in schizophrenia, with both

PET and SPECT. Several PET-SPECT studies have been carried out to date, all showing decreases or no change. Some studies have inconsistently demonstrated decreased binding in the thalamus, temporal cortex, amygdala, and cingulate cortex. Recent data showed DA deficits extending to most cortical regions and even to other extrastriatal subcortical regions not previously considered to be "hypodopaminergic" in schizophrenia. These findings yield a description of extrastriatal and striatal dopaminergic dysregulation in schizophrenia.

As the vast majority of studies focused on the dopamine system in patients with schizophrenia, and this is the use for which most PET and SPECT radioligands were developed and validated, it is helpful to present a summary in the shape of Table 12.9–2. As described above, there are increasing lines of evidence that the glutamatergic system is dysfunctional in schizophrenia. This, in turn, may lead to especially positive symptoms in schizophrenia, where antipsychotic medications appear to have benefits. As described by studies of Grace and others, one unifying theory may be described by two states of dopamine: A tonic state usually associated with extrasynaptic dopamine (homeostatic or basal level) and a phasic state, which is more episodic and perhaps more associated with symptomatology such as hallucinations usually associated with intrasynaptic dopamine. As shown in Table 12.9–3, the pre-, post-, and intrasynaptic measurements of dopamine would be quite compatible with this phasic–tonic dopamine theory. In this theory, patients with schizophrenia have lower tonic dopamine and hence less inhibition of their phasic dopamine (thereby alluding to the hyperdopaminergic state). Indeed, as shown in Table 12.9–3, lower tonic dopamine would be consistent with upregulation of the presynaptic enzymes of DDC as measured by [^{18}F]FDOPA (multiple studies showing elevations in schizophrenia), elevated amphetamine-induced DAR (two centers, three studies), and elevated D_2-like receptor postsynaptic in response to the lower tonic dopamine (multiple studies, primarily one site). In the future, it may be possible to integrate other abnormalities, such as serotonin. Once glutamate studies have been fully verified with multiple radioligands, this should also contribute to this model.

Molecular Imaging of Serotonin in Schizophrenia

The second major neurotransmitter system studied in schizophrenia is serotonin. This has most recently been driven by theories of the mechanisms of action of second-generation antipsychotics. However, the role of serotonin in schizophrenia can also be traced back to the psychotic symptomatology from the hallucinogenic effects of lysergic acid diethylamide (LSD), which is chemically similar to serotonin.

Estimation of the Density of Serotonin 2A Receptors and Serotonin 1A Receptors. Initial brain imaging studies of serotonin examined the 5-HT_{2A}

receptors. Indeed 5-HT_{2A} receptors were originally imaged in the cortex with nonselective radiotracers such as [^{11}C]NMSP. A number of postmortem studies have suggested decreased 5-HT_{2A} binding in the prefrontal cortex, but PET studies in drug-free or drug-naive patients with schizophrenia have found normal 5-HT_{2A} receptor binding. One study demonstrated significant decreases in the prefrontal cortex in drug-naive schizophrenic patients, and another study demonstrated a decrease in cortical binding in drug-free patients. Estimation of the density and distribution of serotonin receptors in the living human brain is an area that merits further investigation as more 5-HT_{2A} radioligands are now available such as [^{18}F]altanserin.

More recently, the ability to measure 5-HT_{1A} receptors has led to investigations showing increases in binding in multiple brain regions, including the medial temporal cortex, using PET imaging with [^{11}C]WAY100635, a potent 5-HT_{1A} antagonist. Subsequent studies have shown decreased binding using the same radiotracer in the amygdala, while a third showed no differences. Only some of the imaging studies have confirmed the results of postmortem studies, which suggest increases in 5-HT_{1A} in cortical areas, but more novel radiotracers show promise for use in schizophrenia.

Estimation of the Density of the Serotonin Transporters (SERT). The second major serotonin imaging area focuses on the serotonin transporters (SERT). Initial studies carried out with nonselective SPECT radiotracers such as [^{123}I]β-carbomethoxy-3-β-(4-iodophenyl)-tropane ([^{123}I]-β-CIT) and amino-4-(2-[^{11}C]dimethylaminomethyl-phenylsulfanyl)-benzonitrile ([^{11}C]DASB), which labeled SERT in the midbrain and where no differences were found. This is despite the fact that some postmortem studies have shown decreases in SERT in the frontal cortex and the cingulate cortex.

FIGURE 12.9–4. Alpha 4 beta 2 and alpha 7 nAChR human PET scans. (**left**) alpha 4 beta 2 nAChR axial slice of healthy volunteer showing high thalamic uptake and (**right**) alpha 7 nAChR axial slice of healthy volunteer showing more uniform cortical uptake.

Molecular Imaging of Serotonin Release. Despite a long attempt to measure intrasynaptic serotonin release in analogy to DAR, this may have been accomplished only recently. Erritzoe used the 5-HT_{2A} receptor agonist radioligand, [^{11}C]CIMBI-36, and 0.5 mg/kg oral D-amphetamine challenge to report synaptic 5-HT changes of up to 14%. This opens opportunities for investigating such studies in schizophrenia.

Molecular Imaging of Cholinergic Receptors in Schizophrenia

Acetylcholine represents another key neurotransmitter system likely to play a role in the pathogenesis and pathophysiology of schizophrenia. The neuronal receptors for acetylcholine in the brain are subdivided into two primary classes: Muscarinic and nicotinic. Both muscarinic and nicotinic acetylcholine receptors participate in the development and maintenance of schizophrenia.

Estimation of the Density of Muscarinic Acetylcholine Receptors. One study of the muscarinic acetylcholine receptor (mAChR) system using SPECT and 3-quinuclidinyl-4-[^{123}I]iodoenzilate([^{123}I]IQNB), a potent antagonist of muscarinic receptors, has shown a very marked decrease of mAChR in schizophrenia, consistent with some postmortem studies. However, the functional role of this finding is not fully understood. Using the same radiotracer, the investigators demonstrated greater mAChR occupancy by clozapine than

olanzapine, consistent with the observation of lesser extrapyramidal side effects (EPS) associated with the two drugs.

Estimation of the Density of Nicotinic Acetylcholine Receptors. Some preliminary studies are proceeding to determine if the decreases in nicotinic acetylcholine receptors (nAChRs) observed in postmortem studies are also observed with PET imaging. This is quite relevant to schizophrenia, given the high prevalence of smoking among patients with schizophrenia. More recently, it has been possible to image alpha-7 nAChR, the subtype most associated with cognition in schizophrenia, which Wong et al. have shown using [^{18}F]ASEM, as shown in Figure 12.9–4. The first successful human PET tracers show evidence of some reduction in V_T in schizophrenia, as predicted by the pioneering postmortem work of Freedman. The evidence that not all subjects had reductions suggests this could be related to symptoms and severity of illness and will await larger samples. Also, the evidence that in vivo alpha-7 nAChR occupancy could be measured with unlabeled DXMB-A (GTS-21), an IND-approved first-generation drug, offers opportunities for target engagement of next-generation alpha-7 treatments for cognition.

Molecular Imaging of Histamine H_1 Receptors in Schizophrenia

The histamine H_1 system has also been implicated as having a role in the pathophysiology of schizophrenia. Molecular imaging with [^{11}C]doxepin has shown reductions of BP values for H_1 receptors in the frontal and prefrontal cortices and the cingulate gyrus among medicated patients with schizophrenia.

Molecular Imaging of Benzodiazepine Receptors in Schizophrenia

Deficient inhibitory neurotransmission of GABA, an inhibitory neurotransmitter, has also been implicated in the pathophysiology of schizophrenia based on postmortem studies. However, PET studies of the benzodiazepine receptors have been inconclusive.

Molecular Imaging Studies of the Glutamate System in Schizophrenia

Glutamate, the excitatory neurotransmitter, likely plays multiple roles in the pathogenesis and pathology of schizophrenia. One approach is to directly image one of the sites of the NMDA receptor channel, the PCP site. This was done with preliminary studies with *N*-(1-naphthyl)-*N′*-(3-[^{123}I]iodophenyl)-*N*-methylguanidine([^{123}I]CNS1261), which binds to the PCP site in the thalamus and other brain regions. This radiotracer binding is reduced by ketamine, an antagonist of the NMDA receptor, which also binds to this site in part. Although initial radiotracer binding studies did not show differences in patients with schizophrenia compared to healthy controls, treatment with clozapine did reduce

the binding of [^{123}I]CNS1261. This suggests that clozapine exerts some of its action through the PCP site of the glutamate system. Since negative symptoms of schizophrenia were measured to be increased, one possibility is that the glutamate hypothesis of schizophrenia may include reductions of glutamate that lead to negative symptoms. Furthermore, blockade of the NMDA receptor by glutamate antagonists may precipitate positive symptoms of schizophrenia, as shown by the administration of ketamine in humans. At the same time as the ketamine challenges, negative symptoms of schizophrenia are increased as measured by the Brief Psychiatric Rating Scale (BPRS). Thus, the glutamate hypothesis of schizophrenia proposes that reductions of glutamate in the brain lead to negative symptoms of schizophrenia.

Even in healthy controls, ketamine induces hallucinations; hence the ketamine challenge is often considered a human model of mimicking schizophrenia symptoms. Studies involving ketamine infusion have been shown to significantly reduce the binding of [^{11}C]FLB 457 in the posterior cingulate/retrosplenial cortices, which suggests intrasynaptic DAR due to competition of endogenous dopamine with the radiotracer binding. This has further been supported by microdialysis studies in rodents. At the same time, ketamine-induced psychotic symptoms were associated with the changes in the radiotracer binding.

These results suggested that cortical dopamine mechanisms may relate to ketamine-induced psychotic-like symptoms in humans. The second study showed that psychotomimetic doses of (*S*)-ketamine decreased the in vivo binding of [^{11}C]raclopride to striatal D_2-like receptors along with eliciting psychotic-like symptoms with alterations in mood and cognition, and hallucinations. This decreased the raclopride BP by approximately 17% in the ventral striatum, 14% in the caudate, and 14% in the putamen, suggesting an increase in intersynaptic dopamine (i.e., DAR). The change in raclopride BP in the ventral striatum also correlated with heightened mood, including euphoria and grandiosity. This showed additional evidence that the glutamate NMDA receptor may contribute to psychotic symptoms.

Even in some but not all normal volunteers, ketamine-induced changes in [^{11}C]raclopride occurred, that were greater than placebo. In the studies where the changes exceeded placebo, they were not greater than those caused by the intravenous amphetamine, but the ketamine-induced changes were correlated with symptoms seen in schizophrenia. In summary, there is early evidence of this relationship between indirect NMDA antagonists and enhanced DAR in the striatum and elsewhere and extrastriatal areas. Such challenge studies with NMDA antagonists may simulate a hypoglutamatergic state, which is increasingly thought to be consistent with schizophrenia and the downstream effects on dopamine and may also underlie positive symptoms.

Interestingly, studies with acute ketamine did not alter serotonin binding with [^{18}F]altanserin in healthy volunteers. The authors considered this to be more of a

technical finding. [^{18}F]altanserin may be more stable in acute ketamine challenges but might be useful in studying chronic plastic effects of ketamine on 5-HT_{2A} receptors. This does not imply that NMDA antagonists have no effect on serotonin, which remains an unanswered question.

Glutamate and dopamine likely interact in people with schizophrenia. Blockade of the NMDA receptors by glutamate antagonists may precipitate positive symptoms of schizophrenia and produce DAR in the lateral prefrontal and anterior cingulate cortex.

A recent review of molecular imaging of the glutamate system has suggested that, except for ligands of the GluN2B subunit of NMDA receptors, there has been little success in developing radiotracers for imaging ionotropic glutamate receptors. In contrast, mGluR receptor imaging, especially mGluR5, has been used in schizophrenia, fragile X, autism spectrum disorders, substance abuse, alcohol use disorders, and aging and has been more successful.

Cannabinoid PET Imaging in Schizophrenia

An important neurotransmitter system in schizophrenia that may play a role in the developing brain and the risk for psychosis is the cannabinoid system. Three PET ligands ([^{11}C]OMAR, [^{18}F]MPEP, and [^{18}F]MK9470) have been developed and applied to cannabinoid receptor type 1 (CB1) imaging in schizophrenia. One of the first studies of [^{11}C]OMAR showed a fall with age, and a subset of patients with schizophrenia showed elevations beyond the 95% prediction limits of the distribution volume V_T versus age. Another study with a larger sample found decreases in binding with 25 male-only SCZ subjects (SCZs) (18 antipsychotic treated and 7 antipsychotic free amygdala, caudate, posterior cingulate cortex, hippocampus, hypothalamus, and insula. Also, a study using a different CB1 tracer ([^{18}F]MK-9470) showed elevations in the ventral striatum related to negative symptoms. Despite the discrepancies, a subsequent schizophrenia postmortem study in collaboration with the Lewis and Wong labs with [^{3}H]OMAR in the same tissue that showed decreases in mRNA CB1 showed elevations consistent with the original Wong et al. 2010 findings. Also relevant is the finding of elevated male CB1 compared to females using [^{18}F]FMPEP-d_2, where CB1R availability was, on average, 41% higher in males with a regionally specific effect larger in the posterior cingulate and retrosplenial cortices. [^{11}C]OMAR healthy control females had significantly higher V_T estimates than males in all brain regions examined. This may help explain more recent findings using the 3rd generation PET CB1 ligand [^{18}F]FMPEP-d_2 and [^{11}C]MePPEP, where availability of CB1R was lower in antipsychotic-treated and untreated cohorts relative to matched controls. Exploratory analyses indicated that greater reductions in CB1R levels were associated with greater symptom severity and poorer cognitive

functioning in male patients. These discrepancies and sex differences need to be addressed with larger samples and perhaps more optimal CB1 PET radioligands.

Opiate PET scanning in Schizophrenia

Using [^{11}C]carfentanil PET scans in 19 schizophrenia patients and 20 age-matched healthy controls, Ashok et al. showed a significantly lower MOR availability in patients with schizophrenia in the striatum (Cohen's d = 0.7) and the hedonic network. They also reported a marked global increase in inter-regional covariance of MOR availability in schizophrenia, largely due to increased cortical-subcortical covariance. This may relate in part to the opiate-dopamine interaction.

Molecular Imaging of Other Neurochemical Systems

Although PDE10A, a second messenger site, has been considered a therapeutic site, Marques et al. found that patients with schizophrenia have normal availability of PDE10A in brain regions thought to be involved in the pathophysiology of this disorder and concluded that it does not support an altered PDE10A availability in schizophrenia. Unfortunately, PDE10A-targeted medications have not shown efficacy in schizophrenia.

Neuroinflammation in Schizophrenia. Neuroinflammation has been associated with schizophrenia throughout the literature. This has included elevated cytokines that may be due to activated microglia. The neuroinflammatory observation seems to be most associated with early illness stages and patients with acute psychosis symptom exacerbations. The current standard in TSPO PET studies for investigating neuroinflammation in schizophrenia shows discrepancies in outcomes. Moreover, this method requires the additional step and cost of a priori genotyping. Studies with TSPO PET with first and second generation radioligands have not convincingly shown elevations in chronic schizophrenia. TSPO suffers from variable signal-to-noise and, more seriously, the need to genotype subjects to separate high and possibly midaffinity binders which can be studied but omitting those with low-affinity binding. Recent reviews have cast doubt on TSPO as a schizophrenia imaging target, and meta-analyses have shown only small elevations and others none. Recent reviews have even suggested decreases in schizophrenia and acute psychosis. Despite inconsistency with TSPO PET, studies have shown elevations of plasma inflammatory markers, including IL-6 in plasma and CSF. Cox-2 is elevated in schizophrenia, but PET ligands are not yet well developed nor for cannabinoid (CB2). Recently, [^{11}C]S1P1 has been developed for human use and may be a promising alternative. Findings of Chand and colleagues have found a direct agreement of mRNA, protein S1P1 (the latter which is measured by [^{3}H]S1P1 autoradiography as a surrogate for PET) in one of two subgroups of patients who died with schizophrenia where both mRNA and autoradiography shows elevations

compared to another subgroup where there was no elevations by comparison nor different from controls. It is provocative but conceivable that this elevation of S1P1 in one subgroup of patients with schizophrenia corresponds to one of the two distinct subtypes of patients identified by sMRI by Chand in two large machine learning studies (see below section) with clinical differences as well. Thus there is great potential for studying neuroinflammation (or related mechanisms) with other neuroinflammatory tracers like S1P1.

MOLECULAR IMAGING IN DRUG DEVELOPMENT FOR TREATMENTS IN SCHIZOPHRENIA

One of the most challenging aspects of psychiatric pharmacotherapy is the administration of clinically effective drug dosages that cause no or minimal side effects. A recent review outlines many of the challenges of antipsychotic action. At a given dose, plasma concentrations of psychotropic drugs vary extremely because of large inter-individual differences in absorption, metabolism, and excretion. PET and, more recently, SPECT have been used extensively to characterize the relationships between the occupancy of target molecules in the brain (neurotransmitter receptors and transporters) and plasma concentrations of the respective drug. This has been attempted to correlate with clinical efficacy and side effects. PET occupancy measures have now reached the status of almost surrogate markers that have been proven to be critical in decision-making in the development of new psychotropic drugs, especially for choosing a dose for expanded clinical trials. Determination of the appropriate occupancy level for various classes of drugs is vital to streamlining drug development. These studies have also helped elucidate the mechanism of action of some psychotropic drugs, including some of the newer antipsychotics.

D_2 Receptor Occupancy and Beneficial and Adverse Effects of Antipsychotics

With regard to the relationship between drug kinetics in plasma and the brain, as well as clinical effects and side effects, antipsychotics belong to the best-explored drugs. Lars Farde and collaborators demonstrated that clinically effective doses of antipsychotics occupy D_2-like dopamine receptors in the range between 65% and 90%. The suggestion of a “therapeutic window” between 60% and 80% striatal D_2 receptor occupancy for sufficient treatment response and a “ceiling” of around 80% occupancy for EPS was later confirmed by the same and a number of other groups (Fig. 12.9–5). Although the class of antipsychotics is characterized by marked pharmacologic heterogeneity, the general rule that the incidence of EPS increases in a dose-dependent manner does also apply to most of the second-generation antipsychotics, including olanzapine and risperidone. They lose their

“atypical” properties when striatal D_2 receptor occupancy is raised above a threshold of approximately 80%. The 5-HT_2 antagonism, which characterizes most of the second-generation antipsychotics, seems to protect from EPS only at moderate doses; this preservation is lost at striatal D_2 receptor occupancies above the 80% threshold. Thus, when the doses of these drugs are raised above a certain threshold (usually approximately 6 mg for risperidone, 30 mg for olanzapine, and 160 mg for ziprasidone [Geodon]), striatal D_2 occupancy increases to levels that are associated with a higher incidence of EPS.

FIGURE 12.9–5. Previously unpublished composite of two studies reported by Farde et al. (1988, 1992), showing degree of haloperidol saturation of dopamine D_2/D_3 receptors measured by PET of [11C]raclopride binding under different degrees of competition. Abscissa unit is arbitrary relative haloperidol concentration. (Data from Farde L, Wiesel FA, Halldin C, Sedvall G. Central D2-dopamine receptor occupancy in schizophrenic patients treated with antipsychotic drugs. *Arch Gen Psychiatry.* 1988;45(1):71–76. doi: 10.1001/archpsyc.1988.01800250087012; Farde L, Nordström AL, Wiesel FA, Pauli S, Halldin C, Sedvall G. Positron emission tomographic analysis of central D1 and D2 dopamine receptor occupancy in patients treated with classical neuroleptics and clozapine. Relation to extrapyramidal side effects. *Arch Gen Psychiatry.* 1992;49(7):538–544. doi:10.1001/archpsyc.1992.01820070032005.)

However, there are a few exceptions to this general rule. Some second-generation antipsychotics do not induce EPS, even when their doses (or plasma concentrations) are raised to unusually high values. In those cases, the upper threshold of the “therapeutic window” is defined by other side effects rather than EPS. This pharmacologically heterogeneous group of antipsychotics can be differentiated by the distinct characteristics of these drugs in PET studies. Clozapine and quetiapine (Seroquel) occupy a maximum of 60% to 70% of striatal D_2-like dopamine receptors, even at extremely high doses or plasma levels. Twenty-four hours after the last administration of quetiapine, a significant occupancy of striatal D_2 receptors is not detectable anymore. These particular characteristics of clozapine and quetiapine are most likely due to their low affinity rather than their rapid dissociation (k_{off}) from the D_2 receptor. Thus, the tolerability and safety of these drugs are limited by anticholinergic, antihistaminic, and α-adrenergic rather than EPS side effects. On the other hand, the dopamine partial agonist antipsychotics (aripiprazole, [Abilify]; brexpiprazole, [Rexulti]; cariprazine, [Vraylar]) lead to complete saturation of striatal D_2 receptors at clinically used doses, although the incidence of EPS is very low. Mechanisms of action of aripiprazole have been reviewed for PET and in vitro/in vivo characterization for possible future medications. Again, the tolerability of these three drugs is not restricted by the occurrence of EPS but by other side effects such as psychomotor activation (Fig. 12.9–6). The characterization of aripiprazole, brexpiprazole, and cariprazine as partial dopamine agonists explains this unique feature. Thus, the “therapeutic window” for treatment with most antipsychotic drugs is defined downward by a minimum D_2 receptor occupancy, which must be achieved, and upward by the EPS threshold. This rule applies both to first- and second-generation antipsychotics, with the exceptions of dopamine partial agonists and some low-affinity antagonists, including clozapine and quetiapine.

FIGURE 12.9–6. Relationship between aripiprazole (Abilify) daily dose, mean D_2 and D_3 receptor occupancy in the putamen, and clinically expected and used aripiprazole doses. *Horizontal lines* indicate the hypothesized therapeutic window between 60% and 80% striatal D_2 receptor occupancy. The *light-shaded area* designates the dose range that should lead to receptor occupancy within this therapeutic window, whereas the *dark-shaded area* indicates the dose range that has proved to have antipsychotic efficacy. (Reproduced with permission from Gründer G, Carlsson A, Wong DF. Mechanism of new antipsychotic medications: occupancy is not just antagonism. *Arch Gen Psych.* 2003;60(10):974–977. doi:10.1001/archpsyc.60.10.974. Copyright © 2003 American Medical Association. FIGURE 12.9–7. Chemical Structures of FDA approved (four) or under review (one-) antispsychotics. Aripiprazole (Abilify), Lumateperidone (Caplyta), Lurasidone (Latuda), Brexpiprazole (Rexulti) all FDA-approved and n-methylamisulpride (LB-102) in phase 2 pending all have used PET for target engagement of the dose in phase 1 leading to dosing in schizophrenia.

Receptor occupancy of the D_3 receptor has been suggested as a possible treatment for schizophrenia. Blonanserin has a high affinity for D_3 and D_2 receptors in vitro. [^{11}C](+)PHNO has been used to directly measure both D_3 and D_2 in healthy humans after a single dose of 12 mg blonanserin for the D_2-rich region was 0.39 ng/mL, and EC_{50} for the D_3-rich region was 0.40 ng/mL and target engagement in schizophrenia, with an average occupancy by blonanserin (12.8 ± 5.6 mg/day) of EC50 was 0.30 ng/mL for D_2 receptor for caudate and putamen.

New uses of first-generation, previously efficacious antipsychotics include nonracemic amisulpride (SEP-4199) and methyl amisulpride (LB-102) (Fig. 12.9–7).

Extrastriatal Occupancy/Target Engagement. However, all the observations mentioned above were made with reference to receptor occupancy in striatal structures only. With the advent of high-affinity radiotracers belonging to the class of substituted benzamides, such as [^{18}F]fallypride, it became possible to visualize and quantify extrastriatal dopamine receptors. Earlier PET studies with the moderate affinity D_2 or D_3 antagonist [^{11}C]raclopride demonstrated that the second-generation antipsychotics, clozapine, and quetiapine occupy striatal D_2 or D_3 receptors to a significantly lesser extent than other antipsychotics. It was later consistently shown in studies with high-affinity ligands that these two compounds nonetheless occupy a significantly higher proportion of temporal-limbic than striatal D_2 or D_3 receptors. Investigators have demonstrated that the clinical antipsychotic efficacy of clozapine is likely more related to its binding in the

temporal cortex than to its striatal binding. This “preferential” extrastriatal binding of second-generation antipsychotics has since been shown for several other second-generation antipsychotics, at least to a modest extent (Figs. 12.9–7 to 12.9–9).

These findings have important implications not only for drug development but also for clinical practice. Once a plasma concentration range that leads into the “therapeutic occupancy window” has been established using PET, it can be tested to assess if this range is the most useful in large patient populations. This has indeed been demonstrated for various antipsychotic drugs. A well-documented and clinically important example is risperidone. PET studies show that at 6 mg of risperidone daily, the highest dose administered under usual clinical conditions, a significant proportion of patients present with striatal D_2-like occupancies sufficient to cause EPS. In contrast, a daily oral dose of risperidone of 3 to 4 mg produces a striatal D_2-like occupancy in the range of 70% to 80% in most patients. The available data suggest that the 80% threshold associated with a higher probability of EPS is reached with a plasma concentration of approximately 40 ng/mL. A plasma concentration of approximately 15 ng/mL is associated with 60% striatal D_2 occupancy. The same therapeutic window seems to apply to long-acting injectable risperidone. Clinical studies with long-acting injectable risperidone at various doses have demonstrated that a dose of 75 mg (used in clinical testing but is not approved) is associated with a relatively high EPS incidence and correspondingly high plasma concentrations above 40 ng/mL. Most patients treated within the approved dose range of 25 to 50 mg every 2 weeks present with plasma concentrations in the range of 15 to 40 ng/mL. Indeed, the 25 mg dose might be too low in some patients. This example illustrates that the knowledge of an individual’s plasma level can provide meaningful information on psychotropic drug concentrations at brain target molecules.

Dopamine Receptor Occupancy and Relapse. Using PET occupancy studies as the rationale, a recent study has suggested that when antipsychotics are reduced, it should be done gradually (over months or years) and in a hyperbolic manner (to reduce D_2 blockade “evenly”). For example, reducing by one quarter (or one half) of the most recent dose of antipsychotic, equivalent approximately to a reduction of 5% (or 10%) age points of its D_2 blockade, sequentially (so that reductions become smaller and smaller in size as total dose decreases), at intervals of 3 to 6 months, titrated to individual tolerance.

Serotonin Occupancy by PET. For almost all of the newer, second-generation, and partial agonist antipsychotics, high occupancy of serotonin 5-HT_{2A} receptors by these drugs has been documented. While 5-HT_{2A} occupancy is substantially higher than D_2 occupancy under treatment with the D_2 antagonists, including

olanzapine, quetiapine, and risperidone, 5-HT_{2A} occupancy under treatment with one of the three available partial agonists (aripiprazole, brexpiprazole, cariprazine) is lower than D_2 occupancy, in the range between 20% and 40%. The contribution of antagonism by this receptor to the clinical effects of these compounds remains controversial; it may reduce the risk for EPS and possibly improve negative symptoms and cognitive dysfunction. With [^{11}C]NMSP, Gründer et al. first showed the dissociation of brain persistent 5-HT_{2A} occupancy of a single dose of 10 and 20 mg of unlabeled MDL100,907, a selective serotonin 5-HT_{2A}-selective antagonist, versus the relatively rapidly declining plasma concentration. Occupancy studies of quetiapine and [^{18}F]altanserin as the radiotracer have shown a significant positive correlation between neocortical binding prior to treatment and subsequent increases in BMI. At follow-up, the 5-HT_{2A} receptor occupancy was positively correlated with BMI increase.

FIGURE 12.9–8. Extrastriatal dopamine binding with [^{18}F]Fallypride. Representative sagittal (**left**), transversal (**middle**), and coronal (**right**) images from positron emission tomography (PET) with [^{18}F]fallypride ([^{18}F]FP), a radiotracer for extrastriatal D_2/D_3 receptors in the brain, of a 24-year-old man with his first episode of schizophrenia treated with aripiprazole until 78 hours before the tomography. The average striatal D_2/D_3 receptor occupancy was 82%. At the moment of tomography the aripiprazole serum concentration was 106 ng/mL. The striatal and extrastriatal D2/D3 receptor-binding profile of clozapine in patients with schizophrenia. *Neuropsychopharmacology.* 2006;31:1031, with permission from Springer Nature. doi:10.1038/sj.npp.1300931.)

Occupancy Studies of Other Molecular Targets with Potential Relevance in Schizophrenia

Because of its increasing relevance for the pathophysiology of schizophrenia, molecular targets related to glutamatergic neurotransmission have become a topic of major interest in molecular imaging research for more than a decade (see above). Target engagement of some new drugs binding to these targets has been evaluated in PET studies that provided new insights into the clinical relevance of these compounds. One of the targets that attracted significant attention was the glycine transporter type 1 (GlyT1). In preclinical models, GlyT1 inhibitors markedly increase the glycine concentration in the glutamate synapse, putatively at least partly reversing the deficit in glutamate neurotransmission that is believed to underlie aspects of the psychopathology of schizophrenia. Several radiotracers for the GlyT1 have been developed and subsequently used in occupancy studies

with unlabeled inhibitors Wong and colleagues showed that the GlyT1 inhibitor bitopertin occupies the GlyT1 transporter in a dose-dependent fashion, with the highest administered dose, 175 mg daily, occupying around 85% of the target. However, in clinical studies, the dose with the best, albeit not sufficient, efficacy against negative symptoms was 10 mg daily. At that dose, a maximum of only about 40% of the GlyT1 is occupied. Studies in monkeys support the view that GlyT1 inhibitors exert beneficial effects on prefrontal function in cognitively disturbed animals at GlyT1 occupancy values of 10% to 30% and that these effects are lost at higher occupancies. It is presently unclear how these findings have to be interpreted and whether the clinical development of this class of drugs should be further pursued. PET tracers for other glutamatergic targets, such as metabotropic glutamate receptors, have been developed; to our knowledge, none of them have advanced to application in human PET studies of target engagement of investigational compounds, in part due to the absence of robust PET ligands such as for $mGluR_{23}$ a previous important therapeutic target in schizophrenia.

ISSUES OF QUANTIFICATION OF NEURORECEPTORS, TRANSPORTERS, AND INTRASYNAPTIC NEUROTRANSMITTERS

Controversy over Dopamine Molecular Imaging Markers

The original findings in postmortem studies of Dopamine D_2/D_3 receptors suggested elevations consistent with the dopamine hypothesis of schizophrenia. These findings in the late 1970s were potentially confounded by medication effects. The advent of molecular imaging in vivo in schizophrenia allowed studies without the confound of medication effects. Initial studies with [^{11}C]NMSP were first reported in 1986 by Wong et al. and replicated with his colleagues, and [^{11}C]raclopride by Farde et al. in the same time period did not show elevations and hence the inconsistent results; however, recent meta-analyses have shown average elevations of dopamine D_2/D_3 receptors across a number of D_2/D_3 PET radiotracers.

More consistent findings have revealed elevated FDOPA metabolism measures in schizophrenia with and without treatment. Another but less consistently reproduced finding is elevated DA release following intravenous amphetamine challenge. Also, at least two studies showed increased release of DA concentration following an intravenous amphetamine challenge. Here we describe the details and potential pitfalls of quantification of pre versus postmeasures of intrasynaptic DA in schizophrenia. Finally, the details of occupancy (i.e., target engagement) of drugs in relation to therapy are nontrivial in the absence of a

proper region of reference with no specific binding, as is the case with multiple neuroreceptor systems. Here, we describe the use of so-called inhibition plots of drug occupancy in cases of absent reference regions of no binding:

Reports from three studies claimed increased DA release after amphetamine administration, judged from the reduction of the BP of tracer benzamide ligands ([^{11}C]raclopride or [^{123}I]IBZM), calculated relative to the cerebellum as a reference region with no binding. However, the reference region approach can be shown to potentially underestimate the change of BP change to such an extent that no significant change is evident, although the lack of a measurable change is no proof of absent elevated DAR. The only definitive method of accurate determination of the decline of BP depends on measures of tracer concentrations in the arterial circulation that supplies the regions in question, such as TREMBLE (Transient Receptor Equilibrium Method of Bolus Ligand Estimation), see below.

It has been shown that inhibition of dopamine synthesis through AMPT results in lower estimates of BP in patients with schizophrenia versus healthy control subjects. Although there is no difference between BP estimates in patients with schizophrenia and healthy control subjects with [^{11}C]raclopride imaging of dopamine receptors in the absence of AMPT, the evidence suggests higher baseline levels of intrasynaptic DA in the patients with schizophrenia. The same finding was evident from the increased apparent affinity of [^{11}C]NMSP in patients with schizophrenia (Gjedde and Wong, 2001). This can also be shown from the increased baseline DA levels in patients with schizophrenia when the measure of BP is consistent with elevated values of receptor density (B_{max}) in the patients. When baseline BP estimates of patients with schizophrenia are greater than baseline BP estimates from healthy control subjects in the absence of elevated intrasynaptic DA and identical binding affinities (K_D), it follows that the maximum number of receptors in patients with schizophrenia (B_{max}^{SCZ}), equal to the BP relative to the affinity constant (BP^{SCZ}/K_D), is greater than the number of receptors in control subjects (B_{max}^{ctr}) that equals the BP relative to affinity (BP^{ctr}/K_D) in this group of subjects, as further evidence of the presence of elevated D_2/D_3 receptor numbers as measured by PET in the patients with schizophrenia.

Pharmacokinetics of Dopaminergic Neurotransmission. In Figure 12.9–10, the 50% inhibitory concentration or IC_{50} of the tracer depends both on the receptor's affinity toward the tracer and the concentrations of competitors.

The most commonly reported variable obtained with imaging of dopaminergic neurotransmission is the ratio between the density of receptors and the affinity constant, known as the BP. Both terms are part of Michaelis' and Menten's steady-state solution (1913) to the binding equations as follows,

FIGURE 12.9–10. In vitro versus in vivo action of first-generation antipsychotics. Relationship between IC50 values at dopamine receptors and therapeutic dose of neuroleptics in treatment of schizophrenia. The IC50 values are the concentrations of the antipsychotic drugs that reduce the stereospecific component of [3H]haloperidol binding by 50%. The abscissa indicates the average values of doses used in schizophrenic patients. (Redrawn from Seeman P, Lee T, Chau-Wong M, Wong K. Antipsychotic drug doses and neuroleptic/dopamine receptors. *Nature.* 1976;261:717–719, with permission from Springer Nature. doi: 10.1038/261717a0.)

$$B = \frac{B_{max}\ C}{K_D + C} \qquad (1)$$

where B is the bound quantity of the ligand, B_{max}, the maximum number of binding sites, C is the unbound ligand's concentration, and K_D is the Michaelis–Menten dissociation constant or half-saturation binding concentration of the ligand. The BP is the ratio between the bound and unbound ("free") quantities of a ligand, including an endogenous ligand, relative to the receptor's affinity for this ligand, that is, multiplied by the Michaelis–Menten half-saturation constant of the receptor toward the ligand in question. The two definitions of the BP express the potential in terms of available receptors (i.e., receptors not occupied by ligands) or in terms of the concentrations of ligands, as follows,

$$BP_{ND} = \frac{B^*}{C^*} = \frac{B_{max}}{C^* + K_D^* \quad 1 + \frac{C_i}{K_I}} = \frac{K_I B_{max}}{K_D^* (K_I + C_I)} = \quad \frac{K_I}{K_D^*} \quad \frac{B_i}{C_i} \tag{2}$$

where the asterisks refer to the radiotracer. The symbol BP_{ND} represents the BP, and the remaining symbols represent the masses or concentrations of specifically bound ligand (B^*), unbound tracer (C^*), the maximum number of binding sites (B_{max}), affinity toward the ligand (K_D), and the affinity toward any competing endogenous ligand (K_I) with a presence as mass or concentration in the vicinity of the receptors (C_i) sufficient to occupy a significant number of receptor sites (B_i) as mass or concentration (Fig. 12.9–11). Note that the BP is a unitless ratio that requires that the variables of the ratio have identical units.

The specific definitions depend on the process and the conditions, but generally, the magnitude of k_3 is related to the quantity of protein and the concentration of the tracer, while k_4 is the decay constant of the pool of retained substance. Depending on the steady state, the definitions are,

FIGURE 12.9–11. Three-compartment model. Three-compartment model of receptor binding of ligand. The transfer coefficients are clearances (units of flow) or rate constants (units of reciprocal time or clearance relative to volume of distribution), the former shown by upper-case symbols, the latter by lower-case symbols. The clearance shown as K1 is the blood–brain clearance, and the rate constant shown as K_2 is the fractional clearance from the precursor pool in brain. For definition of remaining rate constants, see text. (Reprinted from Phan JA, Wong DF, Chang NHS, et al. Transient equilibrium determination of dopamine D2/D3 receptor densities and affinities in brain. *Front Nucl Med.* 2022;2:1030387. © 2022 Phan, Wong, Chang, Kumakura, Bauer and Gjedde. doi:10.3389/fnume.2022.1030387.)

$$k_3 = k_{on}\left(B_{max} - B\right) \tag{3}$$

and

$$k_4 = k_{off} \tag{4}$$

or

$$k_3 = k_{on}\ B_{max} \tag{5}$$

and

$$k_4 = k_{off}\ \ 1 + \frac{C}{K_D} \tag{6}$$

where k_3 and k_4 define the respective association and dissociation constants, of which only k_4 is a symbol that represents rate constants. The ratio k_3/k_4 is a

function of the amount of protein (such as the density of receptors) and the affinity for the tracer. The ratio is, therefore, an index of the tissue's potential for retention. In the case of binding, the definitions show that this ratio is also the BP defined earlier. The exact solutions are those given by Gjedde et al. (1986) with the calculation of the receptor density from multiple estimates of the BP when the quantity of bound ligand is known for each estimate. The bound quantities, in principle, include both endogenous and exogenous ligands, such as a drug given to reduce the BP of the tracer by competition for binding.

Estimates of the receptor density are not routinely measured in human PET studies anymore because they require significant occupation of the receptors by a ligand with a specific pharmacodynamic effect. The procedure consists of giving a pharmacologically active dose of a ligand together with the tracer (e.g., 7.5 mg oral haloperidol in the case of [^{11}C]NMSP by Wong et al. (1986, 1997 or with unlabeled raclopride together with tracer [^{11}C]raclopride in the case of Farde et al. 1986)). As many as five different estimates of the BP have been made to complete Scatchard or Eadie–Hofstee plots of the binding, as shown in Figure 12.9–12, where the specific activity was reduced by increasing amounts of carrier-added unlabeled raclopride.

	MPTP	Control_1	Control_2	AMPH
Bmax	31	25	21	23
Kd	13	13	14	26
Std. Error				
Bmax	1.3	1.6	0.66	1.1
Kd	0.86	1.3	0.65	1.8

FIGURE 12.9–12. B_{max} and K_d estimates from multiple specific activities with [^{11}C]raclopride in nonhuman primates studies. Eadie–Hofstee plots of dopamine receptor density and radioligand affinity, determined with [^{11}C]raclopride in monkeys rendered parkinsonian by means of MPTP administration, in comparison with control monkeys. Eadie–Hofstee and Scatchard plots are linear renditions of the equation that defines the binding potential. This is also the equation of the Scatchard plot, in which the abscissa is the total quantity of bound ligand (**B**), usually determined from the specific activity and binding potential of the radioligand. The ordinate is the binding potential (BP_{ND}), determined as the ratio of bound to unbound ligand from binding regions-of-interest and a reference region of no binding, or from regression analysis estimates of the rate constants k_3 and k_4 or their ratio k_3/k_4, which equals the binding potential at steady-state. (The Eadie–Hofstee plot is drawn from data reported by Holden JE, Jivan S, Ruth TJ, Doudet DJ. In vivo receptor assay with multiple ligand concentrations: an equilibrium approach. *J Cereb Blood Flow Metab*. 2002;22(9):1132–1141.)

Calculation of Receptor Occupancy

For antipsychotics as well as a number of antidepressants, occupancies of 60% to 80% of dopamine receptors yield the best therapeutic effect. The receptor occupancy plotted against the plasma level of the drug essentially is a Michaelis–Menten graph of the therapeutic “window of opportunity” for a neuroleptic. This

also appears to be true for partial agonists as well as antagonists of the dopamine receptors. This calculation is straightforward when there is a reference region, such as when measuring D_2/D_3 receptor occupancy.

FIGURE 12.9–13. Three inhibition plots for target engagement in absence of reference region. Three linearization plots, Saturation, Inhibition, and Occupancy plots, plotted from data acquired by Horti et al. (2014) for an inhibition dose of 0.5 mg, as discussed in relation to Equations (7)–(13) in the text and by Khodaii et al. (2022). (Data from Horti AG, Gao Y, Kuwabara H, et al. 18F-ASEM, a radiolabeled antagonist for imaging the α7-nicotinic acetylcholine receptor with PET. *J Nucl Med.* 2014;55(4):672–677. doi:10.2967/jnumed.113.132068.) (See eBook for color images.)

Neuroreceptor studies of the brain in vivo using PET require comparisons of the magnitudes of BPs (BP_{ND}) of radiopharmaceutical receptor ligands at more or less inhibited receptor states from obtaining estimates of receptor density and affinity. The quantitative determination of BP_{ND} uses a fundamental equation of receptor availability to obtain separate estimates of radioligand BPs of a specific radioligand (Equation 2).

Application of any one of the three linearizations shown in Figure 12.9–13 is the first step toward the determination of the BP (BP_{ND}, also known as receptor availability) that is the foundation of the receptor binding analysis. The need for these equations arises when radioligands are applied for which a proper reference region with no specific binding of the ligand either does not exist or is not known to exist. In these cases, the three linearized versions of the basic receptor availability equation have been derived for the purpose of estimating the magnitude of the reference distribution volume of the radioligand in a region of nondisplaceable (i.e., nonspecific) binding (V_{ND}) by simple linear regression. The symbol V_{ND} refers to the distribution volume of the nondisplaceable tracer in the nonbinding compartment, also known as the partition volume or partition coefficient of the ligand.

Three different graphical plots emerged when the authors of publications by Lassen et al. (1995), Gjedde and Wong (2000), and Cunningham et al. (2010) linearized the basic equation of receptor availability to obtain the plots that we

here refer to as the Saturation, Inhibition, and Occupancy plots (Equations 11 to 13 below). The plot names avoid the uncertainty of the authors associated with the Occupancy Plot solution (Equation 12), referred to by some authors as the Lassen Plot, although "Lassen" is the name more appropriately applied to the plot (Equation 11) that Lassen et al. actually derived and reported.

In the present examination of the plots of competition, we linearized the formulation of the fractional receptor availability (Equation 7) into the three equations underlying the different regressions that we refer to as the Saturation, Inhibition, and Occupancy plots. The purpose of all three linearizations is to obtain an estimate of the reference volume of distribution V_{ND} required to calculate the BP_{ND} of a radioligand. The quantitative determination of the BP (BP_{ND}) uses a fundamental equation of receptor availability to obtain separate estimates of radioligand volumes of distribution of a specific radioligand that yield a variable now generally known as "availability" (α),

$$\alpha = 1 - s = \frac{V_{T(i)} - V_{ND}}{V_{T(b)} - V_{ND}} \qquad (7)$$

that is, the formulation of relative or fractional receptor availability (1 – *s*) in terms of the relevant volumes of distribution when the term *s* represents the occupancy of the ligand. The volume of distribution terms represents the baseline and inhibition states of the radioligand, including the values of the total volumes of distribution (V_T). Of the terms, $V_{T(i)}$ represents the degree of inhibition by binding, that is, the apparent total volume of distribution of the sum of the specifically bound and nonspecifically dissolved ligand molecules occupying the receptor. The term $V_{T(b)}$ represents the baseline state of the apparent total volume of distribution, that is, when the receptor is not occupied by a specific inhibitor. Application of any one of the three linearizations presented here is the first step toward the determination of the magnitudes of BP_{ND} (or receptor availabilities) that is the foundation of the receptor binding analysis. The term BP_{ND} enters into the particular Eadie–Hofstee version of the linearized Michaelis–Menten equation that yields both the maximum binding (B_{max}) and the affinity coefficient (Michaelis half-saturation content or mass), K_D', of the receptors,

$$B = B_{max} - K_D \, BP_{ND} \qquad (8)$$

where *B* is the quantity of bound ligand. As above, the symbol BP_{ND} represents the ratio of the volumes of distribution of specifically bound ("displaceable") and nonspecifically bound ("nondisplaceable") ligand quantities. To determine the BP_{ND} of a radioligand, the volumes of distribution are entered into the relationship that defines the BP_{ND} (Equation 2),

$$BP_{ND} = \frac{V_T - V_{ND}}{V_{ND}} \quad (9)$$

which is applicable both to the receptor binding baseline and to multiple degrees of receptor blockade, provided the V_{ND} estimate is unaffected by the blockade. To calculate the value of BP_{ND}, it is necessary to know the distribution of unbound ligands in a region of no binding. However, the linearizations presented below serve to determine the reference volume of distribution of radioligands when the value of the volume (i.e., as applicable to a region of absent specific binding) is not known. From the volumes of distribution of the radioligand in the absence of displaceable binding, three different linearizations yield the BP_{ND} of radioligands, as shown in Figure 12.9–13.

Saturation Plot. As a novel steady-state approach to the determination of BP_{ND} of tracers with an unknown reference volume of distribution, Lassen et al. in 1995 proposed to compare two levels of receptor occupancy, one essentially at zero for the labeled tracer itself and the other in the midrange of occupancy by addition of unlabeled ligand. To obtain the volume of nonspecific binding, Lassen et al. (1995) linearized Equation (7) to obtain the form of the plot we here call the Saturation plot. The plot yields the estimate of V_{ND} by plotting the baseline volume of distribution ($V_{T(b)}$) as a function of the difference between the baseline and inhibition volumes of distribution,

$$V_T = V_{T(b)} - V_{T(i)} \quad (10)$$

that yields the basic Equation 11 of the Saturation plot,

$$V_{T(b)} = (1/s) \quad V_T + V_{ND} \quad (11)$$

where the estimate of V_{ND} is the ordinate intercept of the linear regression, and the estimate of the reciprocal of the saturation ($1/s$) is the slope of the regression.

Inhibition Plot. Realizing that the uncertain choice of a reference volume of distribution of the ligand can lead to erroneous estimations of the occupancy, Gjedde and Wong (2000) proposed to linearize Equation (7) to obtain the form of the Inhibition Plot. The plot yields the estimate of V_{ND} by relating the inhibited volume $V_{T(i)}$ to the baseline volume $V_{T(b)}$ by linear regression, as shown in Equation 12 (also see Table 12.9–2),

$$V_{T(i)} = (1 - s)V_{T(b)} + sV_{ND} \quad (12)$$

where the estimate of V_{ND} is obtained as the intercept of the linear regression line with the line of identity.

Occupancy Plot. In 2010, Cunningham et al. inverted the axes of the Saturation plot to obtain the plot of Equation 13 below. The authors presented the axes of the inverted Saturation plot as the plot we here call the Occupancy Plot to avoid the lack of specificity of the term "Lassen Plot." The linearization of the Occupancy Plot treats the differences between the volumes of distribution at the baseline and challenge conditions, represented by V_T as for the Saturation plot, shown here as a function of the baseline volume of distribution,

$$V_T = sV_{T(b)} - sV_{ND} \qquad (13)$$

where V_{ND} is the abscissa intercept. It is evident from the derivations that the Saturation and Occupancy plots have mutually inverted axes.

Based on goodness of fit parameters and with two regression methods (Least Squares and Deming II), we have shown the Inhibition and Occupancy plots to have higher degrees of convergence, most likely because of the absent commingling of the dependent and independent variables characteristic of the Saturation or original "Lassen" plot. Concerning the effect of the regression method (Least squares and Deming II), the average differences of results of the Inhibition and Occupancy plot linearizations on average are less than 1% and, as such negligible. In contrast, there is more than a 35% difference between the results of the Saturation plots by Least Squares and Deming II regressions because of the violation of the negligible variability rule for independent variables. Noise analysis shows that the three plots result in the same parameter estimates in the absence of noise, but in the presence of noise, the Inhibition and Occupancy plots yield higher and closer degrees of convergence.

Also, the inhibition plot has been extended to include additional effects of plasma and brain protein binding (Phan et al., 2017). Accurate quantification of target engagement (occupancy) of receptor-mediated antipsychotic treatments is vital, especially in the absence of a reference region for the receptor of interest. This is more common for newer receptor targets (e.g., CB_1, or α7 nAChR) regardless of the PET ligand, so the issue is fundamental to quantification in the assessments of new treatments offered to patients with schizophrenia.

MOLECULAR IMAGING AND GENETICS

Schizophrenia has a heritability of about 80%, but the detailed molecular genetic basis of the disease remains to be fully determined. Molecular brain imaging, as applied to the study of schizophrenia, can be a useful means to quantify mediators of this genetic vulnerability. Two approaches have been applied. Molecular imaging studies have been performed in individuals at genetic risk for schizophrenia. Increased cortical D_1 and caudate D_2 densities have been observed in monozygotic compared to dizygotic siblings of patients with

schizophrenia. First-degree relatives of patients with schizophrenia have displayed increased uptake of [^{18}F]6-fluorodopa ([^{18}F]FDOPA) in caudate-putamen. These observations in at-risk samples are consistent with neuroreceptor binding studies in patients with schizophrenia who have demonstrated increased D_1, D_2, and FDOPA uptake. These studies highlight the potential role of molecular brain imaging in identifying genetic markers for schizophrenia as well as individuals at risk for the disease who might benefit from pharmacologic intervention. Furthermore, the potential role of molecular brain imaging in identifying genetic markers for schizophrenia is confirmed by the findings of a decrease in the prefrontal and cortical binding of 5-HT_{2A} receptors using PET and [^{18}F]altanserin in subjects at enhanced risk of schizophrenia. Those subjects at risk who developed first-episode psychosis showed an additional decrease of 5-HT_{2A} receptor BP in the caudate in comparison to the “nonconverters,” suggesting that the progressive reduction of 5-HT_{2A} receptor binding in the caudate could provide an indicator of illness activity and help to predict imminent conversion to schizophrenia. This study’s findings, although interesting, may be diminished by the very low concentration of 5-HT_{2A} receptors in the caudate, which makes it problematic to measure their binding. The second approach is to characterize genetic polymorphisms of the same transporters or receptors that are being imaged.

The use of molecular imaging also seems helpful in clarifying the contribution that different genotypes associated with dopamine receptors play in defining the phenotypic expression of the receptors themselves in schizophrenia. Impaired DAT function has been thought to be involved in antipsychotic-induced EPS. Nonetheless, studies so far conducted have been negative in this regard. The frequency of the more common alleles of the variable number of tandem repeats (VNTR) polymorphism of the DAT gene (SLC6A3) was not preferentially associated with patients who had EPS. Furthermore, no significant differences in DAT BP have been found among the three major VNTR genotype groups. Additionally, no significant association has been found between VNTR polymorphism and amphetamine-induced DAR and DAT BP density in patients with schizophrenia. These studies seem to suggest a lesser role for DAT as compared to D_2 or D_1 receptors in the pathophysiology of schizophrenia. Although not in patients with schizophrenia but with significant implications for patients with this disease is a study to determine whether common gene variants of the brain dopamine pathway explain the variability in nicotine-induced DAR. For subjects who smoked during imaging, those with at least one 9 allele of the dopamine transporter variable nucleotide tandem repeat, fewer than seven repeats of the D_4 variable nucleotide tandem repeat, and the Val/Val catechol-O-methyltransferase (COMT) genotype had greater decreases in BP (an indirect measure of DAR) with smoking than those with the alternate genotypes. An overall decrease in ventral

caudate/nucleus accumbens BP in those who smoked compared with those who did not smoke was also found. These findings suggest that dopamine system genotype variabilities explain a significant proportion of the interindividual variability in smoking-induced DAR and indicate that smoking-induced DAR has a genetic predisposition. COMT has been shown to be critical for prefrontal dopamine flux and prefrontal cortex-dependent cognition and activation. Several potentially functional variants in the gene have been identified, but considerable controversy exists regarding the contribution of individual alleles and haplotypes to the risk for schizophrenia.

A pattern of inefficient prefrontal cortex engagement during working memory studied with fMRI has been found in normal volunteers in association with the Val158Met polymorphism of the COMT gene. A polymorphism of the metabotropic glutamate receptor 3 or GRM3, a G protein-linked receptor modulating synaptic glutamate, has also been associated, even in normal subjects, with a pattern of inefficient prefrontal cortex engagement during working memory studied with fMRI analogous to that found with COMT. A recent study has observed an apparent epistatic interaction of these two genes on the engagement of the prefrontal cortex during working memory. Specifically, the *GRM3* genotype putatively associated with suboptimal glutamatergic signaling was significantly associated with inefficient prefrontal engagement and altered prefrontal-parietal coupling on the background of the COMT Val-homozygous genotype. Conversely, COMT Met-homozygous background mediated against the effect of *GRM3* genotype. These findings extend putative brain dopaminergic and glutamatergic relationships indexed by COMT and *GRM3* to a systems-level interaction in human cortical circuits implicated in working memory dysfunction, such as in schizophrenia.

ROLE OF ARTIFICIAL INTELLIGENCE AND MACHINE LEARNING IN SCHIZOPHRENIA SUBTYPING AND HETEROGENEITY ANALYSIS

Brain imaging methods, especially PET and structural MRI (sMRI), followed by advanced analytical approaches, have emerged as one of the encouraging research pillars in schizophrenia and many other mental diseases. Machine learning (ML) is a subfield that lies in a broadly named artificial intelligence (AI) field and is the current state-of-the-art standard that has emerged substantially in recent years. However, our success is heavily dependent on the accurate quantification of these imaging measures, as the effects of interest in schizophrenia are subtle, spatially distributed, and complicated in nature. The majority of current image analytics commonly overlook the heterogeneity of imaging phenotypes of schizophrenia. This means if certain neuroanatomical and molecular patterns are observed in some but not in all individuals with schizophrenia, these analytics are prone to confound the observed brain patterns.

There is a large body of literature suggesting that individuals with schizophrenia exhibit highly heterogeneous genetic profiles, clinical symptoms, illness course, and treatment response. Despite extensive efforts, understanding schizophrenia mechanisms and developing targeted, personalized clinical treatment are not encouraging, partly because there is still a substantive need for highly accurate and reproducible analytical methods.

FIGURE 12.9–14. Dopamine D_2/D_3 PET with occupancy. Representative transversal images from positron emission tomography (PET) with [^{11}C]raclopride, a radiotracer for striatal D_2/D_3 receptors in the brain, of a healthy adult volunteer without medication (**left**) and after treatment for 14 days with either 2 mg (**middle**) or 30-mg (**right**) aripiprazole (Abilify). The baseline study (**left**) demonstrates marked uptake of the radiotracer in the striatum (caudate nucleus and putamen) indicating a high density of striatal D_2/D_3 receptors. After treatment with 2 mg aripiprazole for 14 days, approximately 70% of the D_2/D_3 receptors in the striatum are occupied by aripiprazole so the radiotracer uptake is markedly reduced (**middle**). After treatment with 30-mg aripiprazole for 14 days, almost all of the D_2/D_3 receptors in the striatum are occupied by aripiprazole so the radiotracer uptake is almost completely blocked (**right**). These results confirm that aripiprazole occupies the D_2/D_3 receptors in the striata of healthy adults in a dose-dependent manner, and that clinical doses of the drug lead to almost complete saturation of striatal D_2/D_3 receptors. (Modified from Yokoi F, Gründer G, Biziere K, et al. Dopamine D2 and D3 receptor occupancy in normal humans treated with the antipsychotic drug aripiprazole (OPC 14597): A study using positron emission tomography and [11C]raclopride. *Neuropsychopharmacology.* 2002;27:248, with permission from Springer Nature. doi:10.1016/S0893-133X(02)00304-4.)

A recent study by Chand and colleagues speaks directly to this type of weakness using newly developed data-driven ML methods in large international consortium-based schizophrenia and control samples. This study was different from the previous subtyping, where schizophrenia patients are typically subtyped using only the schizophrenia patients, which risks that the subtypes are confounded by the staging of disease patterns, age, sex, and imaging protocols

based on the similarity metrics. However, in Chand and colleagues, schizophrenia patients are subtyped based on their relative deviations in diverse directions from controls, where the potential confounds such as age, sex, race, and imaging protocols are nullified by balancing patient and control groups.

In the report by Chand and colleagues, the first subtype was characterized by widespread reductions of white matter volume and gray matter volume correlating with illness duration and poorer premorbid functioning. In contrast, the second subtype was associated with overall normal brain structure except for enlarged striatal and internal capsule volumes. The prevalence of the first subtype of schizophrenia was ~63%, and the second subtype of schizophrenia was ~37%. Thus if those patients are grouped together (without subtyping) and compared with controls, the imaging patterns will be similar to that of the higher prevalence group (~63%, the first subtype), and the patterns of the lower prevalence group are confounded in the current standard case-control comparisons. These findings have been recently replicated using a different newly developed multi-scale ML methodology. These neuroanatomical subtype signatures of schizophrenia have also been replicated in an independent dataset, and their expressions are quantified in psychosis-spectrum/typically developing youths and adults. Schizophrenia subtype signature expressions are associated differentially with psychosis symptoms, cognition, and genetic risk, potentially reflecting underlying neurobiologic vulnerability. Data-driven ML approaches of these studies can be applied to PET imaging with different radioligands and/or by integrating *complementary* information of sMRI and PET to better parse out the underlying disease heterogeneity in schizophrenia. Imaging measures are highly dimensional, but relating them to clinical, cognitive, molecular, or other risk factors is often challenging and requires an informed data summarization-based framework. The ML approach by Chand and colleagues places each subject in a 2D space formed by the two schizophrenia types and thus helps simplify the relationships among these different measures, which are interpretable and clinically valuable. Future PET studies in schizophrenia will benefit by incorporating such newly developed data-driven ML/AI methodologies. One of the potential challenges is that current PET studies in schizophrenia have smaller sample sizes. The molecular imaging communities can thus encourage data sharing to achieve larger samples needed to apply and validate ML models. The optimistic goal is to extract critical information on the heterogeneity of schizophrenia and contribute to precision medicine of diagnosis and treatment of schizophrenia.

MOLECULAR IMAGING IN CLINICAL PRACTICE

Molecular Imaging in the Treatment of Schizophrenia

Molecular imaging may become a tool to evaluate treatment effectiveness for people with schizophrenia. For example, traditional antipsychotic agents typically produce maximal therapeutic effects with minimal adverse effects when 75% to 80% of the dopamine D_2 receptors are occupied. Similarly, receptor occupancy can be demonstrated by means of PET for dopamine receptors with atypical antipsychotic agents (Fig. 12.9–14). Thus, administration of a molecular imaging procedure to an unimproved person with schizophrenia before and after typical therapeutic doses of a dopamine D_2 receptor blocking drug may demonstrate markedly low occupancy of dopamine D_2 receptors, thus explaining why the person does not benefit from a typical dose of a drug. Alternatively, if the occupancy is not low, the imaging study can help to identify groups of patients who might benefit from medications other than dopamine antagonists. Similarly, molecular imaging of dopamine and serotonin transporters and receptors before and after the administration of novel therapeutic agents may provide evidence for the typical effects of innovative therapeutic agents for schizophrenia. Thus, molecular imaging of neurotransmitter systems in people with schizophrenia may become tools to monitor putative therapeutic interventions. Additionally, molecular imaging of neurotransmitter systems in people with schizophrenia may provide evidence for or against future therapeutic interventions for a particular individual with schizophrenia.

FUTURE DIRECTIONS

The future of molecular imaging in schizophrenia is closely linked to the progress in the discovery and understanding of the molecular mechanisms related to the etiology and pathophysiology of the disease. The role of the glutamatergic system has become increasingly clear over the past decade. Both NMDA and non-NMDA glutamate receptors have been implicated in the pathophysiology of positive, negative, and cognitive symptoms of schizophrenia. A hypofunction of cortical glutamate has been postulated to interact with subcortical dopamine to cause increased release of presynaptic dopamine and elevated numbers of postsynaptic dopamine receptors. There is a need to develop ligands for glutamatergic receptors like metabotropic glutamatergic receptors type 2/3 (mglu2/3), whose agonist has recently been utilized for the treatment of schizophrenia. Likewise, there exists a tremendous future role for ligands for (1) the glycine and serine modulatory sites of the NMDA receptor and (2) the enzyme racemase that regulates the production of d-serine in the brain. Furthermore, the study of nicotinic receptors in vivo in patients with schizophrenia has also been limited by the availability of probes (especially the α7 subtype) for these receptors that likely play a significant role in the mechanisms of schizophrenia. New probes are also needed to image those neuronal structures (i.e., cytoskeleton proteins) involved in

neuronal migration and synaptic formation, and that form the basis of the neurodevelopment hypothesis of schizophrenia.

12.10 Neurocognition in Schizophrenia

PHILIP D. HARVEY, PH.D.

NEUROCOGNITIVE IMPAIRMENT IN SCHIZOPHRENIA

Neurocognition as a Core Feature of Schizophrenia

Neurocognitive impairment in schizophrenia is clinically relevant and profound. Patients with schizophrenia perform one to two standard deviations below healthy controls on various neurocognitive tests. The severity of this impairment is greatest in the domains of memory, attention, working memory, problem-solving, processing speed, and social cognition. These deficits are present prior to the initiation of antipsychotic treatment and are not caused by psychotic symptoms in those patients who are able to complete testing, which includes the overwhelming majority. Many of the various neurocognitive deficits in schizophrenia have been shown to be associated with functional outcomes such as difficulty with community functioning, difficulty with instrumental and problem-solving skills, reduced success in psychosocial rehabilitation programs, and the inability to maintain successful employment. Neurocognitive deficits are better able to explain important functional outcomes such as work performance and independent living than positive or negative symptoms.

The emphasis on neurocognitive deficits in schizophrenia goes beyond their severity and relation to functional outcomes. Neurocognitive deficits are present to an extent in some patients with schizophrenia prior to the onset of psychosis, are prominent during the prodrome, and are correlated with measurable brain dysfunction more than any other aspect of the illness. Perhaps most importantly, neurocognition is increasingly considered a primary target for treatment.

Despite the importance of neurocognitive impairment in the biology, function, and treatment of schizophrenia, and despite the emphasis placed on neurocognitive impairment by Emil Kraepelin and Eugen Bleuler over 100 years ago, it still is not included as a criterion for diagnosis in the Fifth Edition of the *Diagnostic and Statistical Manual For Mental Disorders* or the eleventh edition of *International Statistical Classification of Diseases and Related Health Problems* (ICD-11) criteria. It is noteworthy, however, that this newest edition of the DSM has extensive discussions of cognition and its relation to disability. These discussions include the recommendation that assessment of cognition and everyday functioning should be a routine part of the assessment of schizophrenia, and the assessment scales section of the DSM-5 (Section 3) includes an assessment of the severity and types of cognitive deficits. Thus, recognition of the importance of cognition in schizophrenia is now truly “official” and viewed as centrally important to the assessment of the condition.

Profile and Magnitude of Neurocognitive Impairment Associated with Schizophrenia

The level of severity of impairment in performance on neurocognitive tests is strong evidence of the importance of neurocognitive deficits in schizophrenia. Neurocognitive deficits appear to be present in patients with schizophrenia early in the course of the illness. A number of studies have demonstrated that, on various neurocognitive test domains, unmedicated patients with either first-episode or chronic schizophrenia perform close to two standard deviations below healthy controls (Fig. 12.10–1). Further, those cases which are apparently in a prodromal state and covert to psychosis have more severe cognitive deficits at the time of the detection of their state than those cases that do not convert. The most striking aspect of the profile of neurocognitive deficits in patients with schizophrenia is that so few neurocognitive functions remain similar in level of performance compared to healthy controls. In fact, an estimate of the severity of neurocognitive impairment in patients with schizophrenia, based on an examination of the most methodologically sound studies completed, suggests that many important neurocognitive functions are in the impaired range (one to two standard deviations below the normal mean). Meta-analysis of over 300 studies shows a consistent and stable difference between patients with schizophrenia and healthy controls in a wide range of domains of neurocognitive functioning (Fig. 12.10–2).

Neurocognitive tests often assess more than one domain of functioning, and many tests do not fit neatly into a single domain. Thus, descriptions of the profile of neurocognitive deficits in schizophrenia have varied across literature reviews and can be confusing to the nonpsychologist. The domains that are most consistently cited as being severely impaired in schizophrenia are verbal memory, executive functions, attention or vigilance, verbal fluency, and motor speed. Deficits in social cognition also appear to be severe, but there is less normative data available on healthy people to provide information about the severity of impairment. The opinion of a group of experts who served on the Neurocognition Subcommittee for the Measurement and Treatment Research to Improve Cognition in Schizophrenia (MATRICS) Project is that the most important domains of neurocognitive deficit in schizophrenia are working memory, attention/vigilance, verbal learning and memory, visual learning and memory, reasoning and problem-solving, speed of processing, and social cognition. These domains were chosen because they were viewed as substantially impaired, separable from one another, and to have demonstrated relationships to functional outcomes such as independent community living.

FIGURE 12.10–1. Impairment in major cognitive domains in first-episode patients compared to patients with schizophrenia in general. Based on two systematic meta-analyses: Mesolam-Gately et al. (2009) for first-episode patients and Dickinson et al. (2007) for patients in general. (Data from Mesholam-Gately RI, Guiliano AJ, Goff KP. Neurocognition in first episode schizophrenia: a meta-analytic review. *Neuropsychology*. 2009;23:315–336; Dickinson D, Ramsey ME, Gold JM. Overlooking the obvious: a meta-analytic comparison of digit symbol coding tasks and other cognitive measures in schizophrenia. *Arch Gen Psychiatry.* 2007;64:532–542.)

FIGURE 12.10–2. Effect sizes for six different domains on the Measurement and Treatment Research to improve cognition in schizophrenia (MATRICS) batter. Data were collected at screening assessments for participants who were enrolling into cognitive enhancement pharmacologic trials (n = 2,616). The processing speed domain has three tests, symbol coding, Trail Making Part A, and Animal naming. Working memory has two tests: the Maryland Letter Number Span and WAIS Spatial Span. All other domains are defined by a single test.

Attention/Vigilance. *Vigilance* refers to the ability to maintain attention over time. A standard vigilance test used in many studies is the continuous performance test (CPT). The "Identical Pairs" version of the CPT requires that

patients attend to a series of two- to four-digit numbers presented sequentially on a computer screen at a rate of one per second. Patients respond with a button press on the computer mouse or keyboard each time a number is identical to the previous number. This type of CPT reveals moderately severe vigilance impairments in patients with schizophrenia. Many neurocognitive tests require intact vigilance for good performance, even if the test itself is not a measure of "pure" vigilance.

Impairments in vigilance can result in difficulty following social conversations and an inability to follow important instructions regarding treatment, therapy, or work functions. Simple activities like reading or watching television can become labored or impossible. Reviews of the literature have suggested that vigilance deficits in patients with schizophrenia are related to various aspects of the outcome, including social deficits, community functioning, and skills acquisition.

Verbal Learning and Memory. *Verbal memory* functioning includes, but is not limited to, abilities associated with learning new information, retaining newly learned information over time, and recognizing previously presented material. In general, patients show larger deficits in learning than in retention. The findings for recognition are more equivocal, with most studies suggesting relatively mild deficits, although large deficits have also been reported.

The tests used to measure learning typically involve the ability to learn lists of words or written passages. Verbal list learning tasks usually require the patient to listen to 12 to 16 words, then immediately recall as many of the words as possible. Using the California Verbal Learning Test, healthy controls can recall about 8 of 16 words after the first trial; patients with schizophrenia can recall only about 5. After five consecutive trials of the same word list, most controls can recall at least 13 of the words, while patients with schizophrenia, on average, can recall only nine. Thus, patients with schizophrenia are not only impaired in their ability to immediately recall verbal material but they are also impaired compared to controls in their ability to learn over time. Patients are also impaired in recalling more engaging verbal material, such as stories. Much empirical evidence points to the connection of verbal memory impairment with impairments in everyday activities and occupational deficits in patients with schizophrenia. Success in many modern endeavors requires the ability to learn information that is presented in a verbal context. Interestingly, there is little evidence that people with schizophrenia forget more verbal material than they have learned than healthy controls, with rapid forgetting being much more common in cortical dementias such as Alzheimer disease.

Visual Learning and Memory. Since visual information is not as easily expressed as verbal information, fewer tests sensitive to the deficits of schizophrenia have been developed. Most tests expose subjects to one or more

verbal figures and require the subjects to draw them from memory or to indicate which among an array of figures was previously presented.

Studies of the relationship between poor visual memory and functional outcome have yielded mixed findings. Visual memory has been found to correlate modestly with employment status, job tenure, psychosocial rehabilitation success, social functioning, quality of life ratings, and strongly with functional capacity. Other studies have reported no significant correlations. It may be that tests of visual memory are simply less sensitive to an impairment or have other measurement problems.

Reasoning and Problem Solving. Although there are numerous tests of reasoning and problem-solving, also described in some contexts as “executive functioning,” the most well-known and frequently utilized in schizophrenia research is the Wisconsin Card Sorting Test (WCST). In this test, patients are given a deck of cards with various numbers of colored shapes on them and are asked to match their cards to four “key” cards that also have shapes on them that differ by color, form (i.e., shape), and number. The first principle to which the subject needs to learn to sort the cards is *color*. After a patient demonstrates that they have learned that *color* is the correct sorting principle, the principle changes to *form* without warning. Repeated sorting attempts by the previously correct principle are referred to as *perseverations*, and patients with schizophrenia, like patients with frontal lobe damage, often make these errors. In fact, the very poor performance of patients with schizophrenia on the WCST and the reduced activity of the dorsolateral prefrontal cortex during the performance of this test led to a widespread pursuit of the hypothesis of frontal hypoactivation in schizophrenia. It is important to note, however, that the WCST measures a variety of neurocognitive functions, including vigilance as well as visual memory, and is not a “pure” measure of executive functions.

The rules of society and the workplace change regularly, and success in these arenas is often measured by one’s ability to adapt to changes. Patients with schizophrenia who are impaired in measures of reasoning and problem-solving often have difficulty adapting to the rapidly changing world around them.

Speed of Processing. Many neurocognitive tests require subjects to process information rapidly and can be compromised by impairments in processing speed. A standard example of this type of task is the Wechsler Adult Intelligence Scale Digit Symbol Test. Each numeral (1 through 9) is associated with a different simple symbol. Subjects are required to copy as many of the symbols associated with the numerals as possible in 120 seconds. This nonspecific neurocognitive impairment has been found to correlate with a variety of clinically important features of schizophrenia, such as daily life activities, job tenure, and independent living status. It is also sensitive to medication side effects such as somnolence and extrapyramidal symptoms. It has been argued that processing speed tasks

such as digit symbol and symbol coding may be the strongest neurocognitive discriminator between schizophrenia patients and healthy controls. Neurocognitive data from 1,331 schizophrenia patients assessed prior to treatment randomization for the National Institute of Mental Health (NIMH) Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) schizophrenia trial suggested that a digit symbol task accounted for more variance in the overall composite score than any other measure. Thus, while seemingly a small component of the profile of neurocognitive deficits in schizophrenia, brief measures of processing speed have a very important role in characterizing relevant aspects of neurocognitive impairment.

The relevance of these deficits is clearly demonstrated by the effect of reduced processing speed on the ability of some schizophrenia patients to keep in step with the task-oriented jobs that are frequently held by patients with schizophrenia. Psychomotor slowing has the potential to affect many different aspects of everyday life as well as hamper performance on many other cognitive testing measures.

Verbal Fluency. Most neurocognitive assessments in treatment studies of schizophrenia have included measures of verbal fluency as a separate domain of functioning. Most tests of verbal fluency measure either phonologic fluency (also referred to as letter fluency) or semantic fluency. *Phonologic fluency* refers to a patient's ability to produce as many words as possible beginning with a particular letter (e.g., "F") within, for instance, 60 seconds. *Semantic fluency* refers to the ability to produce words within a particular meaning-based category, such as "animals." Not only do schizophrenia patients produce fewer words than normal controls, but they are more likely than healthy people to produce words that are not outside the required category. Impaired verbal fluency can damage functioning in social and vocational settings by making communication difficult and awkward.

Immediate/Working Memory. *Immediate memory* refers to the ability to maintain a limited amount of information "online" for a brief period of time (usually a few seconds). Repeating a string of digits (digits forward) is an example of immediate memory. The definition of working memory, on the other hand, is more complex and varies across studies. Some investigators consider working memory to be synonymous with immediate memory, whereas others describe that it should require some manipulation of the information being held online. For example, repeating a series of digits in the reverse order than they were presented (digits backward) requires maintenance of the initial string and an active manipulation because the information needs to be both held online and then subsequently reordered. Patients typically show deficits on both tasks. Visual working memory tasks involve keeping a visuospatial stimulus, such as a dot on a computer screen or a series of visual objects, in mind while working on a related or unrelated task.

Working memory has been described by various authors as a core component of the neurocognitive impairment in schizophrenia and is related to functional outcomes such as employment status and job tenure. Much of the clinical relevance of working memory deficits in schizophrenia comes from strong correlations that working memory measures have with a variety of other neurocognitive domains impaired in schizophrenia, such as attention, planning, memory, and intelligence. In addition, the advanced understanding of the neuroanatomy of working memory functions in human and nonhuman primates adds to our understanding of impairments in working memory in schizophrenia. This neuroanatomical work has suggested that neural circuitry that includes prefrontal cortical regions mediates aspects of working memory functions and that this circuitry may be impaired in schizophrenia.

Social Cognition. Theory-of-mind skills and social and emotional perception have been the general focus of the literature on social cognition in schizophrenia. *Theory of mind* is the ability to infer another's intentions and/or to understand the mental states of others. Individuals with schizophrenia perform poorly on measures of theory-of-mind abilities. The evidence regarding whether impairments in theory-of-mind skills are independent of a general neurocognitive deficit is mixed, although the most recent data suggest minimal overlap. Facial affect recognition and social cue perception are the two general areas into which studies of social perception in schizophrenia can be broken down. Reviews of the literature on facial affect recognition suggest that individuals with schizophrenia have stable deficits on tests of facial affect perception compared with healthy controls and psychiatric controls and that perception of negative emotions and fear may be particularly impaired. Tests of social cue perception use more dynamic stimuli that require multiple sensory modalities, such as watching videotapes of persons interacting. Patients with schizophrenia show consistent impairments in these tasks. In particular, they have more difficulty discerning other individuals' goals and intentions than what they are wearing or saying.

Although a variety of reports have described the strong relationship between general neurocognitive impairments and social deficits in schizophrenia, there is growing evidence that social cognition is more strongly related to social impairments in schizophrenia, even after controlling for performance on neurocognitive tasks. Path analysis has been used to suggest that the relationship between neurocognitive impairment and social deficits is almost entirely mediated by impairments in social cognition.

Prevalence of Neurocognitive Deficits in Schizophrenia

About 15% of patients with schizophrenia (and 85% of the general population) are rated as "unimpaired" by clinical neuropsychological assessment. However, these patients tend to have the highest levels of premorbid functioning and demonstrate

neurocognitive functioning that is considerably below what would be expected of them based on their premorbid levels and the educational level of their parents. Data from 150 patients with schizophrenia suggest that up to 98% of patients perform more poorly on neurocognitive tests than would be predicted by their parent's level of education. In addition, comparisons of monozygotic twins discordant for a formal diagnosis of schizophrenia suggest that almost all affected twins perform worse than their unaffected twin on neurocognitive tests, although the unaffected twins are performing more poorly than expectations based on previous educational attainment. Therefore, it is likely that almost all patients with schizophrenia are functioning below the level that would be expected in the absence of the illness.

Experts in neurocognition and schizophrenia have come to a clear consensus that neurocognitive impairment is a core feature of the illness. The profile of deficits is broad, severe, and likely present in most, if not all, patients. Neurocognitive impairment has clear clinical relevance, as neurocognitive impairment interferes with the everyday lives of patients in many important ways, from limiting social relationships to reducing the likelihood of employment. Further, cognitive impairments in schizophrenia are similar across different countries, educational systems, and racial and ethnic groups, suggesting the minimal influence of environmental and social variables.

NATURAL HISTORY OF NEUROCOGNITIVE IMPAIRMENT

Although the development of neurocognitive deficits in schizophrenia patients follows a predictable pattern over time, it, of course, can vary greatly in any individual. In most patients, detectable deficits may be present in childhood, followed by a decline in neurocognitive function that occurs sometime prior to the first episode. However, many individuals with schizophrenia demonstrate no obvious neurocognitive deficits prior to the onset of psychosis. In most patients, the severity of neurocognitive impairments becomes greater around the time that psychosis develops. The long-term stability of neurocognitive impairment over time in the majority of patients is clear. It is also clear that progress of deficits over the illness is generally absent, even in very poor outcome cases, until later life and then is limited to a subset of cases (Fig. 12.10–3).

FIGURE 12.10–3. Course of neurocognitive impairment in schizophrenia. The Y axis is the number of standard deviations below the mean of healthy controls throughout the course of the illness. The course of cognitive decline between the premorbid phase and onset of illness is not well known. It is controversial whether patients with chronic schizophrenia have cognitive decline over time.

The Genetics of Neurocognition in Schizophrenia

Neurocognitive impairment in patients with schizophrenia has a clear heritable component. First-degree relatives of individuals with schizophrenia are impaired on a variety of neurocognitive measures, with effect sizes ranging from small to medium. The relationship between the heritability of schizophrenia and related neurocognitive deficits has been estimated, with overall intelligence quotient (IQ) and working memory demonstrating phenotypic correlations with the presence of schizophrenia that appear slightly higher than other aspects of neurocognition. The heritability of neurocognitive impairments in schizophrenia families appears to be moderate t (h^2 = 0.25 to 0.40) and larger than their environmental correlations. A number of aspects of neurocognition have been tentatively linked to specific genes or single nucleotide polymorphisms (SNPs). Some of these findings have been replicated, and most genes associated with cognitive deficits to date implicate the functioning of the glutamatergic system. Searches for the genomics of cognition in schizophrenia may lead to clues about the origin of disability, the etiology of schizophrenia, and similarities and differences between schizophrenia and other severe mental illnesses such as bipolar disorder.

Deficits in Children at Risk for Schizophrenia and Follow-Back Studies

Individuals who are genetically vulnerable to schizophrenia have notable neurocognitive impairments, while individuals who are examined with neurocognitive assessments before they develop schizophrenia are found to have impairments in a variety of areas. High-risk studies of children with one or two

biologic parents with schizophrenia have suggested that attention deficits can predict which children will develop schizophrenia in the future.

Several studies have utilized the “follow-back” method of identifying adult patients with schizophrenia and then linking these patients with their records of neurocognitive assessments performed while they were children or adolescents. In the UK National Survey of Health and Development Study, data from 5,362 people indicated that children who went on to develop schizophrenia as adults differed significantly from the general population in a variety of neurocognitive and behavioral domains. Low educational test scores in verbal, nonverbal, and mathematics at all ages assessed were significant risk factors. Similar findings were generated from a population-based study that investigated the risk of schizophrenia in a sample of 50,000 18-year-old males conscripted into the Swedish army between 1969 and 1970. In the United States, scores from grades 4, 8, and 11 on the Iowa Tests for 70 children who later developed schizophrenia show no significant differences from controls in grades 4 and 8. However, for children who developed schizophrenia, test scores dropped significantly between grades 8 and 11, corresponding to the onset of puberty. Yet limitations of this study, including a small sample size and a nonrandom sample, restrict the generalizability of these results.

Several studies have utilized a link between the Israeli Draft Board Registry and the National Psychiatric Hospitalization Case Registry. Israeli law requires that all adolescents between the ages of 16 and 17 undergo a preinduction assessment to determine their intellectual, medical, and psychiatric eligibility for military service. This assessment is compulsory and is administered to the entire unselected population of Israeli adolescents. It includes individuals who will be eligible for military service, as well as those who will be excused from service based on medical, psychiatric, or social reasons.

The results suggest that neurocognitive functions are significantly impaired in adolescents who are later hospitalized for schizophrenia. These deficits precede the onset of psychosis in young people destined to develop schizophrenia. Along with social isolation and organizational ability, neurocognitive deficits are significant predictors of which young people will eventually develop a psychotic disorder. One study from this series examined the neurocognitive performance of 44 patients with a first episode of schizophrenia who had previously undergone neurocognitive assessment as part of their registration with the Israeli Draft Board. The stability of the deficits in these patients suggests that most of the neurocognitive impairment seen occurs prior to the first psychotic episode. These follow-back studies consistently demonstrate that neurocognitive impairment precedes the onset of illness in schizophrenia and schizoaffective illness. However, the impairments are small on average and, to date, have not proven useful for identifying cases at higher risk for developing schizophrenia.

Prodrome

Neurocognitive deficits are also found in individuals who are identified as being at "ultrahigh" risk for schizophrenia by virtue of their family history of schizophrenia in a first-degree relative or the manifestation of mild signs and symptoms consistent with the prodromal symptoms of schizophrenia. Preliminary data also suggests that olfactory identification and verbal memory deficits may help to predict which individuals at ultrahigh risk will develop schizophrenia. These findings are particularly interesting given that neurogenesis continues later into adulthood in the brain regions that contribute to these functions. However, at present, the ability of these neurocognitive deficits to predict which young individuals will eventually develop schizophrenia is weak. Since schizophrenia is a rare illness (about 1% of the population) and the percentage of individuals at ultrahigh risk for schizophrenia who eventually develop the illness ranges from 10% to 40%, a predictive factor must be highly specific to be useful in clinical practice; otherwise, an unacceptably large number of young people will be falsely identified as vulnerable to schizophrenia. The results from large-scale studies have shown that in cases with identifiable prodromal symptoms, cognitive impairments are present at the time of the detection of prodrome, and those cases with the greatest impairments are at the highest risk of developing psychosis.

First Episode of Psychosis Studies

Once psychosis develops, neurocognitive deficits are severe. Patients with a first episode of schizophrenia who have never taken antipsychotic medication already exhibit neurocognitive impairment of a magnitude similar to cases with an established illness. Motor functions and language functions may be more mildly impaired prior to treatment with antipsychotic medication. Initial treatment with antipsychotic medications does little to benefit these neurocognitive deficits.

Neurocognitive Changes in Patients Recovering from Acute Exacerbation

Several studies have investigated the longitudinal course of neurocognitive deficits in schizophrenia by repeatedly assessing neurocognition in samples that combine first-episode patients and those who have had an acute exacerbation of their symptoms. Patients recovering from an acute exacerbation of illness do not appear to demonstrate improvements in the severity of their neurocognitive impairment, despite clear improvements in symptoms with treatment.

Longitudinal Change in Neurocognitive Function

There are many age-related changes in neurocognitive functioning in the healthy population, especially in motor speed and memory functions. The magnitude of change in long-term memory and the ability to access and utilize previously

learned material is more modest. Reading and vocabulary are tests of “old learning” or “crystallized intelligence.” Baseline functioning can thus be estimated from performance on these tests that show minimal aging-related changes. The prospect of detecting neurocognitive decline with aging is diminished due to floor effects on numerous tests. The types of neurocognitive functions that change with normal aging, such as new learning and recall, attention, and processing speed, are related to the deficits most commonly observed in schizophrenia patients early in life. Thus, aging-related changes may affect those functions that are already severely impaired in adults with schizophrenia.

The notion of neurodegeneration in schizophrenia has been controversial. Evidence has been presented that suggests that schizophrenia is a neurodegenerative process, and some have concluded that schizophrenia is progressive. However, with a few notable exceptions, cross-sectional studies generally have not found evidence of increased neurocognitive impairment in association with duration of illness, and older patients under the age of 65 do not manifest greater impairment than younger patients. Definitive answers to questions regarding the possible progression of neurocognitive impairment in schizophrenia must come from longitudinal studies.

Recent studies have shown a complex relationship between relapse, re-treatment with antipsychotic medications, changes in cortical structure, and changes in cognition. Several studies have shown that there is a loss of white and gray matter and ventricular enlargement seen following relapses due to medication discontinuation after initially successful treatment. One study has shown that these progressive changes in brain volume are correlated with the progression of impairments in executive functioning. The mechanism through which brain volume is reduced following relapse is unclear and why only some studies show a cognitive decline in early-course patients is unknown, but attention to this topic may help to understand both the course of cognitive functioning in relapsing patients and the initial origin of these cognitive deficits.

Neurocognitive Functioning in Older Adult Patients

Neurocognitive impairment in schizophrenia may worsen over time in at least a subgroup of older adult patients with schizophrenia. In older schizophrenic patients with a lifetime of poor functional outcomes, prominent neurocognitive impairments resembling dementia have been reported.

Based on cross-sectional studies, older adult patients with schizophrenia appear to show some decline in neurocognitive function toward the end of life. However, this decline may be restricted to those patients who had an early onset of illness, a long period of psychosis prior to antipsychotic treatment, or a lifetime of poor functioning. Some of the inconsistency of these results may derive from the subject selection processes in these studies. The patients who are available for these studies tend to be residents at tertiary care facilities that house only the

patients with the greatest deterioration in functional ability. Finally, the neurocognitive decline in some older adult patients with schizophrenia has been found to be associated with tardive dyskinesia and neurologic dysfunction and could potentially be an outcome of decades of antipsychotic treatments and unenriched environments.

Summary

Several studies have demonstrated that neurocognitive impairment is present in a milder form prior to the onset of psychosis in young people destined to develop schizophrenia. Neurocognitive impairment is severe in patients who have experienced their first psychotic episode, even before antipsychotic treatment is initiated. Although some early-phase patients may demonstrate a slight improvement in neurocognitive impairment with treatment, many patients' neurocognitive abilities do not improve at all. Following this early phase, neurocognitive impairment appears to be remarkably consistent compared to functioning early in life, even in the presence of positive and negative symptom changes, although few longitudinal studies have had follow-up periods of longer than 5 years. The course of neurocognitive impairment in older adult patients is uncertain, but some studies suggest that patients with the most chronic courses of illness may manifest a further, albeit gradual, neurocognitive decline in the latest years of life.

RELATIONSHIP OF NEUROCOGNITIVE IMPAIRMENT TO SCHIZOPHRENIA SYMPTOMS

This section addresses the relationship between neurocognitive impairment and symptoms. If neurocognitive deficits were the result of the symptoms of the illness, then the deficits would disappear simultaneously with symptom reduction. However, this does not occur in patients with schizophrenia. In contrast to some patients with psychotic bipolar illness, whose performance on neurocognitive tests may improve somewhat when their psychosis remits, the performance of the patients with schizophrenia does not change when psychotic symptoms are minimized.

Cross-Sectional Studies of the Relation to Symptoms of Schizophrenia

Neurocognitive deficits are largely separate from both the positive and negative symptoms of the disorder. Cross-sectional relationships between neurocognition and positive symptoms, particularly for hallucinations and delusions, are usually quite weak. Generally, the variance shared by these variables is considerably less than 10%. Relationships tend to be slightly stronger between neurocognition and negative or "deficit" symptoms.

Positive Symptoms

It has been repeatedly reported that neurocognitive ability is not strongly correlated with the severity of psychotic symptoms in patients with schizophrenia. During periods of acute exacerbation, the severity of positive symptoms has been found to be significantly correlated with *better* performance in select domains of neurocognitive function. Although some exceptions exist, such as isolated reports of significant correlations of positive symptoms with working memory, source monitoring, and auditory distractibility, the overall trend is for general neurocognitive impairment not to be correlated with positive symptoms. The correlations between positive symptoms and neurocognitive function in five different domains and an overall composite score collected from 1,331 schizophrenia patients during the baseline period of the NIMH CATIE trial were near zero, with P values greater than 0.05 despite the tremendous statistical power in this study. Given that over 91% of patients were able to complete neurocognitive testing in this all-comer trial, it is clear that the absence of a relationship between neurocognition and positive symptoms is generalizable. This low correlation is also found in various patient samples, including first-episode, chronic, and older adult samples, supporting the idea that positive symptoms are not the sole cause of the neurocognitive impairment found in any schizophrenia patient population.

Various factors may mediate the absence of a relationship between neurocognitive deficits and positive symptoms. The low validity and temporal stability of positive symptom assessment may be a crucial factor. The subjective report of a psychotic patient may not reflect the true level of the patient's psychosis, and these symptoms change considerably over time compared to neurocognitive deficits, which are temporally stable. Another factor is that the exclusion of patients who are too psychotic to be tested may weaken any potential correlation between the severity of psychosis and neurocognitive impairment. However, the 91% success rate in CATIE suggests that this limitation may be overstated. Finally, those patients who have more intact neurocognitive abilities may be better able to recall and express their internal state, including detailed delusions and hallucinations. These patients would thus receive higher scores on positive symptom rating scales, resulting in a reduction in any potential correlation between positive symptoms and neurocognitive impairment. There are clear limitations to the assessment of positive symptoms, and the absence of cross-sectional correlations between positive symptoms severity and neurocognitive impairment may be more complex than can be determined in typical research designs.

Negative Symptoms

Neurocognitive dysfunction is correlated with various types of negative symptoms. The greater variance shared between neurocognition and negative symptoms

compared with positive symptoms may result from measurement overlap. For instance, tests of verbal fluency and the negative symptom of “poverty of speech” both measure the level at which a patient generates speech. A patient who generates speech at a slow rate will do so during a test of verbal fluency as well as in an interview during which they are being rated for poverty of speech.

Empirical studies suggest that motor functions are strongly correlated with negative symptoms, job success, and outcomes. Deficient motor skills are represented in both the negative symptom and the neurocognitive dysfunction domain since symptoms such as blunted affect and motor retardation are observational measures of motor functioning. Thus, impaired motor skills lie at the core of negative symptoms of schizophrenia in many ways.

The association between reduced motivation and poor performance of patients with schizophrenia on neurocognitive tests is complex. Although monetary reinforcement has been shown to improve performance on effortful neurocognitive tests such as the WCST in some studies, others have not. Increases in pupil size are associated with increased neurocognitive processing demands. Therefore, pupillary response can measure engagement in a task. If the neurocognitive deficits of schizophrenic patients were due to a lack of interest or motivation, their pupillary response would be low throughout the period of neurocognitive assessment. Only during high processing conditions do patients have abnormal pupillary responses, suggesting they put forth a normal amount of effort when being given neurocognitive tests of modest difficulty, yet their decreased processing capacity leads them to be unable to engage in difficult tasks. Other studies in this have similarly found that patients do not increase their effort as task difficulty increases, even in the face of financial rewards that differentially reward more effort. These findings do not suggest that performance on neurocognitive tests is affected in general by poor motivation but that motivation does need to be considered as a factor.

On the contrary, neurocognitive deficits may cause reduced motivation or the appearance of reduced motivation. First, patients who are cognitively capable of engaging in a task or a social interaction may *appear* not to be motivated to succeed in that endeavor. Further, individuals with neurocognitive deficits are often less likely to be motivated to have goals and pursue them. Patients with neurocognitive impairment are likely to be met with failure if they attempt to pursue employment, social, and even recreational avenues that require a suitable neurocognitive skill. Repeated failures are likely to cause discouragement and reduced motivation in anyone, including people with schizophrenia.

In sum, a cross-sectional correlation between negative symptoms and neurocognitive impairment has been consistently reported, but the magnitude of this relationship is modest. The directionality of the relationship between these aspects of schizophrenia is complex and not well understood.

Formal Thought Disorder

Deficits in semantic memory may lie at the heart of the neurocognition–thought disorder relation. This argument is supported by empirical data suggesting that the difference between semantic fluency (the number of names of animals produced in 60 seconds) and phonologic fluency (the number of words beginning with “F” produced in 60 seconds), an indication of the severity of the impairment of the “semantic network” in schizophrenic patients, predicted the severity of their formal thought disorder. Thus, a patient’s inability to have verbal information available (referred to as *semantic priming*) may be the most important neurocognitive factor in formal thought disorder. Other hypotheses regarding the cognitive origins of formal thought disorder include deficits in working memory (i.e., being confused about what has already been said in a conversation) and attentional focus.

Affective Symptoms

Since many patients with schizophrenia also report depressed mood, if not a full depressive disorder, and since depression is associated with some neurocognitive impairment, the role of depressed mood in neurocognitive impairment is important. Very few studies have examined this relationship directly. Furthermore, the distinction between depressive symptoms and negative symptoms is sometimes difficult for raters and clinicians to make, although they appear to be separate dimensions of schizophrenia based on factor analyses. Higher depression scores are significantly correlated with poorer verbal memory, which remains even when psychomotor retardation and processing speed performance are controlled statistically. Thus, depression may influence the association between negative symptoms and neurocognitive impairments, and it may also have a direct deleterious effect on some domains of neurocognitive impairment.

The cross-sectional correlations between neurocognitive impairment and symptoms are weaker than might be expected and vary depending on the symptom domain. The consistency of this finding strongly supports the idea that neurocognitive impairment is not caused by psychosis. The episodic nature of symptoms in schizophrenia in the context of the high temporal stability of neurocognitive impairment contributes to their disassociation.

Longitudinal Course of Neurocognition and Symptoms

The relative independence of neurocognitive impairment and symptoms in cross-sectional studies appears to be supported by longitudinal studies. When patients with schizophrenia are successfully treated with antipsychotic medications, the severity of their symptoms is substantially reduced. However, if neurocognitive function improves with first-generation antipsychotic treatment, the effects are small.

The stability of neurocognitive impairment occurs in the context of frequent variability of the symptoms of schizophrenia, especially the positive symptoms. When patients are tested during a psychotic exacerbation and then again when symptoms have improved considerably, 1 to 2 years later, the neurocognitive function is very stable over time. Over a 1-year interval, neurocognitive deficits and negative symptoms are significantly correlated at each of the assessments, but there is little predictive relationship between these variables over time. If negative symptoms were somehow causing poor performance on neurocognitive tests (or vice-versa), then a longitudinal relationship between these variables would be expected. Second, when the differential relationship between neurocognitive and negative symptoms and adaptive functioning deficits has been examined, neurocognitive impairments have been found to be more strongly correlated with functional deficits, particularly in everyday activities and vocational outcomes, than negative symptoms. Third, in those patients whose functional status worsens over time, changes in neurocognitive impairment predict the level of change, while changes in negative symptoms do not. These data provide yet another line of support for the relative independence of these domains and the importance of neurocognitive impairment in the mediation of functional difficulties.

Another way to investigate the longitudinal relationship between neurocognitive impairment and symptoms is to calculate the correlation between change in neurocognitive impairment and symptom change. This approach addresses the issue of *pseudospecificity*, that is, changes in neurocognition caused by other clinical changes. Several studies have performed such analyses, and though results are mixed, the findings have generally suggested that symptom change does not contribute substantially to neurocognitive change.

The literature consistently demonstrates that neurocognitive deficits are not caused by the symptoms of schizophrenia. Most impressive are the negligible cross-sectional correlations between various domains of neurocognitive function and the positive symptoms of the illness. Although other aspects of schizophrenia, such as negative symptoms, appear to correlate with neurocognitive impairment, there is as much or more evidence supporting the idea that neurocognitive impairment causes negative symptoms, just as there is evidence that negative symptoms cause neurocognitive impairment. Although there is limited evidence of a relationship between changes in neurocognitive impairment and changes in symptoms over time, there is certainly no clear evidence that changes in neurocognitive impairment are caused by symptom changes.

CLINICAL IMPORTANCE OF NEUROCOGNITIVE IMPAIRMENT

Cross-Sectional Correlations with Function

Although the literature on neurocognitive impairment suggests that it is not strongly correlated with symptoms, it has been consistently proven to be related to a variety of other important aspects of the illness, such as social functioning, functional impairments, unemployment, quality of life, relapse prevention, medical status, and economic cost. Neurocognitive impairment also has considerable power to predict functional status years later.

Relationship of Neurocognitive Impairment to Functioning

Functional outcome in schizophrenia is difficult to define and measure. The three types of functional outcomes that most studies of neurocognitive deficits have examined are community (social and occupational) outcome, the ability to solve simulations of interpersonal interactions, and success in psychosocial rehabilitation programs. Strong support for associations between key areas of neurocognition and functional outcome are offered by several reviews of the literature.

The connection between actual community functioning and neurocognition has been weaker than the strong link between laboratory measures of community functioning or skills acquisition and neurocognition. In a 1-year follow-up study of patients with first-episode psychosis, the size of the correlations between the number and quality of actual social relations and various neurocognitive measures were found to be in the 0.25 to 0.35 range.

All of the key neurocognitive domains reviewed above have demonstrated significant relationships to functional outcome, with effect sizes in the medium range. Neurocognitive impairments are also correlated with deficits in the performance of specific skills critical for independent living.

Neurocognitive Impairment and Unemployment

Several studies of neurocognitive performance and vocational functioning have been conducted in rehabilitation settings. Lower ratings of work behavior and performance are related to poorer baseline scores on verbal memory tests and the WCST. Additionally, improvement in patient work performance in a 6-month work rehabilitation program was predicted by better baseline performance on various neurocognitive tests.

Studies examining correlates of competitive employment have consistently emphasized the role of neurocognition. Patients enrolled in school full-time or holding competitive employment show superior performance across measures of working memory, sustained attention, problem-solving, and episodic memory when compared to unemployed patients, with the scores of part-time workers falling between the other two groups. In addition, vocational functioning is significantly associated with performance on the speed of processing tasks such as Trailmaking A and B.

The determinants of employment in patients with schizophrenia are complex and involve a variety of socioeconomic variables that are outside a clinician's control, such as the availability of disability payments. However, beyond these societal factors, neurocognitive performance plays a more important role than clinical symptoms in the ability of patients with schizophrenia to work and in the ability to benefit from work support programs.

Neurocognitive Impairment and Quality of Life

Quality of life is often defined by the quality of a person's social, occupational, and interpersonal aspects of life, all of which are related to neurocognitive functioning. Reductions in quality of life are more strongly associated with neurocognitive deficits than other symptomatic features of the illness. Specifically, the relationship between subjective experience and social functioning has been shown to be mediated by executive functioning. Patients have less realistic impressions of their social functioning if they also have more severe executive deficits. One study of patients with schizophrenia that examined the relationship between coping abilities and neurocognitive dysfunction suggested that more severe executive and memory deficits are related to decreased use of coping mechanisms. Neurocognitive deficits have also been found to predict the long-term quality of life in a few studies. However, persistent symptoms also have an impact on quality of life, and clinicians need to balance the impact of treatment on these two aspects of the disorder separately.

Neurocognitive Impairment and Relapse Prevention

Neurocognitive functions have been shown to be the strongest predictors of a patient's ability to manage medications. Neurocognitive deficits contribute to patterns of medication mismanagement that are associated with poor adherence and risk of relapse. In one study, memory impairment was the strongest predictor of partial compliance. Patients performing poorly in medication management tests have also demonstrated poor global scores on a cognitive assessment battery. Decreased medication compliance in schizophrenic patients has been shown to be related to poor performance on tests of attention and visual memory. Since antipsychotic medication has little impact on neurocognitive deficits, there can be a fair amount of confidence that the direction of causation is running from neurocognitive impairment to decreased medication compliance.

Neurocognitive Impairment and Medical Comorbidity

Neurocognitive impairment is also related to medical comorbidities in schizophrenia. Neurocognitive deficits related to organization (such as reasoning and problem-solving) directly affect patients' ability to seek treatment for medical problems. In older adult patients with schizophrenia, neurocognitive and functional

impairments predict the later incidence of new-onset medical problems, while medical problems do not predict the subsequent worsening of neurocognitive and self-care deficits. The inability of patients with schizophrenia to reduce damaging habits such as smoking has been correlated with deficits in memory and attention. Thus, neurocognitive impairments directly affect new-onset medical problems in older patients.

The Costs of Neurocognitive Impairment

Neurocognitive impairment is also a major factor in the direct and indirect costs associated with schizophrenia. Factors leading to the increased cost include loss of ability for self-care, level of inpatient and outpatient care needed, and loss of productivity (for both patient and caretaker). Although neurocognitive impairment by itself is rarely a reason for acute hospitalization of a patient with schizophrenia, it may contribute to the overall length of hospitalization. It may also lead to early admission to nursing homes or long-term care facilities in the case of older adult patients and other patients who are consistently unable to live in the community.

Neurocognitive impairment is the single greatest contributor to the functional disability of schizophrenia. Patients whose symptoms have remitted continue to experience profound neurocognitive deficits that interrupt their ability to function independently, benefit from rehabilitation programs, find and maintain employment, and experience healthy levels of quality of life.

NEUROCOGNITION AND FUNCTIONAL CAPACITY

In the last years, research has focused on the relationships between neurocognitive performance and the ability to perform everyday functional skills. These skills, including financial skills, shopping, travel and transit, and self-maintenance, have been shown to relate to real-world deficits in these areas. Functional capacity assessment instruments, such as the University of California–San Diego Performance-based Skills Assessment (UPSA), require patients to complete a series of challenging and relevant everyday tasks such as making a doctor’s appointment, paying a bill, or planning for a leisure activity. One possible mechanism of the impact of neurocognitive deficits on everyday disability is by inducing impairments in the ability to perform the skilled acts that are required for everyday functioning. Research studies have shown very high and consistent correlations between neurocognitive performance and functional capacity measures, and these same studies have shown that functional capacity measures may be more closely related to real-world functional outcomes than neurocognitive deficits are.

TREATMENT OF NEUROCOGNITIVE IMPAIRMENT

As described in the preceding sections, neurocognitive impairment in patients with schizophrenia has a devastating impact on various aspects of their illness and their lives. The search for treatments that can improve neurocognition has accelerated in recent years. Although antipsychotic medications have a pronounced beneficial impact on psychotic symptoms, there is currently little pharmacologic relief that can be provided for the neurocognitive impairment found in patients with schizophrenia.

Impact of Antipsychotic Treatment on Neurocognition

For decades, patients with schizophrenia were treated with excessively large doses of conventional, first-generation, “typical” antipsychotics, which may have had direct adverse neurocognitive effects. Larger doses of conventional antipsychotics cause lethargy, somnolence, and extrapyramidal symptoms, all of which impair neurocognition. In addition, the anticholinergic medications that are used to control side effects cause additional neurocognitive impairment. Further, lowering dosages of conventional antipsychotic medications has some modest neurocognitive benefits, supporting the idea that the negative impact of first-generation antipsychotics may be dose-dependent. As lower doses did not make neurocognitive impairment less severe than that seen in never-medicated patients, the impact of these older antipsychotic drugs at lower doses is less clear.

Although many studies and meta-analyses have suggested that second-generation, “atypical” antipsychotic treatments provide greater neurocognitive benefit to schizophrenia patients than first-generation antipsychotics, many of these studies have had substantial weaknesses, such as small sample sizes, short duration of treatment, no comparator or a comparator of relatively high doses of first-generation antipsychotic treatment, and inattention to important clinical factors such as the relationship of neurocognitive improvement with symptom change, anticholinergic treatment, and change in extrapyramidal symptoms. The impact of these various design weaknesses on study results is controversial.

The NIMH CATIE schizophrenia trial provided the opportunity to examine the neurocognitive effects of antipsychotics without these methodologic weaknesses. This study assessed the neurocognitive effects of four second-generation medications, olanzapine (Zyprexa), quetiapine (Seroquel), risperidone (Risperdal), and ziprasidone (Geodon), and a representative first-generation medication, perphenazine (Trilafon), using randomized, controlled, double-blind methods in 817 patients. The neurocognitive measures in this trial improved in each treatment group after 2 months of treatment, and none of the groups were statistically distinguishable from the others, including patients receiving the older medication, perphenazine. However, the amount of improvement in these patients was interpreted to be consistent with practice effects and expectation biases,

suggesting that the effect of antipsychotic medications on these patients was negligible.

Less is known about the effects of antipsychotic treatments on patients with first-episode psychosis. Two industry-sponsored studies have suggested that olanzapine and risperidone improve neurocognition more than even low doses of haloperidol (Haldol) in first-episode patients, but the lack of improvement in haloperidol patients appears to be associated with other clinical changes and side effects in these patients. The amount of neurocognitive improvement in these studies is also small and may be consistent with practice and expectation effects.

The Search for Pharmacologic Treatments for Neurocognition

Although neurocognition is increasingly viewed as a central feature of the disorder, the inability of antipsychotic treatment to improve neurocognition has led to broad efforts to identify pharmacologic treatments that may provide neurocognitive benefit to patients with schizophrenia. Currently, many large- and medium-sized pharmaceutical companies have compounds in their development pipelines that are being considered as possible treatments for the neurocognitive deficits of schizophrenia. There have been some failures and false starts in this area, and at present, there are no U.S. Food and Drug Administration (FDA) approved treatments for neurocognition in schizophrenia.

Cognitive Remediation

A variety of cognitive remediation programs have been developed to address neurocognitive deficits in schizophrenia, with recent refinements of these programs going beyond older drill and practice exercises and moving toward teaching strategies to improve neurocognitive functioning, compensatory strategies to reduce the effects of persistent neurocognitive impairments, and group exercises aimed at the deployment of the trained skills. In contrast to earlier strategies that converted neurocognitive rehabilitation programs designed for individuals with brain injury following healthy premorbid histories and were found to be too rote and tedious for patients with schizophrenia, these newer strategies are engaging and perceived as entertaining by patients. The potential for the success of these programs to improve neurocognition and functional outcomes in patients with schizophrenia has been supported by a number of recent studies.

A meta-analysis of 26 randomized clinical trials involving a total of 1,151 patients concluded that neurocognitive remediation produces moderate improvements in neurocognitive performance and, when combined with psychiatric rehabilitation, also improves functional outcomes. Unfortunately, the largest of the trials had only 67 patients, and each study was conducted in a single or a small number of settings with highly trained research personnel. Since that time, there have been several larger studies that supported the benefits of cognitive remediation, particularly in concert with psychosocial interventions, for

improving both cognitive test performance and improving everyday outcomes. Further, as in the pharmaceutical industry, the tendency of the developers of neurocognitive remediation programs to evaluate the efficacy of their own programs without bias has been questioned. Thus the generalizability of these findings is limited, and the real-world applicability of neurocognitive rehabilitation is unknown.

One relevant controversy in this research area is that pharmacologic interventions to improve neurocognition may only be minimally effective if patients with schizophrenia are not exposed to rich neurocognitive environments or receive targeted psychosocial interventions. A new compound that has the potential to have a beneficial neurocognitive effect by altering the neurochemistry of neurocognition in the human brain may be prevented from demonstrating benefit if patients do not have sufficient daily neurocognitive stimulation, which is frequently the case in many patients with schizophrenia. It is likely that one of the mechanisms of neurocognitive improvement in schizophrenia will be enhanced neuroplasticity, which is often experience-dependent. Thus, neurocognitive enhancement trials in schizophrenia may require neurocognitive remediation in all subjects to test the effectiveness of new compounds adequately.

Table 12.10–1.
Advantages and Disadvantages of Selective Neurocognitive Assessment Strategies

	Advantages	Disadvantages
Performance-Based: Neuropsychological Tests		
MCCB	Developed by an expert panel relatively full coverage	Some domains defined by a single test
BACS	Takes 30 minutes Available in a tablet version	Domain-level analysis not possible
rBANS	Abbreviated assessment Co-normed with other measures	Does not assess some critical domains
Performance-Based: Functional Capacity		
UPSA	Highly correlated with cognitive test performance Abbreviated highly valid versions available	Some items are now outdated Only a single Form
VRFCAT	Engaging VR assessment with multiple forms All instructions and responses recorded	The evidence for sensitivity to treatment responsive is not extensive
Interview-Based Functional Capacity		
SCoRS/CAI	Extensive data on convergence with performance-based tests Very low burden	Informants required for valid assessment data

MCCB, MATRICS Consensus Cognitive Battery; BACS, Brief Assessment of Cognition in Schizophrenia; r-BANS, Repeatable Battery for the Assessment of Neuropsychological Status; UPSA, UCSD Performance-Based Skills Assessment; VRFCAT, Virtual reality Functional Capacity Assessment Task; SCoRS, Schizophrenia Cognition Rating Scale; CAI, Cognitive Assessment Interview.

Summary

There are currently no clearly effective treatments for neurocognitive impairment in schizophrenia. Larger doses of first-generation antipsychotics, perhaps especially the higher potency medications like haloperidol, may have a deleterious effect. Despite initial hopes to the contrary, it appears as though even the second-generation antipsychotic medications do not provide more than minimal benefit for neurocognitive impairment. A broad effort is currently underway to find new medications that may serve as “cotreatments” to

antipsychotics to benefit neurocognition specifically. A few limited studies have suggested that neurocognitive remediation programs may have modest beneficial effects on neurocognition in patients with schizophrenia, and large-scale efforts are needed.

METHODS OF ASSESSMENT

A large number of tests have been developed to assess neurocognition, and various batteries comprised of these tasks have been employed in clinical practice and research with schizophrenia patients (Table 12.10–1). The most useful method of assessment will depend on the clinical or research questions being addressed, the study settings, and the available resources. A battery comprised of many different tests that may take several hours to complete has the advantage of enhanced reliability of neurocognitive estimates and will allow the assessment of various domains of neurocognition. However, these long test batteries have the disadvantage of a patient, tester, and resource burden. In addition, missing data and attrition rates may increase, which may be higher in most impaired subjects, thus skewing results. If the research or clinical question involves the efficacy of treatment intervention on neurocognition, a composite score from a small battery may be sufficient and allow for a larger number of patients to be assessed while requiring less staff resources. If, however, the question involves relative strengths and weaknesses of various neurocognitive domains, a thorough battery composed of multiple tasks in each domain may be required. If the question is primarily focused on one neurocognitive domain, a brief general battery in combination with multiple tests of the domain of primary interest is likely to be appropriate.

A recent development in neurocognitive assessment for clinical trials is the availability of computerized test batteries that allow direct data transfer to study databases. These methods offer the hope of minimizing rater error and reducing the costs required for human quality assurance. However, many of these methods have not been fully validated, and, therefore, results obtained using them must be evaluated carefully and scientifically. Many of these tests have been made commercially available without nearly as much information on their validity as would be hoped for.

Complex experimental procedures derived from cognitive neuroscience have also been used to characterize detailed aspects of the neurocognitive impairments in schizophrenia. These procedures have the potential to be useful since the underlying neurobiologic circuitry that mediates these functions has been uncovered in animal and human studies. However, care must be taken when inferring an etiologic basis or treatment strategy for schizophrenia based on the performance of patients on these tasks. The outstanding question remains whether interventions that improve the performance of patients on these tasks

would have any effect on functionally relevant cognitive ability or on functional outcomes, as correlations with everyday outcomes have sometimes been found to be low. These cognitive neuroscience tasks have been particularly appealing for use in genetic studies as tools to quickly assess an endophenotype that might reflect a specific genotypic vulnerability to schizophrenia.

Finally, neurocognitive deficits in schizophrenia and the impairments in everyday functioning that they mediate have begun to be measured with methods that may more closely track changes in functional outcomes. Interview-based assessments of neurocognition, such as the Scale for Cognition in Schizophrenia (SCoRS) and the Cognitive Assessment Interview (CAI), have been developed for use in clinical practice and clinical trials. These measures involve addressing a series of questions about the severity of neurocognitive impairment and how these impairments reduce functioning in daily life. Their strength is that they can be completed in a short time period (15–30 minutes) and yield a reliable estimate. However, information obtained directly from patients with schizophrenia tends to have reduced reliability and validity, and a caregiver or other informant is usually needed to provide information from an objective perspective. Performance on these tests is highly correlated with levels of functioning in everyday life, and it is believed that improvements in these tasks herald the potential for real-world change.

12.11 Phenotypes of Psychosis

BRETT CLEMENTZ, PH.D.

Every case of psychosis defies explanation. Consider the anatomy professor at an esteemed university. He is a small man with small features, Einstein-esque hair, a crackling intellect, and long history of academic success. His eyes are unremarkable, windows to the soul of the common man or genius. Without warning or expectation, the professor develops a florid psychosis, with a disturbance pervasive and profound. A meager improvement over many years becomes life in a state hospital's locked ward, with vanishing hope of recovery or even semblance of an independent existence. Reminiscent of John Nash, the professor still expresses complex thoughts, despite vivid and tormenting visual hallucinations that treatments leave unaltered.

To see the professor, it is necessary to schedule an appointment. Because like scientists at Los Alamos during the race to thermonuclear deliverance, the professor works at the forefront of psychiatry. There is little time. The mission is too important. His laboratory contains a wooden, dark-stained, heavy, and worn library table in the middle of a secure facility. The table has held many stories and sustained many dreams. The professor sits on the long side, facing the door, sometimes rising to pace. The pressure to complete his mission is palpable.

Piles of papers litter the table, scattered in no apparent order. Each page has a freehand drawing of the human eye. Combining exceptional artistic and intellectual talents and deep anatomical knowledge, the professor compulsively draws the retina. Beautiful. Anatomically precise. Each retina contains prisms, refracting machines for morphing the visual world. Simple prisms, elaborate

designs, small prisms, large ones, mixed small and large, all within each retina. “The core of psychosis is in the eye,” the professor believes. He carefully considers each design, asking whether the prismatic machine modifies visual input to illuminate the dark side of the moon. To test the theory, he draws refracting lines on each design, from prism to prism, seeking the origin of his hallucinatory world. But each design is discarded in disgust with the realization of its failure. His eyes, these retinae, refuse to reveal their secrets. (A special thank you to Dr. Carol Tamminga for discussing the details of this case. Carol is a colleague, friend, intellectual powerhouse, and matchless role model for young women scientist-practitioners.)

A knowledgeable clinician may say this case is clear. It is there for all to see. The essence of schizophrenia, the professor’s diagnosis, the most devastating of serious psychiatric conditions, is apparent. The description supports the diagnostic conclusion. But does it really? The hallmark of science, including clinical science, is not pursuing support for your most cherished ideas but seeking their refutation. Superficially, the anatomy professor checks enough phenomenologic boxes for a schizophrenia diagnosis: chronic unremitting hallucinations, delusional elaboration of his warped sensory experience, a calamitous plunge from a previously high level of functioning, lack of interest in activity other than search for the cause of his hallucinatory torment, all against the backdrop of a clear sensorium. But there are inconsistencies: poor cognition is often believed to characterize schizophrenia—this was not true of our professor. Our psychiatric forebearers, historical giants like Kraepelin and Bleuler, believed disorders of thought characterize this most devastating of psychiatric conditions—this was not a feature of our professor. Schizophrenia psychosis typically onsets in the late teens to early 20s—but the professor became ill later in life after considerable occupational success.

This case, like every case of psychosis, defies explanation. How did this happen? Does focusing on clinical phenomenology alone, sensational bits of a clinical picture, bend our perceptions? Is there a different path to illuminating the specter of psychosis, what Irv Gottesman called the epigenetic puzzle?

DO CLINICAL EXPERIENTIAL PSYCHOSIS DEFINITIONS CAPTURE BIOLOGIC REALITY?

In 2013, a new Diagnostic and Statistical Manual of Mental Disorders (DSM-5) was published. This manual uses clinical phenomenologic and experiential features alone, not laboratory tests, to subtype psychosis syndromes, including schizophrenia, schizoaffective disorder, and bipolar disorder with psychosis. Operational diagnostic criteria, the backbone of these manuals, facilitate diagnostic *reliability* for bipolar disorder with psychosis and schizophrenia, although they are less successful for schizoaffective variants.

The *validity* of these diagnostic distinctions is debatable. Clinical features do not uniquely differentiate psychosis syndromes. This has been known for decades. A National psychiatric treasure, Dr. Will Carpenter of the Maryland Psychiatric Research Center and Chief Editor of *Schizophrenia Bulletin,* highlights this fact at every opportunity. Poor outcome patients (traditionally considered a hallmark of schizophrenia psychosis) often have prominent affective symptoms and bipolar disorder family histories. Considerable overlap exists across psychosis diagnoses on neurocognitive features, although schizophrenia cases tend to have more severe cognitive dysfunction and negative symptoms. Family, twin, and adoption studies indicate the importance of shared constitutional and genetic factors to risk for both bipolar disorder with psychosis and schizophrenia. DSM psychosis syndromes do not "breed true," a fact problematic for the Kraepelinian dichotomy (which persists in the psychiatric consciousness despite Kraepelin's 1920 deep concerns with its veracity). All antipsychotic drugs have a dopaminergic mechanism of action, are only partially effective, and treat psychosis generally, not specific clinical psychosis diagnoses. Apparently, to quote Dr. Steve Hyman, "DSM was a poor mirror of nature."

One could reasonably wonder whether DSM-like psychosis diagnoses have justified their pertinence. As theoretical constructs (hypotheses to be tested rather than entities to be reified), they are only modestly successful. There are certainly statistical tendencies for schizophrenia and bipolar disorder with psychosis to differ in predictable directions on a range of measures; but striking heterogeneity within and overlap between these diagnoses on a range of molecular, genetic, brain imaging, perceptual, neurocognitive, symptomatic, treatment response, and outcome variables challenge the neurobiologic reality of DSM psychosis definitions. Based on experience within the Psychiatric Genetics Consortium, Patrick Sullivan et al. stated the range of genetic findings "strongly suggest that our [current] diagnostic categories do not define pathophysiologic entities." As a result, it seems contrary to contemporary understanding to organize a presentation of laboratory phenotypes around the 2013 DSM psychosis diagnoses.

Experiences from other branches of medicine (oncology, cardiology, neurology) clarify that clinical features alone are largely insufficient for capturing biologically based disease entities. Would circumstances change for our professor if laboratory tests allowed for patient stratification and treatment selection? The National Academies of Sciences proposed revising the classification of disease across all medicine based on molecular and biomarker data rather than relying solely on clinical phenomenology, a charge not obviously embraced by framers of current psychiatric diagnostic manuals. In fairness, the DSM framers had few (if any) sturdy biomarker, molecular, or neurobiologic hooks on which to hang their diagnostic hats.

After decades of research on the neurobiology of psychosis, why is this the case? A standard and somewhat nihilistic answer is that psychiatry is hopelessly complex, its syndromes heterogeneous by their nature and beyond the reach of simple biologic explanations; they are qualitatively different from maladies handled by other branches of medicine. Perhaps, but in over 40 years since the revolutionary publication of DSM-III, the strategy for psychosis diagnoses has not changed, and its validity has not been seriously tested by DSM framers in relation to any competing alternatives. A different explanation is that continued reliance on DSM-type experiential diagnoses, which are allowed to supersede neurobiologic observations, impedes the scientific development of psychiatry enjoyed by other medical disciplines.

NEUROBIOLOGY OF DSM PSYCHOSIS DIAGNOSES

A challenge for modern psychiatry is to identify distinctive biologic substructures of its experientially defined syndromes. Clarifying even a few unequivocal etiologic and neurobiologic mechanisms for psychosis would herald a new revolution for psychiatry. Knowledge of mechanisms would help carve diseases from our current clinical syndromes (which are not diseases but constellations of clinical features untethered from neurobiology) and promote the development of targeted and successful treatments. This was an organizing goal of the Bipolar-Schizophrenia Network for Intermediate Phenotypes (B-SNIP) project from its inception in 2008. B-SNIP is a consortium of scientists, of which I am a member, with a common goal—to fortify the neurobiologic substance of our experientially defined psychosis syndromes. If that is not possible, develop a different means for organizing neurobiology within psychosis that promotes targeted treatment developments, then test that approach against the available alternatives. Other consortia, including the Consortium on the Genetics of Schizophrenia (COGS) and the North American Prodrome Longitudinal Study (NAPLS) group, have complementary goals.

B-SNIP borrowed elements from both dimensional and categorical approaches (which are complementary rather than competitive) for probing the neurobiologic underpinnings of psychosis. Simplistically, a dimensional model is a continuum of severity, with this continuum shading from disease into subsyndromal and normal variants on the construct(s) of interest (e.g., frontal lobe gray matter volume, cortical thickness, neuropsychological measures of cognitive control, oddities of perceptual experience). Categorical models capture qualitative, not just continuous quantitative (dimensional), differences between health and disease and between diseases. In their purest form, such diseases are qualitatively distinct from normalcy. It is unlikely any psychiatric brain disease is a categorical entity like Huntington disease (an autosomal dominant mutation of the Huntingtin gene). Even the characters of Mendel peas (e.g., yellow versus green color) were

quantitative in nature (although “yellow” and “green” can be considered categorical descriptors). The nuances of approaches to nosology in psychiatry have been discussed with considerable sophistication in other publications.

B-SNIP was influenced by the proposals of Craddock, Owen, and colleagues on the reformulation of the psychoses. Initially, B-SNIP had two main organizing hypotheses for understanding psychosis neurobiology and its relationship to clinical manifestations. First, there is evidence for continua of severity on both neurobiologic and symptom features of relevance to psychosis, with schizoaffective variants bordered by psychotic bipolar disorder and schizophrenia on the extremes. For instance, one such continuum could be called “neuro-cognitive capacity,” with humans, not just persons with psychosis, distributed from deficit to surplus. It is evident our professor is closer to the surplus pole despite debilitating psychosis symptoms. A schizophrenia diagnosis alone does not capture this fact. Second, there are etiologic factors independent of a neurocognitive continuum. These factors, superimposed on that continuum, are responsible for cases tending toward a particular clinical manifestation. The cognitive capacity background upon which these etiologic “hits” occur could cause the sometimes confusing and seemingly arbitrary nature of clinical manifestations observed across psychosis cases. Which hit (or hits) did the professor possess that caused a debilitating psychosis despite substantial cognitive capacity? Identification of such hits must matter for treatment development and planning, but this information does not presently exist. Craddock and Owen (2010) formulated a comprehensive model that captures the essence of these propositions (with levels of analysis ranging from genes to intermediate neurobiologic and behavioral features to clinical phenotypic psychosis manifestations).

There are three keys to the success of B-SNIP aims. First, it is crucial to collect psychosis samples of sufficient size (across DSM diagnosis, what is called transdiagnostic assessment) to capture representative clinical and neurobiologic heterogeneity. Small samples account for inconsistent results in the psychosis literature and almost certainly fail to capture sufficient hard-to-classify cases. This was an avoidable obstacle. Larger samples also support more sophisticated analyses.

Second, psychosis-relevant features must be quantified at a level removed from clinical symptomatology. These measures need to encompass a broad range of the neurocognitive and physiologic correlates of psychosis. B-SNIP laboratory measures were selected given their promise for identifying neurobiologic deviations and understanding genetic risk for psychosis (so-called traditional endophenotypes, a term applied by Irv Gottesman to biomarkers that capture inherited predisposition to psychosis). Starting with these measures had a number of useful features: (i) in the late 2000s, they were the most researched endophenotypes for psychosis; (ii) findings would be easily replicable and

portable across diverse clinical and laboratory settings; and (iii) starting at an intermediate level of neurobiologic deviation (between the more basic molecular and structural/functional anatomical and more superficial psychosocial functioning and clinical features) promoted shortening the causal distance between genes and clinical phenes. Associations can be tested in both downward and upward directions in this extensive and complex causal chain, strengthening the theoretical network.

Third, multiple statistically integrated biomarkers, rather than biomarkers considered individually, are required to capture the essence of psychosis disease factors. Epigenetics, etiologic heterogeneity, pleiotropy, and variable expressivity are facts of nature—they influence phenotypic manifestations. Any single biomarker almost certainly fails to precisely define a psychiatric disease. Just as one would never use a single item from the WAIS Information subscale to estimate full-scale IQ, it is overly optimistic to assume a single biomarker adequately assesses any brain function (e.g., context updating in working memory, behavioral inhibition, behavioral response speed). Single laboratory measures are often used in experimental psychopathology and psychiatry, but this weakness in psychosis biomarkers research is easily avoided. B-SNIP statistically integrated multiple individual measures to assess brain functions of interest, enhancing signal-to-noise (e.g., antisaccade response latency and prosaccade latency both index speed of visual orienting; the auditory ERP N100 response during the paired-stimuli task assessing a highly similar neural response as the N100 response during the oddball task).

HYPOTHESIS TESTING AND REPLICATION IN PSYCHOLOGY AND PSYCHIATRY

In psychology and psychiatry, the typical approach is to do statistical tests of differences between groups (it is considered a success to reject the null hypothesis that groups are the same on some measure of interest). This is a logically flawed method for building a knowledge base. Platt (1964), in his “Strong Inference” paper, addressed this point, which was echoed in psychosis research by Dr. Carpenter and colleagues in their 1993 “Strong Inference: Theory Testing and the Neuroanatomy of Schizophrenia.” Typically, we have no other approach for probing the veridicality of our syndromes (our theories are just not as strong as in the “hard sciences,” although we obviously hope to get there). In B-SNIP, we constructed a scenario whereby rejecting the null hypothesis falsified our theory (our theory being that a neurobiologic approach to psychosis subtyping, what we call Biotypes, captures reproducible structure within idiopathic psychosis—structures that may translate to etiologic knowledge and neurobiologically-informed treatments). This scenario also involved extensive replication and cross-validation, both of which are critical to scientific advancement, both of which have

been challenges for psychology and psychiatry. The next two sections cover this ground for DSM psychosis diagnoses and biotypes through a summary of Clementz et al. “Psychosis Biotypes: Replication and Validation from the B-SNIP Consortium.”

B-SNIP RESULTS USING DSM PSYCHOSIS DIAGNOSES AS THE GOLD STANDARD

The focus of B-SNIP is idiopathic psychosis, a clinical phenotype with reliable and quantifiable symptom manifestations. Its presence also suggests the possibility of a severe psychiatric condition in need of treatment. Although fuzzy at its borders, a clinical psychosis diagnosis can be made with acceptable inter-rater reliability. There was no doubt our professor crossed this boundary. The initial B-SNIP goal was to identify neurobiologic features via our dense biomarker panel that were (i) shared between and (ii) distinctive to the major DSM psychosis diagnosis categories (schizophrenia, schizoaffective disorder, bipolar disorder with psychosis). B-SNIP1 (the first iteration of our project) recruited 711 clinically stable persons with psychosis and a community comparison sample of n = 274. Our replication sample (part of the second iteration of our project, called B-SNIP2) included similar numbers of psychosis cases (n = 717) and healthy persons (n = 198). We performed dense phenotyping across multiple levels of analysis (symptoms, social functioning, cognitive, psychophysiologic, brain imaging, and molecular measures) for both samples.

A traditional approach questions whether symptoms distinguish the three psychosis groups. Linear combinations of multiple psychosis-related clinical features were created that best differentiated the three DSM psychosis diagnoses. A complete description of these findings is in our “Testing Psychosis Phenotypes from B-SNIP for Clinical Application,” published in 2020. One practical outcome of this probe is to help clinicians know what clinical features are most closely associated with a particular psychosis diagnosis.

The main outcome is illustrated in Figure 12.11–1. Two dimensions differentiated the DSM groups. One dimension we label ‘CONCORD’ (CONation-COgnition-Reality Distortions) because its primary symptom correlates are hallucinatory behavior, delusions, unusual thought content, lack of judgment and insight, and blunted affect. Schizophrenia cases scored highest and bipolar disorder with psychosis cases scored lowest on this dimension. The other dimension we label ‘affective instability’ because its symptom correlates are depression, sadness, concentration difficulties, anxiety, suicidal thoughts, and lassitude. The affective instability dimension differentiated schizoaffective disorder from schizophrenia and bipolar disorder with psychosis.

FIGURE 12.11–1. Clinical features differentiating DSM syndromes. Standardized scores (and standard errors) are on the y-axis across the two main clinical dimensions of CONCORD (conation—cognition—reality distortion) and affective instability for DSM syndromes. The top 5 clinical features for each dimension are also provided along with their standard scores. SZ, schizophrenia; SAD, schizoaffective disorder; BDP, bipolar disorder with psychosis. (Modified from Clementz BA, Trotti RL, Pearlson GD, Keshavan MS, et al. Testing psychosis phenotypes from Bipolar–Schizophrenia Network for Intermediate Phenotypes for clinical application: Biotype characteristics and targets. *Biol Psychiatry Cogn Neurosci Neuroimaging.* 2020;5(8):808–818. doi:10.1016/j.bpsc.2020.03.011.)

The symptoms differentiating DSM psychosis diagnoses are interesting for three main reasons. First, schizophrenia is not characterized by any special set of clinical features but rather by extreme scores on psychosis symptoms, which describes our professor—this dimension captures a severity continuum. Second, schizoaffective disorder, not bipolar disorder with psychosis, is characterized by affective instability, indicating that this often-maligned diagnosis has a distinguishing presentation. Third, bipolar disorder with psychosis is associated with low scores on CONCORD. Affective instability played no role in bipolar disorder's differentiation from the other DSM groups.

The symptomatic differentiations of the DSM psychosis groups are revealing. The next step investigated the neurobiologic uniqueness of the DSM psychosis diagnoses using our biomarker battery. An overview of the main biomarkers follows.

Brief Assessment of Cognition in Schizophrenia (BACS)

BACS covers multiple cognitive domains (verbal memory, processing speed, reasoning and problem solving, working memory), although a global neuropsychological functioning composite score integrating these domains yields the best measure of psychosis-related cognitive deviation. Dysfunction of cognition is a frequent feature of psychosis.

Pro- and Antisaccade Tasks

Prosaccade tasks require subjects to look as quickly and accurately as possible at a peripheral visual cue—they assess the speed of visual orienting (psychosis cases show slowed or speeded responses). Antisaccade tasks require subjects to look as quickly and accurately as possible at the mirror image location (same amplitude, opposite direction) of a peripheral visual cue, and they assess inhibitory control under perceptual conflict because the visual stimulus and required response location are incompatible (psychosis cases have delayed reaction times and increased error rates). Saccade latency (time from peripheral cue onset to saccade onset) and percentage of error responses (glances to the incorrect spatial location) are recorded for each condition.

Stop Signal Task (SST)

The SST measures the efficiency and adequacy of cognitive control when response activation and generation to a single stimulus location are placed in conflict (there are delayed responses and increased errors in psychosis). In a typical stop signal paradigm, trials begin with a central fixation cross, after which subjects are shown a ‘Go’ cue to the left or right. On a minority of trials, a “Stop” signal is presented at central fixation (with variable delays of, e.g., 50 ms to 250 ms after Go cue onset). Participants are instructed to respond to the Go cue as quickly as possible unless they encounter the Stop signal. Reaction time and proportion of Stop Signal errors are quantified.

Auditory Paired-Stimuli and Oddball-Evoked Brain Responses

Evoked brain responses to repetitive auditory stimuli (paired-stimuli task, used to measure what is sometimes called “P50 gating”) and predetermined auditory targets randomly interspersed with nontarget (or standard) auditory events (oddball task) are deviant in psychosis. These paradigms assess the neural dynamics of preparation for and recovery from auditory sensory activations, neural responses to stimulus salience, and neural differentiation of relevant from irrelevant auditory stimuli. For the typical paired stimuli task, subjects passively listen to multiple (120 to 150) binaural auditory click pairs with a short (500 ms) interval between the two clicks and a long (8 to 10 seconds) interval between the click pairs. This task ostensibly probes the ability to detect stimulus relevance (or

reject stimulus irrelevance), a function deficient in some psychosis cases. For a typical auditory oddball task, subjects listen to hundreds (500 to 600) of auditory stimuli occurring every 1 to 1.5 seconds. Most of the stimuli are the same (1000-Hz tones) and are called “standards,” with 15% to 25% of the stimuli randomly interspersed with the standards, being different (1500-Hz tones)—these are called “targets.” Targets elicit a different brain response from the standards, with the most prominent being the so-called P300 (a positive voltage waveform in the event-related brain potential (ERP) most prominent over central parietal lobe sensors occurring 300 to 400 ms after stimulus onset). P300 measures updating of information in working (or available) memory, a function that is deficient in multiple psychiatric conditions.

Electroencephalography data can be scored in multiple ways. B-SNIP maximizes the use of available information, so auditory-evoked brain responses are scored in both the temporal and frequency domains. Rather than using a single or few sensors (the most typical approach in the psychosis literature), we integrate brain activity over 64 sensors distributed around the whole head to estimate patterns of neural response associated with auditory stimulus processing. Scoring data in the temporal domain yields information on the strength of brain signals in voltage units. These signals are typically used to measure ERPs at specific time points (50, 100, 200, or 300 ms after stimulus onset). Scoring in the frequency domain yields information on brain signals in particular frequency ranges (delta, theta, alpha, beta, gamma); this information also can be quantified as a function of time (e.g., gamma activity in the first 100 ms after stimulus onset). Extracting both voltage and frequency provides more information on complex brain responses than can be obtained using either quantification approach alone.

After data integration within the paradigm set (BACS, stop signal, saccade tasks, electroencephalography paradigms), the outcome is nine biomarker composite variables (what we call bio-factors) used to efficiently compare psychosis and healthy groups. Those bio-factors by DSM diagnosis are shown in Figure 12.11–2A. Bio-factors have familiar names (e.g., P300 ERP), but it is important to highlight that every one of them is a composite of multiple variables (e.g., the P300 ERP has primarily six temporal and frequency domain measures determining the score).

There are three noteworthy features of Figure 12.11–2A. First, as with most measures in the published literature, psychosis cases have deficient values (values below the mean of healthy persons) on most biofactors. Second, biofactor patterns between B-SNIP1 and replication samples for DSM diagnoses are remarkably similar; biofactor structure is reproducible using DSM diagnoses. Third, only the BACS significantly differentiates all four groups [schizophrenia < schizoaffective < bipolar < healthy], capturing a severity continuum. N100 ERP, P300 ERP, antisaccade, and paired-stimuli S2 ERP show similar, but less clear,

severity continua. The P200 ERP is the only biofactor with modestly greater deviation for bipolar disorder with psychosis, and the SST biofactor identifies a DSM psychosis diagnoses with modest effectiveness.

BACS is the only individual biofactor to differentiate all three DSM psychosis subgroups. But using one measure, even a composite measure, is incompatible with the B-SNIP thesis that differentiating psychosis subgroups requires multiple measures. We tried to improve DSM group separations by using all biofactors simultaneously. The outcome of this multivariate analysis is a single severity dimension. The BACS, paired stimuli S2 ERP, antisaccade, and P300 ERP biofactors, in combination, increase the group separation from schizophrenia to bipolar disorder (the most extreme groups) over the BACS alone from 0.74 to 0.89 standard deviation units. Figure 12.11–3A illustrates that the distinction between DSM and healthy groups on this multivariate dimension is minimal. It is hard to imagine even this amount of biomarker data improving treatment selection and outcome predictions for our professor when relying on DSM diagnosis as the gold standard.

A prominent outcome of these B-SNIP biofactor analyses is, like the symptom data, a continuum of psychosis severity. Overlap on neurobiologic features is ubiquitous in the psychosis literature, in this case on measures ranging from basic sensory processing through sensorimotor performance, inhibitory control, target detection, memory functions, and general executive control abilities. DSM diagnosis groups show the same level of overlap on other structural and brain function measures. B-SNIP provides the largest and most comprehensive evaluation of biomarker-endophenotypes by DSM diagnostic status to date. The main outcomes do not support the thesis that DSM psychosis diagnoses capture neurobiologically distinct brain diseases. Differences in degree, rather than differences in kind, of deviation, described the overwhelming majority of DSM diagnosis variance. Perhaps B-SNIP used the wrong laboratory measures to address this issue (although measures were selected for their demonstrated success)—this possibility can be tested (see below).

FIGURE 12.11–2. Biofactor patterns by DSM diagnosis (**A**) and Biotype (**B**). Biofactor means standardized scores (y-axis) are displayed by group and project. Solid lines indicate B-SNIP1 and dotted lines indicate replication sample. Boxed r-values are the correlations between the B-SNIP1 and replication samples. Lines link conceptually related variables (cognition variables on the left and EEG variables on the right). Legends show the number of observations by group. Lines with circle symbols show the healthy data, with their y-axis values adjusted so the average value of B-SNIP1 and the replication sample is zero; the healthy values are the same in both plots. The psychosis groups are displayed as a function of their difference from the healthy means. In relation to the healthy subjects, values below zero indicate deficient values and those above zero indicate exuberant values. (Reprinted from Clementz BA, Parker

DA, Trotti RL, McDowell JE, et al. Psychosis biotypes: replication and validation from the B-SNIP consortium. *Schizophrenia Bulletin.* 2022;48(1):56–68, by permission of Oxford University Press. doi: 10.1093/schbul/sbab090.)

PSYCHOSIS BIOTYPES

Many considerations, including the above analyses, led B-SNIP scientists to question the neurobiologic uniqueness of DSM psychosis diagnoses. B-SNIP's alternative hypothesis is that disease entities within idiopathic psychosis lie orthogonal to DSM definitions, a risky proposition in 2015 when we floated the idea. Work in other medical disciplines indicates that clinical diagnosis alone fails to capture etiologically meaningful diseases. Differentiations using biomarker data reshuffle cases with remarkably similar clinical presentations into distinct disease entities. There is no reason to believe idiopathic psychosis should be any different. As Fischer and Carpenter proposed in 2009: "Psychotic experience is to the diagnosis of mental illness as fever is to the diagnosis of infection—important but nondecisive in the differential diagnosis." If true, to probe the neurobiology of psychosis, we should sidestep DSM clinical diagnoses (except for the presence of psychosis). One alternative is to develop a classification of psychoses informed by clinical neuroscience.

FIGURE 12.11–3. Group Separations by DSM diagnoses and Biotypes. B-SNIP1 and replication samples were combined for these analyses given their high degree of similarity. The outcome of multivariate discriminant analyses, using all biofactors to create functions that optimally separate groups are shown for DSM **(A)** and Biotypes **(B).** There was one significant function that differentiated the DSM diagnosis psychosis groups. Plots show proportion of cases within each group (y-axis) as a function of their standardized discriminant function scores (x-axis). There were two discriminant functions that differentiated the psychosis Biotype groups. The first function on the x-axis captured "Neural Response Magnitude," and the second function on the y-axis captured "Neural Disinhibition." Frequency polygons show the proportion of cases by group at the bottom (Neural Response Magnitude) and right (Neural Disinhibition) of the

central plot that shows the centroids and standard deviation ellipses by group. (See eBook for color images.) (Reprinted from Clementz BA, Parker DA, Trotti RL, McDowell JE, et al. Psychosis biotypes: replication and validation from the B-SNIP consortium. *Schizophrenia Bulletin.* 2022;48(1):56–68, by permission of Oxford University Press. doi: 10.1093/schbul/sbab090.)

B-SNIP leveraged variance in the biomarker panel to capture neurobiologically distinctive psychosis subgroups. The question is how to meaningfully parse psychosis-relevant biomarker variance. We chose a numerical taxonomy method called *k*-means clustering of the nine biofactors. This method forms groups of cases that are defined by their centroids (or center of mass in the nine biofactor space), with all cases in the group being as close to their respective centroid as possible. Only psychosis cases are used in these analyses because the biofactors differentiate psychosis and healthy persons, so the problem is meaningfully parsing variance within psychosis alone.

We quantitatively established that three subgroups best captured neurobiologic variance among the biofactors. Based on *k*-means analyses conducted separately for B-SNIP1 and replication samples, subjects are assigned to one of the three subgroups given their biofactor scores. We call the subgroups psychosis *Biotypes* (biologically distinctive types). Bio-factors by Biotype are shown in Figure 12.11–2B, which is analogous to Figure 12.11–2A, using the same subjects, but now grouped by Biotype.

There are three noteworthy features of Figure 12.11–2B. First, all biofactors differentiate the Biotypes, perhaps not surprising because numerical taxonomy formed maximally homogeneous and distinct subgroups. But the outcome does show that every one of the biofactors is useful, contrary to the DSM analyses. This is a curious outcome because our measures were selected based on results in the literature using DSM diagnoses. This is a lesson in the importance of using samples large and representative versus drawing conclusions from those small and unrepresentative. Second, biofactor patterns between B-SNIP1 and replication samples for psychosis Biotypes are highly similar, indicating the differentiating patterns are reproducible and robust. Third, specific patterns characterize psychosis Biotypes. Biotype-1 and Biotype-2 have a general cognitive deficit as measured by BACS. Biotype-1's most notable defining features are deficient neural activity revealed by low N100 and P300 ERP biofactors indicating difficulty detecting stimulus salience, low ongoing EEG neural activity, low amplitude responses to repeated auditory stimuli as indexed by the PS S2 ERP, combined with slowed response latencies to saccade stimuli. These cases capture the essence of cognitive and physiologic dysfunctions thought to characterize chronic unremitting psychosis. Biotype-2 defining features are greater deviation on cognitive tasks that require inhibitory control in sensorimotor performance as indexed by antisaccade and SST and excessive ongoing EEG neural activity not clearly locked to stimulus registration and the related

accentuation of P200 ERP. Excess neural activity, including problems inhibiting behavioral outputs, describes these cases. While Biotype-3 has modest deviations in general cognition and P200 ERP and modestly larger responses to repeated auditory stimuli (PS S2 ERP), they are like healthy subjects on biofactors. Not surprisingly, these cases have the best social functioning and the mildest symptom presentations. Other analyses from our group show that these results cross-validate, have promising construct validity, and predict outcomes on other laboratory measures not used in Biotypes' creation. This is a promising start.

Just like for DSM diagnoses, we quantified the extent of Biotype group separations using all biofactors simultaneously. The outcome of this multivariate analysis is two dimensions, shown in Figure 12.11–3B. The first dimension, shown on the x-axis, we call "neural magnitude response" because of its substantial contributions from P300 ERP, N100 ERP, ongoing neural activity, and BACS biofactors. This function captures the deficient neural activation of Biotype-1. The second dimension, shown on the y-axis, we call "neural disinhibition" because of its substantial contributions from ongoing neural activity, antisaccade, P200 ERP, and SST biofactors. This function captures the neural overactivity and motor inhibitory failures typifying Biotype-2. These two functions provide respectable standard deviation separations between psychosis groups in Cartesian space (BT1 to BT2 = 2.07; BT1 to BT3 = 2.43; BT2 to BT3 = 2.64; BT3 and healthy did not significantly differ).

Biotype physiologies are remarkably different. It seems improbable the same treatments will address the core features of each subgroup. We can be certain that Biotype-1 physiology does not characterize our professor. Minimal laboratory measurement (less than an hour) would clarify his location in biofactor space. If we studied and diagnosed idiopathic psychosis in this fashion, could we improve our professor's treatment selection and outcome prediction?

As we did for DSM diagnoses, we created linear combinations of the psychosis-related clinical symptoms that best-differentiated Biotypes. The main outcome of this analysis is illustrated in Figure 12.11–4. Two dimensions differentiate the Biotypes. One dimension we call "cognitive deficit psychosis" because its primary clinical correlates are occupational and social deficit scales from the Birchwood, conceptual disorganization, and blunted affect. Biotype-1 cases, with the most profound neurocognitive and physiologic deficits, are the highest (worst scores) on this dimension, and Biotype-3 cases, most normal across biofactors, are the lowest. The other dimension we call 'neuro-affective dysregulation' because its primary clinical correlates are stereotyped thinking, mannerisms and posturing, anxiety, uncooperativeness, and disorientation. This dimension differentiates Biotype-2 from the other two Biotypes.

The symptom correlates of the Biotypes are interesting by virtue of their differences from DSM categories. This is not a surprise. We know DSM diagnoses

and Biotypes are not redundant—Biotype-1 is mostly schizophrenia (40.7%) and schizoaffective disorder (42.3%), Biotype-2 is more schizophrenia (36.9%) and less bipolar disorder (21.8%), and Biotype-3 is disproportionately bipolar disorder (48.6%), but all DSM diagnoses are represented in all Biotypes. Unlike DSM diagnoses, so-called positive psychosis symptoms like hallucinations and delusions are not the main features differentiating Biotypes. This fact is consistent with the position that such clinical features are unhelpful for differentiating neurobiologically distinctive psychosis subtypes. Hallucinations and delusions may be akin to the symptoms of fever, headache, or fatigue and are not useful for differential diagnosis. Perhaps we do overvalue sensational bits of the clinical picture and are distracted from the features that best capture etiologic differentiation within idiopathic psychosis. Worth some thought anyway, especially because the clinical characteristics differentiating the Biotypes provide an intriguing relationship to neurobiology (i.e., Biotype-2, the cases with accentuated neural activity and motor inhibition problems also have differentiating symptom features concordant with neural dysregulation). It may be possible to identify symptomatic features characteristic of neurobiologic types working from the *bottom up* rather than from the *top down* (the approach taken by framers of the DSM). A related approach shows promise in diseases relevant to psychiatry, for instance, 22q11 deletion syndrome.

PSYCHOSIS SYNDROMES: DIFFERENCES IN KIND?

The answer to this question for DSM psychosis diagnoses has been known for some time. Using clinical symptoms alone fails to capture biologic reality. What if psychosis symptoms are like fever, an indicator of pathology, but not the disease in need of treatment? We must provide palliative care for troubling positive symptoms of psychosis, just like we provide antipyretics for pyrexia. The professor deserves such treatment. But perhaps in psychiatry, we confuse a symptom indicating a disease process for the disease process itself. Prominent psychiatric scientists, among them Drs. Carpenter, Casey, Hyman, Insel, and Jablensky question psychiatry's reliance on the clinical descriptive approach. They argue that such persistence impedes the discovery of etiologic mechanisms undergirding discrete disease entities and the development of successful treatments such discoveries may afford.

FIGURE 12.11–4. Clinical features differentiating psychosis biotypes. Standardized scores (and standard errors) are on the y-axis across the two main clinical dimensions of cognitive deficit psychosis and neuroaffective dysregulation for psychosis biotypes. The top five clinical features for each dimension are also provided along with their standard scores. B1, Biotype-1; B2, Biotype-2; B3, Biotype-3. (See eBook for color images.) (Modified from Clementz BA, Trotti RL, Pearlson GD, Keshavan MS, et al. Testing psychosis phenotypes from Bipolar–Schizophrenia Network for Intermediate Phenotypes for clinical application: Biotype characteristics and targets. *Biol Psychiatry Cogn Neurosci Neuroimaging.* 2020;5(8):808–818. doi:10.1016/j.bpsc.2020.03.011.)

An impediment to the development of psychiatric classifications with stronger biologic foundations is the lack of biologic data supporting such distinctions. This is a legitimate concern, but one with a certain level of circularity. Historically, DSM-type psychosis definitions are gold standards for determining the usefulness of neurobiologic measures. To the extent such definitions are orthogonal to neurobiologic reality, the ability to identify the etiologic distinctiveness of psychosis subtypes is severely limited. The B-SNIP project offers proof of concept that eschewing DSM-type clinical psychosis diagnoses makes possible the identification of neurobiologically distinctive psychosis subtypes.

The B-SNIP approach has limitations. The identification of subtypes is determined by the biomarkers used to dissect psychosis, the longitudinal characteristics of the Biotypes are uncertain, and there are probably more than three physiologically distinctive psychosis classes. But the verisimilitude of

Biotypes is supported by multiple external validating measures. Expanding these validations to pharmacologic profiles and molecular foundations is critical. B-SNIP is engaging in clinical trials, using specific treatments to target specific neurobiologic deviations, but so far, the clinical utility of this, or any other, neuroscience approach in psychiatry is unknown. Every patient, including our professor, deserves to know the outcomes that a rigorous approach to experimental medicine in psychiatry will provide. And even if psychiatry becomes a laboratory discipline, every patient deserves to have their troubles heard and understood by treatment staff. This is the way good medicine and good doctors operate. Becoming a laboratory discipline does not mean losing our humanity. It means improving the standard of care. At the very least, we should know if the entrenched approach, rooted in the DSM, is superior to competing alternatives. The B-SNIP consortium is excited for the future and the possibility that our work, and the work of similar research teams, will support a transformative reconceptualization of the psychoses. Maybe then, every case of psychosis, or at least some of them, will be crystal clear.

12.12 Schizophrenia: Pharmacologic Treatment

JOHN M. KANE, M.D., AND CHRISTOPH U. CORRELL, M.D.

Nearly every patient with schizophrenia will benefit from pharmacologic treatment but to varying degrees. Drugs to treat psychosis (aka "antipsychotics"), currently all still reducing postsynaptic dopamine receptor activity, are the mainstay of pharmacologic treatment, being effective for reducing the impact of psychotic symptoms such as hallucinations, delusions, and disorganized thoughts and behavior, as well as related symptoms of agitation and aggression. In many patients, these symptoms can be completely eliminated or reduced to only a mild level. Medications can also decrease the likelihood that symptoms will recur. Nevertheless, negative symptoms and cognitive dysfunction are inadequately treated with currently available medications.

Controlling positive psychotic symptoms is often insufficient for improving the community functioning and the quality of life of patients with schizophrenia. There is also an increased awareness of the serious health problems of patients with schizophrenia and the possible contributing role of some medications. These observations have led to principles of drug treatment that emphasize the necessary, but not always sufficient, role of drugs for psychosis in helping patients achieves their personal goals.

HISTORY

The history of somatic therapies in schizophrenia can be divided into two eras, with the discovery of chlorpromazine (Thorazine)—the first clearly effective drug for psychosis—as the dividing line. During the late 19th and early 20th centuries, schizophrenia was viewed as associated with an inevitable deterioration into dementia. Patients were frequently hospitalized for long periods of time. Somatic treatments were used to help control the most severe symptoms of the disorder. Sedating agents such as bromides and barbiturates were used to control agitation, and

treatments such as hydrotherapy and wet sheet packs were also used for calming effects. In the early 1920s, sleep treatment with barbiturates was introduced, based on the observation of improvement following an overdose of barbiturates. This involved maintaining patients in a highly sedated state for days.

Insulin coma treatment, introduced during the 1930s, involved gradually increasing doses of insulin causing a coma. After an hour of monitoring, glucose was administered, terminating the coma. Up to 20 insulin comas were widely used in the treatment of psychosis, suggesting some apparent effectiveness. It was abandoned when dopamine D2 antagonists were introduced.

Prefrontal lobotomy was proposed as a treatment for serious mental illnesses by Moniz in 1935. Frontal lobe extirpations in monkeys resulted in the appearance of less frustration. Although reports suggest that lobotomy may have been effective in reducing severe psychotic symptoms, worsening occurred in other areas, for example, personality deterioration with impulsive, psychopathic behaviors, as well as impairments in concept formation and planning. Psychosurgery was abandoned after the introduction of effective drugs.

Convulsive therapies were developed because some patients improved after a seizure. Drugs such as camphor and pentylenetetrazol (metrazol) were used initially to induce seizures but were abandoned after Cerletti and Bini introduced electrically induced convulsions. Initially, electroconvulsive therapy (ECT) was administered without anesthetics or muscle relaxants, inspiring fear in many patients, and the lack of muscle relaxants led to injuries from forceful muscle contractions. Modern ECT continues to have a role in certain patients with schizophrenia and is discussed in a later section.

The first effective drugs for psychosis were derived from the rauwolfia plant. Publications from the 1930s and 1940s suggested that these agents were effective for both hypertension and psychosis. Reserpine, the most potent of the rauwolfia alkaloids, which acts as an irreversible vesicular monoamine receptor (VMAT) inhibitor, depleting dopamine and other biogenic amines stored in presynaptic vesicles, was introduced in the early 1950s and was widely prescribed for schizophrenia and other psychotic illnesses. Studies comparing reserpine to dopamine receptor antagonists suggested similar efficacy. However, reserpine’s side effects,

particularly depression, led to preference for dopamine receptor antagonists.

The discovery of chlorpromazine in the early 1950s may be the most important single contribution to the treatment of a psychiatric illness. Laborit, a surgeon in Paris, noticed that administering chlorpromazine to patients prior to surgery resulted in an unusual state in which they seemed less anxious regarding the procedure. In 1952 he convinced Delay and Deniker and other psychiatrists to administer chlorpromazine to psychotic and excited patients. The effects were extraordinary. Chlorpromazine, the prototypical first-generation drug for psychosis (aka FGA) acting as dopamine D2 antagonist, was effective at reducing hallucinations, delusions, and excitement, but caused side effects, including rigidity, tremor, and bradykinesia, that appeared similar to parkinsonism. Because chlorpromazine was effective and relatively easy to use, it and other drugs for psychosis were partially responsible for a substantial reduction in hospitalizations.

Thioridazine (Mellaril) and fluphenazine (Prolixin), as well as newer FGA classes, such as the butyrophenones (e.g., haloperidol [Haldol]) and the thioxanthenes (e.g., thiothixene [Navane]), were then developed. Although these newer agents differed in potency and side effects, all were similar in their effectiveness. Clozapine (Clozaril), the first effective drug for psychosis with negligible extrapyramidal side effects (EPS) and the first “second-generation antipsychotic” (SGA), was discovered in 1958 and first studied during the 1960s. However, in 1976 clozapine was found to have a substantial risk of agranulocytosis resulting in delayed introduction. In 1990, clozapine became available in the United States, for patients responding poorly to other agents. Subsequent SGAs (dopamine D2-serotonin 2A antagonists or partial dopamine D2 agonists) provided new alternatives-risperidone (Risperdal) introduced in 1994, olanzapine (Zyprexa) in 1996, quetiapine (Seroquel) in 1997, ziprasidone (Geodon) in 2001, aripiprazole (Abilify) in 2002, paliperidone (Invega) in 2007, asenapine (Saphris) in 2009, iloperidone (Fanapt) in 2009), lurasidone (Latuda) in 2010, brexpiprazole (Rexulti) in 2015, cariprazine (Vraylar) in 2015, lumateperone (Caplyta) in 2019 and olanzapine-samidorphan (Libalvi) in 2021. Table 12.12–1 summarizes pharmacologic, formulation, and dosing information.

PHASES OF TREATMENT IN SCHIZOPHRENIA

The acute stage is usually characterized by positive psychotic symptoms and related agitation/aggression that require immediate clinical attention. These symptoms may represent a first psychotic episode or, more commonly, a relapse in an individual who has experienced prior episodes. Treatment during this phase focuses on alleviating the most severe psychotic symptoms. Following the acute phase, usually 4 to 8 weeks, patients will generally enter a stabilization phase in which acute symptoms have been controlled, but risk for relapse is high with treatment interruption. During this (up to 6 months) phase, treatment focuses on consolidating therapeutic gains. Next is the maintenance phase with symptoms in relative remission or stable. The goals are to prevent psychotic relapse/exacerbation and improve functioning. Although controlling positive symptoms is a major goal minimization of negative symptoms and cognitive dysfunction is important since negative symptoms and cognitive disturbances can contribute to functional impairment more than positive symptoms.

FIRST EPISODE SCHIZOPHRENIA

The treatment of patients with early-phase illness differs from that of patients with chronic schizophrenia. First-episode patients are generally more treatment responsive, require lower drug doses (approximately 50%), and are more sensitive to side effects. They often have a difficult time accepting their illness and are at high risk for nonadherence, relapse, psychosocial deterioration, and suicidality. Although medication for psychosis is the cornerstone of management, multidisciplinary interventions, such as in coordinated specialty care, focusing on sustained engagement, relapse prevention, physical health, and functional recovery, are paramount.

EFFECTIVENESS OF DRUGS FOR PSYCHOSIS

A large body of evidence supports the effectiveness of dopamine receptor-blocking drugs. Many studies were carried out in the 1960s, addressing skepticism that these agents truly improved psychosis. The 1995 Schizophrenia Patient Outcomes Research Team (PORT) found that about 70% of patients treated with a drug for psychosis achieved relative remission or substantial improvement in contrast to 25% of patients

treated with placebo. Recent meta-analyses of high-quality randomized controlled, parallel-design studies confirmed that dopamine receptor-blocking drugs are significantly superior to placebo for total symptomatology and positive symptoms.

TREATMENT OF ACUTE EPISODES

Indications for Pharmacologic Treatment

Nearly all schizophrenia patients with acute psychotic symptoms will benefit from a drug for psychosis, albeit to different degrees. Aside from relieving the patient from symptoms, there is some evidence indicating that lengthy delays in initiating dopamine receptor-blocking treatment may worsen the long-term course of schizophrenia. This evidence is summarized in a recent review by Howes et al. who found that delays in treatment were associated with significantly poorer results in 9 of 14 meta-analyzable outcomes, including worse symptomatic, social, functional, cognitive, and vocational outcomes. Although the reviewed studies have important limitations, it is probably prudent for clinicians to consider the possibility that untreated psychosis can result in poorer treatment response and prognosis, more frequent relapses, longer time spent in relapse, and, possibly, cortical volume reductions.

However, these data do not mean that all patients need to be treated immediately. A brief delay may permit clinicians to conduct a more thorough diagnostic evaluation and rule out causes of abnormal behavior, such as substance abuse, extreme stress, medical illnesses, and other psychiatric disorders.

Assessment

Whenever possible, patients should receive a physical, neurologic, and mental status examination and a laboratory evaluation before medications are started. Blood tests for complete blood cell count (CBC), electrolytes, fasting glucose and lipid profile, hemoglobin A1C, liver, renal, and thyroid function should be ordered. Other evaluations that should be considered are pregnancy tests in women, as well as human immunodeficiency virus (HIV) and syphilis tests when relevant. Individuals with schizophrenia are at a higher risk for cardiovascular disease than the population at large. As a result, an electrocardiogram (ECG) should probably be done at the

onset of treatment for many patients with cardiac risk factors. In case of sudden onset or neurologic signs, brain magnetic resonance imaging (MRI) and the testing for infectious or autoantibody-related encephalitis should be considered. The presence of movement disorders, particularly pre-existing tardive dyskinesia (TD), should be assessed as this may influence the choice of medication.

Since dopamine receptor-blocking drugs are relatively safe, treatment can usually begin before the results of laboratory tests are known. An exception is clozapine treatment, which should only begin after the patient is confirmed as having a normal CBC. Under emergent conditions, for example, in potentially dangerous situations when patients refuse to cooperate with an evaluation, drugs for psychosis can be administered prior to a medical evaluation.

Selection of a Drug for Psychosis

Although the usefulness of the distinction has been questioned, currently available drugs for psychosis are all postsynaptic dopamine receptor antagonists that can be categorized into two main groups: FGAs, or dopamine D2 receptor antagonists, and SGAs, or dopamine D2-serotonin 2A antagonists and partial D2 agonist-serotonin 2A antagonists (see Table 12.12–1). The FGAs are further categorized as being low, mid, or high potency, with the higher potency drugs having more specificity and greater affinity for D_2 receptors, and a greater tendency to cause EPS. Lower potency drugs are less likely to cause EPS but tend to have more effects on other neurotransmitter receptors and are thus more likely to cause postural hypotension, sedation, weight gain, and anticholinergic effects.

Table 12.12–1. Pharmacologic, Formulation and Dosing Information for Second-Generation Antipsychotics and Selected First-Generation Antipsychotics

Antipsychotic	Principal Liver Enzyme Target	Protein Binding	Bio-Availability	Time to Peak Level	Half-Life	CPZ Dose Equivalent, mg[a]	Typical Starting Dose, mg[b]	Typical Dose Range, mg[b]	Maximum Approved Dose, mg[b]	Dose Strength, mg	Route of Administration/ Formulation
Second-Generation Drugs for Psychosis ("Antipsychotics")											
Partial Dopamine D2 Agonists											
Aripiprazole	2D6 > 3A4	>99%	87%	po: 3–5 hours; im short: 1–3 hours; im long: 5–7 hours	po: 75 hours; im long: 30–47 days	7.5	po: 10–15; im long (gluteal): 400 with 2 weeks oral aripiprazole 10–20	po: 10–30; im long (gluteal): 400 every 4 weeks	po: 30; im long: 400	Tablets: 2, 5, 10, 15, 20, 30; Diss: 10, 15; Liquid: 1 mg/mL (except: 30 mg = 25 mL); im short: 9.75/1.3 mL; im long q 4wk (monohydrate): 300/1.5 mL, 400/1.9 mL; im long q 4 or 6 (882 mg) wk (lauroxil): 441/1.6 mL, 662/2.4 mL, 882/3.2 mL	po, diss, liquid; im short, im long
Brexpiprazole	2D6, 3A4	>99%	95%	4 hours	91 hours	N/A	0.5–1	2–4	4	0.25, 0.5, 1, 2, 3, 4	po
Cariprazine	3A4 > 2D6	91–97%	52% (1 mg)	3–6 hours	2–5 days (didesmethyl-cariprazine: 1–3 weeks)	N/A	1.5	1.5–6	6	1.5, 3. 4.5, 6	po
Dopamine D2–Serotonin 2A Antagonists											
Asenapine	1A2 > 3A4	98	35% (≤2% if swallowed)	0.5–1.5 hours	First: 6 hours, terminal: 24 hours	7.5	5 bid	10–20	20	Tablets: 5, 10	Sublingual (avoid eating or drinking for 10 minutes after administration)
Clozapine	1A2 (30%) > 2C19 (24%) > 3A4 (22%) > 2C9 (12%) > 2D6 (6%)	97%	50–60%	1.5–2.5 hours	12 hours	50	12.5	50–600	900	Tablets: 25, 50, 100, 200; Diss: 12.5, 25, 100, 150, 200; Liquid: 50 mg/mL	po, diss, liquid
Iloperidone	2D6 > 3A4 > 1A2	95%	96%	2–4 hours	18 hours	5	1 mg bid × 1 day, 2 mg × 1 day, then increase 2 mg/d daily to therapeutic dose	12-24	24	Tablets: 1, 2, 4, 6, 8, 10, 12	po
Lumateperone	3A4, UGT	97%	4.4%	1–2 hours	18 hours	N/A	42	42	42	42	po (with a meal, as done in trials)
Lurasidone	3A4	99%	9–19%	1–3 hours	18 hours	25	40–80	40–120	160	Tablets: 20, 40, 80, 120	po (with ≥350 kcal meal)
Olanzapine	1A2, 2D6, 3A4	93%	60%	po: 6 hours; im short: 15–45 min; im long: 7 days	po: 30 hours; im short: 30 hours; im long: 30 days	5	po: 5–10; im long (gluteal): 210/2 weeks or 405/4 weeks (= oral 10), 300/2 weeks (= oral 15 or 20)	po: 10–20; im long (gluteal): 150/2 weeks or 300/4 weeks (= oral 10), 210/2 weeks or 404/2 weeks (= oral 15), 300/2 weeks (= oral 20)	20	Tablets: 2.5, 5, 7.5, 10, 15, 20; Diss: 5, 10, 15, 20; im short: 10/2 mL; im long q 2 or 4wk: 150/1.3 mL, 210/1.3 mL, 300/1.8 mL, 405/2.3 mL	po, diss; im short, im long
Olanzapine + Samidorphan	1A2, 2D6, 3A4	93%	60%	6 hours	30 hours	5	5/10–10/10 (OLZ/SAM)	10/10–20/10 (OLZ/SAM)	20/10 (OLZ/SAM)	5/10, 10/10, 15/10, 20/10 (OLZ/SAM)	po
Paliperidone	<10% first-pass hepatic clearance	74%	28%	po: 24 hours; im long: 13 days	po: 23 hours; im long: 25–49 days	3	po: 6;im long: 234 mg into deltoid day 1, then 156 mg day 8, then 39–234 into deltoid or gluteus every 4 weeks	po: 3–12; im long (deltoid or gluteal): 117–234 every 4 weeks	12	Tablets: 1.5, 3, 6, 9; im long q 4wk: 39 0.25 mL, 78/0.5 mL, 117/0.75 mL, 156/1 mL, 234/1.5 mL; im long q 12wk: 273 0.875 mL, 410/1.315 mL, 546/1.75 mL, 819/2.625 mL	po (ER); im long

Comparisons of Drugs for Psychosis

Numerous studies have examined the comparative effectiveness and tolerability of various drugs for psychosis, and they generally appear to be similarly effective but with substantial differences in adverse effects. However, amisulpride (not available in the United States), olanzapine, and risperidone have been shown in some meta-analyses to produce somewhat greater symptom responses. Clozapine is more effective than other medications for individuals who have psychotic symptoms that persist despite adequate treatment.

Because of the perception of bias in industry-sponsored studies, government-funded agencies in the United Kingdom and the U.S.-sponsored studies intended to produce independent research findings regarding the longer-term effects of FGAs and SGAs. These studies, the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) schizophrenia trial in the United States and the Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study (CUtLASS) in the United Kingdom confirmed that clozapine seemed advantageous for individuals with refractory symptoms, but did not identify clearly important advantages in effectiveness for any other drug or drug class for most patients. Both studies found that people tended to continue taking olanzapine longer than other medications, but neither study found greater reductions in symptoms or improvements in quality of life for olanzapine. Neither CATIE nor CUtLASS found substantial advantages in overall tolerability or acceptability for SGAs over FGAs. The CATIE study found that some drugs, in particular clozapine, olanzapine, and quetiapine, were associated with weight gain and serum lipid abnormalities that are risk factors for cardiovascular disease. These findings have been substantiated by subsequent studies and meta-analyses.

Route of Administration

Usually, patients should initially be treated with an oral medication. Short-acting intramuscular drugs are useful when the patient refuses oral dosing and when a very rapid onset is desired. Intramuscular administration of most drugs for psychosis results in peak plasma levels in about 30 minutes with clinical effects emerging within 15 to 30 minutes (see Table 12.12–1). Most orally administered drugs for psychosis result in a peak plasma level in 1 to 6 hours following administration (see Table 12.12–1).

Long-Acting Injectables

Since nonadherence to drugs for psychosis is common and one of the most relevant and preventable risk factors for insufficient response and relapse, long-acting injectable formulations (LAIs) of several drugs have been developed (see Table 12.12–1). These drugs differ from short-acting compounds in that they are usually started after an initial trial of the oral formulation and are released slowly over a period of several weeks, which is why it can take days or weeks to achieve therapeutic serum concentration and weeks to months to achieve a steady state. As a result, LAIs are helpful for continuation and maintenance treatment. In the United States, the two FGAs, fluphenazine, and haloperidol, have been formulated as oil-based esters formed between the alcohol group of the drug and a long-chain fatty acid. Currently, four SGAs, risperidone, olanzapine, paliperidone, and aripiprazole, are available as LAIs in the United States. Formulations of all four agents are water-based that require biweekly (risperidone, certain doses of olanzapine), monthly (aripiprazole, paliperidone, certain doses of olanzapine), 6-weekly or bimonthly (certain doses/formulations of aripiprazole), or 3-monthly or 6-monthly (certain doses of paliperidone) injections. Oral supplementation, LAI loading doses, or an LAI booster injection is necessary for some medications to initially reach therapeutic blood levels. LAIs of other SGAs are currently in development. Given the consequences of preventable relapse, LAIs should be considered for patients requiring maintenance treatment, including those in the early course of illness. However, relapse can occur on LAI treatment, in approximately 15% of patients in full symptomatic remission and up to 30% in patients not in remission, with substance use and TD increasing relapse risk on LAIs. While the general perception has been that most patients will refuse LAIs, recent data suggest that the majority will agree when LAIs are presented in a team-based shared-decision approach.

Starting Drugs for Psychosis

Prior to starting a drug for psychosis, in a shared decision model clinicians should describe the medication being suggested, its target symptoms, and its possible side effects, particularly those that are common and unpleasant (e.g., muscle stiffness, sedation, akathisia). Patients who are severely disturbed may be unable to participate meaningfully in this discussion. However, most will benefit from information about the benefits

and risks associated with drugs for psychosis. Since patients with schizophrenia may be suspicious, it is particularly important to emphasize participation as collaborators in interpreting medication effects. It is helpful to also involve family members in decision-making.

In some settings, it is necessary for patients to give written or verbal consent prior to receiving a drug for psychosis. This can be a dilemma for patients who are conceptually disorganized and find it difficult to understand the risks and benefits of drug treatment. Under these circumstances, clinicians should adjust the complexity of the discussion to the patient's mental state. Thus, it may be appropriate to provide a limited amount of information that focuses on the most common acute side effects of the medication when the patient is most seriously impaired. As the patient improves, clinicians may then elaborate on the costs and benefits of medication. For example, detailed discussions about TD or weight gain and metabolic side effects associated with chronic treatment may be deferred until the patient has improved and long-term maintenance is considered.

Thus, it is important for psychiatrists to evaluate whether acutely disturbed patients are able to participate meaningfully in decisions about their medication. Clinicians should become familiar with local and state laws that affect a patient's right to refuse or accept drug treatment. The most difficult situation is when a patient who desperately needs medication refuses it. Under some conditions, family members who have been educated about schizophrenia may be helpful in convincing patients to accept medication. Every locality has provisions for treating patients against their will under emergency conditions. Some permit involuntary treatment when certain conditions are met. As patients improve, the majority will eventually accept their own need for medication. Many localities now have laws allowing for compulsory outpatient treatment, particularly for patients who have a history of violent or aggressive behavior.

Dosage Selection

Dosage selection is difficult because the physician is unable to titrate dose against clinical effects due to a variable time delay between initiation and clinical response. Recent studies and meta-analyses report that in 4 to 6 weeks of treatment, the greatest reduction in symptoms occurs first 1 to 2 weeks and little or no response during the first week or two (assuming a

valid diagnosis, appropriate adherence, and therapeutic dose level) is a powerful predictor of subsequent lack of response.

The currently recommended dosage ranges for FGAs and SGAs are in the range of 300 to 600 mg daily of chlorpromazine equivalence. A number of dosage comparison studies and recent meta-analyses have failed to support the routine use of doses higher than the upper level of the approved dose range both in acute treatment and relapse prevention. However, the reverse has also shown to be true, in that doses below the lower level of the approved dose range are associated with a greater risk of nonresponse and relapse in group-level analyses. In the context of nonresponse to adequate doses of drugs for psychosis, it might be appropriate to assess drug blood levels or polymorphisms of the cytochrome-P450 enzymes that are responsible for the liver metabolism of the specific drug (see Table 12.12–1) in order to identify patients who are "pseudo"-resistant because of poor adherence or ultra-rapid metabolism.

Limited data from controlled trials of clozapine support the practice of using doses in the range of 300 to 500 mg daily. However, side effects, particularly sedation and orthostatic hypotension, are often limiting factors. The risk of seizures increases substantially above 600 mg. Plasma levels of 350 to 450 ng/mL, have been recommended, and measuring plasma levels is recommended for poor responders. Therapeutic dose levels of other drugs for psychosis are under-researched.

Large multicenter trials indicate that risperidone is most effective at 4 to 8 mg daily (see Table 12.12–1). Higher doses may lead to EPS and discontinuation without an advantage in increased effectiveness. In the United States, the average dose of risperidone prescribed for schizophrenia is slightly more than 4 mg daily. This suggests that a reasonable practice would be to manage patients with schizophrenia with 4 mg of risperidone and increase the dose if they fail to respond after 4 to 6 weeks. Olanzapine is usually effective in the range of 10 to 20 mg daily (see Table 12.12–1), although a number of case reports describe individuals who demonstrated optimal responses at doses of 25 mg and higher. Case reports also identify patients who had demonstrated substantial improvements when doses of quetiapine were raised well above 800 mg. At this time, there is no evidence that prescribing doses of ziprasidone greater than 160 mg daily increases its effectiveness (ziprasidone should be taken with at least a 500 kcal meal) (see

Table 12.12–1). Similarly, there is no evidence that doses of aripiprazole greater than 30 mg daily are more effective than the recommended range of 10 to 30 mg daily (see Table 12.12–1). Paliperidone's optimal dose range appears to be 6 to 12 mg daily, with higher doses associated with more adverse effects but not better effectiveness (see Table 12.12–1). Asenapine's optimal dose seems to be between 5 mg bid and 10 mg bid, taken sublingually (avoid eating or drinking for 10 minutes after administration) (see Table 12.12–1). Iloperidone's effective dose range is between 6 and 12 mg bid, but titration is needed to avoid orthostatic hypotension (i.e., 1 mg bid on day 1, 2 mg bid on day 2, then increase by 2 mg/day until a therapeutic dose is reached) (see Table 12.12–1). Lurasidone is effective between 40 and 160 mg (taken with at least a 350 kcal meal) (see Table 12.12–1). In the acute studies, brexpiprazole was initiated at 1 mg daily for 4 days, increased to 2 mg daily on day 5, and, if needed, to 4 mg daily on day 8. Cariprazine was initiated at 1.5 mg daily and increased every 1 to 2 days by 1.5 mg daily up to the upper approved dose of 6 mg daily. Finally, lumateperone is currently only approved as a single 42 mg daily dose, which means that no titration is needed (see Table 12.12–1). Some of the more rapid dose titration schemes are clinically adapted to being slower in outpatient and non-acute settings resulting in less initial adverse effect burden.

A number of recent findings suggest a reasonable strategy for treating acute schizophrenia. The dose of a postsynaptic dopamine receptor blocker that is likely to be effective is the dose that occupies an appropriate number of D_2 receptors. For dopamine D2 antagonists, this occupancy is approximately 60% to 70% of D2 receptors measured in the striatum, while for dopamine D2 partial agonists, this occupancy needs to be more than 90%, and for clozapine, quetiapine, and lumateperone approximately 40% postsynaptic dopamine D2 occupancy in the striatum appears to be sufficient for antipsychotic efficacy. The therapeutic response might depend to some extent on processes that occur after these receptors have been occupied for a period of time. This observation is supported by findings from both positron emission tomography (PET) scanning and the measurement of plasma homovanillic acid, which suggest that clinical improvement is not associated with the immediate effects of the drug on dopamine receptors, but on processes that occur later.

Initial dosage should follow labeling guidelines. Time-limited cotreatment with a benzodiazepine or another sedating medication can be helpful while awaiting response to the drug for psychosis. Since most of the improvement on the latter occurs in 2 to 4 weeks, patients should be observed for this interval before changing a drug; however, if there is little or no symptom improvement after 2 weeks, despite adherence to a therapeutic dose level, later response is unlikely to occur, and a switch or dose increase within the therapeutic range, should be considered.

Managing Agitation in Acute Psychosis

Agitation in acute schizophrenia can result from disturbing psychotic symptoms, such as frightening delusions or suspiciousness, or from other causes, including stimulant abuse or akathisia. Patients with akathisia can appear agitated when they experience a subjective feeling of motor restlessness. Differentiating akathisia from psychotic agitation can be difficult when patients are incapable of describing their internal experience. If patients are receiving an agent associated with EPS, usually an FGA, a trial with an anticholinergic medication (helpful for Parkinsonism) or propranolol (Inderal, helpful for akathisia) may be useful in making the distinction.

Clinicians have a number of options for managing psychotic agitation. Dopamine receptor blockers and benzodiazepines can result in relatively rapid calming. An advantage of a drug for psychosis is that a single intramuscular injection of haloperidol, fluphenazine, olanzapine, aripiprazole, or ziprasidone will often result in calming without an excess of sedation. The same is true for inhalable loxapine. Low-potency FGAs are often associated with sedation and postural hypotension, particularly when they are administered intramuscularly. Intramuscular ziprasidone, aripiprazole, and olanzapine are similar to their oral counterparts in not causing substantial EPS during acute treatment. This can be an important advantage over haloperidol or fluphenazine, which can cause frightening dystonia or akathisia in some patients, although coadministration of the anticholinergic benztropine (Cogentin) or the antihistamine promethazine (Phenergan) can reduce the risk of dystonia substantially. Rapidly dissolving oral formulation of olanzapine, risperidone, or aripiprazole may also be helpful as an alternative to an intramuscular injection.

Benzodiazepines are effective for psychotic agitation. Lorazepam (Ativan) has the advantage of reliable absorption when administered

either orally or intramuscularly. The combination of lorazepam with a postsynaptic dopamine receptor blocker has been found to be safer and more effective than large doses of dopamine receptor blockers in controlling excitement and motor agitation. Due to the sedating properties of short-acting injectable olanzapine that may depress respiratory drive, it should not be combined with benzodiazepines within a 2-hour window prior to or after its administration. Finally, the alpha2 agonist dexmedetomidine, which has been available for decades as an I.V. anesthetic has recently been approved in an oral formulation to treat acute agitation in patients with schizophrenia or bipolar disorder.

MANAGING SIDE EFFECTS

Patients will frequently experience side effects of a drug for psychosis before they experience clinical improvement. Whereas a substantial clinical response may be delayed for days or weeks, side effects will often begin quickly. For low-potency drugs, these side effects are likely to include sedation, postural hypotension, and anticholinergic effects, whereas high-potency drugs are likely to cause EPS.

A patient's interpretation of a drug's effectiveness is often influenced by adverse effects and a challenge with psychotic individuals is maintaining the trust of those who may misinterpret experiences and become suspicious. Warning patients of potential side effects can lead to prompt management, improved trust, and better adherence.

Extrapyramidal Side Effects (EPS)

A widely accepted benefit of SGAs is reduced propensity for EPS. Even relatively low doses of high-potency FGAs (e.g., haloperidol 4 mg per day) are associated with more EPS than recommended doses of SGAs. Because EPS can occur with any currently available drug for psychosis, including SGAs, awareness of EPS remains critical.

A common form of EPS is akathisia, a side effect consisting of a subjective feeling of restlessness with or without restless movements, usually in the legs or feet. Patients who experience severe akathisia will often pace continuously or move their feet restlessly while they are sitting. Some complain that they are unable to feel comfortable, regardless of what they do. Severe akathisia can cause patients to feel anxious or irritable, and some reports suggest that severe akathisia can result in

aggressive or suicidal acts. Researchers have estimated that 25% to 75% of patients treated with a high-potency FGAs will experience akathisia. Akathisia is also thought to be a correlate of poor drug response. The dopamine D2 partial agonists aripiprazole, brexpiprazole, and cariprazine can lead to early restlessness that may not be true akathisia, but rather due to early stimulatory effects that are minimized or controlled by switching slowly from a full dopamine D2 antagonist or a sedating or anticholinergic drug to the partial D2 agonist, using a lower starting dose or cotreating temporarily with a benzodiazepine or antihistamine. Often, when the initial restlessness subsides, dose escalation can be tolerated without development of true akathisia. Of note, akathisia rates were significantly reduced with lurasidone despite use of higher doses when the administration was moved from the morning to the evening, suggesting that movement-related side effects that may be peak concentration-related can be minimized when administering the drug in the evening.

Since patients may experience akathisia as irritability or agitation, asking patients whether they are restless or if they have difficulty sitting still can be helpful in early stages of treatment. At this point, a dosage adjustment, a centrally acting β-blocker such as propranolol (at doses between 30 and 90 mg daily or a benzodiazepine, which would also treat psychotic agitation, may provide relief.

Dystonias are probably the most frightening type of EPS. They are intermittent or sustained muscular spasms and abnormal postures affecting mainly the musculature of the head and neck but sometimes the trunk and lower extremities. Common forms of dystonia include abnormal positioning of the neck, impaired swallowing (dysphagia), hypertonic or enlarged tongue, and deviations of the eyes (oculogyric crisis). The rare form of laryngospasm is an acute emergency, requiring I.M or I.V treatment with an anticholinergic, antihistamine, or benzodiazepine. These reactions usually appear within the first few days of therapy. Dystonias are more likely to occur in younger patients, particularly young males.

Drug-induced parkinsonism consists of tremor, muscular rigidity, and a decrease in spontaneous movements resembling the movement disorder in idiopathic parkinsonism and affecting about 30% of patients treated with FGAs. The first evidence of drug-induced parkinsonism may be a diminished arm swing or decreased facial expressiveness. Akinesia can be subtle and can be mistaken for or exacerbate negative symptoms. Risk factors for drug-induced parkinsonism include increasing age and dose,

FGA use, a history of parkinsonism, and underlying basal ganglia damage.

Clinicians have a number of alternatives: reducing the dose, most commonly of an FGA, adding an antiparkinson medication, or changing the patient to an SGA. The most effective medications are the anticholinergic antiparkinson drugs (which are described in another section). Although these medications are frequently effective, they also cause their own side effects, including dry mouth, constipation, blurred vision, and cognitive disturbance. Also, these medications are frequently only partially effective. Anticholinergic use can often be discontinued in the maintenance treatment phase in patients without enduring EPS.

If FGAs are prescribed, clinicians may consider prescribing prophylactic antiparkinson medications for patients who are likely to experience disturbing EPS. These include patients who have a history of EPS sensitivity or those who are being treated with high-potency FGAs. Prophylactic antiparkinson medications may also be indicated when high-potency drugs are prescribed for young men who tend to have an increased vulnerability for developing dystonias. These patients may be good candidates for SGAs. However, the need for chronic anticholinergic treatment should be avoided as indicated above.

Some individuals are highly sensitive to EPS at dosages necessary to control their psychosis. For many of these patients, medication side effects may seem worse than the illness itself. These patients should routinely be treated with drugs associated with lower incidence of EPS, which means that in general SGAs would be preferred to FGAs, although even SGAs can lead to EPS in a dose-dependent fashion. Clozapine, quetiapine, brexpiprazole and lumateperone seem to cause the least EPS, while risperidone, olanzapine, paliperidone, ziprasidone, iloperidone, asenapine, cariprazine, and aripiprazole may cause dose-related EPS.

Tardive Dyskinesia and Other Tardive Syndromes

As with EPS, TD is less common with the SGAs than with conventional drugs, although there is probably a range of risks within both groups of drugs. Prospective studies lasting >6 months demonstrate a significantly lower risk of TD with SGAs (especially aripiprazole and olanzapine) than haloperidol. These results were somewhat expected in that early occurring EPS are significant risk factors for TD. However, the risk of TD is not absent with SGAs, and clinicians must recognize and manage TD.

TD commonly consists of abnormal, involuntary movements of the mouth, face and tongue, trunk, and extremities. The oral-facial movements occur in about three-fourths of TD patients and can include lip smacking, sucking, puckering, and facial grimacing or irregular movements of the limbs, particularly choreoathetoid-like movements of the fingers and toes, and slow, writhing movements of the trunk. Younger patients with TD tend to develop slower athetoid movements of the trunk, extremities, and neck, but coexistence with tardive dystonic movements is not uncommon.

The abnormal movements of TD are usually reduced by voluntary movements of the affected areas and are increased by voluntary movements of unaffected areas increased with emotional arousal and absent during sleep. According to the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), the abnormal movements should be present for at least 4 weeks, and patients should have been exposed to a postsynaptic dopamine receptor blocker for at least 3 months (at least one month in the older adults), and the onset of the abnormal movements should occur either while the patient is receiving the drug or within 4 weeks of discontinuing an oral or 8 weeks after the withdrawal of an LAI.

Prevalence surveys indicate that 25% to 30% of patients chronically treated with an FGA and 7% to 20% of patients chronically treated with an SGA will exhibit symptoms of TD. Three to five percent of young patients receiving an FGA develop TD each year. The risk in older adult patients is much higher. Although seriously disabling dyskinesia is uncommon, in a small proportion of cases walking, breathing, eating, and talking are affected.

Recommendations for preventing and managing TD include: (1) establishing objective evidence that the drug for psychosis is indicated and effective for the individual; (2) utilizing the lowest effective dose of the drug; (3) prescribing cautiously with children, older adult patients, those with EPS and patients with mood disorders; (4) examining patients on a regular basis for evidence of TD; (5) when TD is diagnosed, consider alternatives to the drug for psychosis being used, obtain informed consent, and consider dosage reduction; (6) if the TD does not improve or worsens, consider discontinuing the offending medication if possible, switching from an FGA to an SGA or an SGA to clozapine, or using one of the two recently approved VMAT-2 inhibitors, deutetrabenazine, or valbenazine.

Routine monitoring of TD after reaching the maintenance dose should include individuals <50 years old examination every 6 months if on an FGA and every 12 months if on an SGA. Monitoring for individuals aged ≥50 and high-risk groups should be every 3 months, which includes patients who are sensitive to EPS or treated with an anticholinergic, individuals with affective or organic brain disorders, and those with diabetes, negative or cognitive symptoms, and comorbid substance use disorders.

Other Side Effects

Sedation and postural hypotension can be important side effects for patients who are being treated with low-potency FGAs, such as chlorpromazine or thioridazine, and with clozapine or iloperidone. These effects are often most severe during the initial dosing, and patients receiving these medications, particularly clozapine, may require weeks until they reach a therapeutic dose. Although most patients develop tolerance to sedation and postural hypotension, sedation may continue to be a problem that can interfere with functional attainment. Additionally, some agents have been related to insomnia. Neuroleptic malignant syndrome (NMS) is a rare (approximately 2 cases per 10,000 patient-years) but severe adverse effect of dopamine receptor blockers. Although LAIs cannot be stopped abruptly, mortality and adverse sequelae are not increased when NMS develops during LAI use vs. oral medication. Moreover, >90% of patients were successfully rechallenged with a drug for psychosis, although titration and dosing should likely be slower and lower.

All FGAs, as well as risperidone and paliperidone, elevate prolactin levels, which can result in suppression of the gonadotropin-releasing hormone leading to clinically important suppression in gonadal hormones, affecting the reproductive system, and sexual functioning, including amenorrhea or oligomenorrhea, galactorrhea, decreased libido, erectile dysfunction, or anorgasmia. In addition, elevated prolactin may cause decreases in bone density and lead to osteoporosis. Finally, prolactin-raising medications may increase the risk of breast cancer to a small but measurable degree.

Prior to the introduction of SGAs, elevated prolactin was a consequence of treatment with all drugs for psychosis. Clozapine, quetiapine, and lumateperone, as well as the three partial D2 agonists, aripiprazole,

brexpiprazole, and cariprazine, do not appear to elevate prolactin above normal levels, with partial D2 agonist being able to decrease prolactin levels. As a result, when patients demonstrate side effects related to prolactin, changing patients to a prolactin-sparing agent may be effective. When the prolactin-raising agent cannot be changed, adding 5 to 15 mg of aripiprazole can normalize prolactin levels in a dose-dependent fashion.

Side Effects of Clozapine

As discussed elsewhere in this textbook, clozapine has a number of side effects. The most serious is agranulocytosis. This potentially fatal condition occurs in approximately 0.3% of patients treated with clozapine during the first year. Subsequently, the risk is substantially lower. Those receiving clozapine in the United States must have weekly blood monitoring for the first 6 months, biweekly for the next 6 months, and monthly thereafter.

Clozapine is associated with a higher risk of seizures than other drugs for psychosis (5% at >600 mg.) Seizures can usually be managed by reducing the dose and/or adding an anticonvulsant, usually valproate (Depacon). Myocarditis has been reported to occur in approximately 5 patients per 100,000 patient years, but emerging data suggest that less than half of rechallenged patients develop myocarditis again. Other side effects of clozapine include hypersalivation, sedation, tachycardia, weight gain, fever, and postural hypotension.

Metabolic Side Effects

Patients with schizophrenia are more likely to smoke and suffer from a number of illnesses, including coronary heart disease, diabetes, and hypertension. The high prevalence of these illnesses may explain why individuals with schizophrenia have a 15 to 20 years shorter life expectancy than the general population. This is partly explained by underlying genetic risk as well as inadequate medical care and unhealthy lifestyles-smoking, poor dietary habits, and lack of exercise.

Adverse effects can contribute to these problems. The risk for weight gain and abnormalities in glucose and lipid metabolism is greatest with clozapine, olanzapine, and chlorpromazine. The lowest risk is observed with aripiprazole, brexpiprazole, cariprazine, lumateperone, lurasidone, and ziprasidone, although problems may even occur with these agents, especially in first-episode drug naïve patients. All other agents have an

intermediate risk for weight gain and glucose and lipid metabolism, with the exception of a higher risk for lipid abnormalities with quetiapine.

Health Monitoring in Patients Receiving Drugs for Psychosis

Routine cardiometabolic monitoring is recommended, at a minimum, for the assessment of body weight, blood pressure, and fasting glucose and lipids, ideally with fasting or random hemoglobin A1C at baseline, 3 months, and annually after drug initiation. More frequent assessments are recommended if significant weight gain occurs. When abnormalities are observed, healthy lifestyle counseling or interventions or switching to a lower-risk agent should be considered. If these fail or are not feasible, medications that target significant weight gain (metformin or topiramate) or that treat abnormal blood pressure, glucose, or lipid metabolism may be warranted, and consultation with medical specialists may be needed.

NEGATIVE, MOOD, AND COGNITIVE SYMPTOMS

Negative symptoms and cognitive impairments are major contributors to a social and vocational disability, resulting in placing a greater emphasis on treatment strategies for decreasing these impairments. Carpenter has made an important contribution to this area by classifying negative symptoms into primary and secondary categories. Secondary negative symptoms are those symptoms that may result from other conditions, such as depression, and positive symptoms, such as suspiciousness, sedation, or EPS. EPS is a common cause of secondary negative symptoms, particularly when patients are experiencing akinesia, a side effect that can manifest in decreased speech, motivation, and spontaneous gestures.

The management of secondary negative symptoms begins with the management of the condition that caused these symptoms. For depression, this may include the addition of an antidepressant medication (which can reduce negative symptoms even in the absence of overt depression); for EPS this may involve the addition of an antiparkinson medication, a dose reduction, or a change to another drug for psychosis, usually an SGA, that is associated with less EPS.

If the causes of secondary negative symptoms have been ruled out, the patient is likely to be demonstrating enduring primary negative symptoms. There is no strong evidence that any drug for psychosis is better for

primary negative symptoms. Although some studies suggested that SGAs are more effective in reducing negative symptoms than FGAs, the advantage may be only in reducing secondary negative symptoms due to EPS. Meta-analyses have shown no significant advantages of SGAs over haloperidol in the reduction of negative symptoms. However, until this issue is decided by adequate controlled studies, it is probably reasonable for clinicians to consider changing to an SGA for patients with substantial negative symptoms in an attempt to minimize any that are secondary to EPS. Based on one 6-month study, cariprazine 4.5 mg daily was superior to risperidone 4 mg daily in reducing negative symptoms

Patients with schizophrenia frequently suffer from impairments in memory, attention, and information processing, interfering with social and vocational rehabilitation. As with negative symptoms, cognitive impairments can be secondary to other causes, including depression, substance abuse, or side effects, such as sedation or EPS. Additionally, the anticholinergic effects of either a drug for psychosis or an antiparkinson medication such as biperiden (Akineton) or benztropine can cause cognitive impairments. Decreasing the use of anticholinergic medication by changing to drugs that do not require antiparkinson medications, particularly SGAs, may be helpful. However, cognition was carefully monitored in the CATIE study and did not differ meaningfully among the FGA, perphenazine, and the tested SGAs.

SUICIDAL BEHAVIOR

Patients with schizophrenia and schizoaffective disorder are at risk for suicidal behavior. Approximately 20% to 40% of patients make suicide attempts, and 5% to 10% succeed. Suicidal behavior appears to be an independent domain from psychosis. However, depression and comorbid substance abuse increase the risk. Based on a large-scale study of clozapine (vs. olanzapine) in patients at risk for suicide, clozapine received an indication in the United States for the prevention of suicidal behavior. Clozapine should be considered for unremitting suicidal thoughts.

STRATEGIES FOR POOR RESPONDERS

Approximately 40% to 50% of acute psychoses will experience a remission of positive symptoms or experience only mild symptoms with treatment. The remaining 50% to 60% of patients will improve but will still demonstrate positive symptoms. Rather than categorizing patients into responders/nonresponders, consider the degree to which the illness is improved by medication. Some patients require chronic institutionalization. Others will respond to a medication with substantial improvement but still demonstrate persistent positive symptoms, such as hallucinations or delusions.

Before deciding that a particular medication is not working ensure that the diagnosis is correct, rule out substance-related or medical reasons, ensure that the patient has been adherent to the medication, and that they received an adequate trial. A 6-week duration on an adequate dose of a drug for psychosis represents a reasonable trial. If patients demonstrate even a mild amount of improvement during this period, it may be reasonable to wait before changing a medication, since some may improve at a steady rate for 3 to 6 months. However, early lack of at least minimal improvement (i.e., within the first 2 weeks) seems to identify a subgroup of patients who achieve a lower level of response even after 3 months of subsequent treatment. It may also be helpful to confirm that the patient is receiving an adequate dose by monitoring plasma concentration (if the patient is receiving a drug with an established therapeutic level) or to establish nonadherence. This information is available for a number of drugs, including clozapine, fluphenazine, haloperidol, perphenazine, risperidone, and trifluoperazine (Stelazine). A very low plasma concentration may indicate that the patient has been partially or noncompliant. It may also suggest that the patient is an ultrarapid metabolizer or the drug is not being adequately absorbed (e.g., if not taken with food in case of ziprasidone and lurasidone). Polymorphisms of the cytochrome-P450 enzyme system can be assessed to identify atypical metabolizer profiles. Under these conditions, raising the dose may be helpful. If the level is relatively high, clinicians should consider whether side effects may be interfering with therapeutic response.

With a poor response, many clinicians will consider raising the dose above the usual therapeutic level; however, nearly all studies found that doses above the labeled threshold were not associated with greater improvement. This suggests that changing to another drug is more likely to be helpful than changing to a high dose.

If a patient has responded poorly to an FGA, it is unlikely that this individual will do well on another FGA. Studies suggest that a poor response to one FGA is likely to be followed by a poor response to another. This has led many clinicians to change to an SGA in the hope that a somewhat different profile of receptor interactions may lead to a better response. However, this is often not the case.

Clozapine can be effective for patients who respond poorly to other drugs for psychosis. Important evidence of clozapine's advantages in this population comes from a multicenter trial reported by Kane et al. in 1988 in which clozapine was compared with chlorpromazine. Patients in this study were a severely psychotic group of individuals who had failed trials with at least three drugs for psychosis. Clozapine was significantly more effective than chlorpromazine in nearly every dimension of psychopathology. Thirty percent of clozapine patients met improvement criteria at 6 weeks compared to 4% of patients on chlorpromazine. As many as 60% of patients are likely to meet these same improvement criteria when maintained on therapeutic doses of clozapine for 6 months.

There is also evidence suggesting that risperidone and olanzapine may be helpful when an FGA is only partially effective. At least one controlled trial with each of these drugs has shown superiority to FGAs in poor or partial responders or "noninferiority" to clozapine. However, other studies suggest clozapine to be superior. The CATIE and CUtLASS trials also confirmed clozapine's superiority when FGAs or SGAs have failed. A number of meta-analyses have been conducted supporting clozapine's superiority in patients with refractory symptoms. Given clozapine's side effects profile, a case can be made for first-trying patients on risperidone or olanzapine when they have responded poorly to an FGA. If patients fail to respond adequately, a trial of clozapine is warranted. Since partial nonadherence is a common cause of treatment "resistance," a trial with an LAI should be considered before switching to clozapine.

There has been an increase in the use of polypharmacy. Although there are a variety of factors contributing to such practice, a poor initial response to monotherapy is often cited as a reason, but patients also end up on two or more drugs for psychosis if they start improving during a switch. There are very little controlled data supporting combining drugs for psychosis for treatment-resistant patients, except possibly for augmenting a dopamine antagonist with a partial D2 agonist for negative symptoms. However, in a nationwide database study from Finland, eight of the 10

most effective strategies for preventing hospitalization involved the use of two drugs for psychosis. These results could be biased by keeping patients on two drugs preferentially who improve during a switch, and most superior combinations were with clozapine or an LAI.

Other “augmentation” strategies for positive symptoms with benzodiazepines, lithium, antiepileptics, antidepressants, etc., have been studied to some extent, but controlled trials and meta-analyses are generally negative or biased toward small and poor-quality studies. These findings do not rule out the possibility of individual benefit for some patients; however, the data supporting the potential value of clozapine are far more consistent. The use of adjunctive medications to treat symptoms of affective disturbance, anxiety, agitation, etc., may be more appropriate.

ECT is also a treatment of last resort for refractory individuals, even those not adequately responding to clozapine.

MAINTENANCE THERAPY

During the maintenance phase, patients are often in a relative state of remission with only minimal positive psychotic symptoms or at a stable plateau with moderate symptoms. The goals are to prevent psychotic relapse or exacerbation and to improve functioning. Medications are important in preventing/delaying relapse and helping to manage functional impairments. The art of maintenance treatment is complicated by medication side effects, lack of patient insight, cognitive or organizational abilities, and varied motivation to continue long-term treatment. Titrating dosage in maintenance treatment is difficult because the relapse/exacerbation that can result from too low a dose is not likely to occur for weeks to months. Recent meta-analyses suggest that maintenance doses should neither be higher nor lower than the dose range for acute treatment.

Drug and Route of Administration for Maintenance Therapy

Those maintained on a drug for psychosis have a much lower relapse rate than patients who have their medications discontinued. Pooling large amounts of data suggests that 15% to 25% in a year will experience a relapse while receiving medications and 50% to 75% will relapse without medications. Clinicians are often tempted to discontinue medications in patients who have been well and stable for prolonged periods of time.

Unfortunately, these patients also have high relapse rates when their medications are discontinued. Other evidence indicates that patients who experience relapses while they are receiving a drug for psychosis have milder episodes than patients who relapse off medication. It has been suggested that patients who had their medications discontinued are more likely to show dangerous behavior and/or be admitted involuntarily.

TD has been a major concern in establishing the benefit-to-risk ratio of long-term treatment. Even with FGAs, experts agreed that the benefits of maintenance treatment outweighed the risks. As SGAs have been introduced with a substantively reduced risk of TD, one of the major concerns about long-term treatment has been diminished.

The evaluation of benefit-to-risk has been particularly challenging in those patients who have experienced only one psychotic episode and have responded well to treatment. It is important to recognize that although many such patients achieve remission, recovery (which includes sustained, relatively normal social and vocational adjustment) is far less common.

It has been well established that even patients who have had only one episode have at least a four in five chance of relapsing at least once over the next 5 years, and that stopping medication is the most significant risk factor. At the same time, it is often difficult for late adolescents or young adults to accept the nature of their illness and the need for ongoing pharmacotherapy. This represents a psychotherapeutic and psychoeducational challenge to clinicians and underscores the importance of combining psychosocial treatments, family therapy, vocational rehabilitation, and pharmacologic management.

Although published guidelines do not make definitive recommendations about the duration of maintenance treatment following the first episode, recent data suggest that 1 or 2 years might not be adequate. This is a particular concern when patients have achieved good employment status or are involved in educational programs, as they have an enormous amount to lose if they experience another psychotic episode. Furthermore, recent data indicate that all-cause mortality and mortality due to suicide and cardiovascular illness are reduced with continued versus discontinued medication treatment, particularly LAIs. The seeming paradox that medications that can increase cardiometabolic burden reduce cardiometabolic mortality has recently been elucidated, showing that in within-subject analyses, patients on drugs for psychosis were also

more adherent to medications used to treat cardiovascular morbidity and prevent mortality.

It is generally recommended that multiepisode patients receive maintenance treatment for at least 5 years. However, this recommendation is based on controlled data until this time, and the implication that discontinuing medication at that point is not without substantial risk is a mistake. Therefore, many experts would recommend pharmacotherapy on an “indefinite” or “for the foreseeable future” basis.

The first 3 to 6 months following an acute episode or relapse is a period of particular vulnerability. With short lengths of hospital stay, adequate linkages with ambulatory programs are critical to ensure continuity of care. After stabilization for 6 months, gradual dosage reduction may be attempted, but its need is unclear if there are no limiting adverse effects that are dose-related, given data that doses below the minimally effective dose in an acute exacerbation significantly increase the risk of relapse. Given reduced concern regarding TD and the lack of a strong dose-response curve for weight gain, one could argue that there is less incentive to search for the lowest effective dose for maintenance treatment with SGAs.

There are some data, including a large meta-analysis, suggesting that the SGAs are more effective in preventing relapse than FGAs. Our impression at present is that this advantage is not due to enhanced compliance. Although there are data suggesting some improvement in adherence with SGAs, these differences are modest at best.

Nonadherence rates with long-term drug treatment are very high. Average estimates suggest that more than 40% to 50% of patients become at least partially noncompliant within 1 or 2 years. Given the high rates of relapse following discontinuation of medication and the potentially severe consequences (loss of job, interference with school, family burden, suicidality, homelessness, aggressive or violent behavior), attempts to enhance adherence are critical. Although psychosocial treatments focusing on adherence can be helpful, the use of LAIs should be considered a preventive measure and not just reserved for patients who have repeatedly experienced nonadherence and subsequent relapse.

Given these data, LAIs are a valuable treatment option that appears to be underutilized. Recently, the superiority of LAIs over oral drugs for psychosis with regards to hospitalization or relapse has been demonstrated across three research designs, including randomized

controlled trials, large naturalistic cohort studies, and mirror image studies where patients serve as their own control.

There are a number of potential advantages of long-acting injectable medication. First, data show that nonadherence is less likely with LAIs. Second, clinicians immediately know when nonadherence occurs and have time to initiate appropriate interventions before the blood levels become nontherapeutic. Third, there is less day-to-day variability in blood levels, and peak concentrations are lower, potentially making it easier to establish minimum effective doses. Finally, many patients who have had experience with such treatment often prefer it, and most may agree to try an LAI when offered appropriately, for example, in a motivational interviewing shared decision-making framework.

INTEGRATING PHARMACOTHERAPY AND PSYCHOSOCIAL TREATMENT

Most patients with schizophrenia will benefit from a combination of pharmacotherapy and psychosocial treatments. This effect is particularly powerful in the case of coordinated specialty care. Recent improvements in both pharmacotherapy and psychosocial domains suggest that the overall outcome of this disorder can be improved if patients receive the optimal forms of both treatments at the appropriate stage of their illness. Psychosocial treatments are probably the most effective when patients have recovered from severe psychotic episodes. During the acute psychotic phase, clinical management should emphasize maintaining cooperativeness and trust. This focus is particularly important when there is overt suspiciousness or a tendency to misinterpret the intentions of the treatment team. A successful strategy is likely to include psychoeducation, including clear explanations of the rationale for treatment and possible drug side effects. Since family members may be important allies in ensuring cooperativeness, family psychoeducation programs are helpful during this phase.

It is difficult to generalize about the interactions of drugs for psychosis and psychosocial treatments for stable patients since psychosocial treatments can be quite different in their content and their goals. Nevertheless, it seems that effective pharmacotherapy benefits the efficacy of psychosocial treatments, while psychosocial interventions can benefit pharmacotherapy with improved adherence as one outcome.

Other studies have indicated that psychosocial treatments, particularly family treatment, may decrease the amount of stress that the patient experiences within the family and that this, in turn, decreases the amount of medication required by the patient and the risk of relapse. A recent meta-analysis of 20 psychological interventions targeting relapse prevention, given mainly adjunctively with pharmacotherapy for psychosis, found the following interventions to be superior to usual care at 1 year: family interventions, relapse prevention programs, cognitive behavioral therapy, family psychoeducation, coordinated specialty care, and patient psychoeducation.

DRUG DEVELOPMENT FOR SCHIZOPHRENIA

Studies, such as CATIE and CUtLASS, and meta-analyses indicate that both FGAs and SGAs have limits to their effectiveness. Although these agents are often effective in reducing the severity of positive symptoms, their effects on cognitive and negative symptoms are often inadequate. These domains are important since the long-term functional outcome—or the ability of patients to function in work, school, and social relationships—is related to the severity of these symptoms. Moreover, a significant subgroup of patients is partially or fully treatment-resistant regarding positive symptoms. Furthermore, the current availability of one single proven mechanism of action for the treatment of psychosis, postsynaptic dopamine receptor blockade, does not allow rational polypharmacy. These shortcomings have led to a search for medications that have a different mechanism of action and/or specific effects on residual positive, negative, and cognitive symptoms.

Ongoing activity has focused on identifying drugs for psychosis with mechanisms other than postsynaptic dopamine receptor blockade, hoping to improve the efficacy and tolerability of currently available agents but also to possibly facilitate treating patients who insufficiently benefit from available drugs. Recently, several novel mechanisms of action have been tested that show promise, including muscarinic autoreceptor activation, trace amine-associated receptor agonism, serotonin 2A antagonism/inverse agonism, and glycine transport reuptake inhibition. Whether any of these mechanisms with positive phase 2 data will lead to final approval remains to be seen.

Considerable attention has focused on cognitive impairments as a target for drug development in schizophrenia. This has included the development of, and agreement on, measurement batteries for cognitive dysfunction. The FDA and other agencies have clarified that to approve drugs for cognitive impairments associated with schizophrenia, the drug is required to separate from placebo both on a cognitive and a functional coprimary outcome measure. Currently, a few drugs addressing varied molecular targets are in different stages of development.

Another activity has focused on drugs that may improve negative symptoms of schizophrenia. Consensus on targets, designs, and measurement tools has prepared the ground for large development programs. However, like in the area of cognitive dysfunction, despite many attempts and promise in the area of proglutamatergic mechanisms, to date, no drugs have been approved for negative symptoms, though a number of agents are currently in clinical trials.

If studies of specific drugs for negative symptoms and cognitive impairments are successful, future treatment of schizophrenia may involve a drug for positive symptoms and comedications for other symptom domains, leading to improved functional outcomes. Whether any of these or other drug mechanisms will also enhance efficacy for positive symptoms remains to be seen, but additional mechanisms of action for the treatment of all domains of schizophrenia are highly desirable.

12.13 Psychiatric Rehabilitation

Robert E. Drake, M.D., Ph.D., Gary R. Bond, Ph.D., and Dror Ben-Zeev, Ph.D.

Approximately 5% of adults in the United States experience disability due to a serious psychiatric illness such as schizophrenia. Psychiatric rehabilitation denotes a wide range of interventions to help people with disabilities due to mental illness improve their functioning, quality of life, and recovery by enhancing the opportunities, skills, and supports they need to succeed in regular adult roles and in the environments of their choice. Regular adult roles include living independently, attending school, being employed in a competitive job, having positive relationships with family, having friends, pursuing leisure activities, and having intimate relationships. Psychiatric rehabilitation emphasizes relative independence, self-management of illness, self-efficacy, and community integration, including avoidance of dependence on professionals and segregated settings.

Psychiatric rehabilitation has become a fundamental component of the treatment for schizophrenia, consistent with current knowledge regarding the etiology, pathophysiology, manifestations, treatment, and course of the disorder. Current evidence, reviewed in other chapters, indicates that schizophrenia is almost certainly a heterogeneous set of disorders causally related to genetic factors, prenatal and perinatal insults, and postnatal stress. Although the definitive neurobiologic substrate of the disorder remains uncertain, many patients manifest mild neurodevelopmental abnormalities related to attention, cognition, social function, and motor function in childhood, long before the onset of overt psychotic illness. Research on schizophrenia shows that many but not all patients exhibit abnormalities of neural structure, circuitry, and function. Clinically, the disorder is characterized by positive symptoms of psychosis, such as hallucinations and delusions; negative symptoms, such as lack of

motivation and poverty of speech; cognitive deficits, such as problems with memory and executive functioning; and psychosocial difficulties, such as poor social role performance, chronic unemployment, high rates of substance abuse, and increased risk for homelessness, victimization, and other problems. Long-term follow-up studies have shown over many years that about 10% to 15% of schizophrenia patients recover completely, and most others improve significantly (Bleuler termed the usual course "healing with scarring"), but some continue to experience symptoms, cognitive difficulties, and psychosocial problems for decades.

Antipsychotic medications often reduce positive symptoms of psychosis, but they have limited impact on negative symptoms, cognitive impairment, and psychosocial functioning. For the great majority of patients, medications do not restore premorbid levels of functioning and do not produce normative role performance. Some 20% or more of schizophrenia patients have psychotic symptoms that do not respond to antipsychotic medications, and many experience only a partial symptomatic response. Further, medications do not reverse the consequences of stigma, impaired learning, failure to master adult developmental tasks, and social withdrawal. Therefore, maximizing functional recovery through psychiatric rehabilitation is critical for most patients.

Current interventions for schizophrenia are multifaceted. Historically, rehabilitation specialists distinguished rehabilitation from treatment by its focus on improving functional performance rather than controlling symptoms of illness. Rehabilitation specialists also argued that they focused on the patient's strengths rather than deficits. In practice, however, these distinctions are not valid. Many cognitive behavioral, skills training, technology, and supportive interventions aim to improve the management of symptoms as well as functional status, and most rehabilitation specialists take strengths and deficits into account. In this book, several interventions for schizophrenia could be classified as treatment or rehabilitation, and the authors have divided up a selection of current interventions for the sake of illustration. Readers should consult both chapters.

This chapter illustrates several approaches to psychiatric rehabilitation with specific models and examples. Presenting the entire field is beyond our scope, but interested readers should consult textbooks listed at the end of the chapter.

HISTORY

Current approaches to psychiatric rehabilitation represent the confluence of several historical traditions. In the 19th century, the reform movement called moral treatment emphasized putting people with mental illness in benign environments and normal roles, though usually in institutions. Moral treatment recognized that participation in education, work, social activities, and other normal roles could have a healthful effect.

In the United States, government programs for the employment of people with disabilities began after World War I for people with physical disabilities and were subsequently extended to those with psychiatric disabilities in 1943. These early programs transferred ideas from physical rehabilitation to psychiatric rehabilitation and emphasized employment.

Deinstitutionalization and the development of community mental health centers in the 1960s and 1970s not only transferred the locus of care for people with schizophrenia to the community but also promoted interest in making services accessible, comprehensive, and focused on helping people to function in regular environments and roles. With leadership from the National Institute of Mental Health and the Center for Mental Health Services of the Substance Abuse and Mental Health Services Administration, the community mental health ideology evolved into the community support system model, which included approaches such as case management, assertive outreach, coordination, integration, continuity, advocacy, self-help, supported employment, supported education, supported housing, self-management, and an emphasis on personal goals. The community support system model enlarged the role of community mental health and rehabilitation beyond reversing the disabling effects of institutionalization to include the prevention of disability among young adults with severe psychiatric illness who had minimal experience in hospitals.

In the early years of deinstitutionalization, patients and nonprofessionals came together to form psychosocial clubs, such as Fountain House in New York and Thresholds in Chicago, to promote mutual aid and self-help. The early self-help clubs transformed into a range of psychosocial rehabilitation centers around the country. Despite great diversity, these centers consistently emphasized mutual support, strategies for coping, health promotion rather than a focus on illness, normative roles such as worker, and belief in the potential for productivity.

Current ideas regarding psychiatric rehabilitation emerged directly from these activities.

Developments in the fields of skills training and environmental modification have also stimulated modern approaches to rehabilitation. Skills training methods derived from social learning principles have been applied to numerous areas of everyday functioning: for example, daily living tasks, social activities, employment, education, housing, relating to the health care system, and managing one's illnesses. Approaches to making environments more accommodating are considerably more diverse. They range from collaborative work with families, landlords, and employers, to a wide range of strategies used in the community to remove barriers faced by people with mental illness related to societal stigma, legal constraints, economic disincentives, and rigidities in the health care system.

The consumer-initiated movement called "recovery" became an influential ideology for advocates and mental health care systems during the 1990s. Recovery has numerous definitions, but the ideology includes hope, self-management, pursuing personal goals, finding meaning in life, and participating fully in the community. Since rehabilitation has always been patient-centered, recovery goals for most patients are isomorphic with rehabilitation goals.

Most recently, health information technology has been expanding rapidly to enhance self-management and rehabilitation goals. Web-based and mobile technology tools give people with mental disorders and their families immediate access to the latest information, local resources, research, and rehabilitation tools. Increasingly, these tools are shifting control of decision-making and management from professionals to patients and families.

OVERVIEW OF TECHNIQUES

Psychiatric rehabilitation uses three basic approaches: creating opportunities, providing supports, and increasing skills. In practice, these three approaches are combined in nearly all models of psychiatric rehabilitation.

People with mental disorders have been discriminated against, stigmatized, and treated unfairly in nearly every society, even compared to people with other disabilities. In the past, long-term institutionalization was

the primary mechanism; today segregation and lack of opportunity persist in the community. Sensationalism in the media constantly reinforces stigma. Psychiatrists and other professionals often convey stigmatizing attitudes and beliefs. Psychiatric rehabilitation aims to increase opportunities for normative housing, education, employment, socialization, leisure, and other activities that represent full citizenship under the rubric of community integration. To increase opportunities, rehabilitation specialists use legal mechanisms, regulations, community action, social networks, family supports, and personal relationships.

The second basic approach to psychiatric rehabilitation is to provide intensive supports. People with mental illness often need extra supports to succeed initially in functional roles. Once achieving success in a specific setting, such as school or work, supports are typically withdrawn substantially or completely, as the experience itself increases self-efficacy, functional skills, and natural supports.

Increasing personal skills for illness management and social functioning is the third basic technique of psychiatric rehabilitation. Due to cognitive, experiential, and neurologic difficulties, people with schizophrenia often need to enhance their abilities to manage their internal experiences, social environments, and roles they are pursuing in the community. Skills training has been a core feature of rehabilitation for decades. As we illustrate below, more of the learning is now shifting from professionals to technology tools.

We illustrate how opportunity, support, and skills combine by describing three current approaches: Housing First, Individual Placement and Support (IPS), and FOCUS. These specific examples cover only a small part of psychiatric rehabilitation but do demonstrate the enormous potential to improve life for people disabled by schizophrenia.

SUPPORTIVE HOUSING

Homelessness and Housing

Mental health researchers have often described homelessness as a psychiatric problem, suggesting that people cycle through homelessness and hospitalizations because of severe mental illness, poor treatment, or a combination of both. By contrast, homelessness researchers from other backgrounds, such as anthropology, epidemiology, and housing, consider homelessness to be primarily due to a lack of affordable and appropriate

housing. Research shows that people with the most severe mental disorders and social disadvantage, for example, schizophrenia complicated by poverty and drug addiction, need safe housing, supports, and treatment.

The more difficult questions relate to the type of housing and connection to services: Do some people need to be in supervised, congregate housing, or is that a prejudice of mental health professionals from the deinstitutionalization era? If many people want independent housing, do they need to be stable and engaged in treatment first? Alternatively, can they succeed in independent housing before they are engaged and committed to treatment? Policymakers, researchers, clinicians, patients, and advocates have debated these issues for more than four decades. Meanwhile, homelessness persists and has worsened in many areas of the United States.

Housing Models

Traditional approaches to housing people with schizophrenia and serious mental illness used segregation, congregate living, and staff within the housing or linkage with required clinical services. Segregated housing included nursing homes, group homes, family care homes, boarding homes, and housing units within the same building and closely overseen by mental health workers. All of these models assumed that people with serious mental disorders were not competent to live on their own and needed constant supervision, which was most easily provided by grouping them together. As an alternative, people were placed in independent apartments, often owned by the mental health system, because they agreed to participate in mental health treatment.

In the early 1980s, research clinicians developed assertive community treatment (ACT) for the express purpose of helping people to leave the hospital and maintain tenure in the community. ACT initially involved moving a multidisciplinary team out of the hospital with the patients to provide comprehensive services 24 hours a day, 7 days a week. The team helped people to find housing and develop independent living skills, usually by providing intensive supports in the community. For example, care managers in the community would help people learn to shop in their neighborhoods, use public transportation, prepare meals in their apartments, take their medications, and find activities and friends. Learning these skills in natural environments rather than in treatment

centers was more effective and obviated the need to transfer skills from the clinic to the community.

Encouraged by the success of ACT and as a reaction against the paternalistic psychiatric practices common in that era, advocates for community integration developed a set of housing principles that they labeled “supported housing.” Core principles included normalized permanent housing (regular tenancy agreements, assurance of privacy, location in integrated communities), client choice in type and location of residence, assistance in finding affordable housing, individualized and flexible support, separation of housing, and mental health services. Research showed that most people preferred living in their own apartments or homes rather than in supervised congregate housing and were able to live in scattered-site apartments.

The next question was readiness. Did people with mental illness need to be stable and participating in mental health care before finding an independent apartment? Studies of a supported housing model called Housing First answered this question. A systematic approach to reversing homelessness, Housing First combines two primary interventions: offering homeless people affordable housing of their choice as rapidly as possible and providing supportive services to help them succeed in housing. To ensure that residents can afford housing, some Housing First programs provide housing vouchers or subsidies. The approach does not require that people participate in treatment or any mental health program as a precondition for obtaining housing. Instead, Housing First assumes that people need housing as a foundation from which they can pursue other goals.

Typically, Housing First integrates housing assistance with ACT, intensive case management, or some other team-based approach to comprehensive services. The same team assists people in finding affordable housing and helps them learn to live independently and access other services when they have additional needs. Services are not mandatory, coercive, or chosen by professionals: tenants learn about services and make informed decisions, using a shared decision-making model.

James was a 50-year-old man who had been in and out of hospitals, homeless shelters, jails, and mental health centers for over 20 years. He often lived on the streets. Delusions, auditory hallucinations, and paranoia, all responding minimally to medications, accompanied him constantly. Regular marijuana use exacerbated his symptoms and got him entangled with drug dealers and the criminal justice system. James dressed eccentrically, wore a patch over one eye, and preached his religious beliefs in public settings, which occasioned rejections, confrontations with police, and trips to the emergency room. He seemed not to care about housing, failing to stay in several nursing homes, group homes, apartments, and shelters for more than a few weeks.

After a lengthy forensic hospitalization, James came to a Housing First team. Surprised that he was offered an apartment without preconditions, he readily agreed to move into his own place. The team helped him with furnishings, his landlord, shopping, and learning the new neighborhood.

James experienced many challenges, including disagreements with his landlord, restaurant managers, other tenants, drug dealers, and the police. But the team was available to intercede 24 hours a day, 7 days a week, and helped him to resolve many difficult situations. Listening respectfully to delusions and helping with practical matters was the central strategy. For example, James needed assistance to keep other drug users from moving into his apartment. He understood that to keep the apartment, which he liked, he needed to allow the team and his landlord to set limits with these acquaintances. Over time, James found delusional rationales for giving up marijuana, restricting his preaching, having a girlfriend, attending church, and taking a smaller dose of medications. Several team members admired his courage and integrity, and he often called on them for help. He did not return to homelessness, jail, or the hospital over several years.

Research on Supportive Housing

The absence of operationally defined program models limited most of the early research on supported housing and other residential models. The inconsistent and interchangeable use of the labels supported housing, Housing First, and the current term, supportive housing, confounded the

problem. Researchers have not always agreed on the core components of supportive housing, and some principles are value statements not easily translated into objective criteria.

Housing First defined more clearly the core model components, and consequently research has yielded a coherent set of replicated findings. Large-scale pragmatic trials in the United States and Canada have demonstrated that most people with serious mental disorders can maintain independent housing over the long term when they have safe, affordable housing, and adequate psychosocial supports. Housing First studies have also shown that offering housing to people with substance use disorders, again without preconditions, does not lead to the dire consequences that paternalistic approaches assumed. Several studies have found that clients receiving permanent housing assistance are more satisfied with their housing and have reduced use of psychiatric hospitals and emergency rooms. Yet research has not demonstrated that improvement in housing outcomes generalizes to other areas of functioning or to clinical outcomes, such as substance use and psychiatric symptoms.

INDIVIDUAL PLACEMENT AND SUPPORT

History

Impairment of vocational role performance frequently complicates adjustment for patients with schizophrenia and other serious mental disorders, contributing to poverty, loss of self-efficacy, and other sequelae. Across the United States, less than 15% of patients are employed, even though 50% to 75% state that competitive employment is a primary goal. Due to patient interests and historical factors discussed earlier, vocational rehabilitation has always been a centerpiece of psychiatric rehabilitation.

Clinicians, rehabilitation specialists, researchers, and patients themselves have developed many approaches to help people with serious mental illness achieve employment over the last half-century. Most have involved train-and-place models, with extensive pre-employment assessments and preparatory experiences, such as counseling, day centers, sheltered workshops, transitional employment, and skills training. These approaches aimed to evaluate and improve the patient's attitudes, skills, appearance, readiness, and other abilities presumed necessary to obtain and sustain competitive employment. Evaluations of these step-

wise approaches to vocational rehabilitation found that they did not improve the rate of competitive employment; most patients became discouraged, disengaged, or stalled during the preparatory experiences.

Supported Employment

In the late 1980s, the emphasis of vocational rehabilitation began to shift to place-and-train models, termed supported employment, which began in the field of developmental disabilities. According to the federal definition, supported employment involves "competitive work in integrated work settings…consistent with the strengths, resources, priorities, concerns, abilities, capabilities, interests, and informed choice of the individuals, for individuals with the most significant disabilities for whom competitive employment has not traditionally occurred; or for whom competitive employment has been interrupted or intermittent as a result of a significant disability". In contrast to other vocational approaches, supported employment programs (a) did not screen people for work readiness, but helped anyone who wanted to work; (b) did not provide intermediate work experiences, such as prevocational work units, transitional employment, or sheltered workshops; (c) actively facilitated job acquisition, often accompanying clients on interviews; and (d) provided ongoing support once the person was employed.

In the 1990s, a model of supported employment called IPS was developed specifically for people with severe mental illness appeared. IPS, also known as evidence-based supported employment, emphasizes the patient's personal preferences for work, a rapid job search (without extensive pre-employment assessment or training), and individualized supports as needed. Employment specialists provide practical assistance at every stage of the employment process. Jobs are typically part-time, beginning at just a few hours per week and expanding over time. IPS emphasizes regular jobs in the competitive labor market, owned by the employee rather than the rehabilitation program, paid at or above minimum wage, and supervised by the employer.

Several features of IPS supported employment correlate with better employment outcomes and thus are considered evidence-based principles.

1. Zero Exclusion. Supported employment services are available for anyone who wants to work, regardless of symptoms, cognitive

impairments, work history, substance use, or other personal characteristics. Research shows that professionals cannot reliably identify who will succeed or fail in employment.

2. Competitive Employment. The goal of supported employment is competitive employment in work settings integrated into a community's economy. The great majority of clients who seek work want competitive employment, particularly if they are encouraged to believe that they can work. Few clients want sheltered or volunteer jobs.
3. Rapid Job Search. Clients seek employment directly rather than following lengthy pre-employment assessments, training, or practice. Rapid job search means applying for a job within 30 days and typically results in finding the first job within 4 months.
4. Job Development. The employment specialist conducts targeted job development, as opposed to locating any job, to help clients find jobs that match their skills and preferences. Job development often involves the entire team identifying or pursuing relationships with employers.
5. Integration of Rehabilitation and Mental Health Treatment. Supported employment should be an integral component of mental health treatment, not a separate service. Employment specialists are integrated into case management teams, ACT teams, or other multidisciplinary teams. Employment specialists meet regularly with their teams and collaborate on helping their clients to succeed in jobs.
6. Client Preferences. Services are based on clients' preferences and choices. Clients report higher satisfaction and longer job tenure when the jobs are consistent with their preferences.
7. Ongoing Support. Follow-along supports align with the individual client's needs and continue until the employee is independent. The multidisciplinary team provides a range of supports over time, with greater intensity as needed during times of crisis. For example, the psychiatrist may alter medications to help with the initial anxiety of working; the case manager may meet with the family to help them be supportive; and the employment specialist may provide benefits counseling, off-site supports, and skills training.
8. Individualized Benefits Counseling. Many clients who receive disability, welfare, or other benefits fear they could lose these benefits if they work. Individualized, accurate information about benefits often corrects misconceptions and helps clients make good decisions.

Employment specialists typically are college graduates supervised by master's-level vocational specialists. Employment specialists provide vocational assessment, placement, and support, but the multidisciplinary team collaborates throughout. The case manager and medical providers need to encourage clients to try employment. The entire team may help in finding a job and providing supports. For example, the case manager may help solve problems related to interpersonal difficulties on the job, the social worker may meet with the family to understand their concerns about employment, and the psychiatrist may provide extra medications to help with initial anxiety on the job or decrease medications to reduce side effects that interfere with working.

The key to success is finding the right match—a job that aligns with the client's interests, abilities, ways of coping with illness, needs regarding benefits, family situation, and so on. Trying different jobs often leads to an optimal job match.

Antonio was a 45-year-old man who had been a client of a mental health agency for over 10 years. He attended a rehabilitative day treatment program until it was converted to a supported employment program. His case manager encouraged him to think about the possibility of working part-time. Antonio told his case manager that he couldn't work because of schizophrenia and because he was helping to raise his two kids and needed to be home at 3 pm when they arrived home from school every day. The case manager explained to Antonio that going to work doesn't necessarily mean a 40-hour-a-week job and that lots of people in the agency's supported employment program work in part-time jobs, even jobs that are only a few hours a week.

Antonio agreed to meet one of the employment specialists to discuss the possibility of work. Over the next couple of weeks, the employment specialist met with Antonio several times, read his clinical record, and talked with his case manager and psychiatrist. The employment specialist learned that Antonio loved to drive his car, that he had attendance problems in past jobs, and that he was a kind, friendly, and likable person.

Antonio told the employment specialist that he was willing to do any job. He didn't have one specific job in mind. The employment specialist suggested a job at Meals on Wheels as a driver for lunch delivery. Antonio was hired and loved it right from the start. Absenteeism was never a problem because he knew that people were counting on him to deliver their meals. The hours were perfect (10 AM–2 PM), so he could be at home when his kids returned from school. He became good friends with the other people who worked there. He told his case manager that it was wonderful to be bringing home a paycheck again. And best of all, he said, was that his kids saw him going to work just like their friends' dads.

Research on IPS Supported Employment

Research has produced several consistent findings. Interventions that do not target job placement directly, such as housing, counseling, and medications, have very little impact on employment outcomes. In order to

help patients achieve competitive employment, the intervention needs to be specifically directed at this goal.

Interventions that focus on pre-employment counseling, skills training, and practice work do not produce better vocational outcomes of any kind, including type, quality, amount, length, or satisfaction related to employment. Supported employment interventions that focus on direct and individualized placements with follow-along supports produce much better outcomes.

The evidence strongly favors IPS supported employment over other approaches to vocational rehabilitation. Nearly 40 randomized controlled trials show that IPS supported employment produces better employment outcomes, including higher rates of employment, greater earnings, more hours of work, and a longer tenure in jobs. The magnitude of these effects is substantial. For example, rates of employment are two or three times greater in IPS-supported employment programs than in the comparison conditions in the United States. Most of these trials are pragmatic trials conducted with typical patients, providers, and programs. Figure 12.13–1 summarizes competitive employment rates for IPS and control participants in 28 randomized trials.

All types of patients do better in IPS supported employment than in traditional vocational programs: for example, patients with poor vocational histories, those from minority backgrounds, specifically African Americans and Latinx people, those with co-occurring disorders, and inner-city residents who have recently been homeless. Research also shows that patients themselves express high satisfaction with IPS supported employment jobs and that they typically stay in first jobs for 5 to 6 months, just like the general population starting their first jobs. Several long-term follow-up studies indicate that patients maintain initial high employment rates over 5 to 10 years.

FIGURE 12.13–1. Competitive employment rates in 28 randomized controlled trials of individual placement and support.

Although some clinicians still fear that high expectations will destabilize patients with schizophrenia or other serious mental disorders, IPS supported employment services do not produce clinical instability, higher rates of relapse, or other untoward outcomes. On the contrary, patients who are currently in competitive employment appear to benefit in numerous ways and report higher satisfaction with services, better self-esteem, and greater quality of life.

TECHNOLOGY TOOLS

Technology Use Among People with Schizophrenia

People with psychiatric illnesses, including those with schizophrenia, use contemporary technologies in a manner similar to the general population. Survey studies suggest that 80% to 94% of people with schizophrenia access the internet regularly, use email, and use of social networking websites, online forums, chat rooms, and blogs. Moreover, people with serious mental illnesses such as schizophrenia are already using a host of digital resources for mental health reasons: obtaining information about mental disorders and treatments, searching for mental health services, connecting with peers with similar conditions, and engaging with online communities and supports. For example, people with psychiatric conditions are posting video testimonials in which they openly disclose their illness and provide first-person accounts of their symptoms and coping strategies on YouTube, a popular video-sharing website. Their posts receive numerous comments from viewers who describe their own

experiences with illness, provide positive feedback, share symptom management suggestions, and thank the individual for sharing their video. In this manner, a virtual community can support people who may not have access to local support and help erode the stigma that often prevents people from disclosing their mental health struggles.

Mobile-cellular technology is pervasive—one of the fastest-adopted technologies in human history. The number of mobile phone subscriptions has gone from 1 billion in 2001 to over 7 billion in 2017, with over three-quarters of the world's mobile devices now being used in low- and middle-income countries. To contextualize the potential health care implications of such a ubiquitous resource, more people in the world now have access to mobile phones than to working toilets. When mobile phones first became commercially available at the end of the 20th century, they were inaccessible to people with significant disabilities and limited resources. But rapid advancements in the development of mobile hardware coupled with vast expansion in global mobile–cellular infrastructure have contributed to significant drops in the costs of devices, as well as access to data plans. Consequently, the majority of the population can make calls and send text messages using their personal mobile device with relative ease. In the United States, several federal and state programs now subsidize basic mobile phones and monthly call/text minutes to make them accessible to individuals below a certain income level. Thus, many more people with schizophrenia have access to a wealth of information and resources. Survey studies in the United States have shown that 86% to 97% of people with serious mental health conditions own and use mobile technologies, including cellular phones, text messaging devices for the hearing impaired, and smartphones (i.e., mobile phones with significant computational and data storage capacities). Similar access occurs in several European countries and Australia.

Both community-based outpatients and acutely ill inpatients with schizophrenia can use mobile devices successfully. Over two decades of clinical research using mobile devices, including beepers, personal digital assistants (PDAs), and smartphones to record behaviors, symptoms, and functioning, suggest that people with schizophrenia are quite open to using mobile self-tracking tools and that they experience little to no iatrogenic effects from doing so. Even highly symptomatic patients with paranoid schizophrenia have successfully engaged in Ecologic Momentary Assessment (EMA) studies that require them to self-report

distressing thoughts and even illegal substance abuse using mobile devices. People with schizophrenia consistently report their interest in using technologic tools to support illness management and functional recovery. Research groups in different countries have developed innovative technologic approaches that aim to accomplish this goal.

Technologic Approaches for Assessment and Treatment

Web-Based Interventions. People with schizophrenia, their family members, and their supporters can access a range of resources on the internet, for example, illness management programs, chat forums, support groups, and informational webpages. Acceptability, usability, and helpfulness of web resources depend upon whether they were developed with close consideration of the needs of people with severe psychiatric illnesses (i.e., possible cognitive impairments, low literacy, and dexterity problems).

Web resources with appropriately designed user interfaces can be highly engaging and effective. For example, *Coping with Voices*, a self-directed web-based Cognitive Behavioral Intervention addresses the functional impact and distress caused by auditory hallucinations. Users progress through an interactive 10-lesson program at their own pace and revisit content from previous lessons. Video tutorials educate people about psychosis and dysfunctional cognitive styles using interactive games, quizzes, and practice opportunities. Participants who completed *Coping with Voices* experienced reductions in the severity and intensity of auditory hallucinations as well as other psychotic symptoms and general psychopathology.

Schizophrenia Online Access to Resources (SOAR) is a multifamily intervention for people with schizophrenia and their supports. The key elements of the *SOAR* intervention include the empathic engagement of users, education about illness and treatments, and the use of coping strategies. *SOAR* offers three therapy forums: one for people with schizophrenia, one for support persons, and one for both groups. Users can post questions and receive answers from trained clinicians within 24 to 48 hours. *SOAR* also contains a record of responses to previously posted questions, a library of relevant reading materials, and a list of community events, activities, and resources that may be of interest. People with schizophrenia who engage in *SOAR* experience a significant reduction in positive symptoms of psychosis. Support persons also

showed a significant and sustained increase in knowledge about the course and prognosis of schizophrenia.

The *HORYZONS* system is an online platform developed for the long-term recovery of people experiencing a first episode of psychosis. The system delivers several evidence-based and interactive psychosocial interventions and facilitates a moderated online peer-to-peer social networking environment. Users respond to a set of standardized questions that guide the tailored modules that target risk factors for psychotic relapse and other areas that are salient to people in early recovery, including psychoeducation, early warning signs, depression, social anxiety, and stress management. First-episode patients who used the *HORYZONS* system reduced depression and found the approach to be engaging, empowering, and safe.

Mobile Health. The immense capabilities and functionality of mobile technology have led to the development of the interdisciplinary field of Mobile Health (mHealth). Mobile devices can support the delivery of health care in a variety of formats, enabling patients and providers to send and receive calls and text messages, access websites, provide clinical decision support, and capture and transmit data collected in real-time and in users' own environment. Mobile devices with computational capacity can also house health-focused applications (apps) designed to facilitate patient illness self-management.

FOCUS, the first smartphone intervention specifically designed for people with schizophrenia, was developed iteratively and in close consultation with patients and clinicians. The *FOCUS* system can be activated to prompt users multiple times a day with questions about their symptoms, social functioning, mood, medication adherence, and sleep, which appear on the device's touchscreen. Depending on users' responses, the system launches brief interactive interventions in the form of written text, images, and cartoon screens, designed to both give the individual skills they can use in the moment (e.g., relaxation strategies, medication reminders, social skills tips), as well as train the user in techniques that can be generalizable to a range of scenarios (e.g., cognitive restructuring, hypothesis testing, behavioral activation, distress tolerance). In addition to prompted interactions, all *FOCUS* interventions are available on-demand as part of a toolkit that can be accessed at any time. All user responses are recorded on the device, and the system can

send the data to a remote server whenever the phone has connectivity. Authorized individuals (e.g., clinicians and researchers) can access a web-based dashboard summarizing all user responses shortly after they engage the system. People with schizophrenia find the *FOCUS* intervention highly acceptable and useable. Patients who used *FOCUS* experienced a significant reduction in symptoms of psychosis, general psychopathology, and depression. Findings from randomized controlled trials suggest that patients are much more likely to commence treatment and stay engaged in care when assigned to mHealth than a more standard clinic-based group intervention. Moreover, when patients use the *FOCUS* intervention, their use of other time and resource-intensive services drops by approximately 10%.

Lakesha is a 38-year-old woman with schizophrenia who receives community-based mental health services. Lakesha suffers from persecutory ideation and auditory hallucinations that warn her about making eye contact with strangers who are “out to humiliate her.” Despite having access to a host of treatment options, she makes only sporadic use of the available resources because she is apprehensive about using public transportation to get to the clinic, and is concerned about “sitting in the waiting area with a bunch of crazies.” Consequently, she is becoming increasingly isolative and is experiencing greater distress and impairment linked with her symptoms. Lakesha has an elderly mother with whom she is quite close but whom she has been visiting less and less because she is convinced that the local bus drivers intend to kidnap her. Lakesha’s psychiatrist suggested she enroll in a treatment study in which participants are given the *FOCUS* smartphone system for 3 months. Initially, Lakesha thought she would not be able to use the intervention because she was unfamiliar with smartphones. However, after a 45-minute training session with the research staff, she used the device successfully and learned how to operate the touchscreen to respond to *FOCUS* questions and suggestions. Lakesha started using FOCUS that evening and continued to respond to clinical prompts daily. She found the guided breathing techniques to be particularly helpful as she could use them flexibly whenever she wanted, including on the bus ride to see her mother.

After 8 weeks of smartphone intervention use, Lakesha reported leaving her house daily to go to the local store, community center or to visit a neighbor. She reported feeling less anxious about others’ intentions. While she still experienced auditory hallucinations regularly, she described being less concerned about them. She successfully integrated several *FOCUS* strategies into her illness management repertoire and is now able to engage in relaxation exercises and basic thought challenging of dysfunctional beliefs (e.g., “what is the evidence that I’m in danger when I leave the house?”) independently.

Short Message Service (SMS) or text messaging approaches have also been used to support psychiatric rehabilitation for patients with schizophrenia. For example, *Mobile Assessment and Treatment for*

Schizophrenia (MATS) is a mobile phone intervention employed to administer questions and algorithm-driven follow-up suggestions to patients in the areas of medication adherence, social functioning, and management of auditory hallucinations. *MATS* initiates a sequence of brief automated back-and-forth exchanges, including illness-management suggestions drawn from cognitive behavioral treatments for psychosis.

In addition to enabling completely novel treatments, mobile technologies can supplement traditional models of care. Community-based research has shown that patients with psychosis and co-occurring substance use find texting to be a highly engaging method for connecting with their case manager. When a *Mobile Interventionist* used daily texting to check in and provide daily support, patients responded to 87% of the messages sent and rated the therapeutic alliance with the Mobile Interventionist highly. A randomized controlled trial showed that when ACT care is augmented with a texting mobile interventionist, patients with serious mental illness experience improved psychiatric symptom management and self-rated recovery than when receiving ACT alone.

Virtual Reality. Virtual Reality (VR) refers to multimedia techniques in which individuals engage in computer-generated scenarios on a computer screen or head-mounted stereoscopic display that creates a highly immersive 3D environment. VR has been used primarily to facilitate exposure therapy for people with anxiety disorders, but several studies have demonstrated its potential utility in supporting rehabilitation for people with psychosis. These include help identifying contextual triggers for persecutory ideation, learning skills, and practicing job interviews. Preliminary evidence suggests VR may be an effective tool, including benefits from continuous feedback from an on-screen virtual coach.

Technology-Assisted Psychiatric Rehabilitation During a Global Pandemic. The global coronavirus disease 2019 (COVID-19) has proven to have devastating effects on the lives of millions worldwide. Due to the highly infectious nature of COVID-19, comprehensive social distancing policies have been implemented broadly, blocking the ability of psychiatric rehabilitation professionals to provide in-person services. Disruption of clinic-based services coupled with a rise in the needs of people experiencing social isolation, economic upheaval, anxiety, and psychological trauma have propelled health care systems to embrace technology as a primary method to deliver services in a manner that is

unprecedented. Major examples include the widespread implementation of videoconferencing technology as an alternative tool to conduct live telemental health sessions, a sharp increase in the use of clinical messaging services and companies that facilitate texting interactions between patients and remote providers, adoption of mental health apps and loosening of the regulatory restrictions on their use, and distribution of mental health resources through social media, platforms, and online streaming services. While it is not fully clear how the psychiatric rehabilitation landscape will look after the COVID-19 pandemic subsides, it is unlikely that we will see a full return to traditional in-person service models. Some pandemic-related changes in regulatory guidelines and policies that govern the use of technology in mental health care will likely remain. Thus, the coronavirus crisis and the collective response to emergent patient needs will likely prove to be a key catalyst for the adoption of digital mental health technologies.

SUMMARY

Psychiatric rehabilitation comprises a range of techniques and interventions that help people with disabilities related to psychiatric illness to manage their illness, succeed in regular social roles in the community, pursue their personal goals, and “recover” in the sense of moving beyond feeling dominated by illness to create a meaningful life. Rehabilitation requires creating normative opportunities, such as for education, employment, and housing; providing support as needed to ensure success; and helping people acquire the skills and natural supports they want to pursue life goals.

12.14 Medical Health in Schizophrenia

ROBERT J. BOLAND, M.D.

We have known for centuries that people with schizophrenia have shorter lives than the rest of us. In the 1830s, the Council of the Statistical Society of London commissioned one of its fellows, William Farr, to investigate patient mortality in the county asylums. His result was the first study explicitly examining death rates in psychiatric patients, titled *Report on the Mortality of Lunatics*. Drawing on his observations of several English asylums, he detailed the high mortality and the discrepancies between male and female patients and economic groups.

Table 12.14–1.
The "Take Home"

Patients with Schizophrenia are more likely than the general population to

- Die prematurely
- Have a comorbid medical illness
- Be neglected by the medical establishment
- Have an unfavorable clinical outcome

In 1936, Ornulv Odegard, reporting on the mortality rates in Norwegian mental hospitals, observed that they most often died not from their mental illness but tuberculosis and other infectious diseases. Odegard believed that this was partly a function of their environment, with its crowding and poor nutrition. However, he also felt their mental illness contributed in that the apathy it caused left them unwilling to complain or seek medical treatment for their illnesses.

In 1959, when tobacco use was at its highest level, Albert Abraham published *Cardiovascular Disease in Psychotics*, demonstrating a high rate of cardiovascular disease (CVD) in hospitalized patients with schizophrenia. He rejected the popular view of the time that "the

protective life of people with schizophrenia seems to guard them from early onset of degenerative diseases of the heart." By the late 1970s, the accumulated data made it clear that psychiatric patients had higher mortality rates than the general population. However, little was done to understand why this was so.

Today there is ever-growing literature investigating the importance of comorbidities in persons with psychotic disorders. Since 2000, almost 100 systematic reviews and meta-analyses have focused on the physical health comorbidities associated with various mental illnesses. For schizophrenia, there were 15 reviews done between 2000 and 2019. These include two reviews for CVD, five for cancer, two for diabetes, three for metabolic syndrome, and four for other disorders (such as osteoporosis, arthritis, and mixed illnesses).

Taken together, these studies show that physical comorbidities are the rule, not the exception, for patients with schizophrenia. Furthermore, the sociodemographic factors that affect persons with psychosis influence this frequency, and comorbid disorders are becoming increasingly common in older patients with severe mental illness.

Table 12.14–1 summarizes the major points that this chapter will discuss.

ALL-CAUSE MORTALITY IN SCHIZOPHRENIA

Individuals with schizophrenia and other chronic psychotic disorders die about 10 to 15 years prematurely, with men dying about 15 years prematurely and women dying, on average, 12 years. In addition, schizophrenia patients are at higher risk of developing various medical illnesses, are less likely to receive and benefit from appropriate medical treatment, and are more likely to experience unfavorable clinical outcomes. Many of these patients with comorbidity, perhaps as many as two-thirds, have more than one physical disease—"multimorbidity."

Some earlier studies use standardized mortality ratios (SMRs) to quantify the additional mortality risk associated with schizophrenia relative to the general population. SMRs are the ratio of observed to expected deaths within a specified sample or given age range (sometimes 100). The *expected* mortality rate is the rate seen in the general population, whereas the *observed* mortality rate is that seen in the population in question (e.g., those with schizophrenia). It is, therefore, a measure of

relative and not absolute risk. More recent studies, such as the Global Burden of Disease (GBD) study, use such estimates as years of life lost of premature mortality (YLLs), calculated as the number of cause-specific deaths multiplied by a loss function specifying the years lost for deaths as a function of the age at which death occurs. This approach provides a somewhat more accurate estimate of the mortality cost. The most recent analysis from that study includes data up to 2019. However, much of the comorbidity analyses are from the 2010 analysis. That study found that the primary cause of premature death in patients with schizophrenia was due to chronic physical diseases, with CVD accounting for more than 33% of premature deaths. In contrast, suicide, homicide, and accidents accounted for less than 15% of the excess deaths.

The GBDs conclusion is consistent with earlier registry-based studies, such as by Brown and colleagues in 370 schizophrenia patients over 25 years, who found that 81% of patients with schizophrenia died from medical diseases. In their study, the most common diseases were cardiovascular and circulatory diseases, respiratory diseases including pneumonia, endocrine diseases including diabetes, nervous system diseases, and cancer.

In addition, population-based cohort studies consistently identify a significant increase in overall all-cause mortality ranging from two to four times higher in patients with schizophrenia compared to the general population, with somewhat smaller increases sometimes observed in exclusively inpatient samples. In a population-based sample of 7,784 inpatients with schizophrenia analyzed by Osby and colleagues, male and female subjects had an SMR of 2.8 and 2.4, respectively, for death due to any cause. All types of natural causes of death, except cancer in men and nervous system diseases in women, were significantly elevated. Overall, patients were more than twice as likely to die from cardiovascular, cerebrovascular, or respiratory disease. A study by Olfson and colleagues reported on SMRs for over 1 million U.S. Medicaid patients followed for almost 5 million person-years of follow-up, with over 74,000 deaths. Patients with schizophrenia were 3.7 times more likely to die in the follow-up period than the general population. CVD had an SMR of 3.6 and the highest mortality rate (403.2 per 100,000 person-years) of any individual cause. Cancer overall had the next highest mortality rate, with lung cancer contributing the most with an SMR of 2.4 and a mortality rate of 74.8 per 100,000 person-years. Elevated SMRs were also observed for chronic

obstructive pulmonary disease (COPD) (SMR = 9.9) and influenza and pneumonia (SMR = 7.0), suggesting the effects of high smoking rates in this population, as well as for diabetes mellitus (SMR = 4.2, mortality rate = 61.8 per 100,000 person-years). Nonsuicide-related substance-induced death, primarily from alcohol or other drugs, was also a significant cause of death (95.2 per 100,000 person-years). Finally, accidental deaths (119.7 per 100,000 person-years) accounted for more than twice the number of deaths attributable to suicide (52.0 per 100,000 person-years). While much attention understandably goes to the effects of suicide in this population, this large and definitive study from the public sector underscores the critical effects of medical morbidity and mortality in this population.

MEDICAL CAUSES OF EXCESS MORTALITY IN SCHIZOPHRENIA

Despite finding that comorbid medical conditions, rather than unnatural causes of death such as suicide, confer most of the excess mortality seen in persons with schizophrenia, medical comorbidities often remain underdiagnosed and undertreated in these patients. Table 12.14–2 lists the most common medical causes of mortality in schizophrenia.

Table 12.14–2.
Common Medical Comorbidities in Schizophrenia

Cardiovascular disease
- Congestive heart failure
- Cerebrovascular disease
- Coronary heart disease

Type 2 diabetes mellitus

Infectious diseases
- Pneumonia: COVID-19, other viruses, tuberculosis
- HIV
- Hepatitis B, C

Cancer
- Lung
- Breast

Pulmonary disease
- COPD
- Asthma

Cardiovascular Disease

Heart disease is the leading cause of death, accounting for about 1 in every 4 deaths in the United States, and it costs the United States about 363 billion dollars each year. It remains the leading cause regardless of sex, race, or ethnicity. However, non-Hispanic black persons are more than twice as likely to die of heart disease than other races or ethnicities. From 1999 through 2017, the death rates for heart disease have decreased in all groups. However, this decrease has slowed in recent years.

Although heart disease seems to be slowly declining in the general population, this improvement has not included patients with schizophrenia. As mentioned above, CVD is the leading cause of mortality in individuals with schizophrenia and is more common in this group than in the general population. For example, Fan and colleagues reviewed 13 studies with 422,698 patients with schizophrenia who had CVD outcome data. They calculated a pooled relative risk of 1.53 for CVD, 1.2 for coronary heart disease, 1.7 for stroke, and 1.81 for congestive heart failure (CHF). Similarly, a large meta-analysis by Correll and colleagues of more than 3 million patients found that the pooled CVD prevalence for all

patients with serious mental illness (SMI) was 9.9%, significantly higher than the normal controls (odds ratio [OR] = 51.53, 95% CI: 1.27–1.83). In this study, schizophrenia was significantly associated with CVS, coronary heart disease, and cerebrovascular disease. The risk of CVD-related death was also higher than the controls, with a hazard ratio (HR) of 2.45 (95% CI: 1.64–3.65). Other studies have had similar findings with relative risks ranging from two to fivefold.

A systematic review focusing on acute coronary syndrome (ACS, a principal cause of cardiac mortality, is a sudden rupture of atherosclerotic plaques, causing thrombus formation and subsequent infarcts, CHF, and arrhythmias) found that death rates following ACS were higher in patients with schizophrenia than mentally healthy patients. The investigators also found that patients with ACS were at a greater risk for major adverse cardiac events (MACE) following hospitalization. They hypothesized that the causes were multifactorial, including patient factors (CVS risk, poor self-care, socioeconomic factors) and health care–related (treatment bias, prejudice, and suboptimal care).

The Framingham Heart Study (a long-term cohort study funded by the National Heart, Lung, and Blood Institute [NHLBI]) and other large population-based samples have identified modifiable risk factors for CVD and how these risk factors interact. The knowledge gained from these studies has important implications for decreasing cardiovascular-related morbidity and mortality, including in higher-risk populations such as people with schizophrenia. It is important to note that persons with schizophrenia have an increased prevalence of all key modifiable cardiovascular and metabolic risk factors, including obesity, smoking, hypertension, dyslipidemia, and hyperglycemia.

There is some disagreement in the literature as to the influence of sex on cardiac morbidity. For example, a study by Polcwiartek and colleagues looking at CHF data from 2002 to 2017 in more than 20,000 patients found that having an SMI increased the risk of death from CHF in men, but not women. In studying more than 8,000 patients with schizophrenia in the United Kingdom, McCreadie and colleagues found the risk for CHD and stroke higher in men with schizophrenia, but not women. Other studies find the risk to be higher for both sexes but highest in men. The greater risk for men is consistent with the general population.

Most concerning is the disparity in treatment for patients with schizophrenia who develop CVD. For example, Solmi and colleagues

conducted a meta-analysis of 47 studies with a total of more than 1 million patients with comorbid CVD and mental illness. They found a significant disparity in screening between patients with schizophrenia and any CVD versus patients without a mental disorder (OR = 0.611, 95% CI: 0.554–0.673), a greater disparity than for any other mental disorder investigated.

Diabetes Mellitus

Diabetes-related morbidity and mortality significantly affect the general population, increasing overweight and obesity rates in developed countries. Diabetes is currently the seventh leading cause of death in the United States, with 34.2 million people having the disease. One in five people are unaware that they have the disease, and another 88 million people in the United States have prediabetes. After two decades of increases, the incidence of diabetes has slowly decreased from 2008 to 2017, and in 2019, 1.5 million new cases were diagnosed in U.S. adults.

The prevalence of type 2 diabetes mellitus is substantially higher in individuals with schizophrenia than in the general population, with prevalence estimates ranging from two to four times higher. Stubbs and colleagues reviewed 25 studies and found that the prevalence of type 2 diabetes mellitus in people with schizophrenia was 9.5%. Vancamport and colleagues of 22 studies estimated a pooled prevalence of 11.5% for patients with schizophrenia, with a risk of nearly double that in the general population. Similarly, Ward and Druss estimated a median prevalence of 13%. However, they reported a wide variation across different studies, owing to differences in study design, disease detection, and sample sizes. The comorbidity significantly increases the mortality risk for patients with schizophrenia; one population-based study in Hong Kong, for example, estimated an elevated mortality risk regardless of the level of disease or number of complications.

Underrecognition of schizophrenia as a marker for increased risk for diabetes may contribute to the impact of diabetes-related risk on the overall elevated mortality in the absence of extra efforts in primary or secondary prevention. The Canadian Diabetes Association and the American Association of Clinical Endocrinologists have added schizophrenia to the list of risk factors for diabetes in their screening guidelines. However, ongoing evidence generally documents low screening rates for abnormalities in plasma glucose or lipids in this population.

Infectious Disease

In developing countries, infectious disease remains a substantial cause of mortality for persons with and without schizophrenia. This fact has become remarkably more evident during the COVID-19 pandemic. Patients with schizophrenia are at higher risk than the general population for becoming infected with the SARS-CoV-2 and dying from it. A review of seven studies from various countries found increased rates in the range of an OR of 1.3 to 1.53. Similarly, all the studies with relevant data showed increased mortality rates, with ORs ranging from 2.25 to 4.36. Another meta-analysis estimated a mortality risk of about twice that for the general population (OR 2.28, using more than 100 studies). These studies provide compelling evidence to support the notion that the COVID-19 pandemic has disproportionally affected people with schizophrenia. The reasons are multiple and similar to those for other chronic diseases; however, some studies highlight the lower vaccination rates in patients with schizophrenia. In response, the centers for disease control and prevention (CDC) added schizophrenia spectrum disorders to its list of underlying medical conditions associated with a higher risk for severe COVID-19, including it in the category of disorders with solid evidence (along with mood disorders).

Even before the pandemic, infectious diseases were a significant problem among patients with schizophrenia. For example, the human immunodeficiency virus (HIV) infection rate has been estimated at 3% in patients with a severe mental illness, an eightfold increase over the general population rate. Data have shown that knowledge of exposure risks is deficient among these patients. Rates of hepatitis B (23.4%) and C (19.6%) infections are also significantly elevated among those with a severe mental illness, approximately 5 and 11 times the overall estimated population rates for these infections. Studies also consistently show a higher incidence of tuberculosis among patients with schizophrenia than the general population.

Cancer

According to the CDC, there were 1.7 million new cancer cases in the United States in 2018 (the most recent year with available data), and about 600 thousand people died of cancer that year. However, new cancers are decreasing somewhat, from an age-adjusted rate of 481.7 per 100,000 people in 1999 to 435.8 per 100,000 in 2018. Similarly, mortality

has declined, with an age-adjusted cancer death rate of 200.7 per 100,000 in 1999 to 149.2 per 100,000 in 2018.

The association between schizophrenia and cancer risk is an area of some debate. Various studies disagree on whether patients with schizophrenia have a higher risk of cancer than the general population. The majority of studies suggest that the risk for cancer in patients with SMI is similar to the general population. Some, such as a meta-analysis by Li and colleagues, find a slightly decreased risk of cancer in patients with schizophrenia. An important variable is smoking, and studies that try to control for that tend to find much lower risks for cancer in patients with schizophrenia. However, attempts to account for smoking as a variable are inherently problematic given its prevalence in this population.

In addition, the mortality risk from cancer is higher for patients with SMIs. This likely relates to poorer self-care, including a lower likelihood of preventive care or following through with screening. Some psychotic patients are poor historians who may not accurately report symptoms that would usually trigger additional tests. Patients with schizophrenia are more likely to be homeless, with little protection from UV light and greater exposure to various environmental stresses. The metabolic side effects of antipsychotics may contribute to the cancer risk, as do worse dietary habits. In addition, there may be treatment biases, including a tendency to attribute physical symptoms to psychological causes or a nihilism around using potentially complex treatments. Most important is the prevalence of smoking—as discussed later, this remains highly prevalent in patients with schizophrenia.

The risk for cancer in patients with SMI may be higher in patients living in middle- or lower-income countries. One review by Park and colleagues, using 80 articles, found that cancer incidence is rising in these countries, both overall and particularly for patients with SMI. This increase relates to various factors. For example, although cervical cancer accounts for most cancer deaths in these countries, vaccinations (the human papillomavirus vaccine has been available since 2006) remain a low priority for these countries. In addition, cancer detection and screening are inadequate as well. Although these health care inadequacies are problems for the populations, it is worse for patients with schizophrenia.

Pulmonary Disease

Chronic lower respiratory disease, including COPD, is the fourth leading cause of death in the United States, after heart disease, cancer, and accidental deaths. CDC Data from 2019 reports 156,979 deaths from chronic lower respiratory diseases, including asthma, a death rate of 47.8 per 100,000. About 4.6% of Americans have been diagnosed with COPD, emphysema, or chronic bronchitis. However, that number is decreasing some. From 2000 through 2014, the age-adjusted rate for COPD decreased 22.5% for men and 3.8% for women 25 or older. The age-adjusted death rate also decreased for most groups, with the notable exception of black women, increasing 4.2%. In most cases, the cause of death was COPD itself.

Like other chronic diseases, people with schizophrenia have significantly higher COPD, asthma, and pneumonia rates. In a systematic review of 21 studies consisting of over 600 thousand patients with schizophrenia, Suetani and colleagues reported a prevalence of 7.7% for COPD, 7.5% for asthma, 10.3% for pneumonia, and 0.3% for tuberculosis. After adjusting for publication bias, the prevalence of COPD increased to 19.9%. In each case, this is higher than the general population. For example, the OR was 1.82 for COPD, 1.70 for asthma, and 2.62 for pneumonia. These rates are consistent with earlier studies. For example, Zareifopoulos and colleagues, using more restrictive inclusion criteria, reported that people with schizophrenia had an OR of 1.57 for COPD.

This increased risk undoubtedly relates to the several risk factors shared between schizophrenia and respiratory diseases. Most important, again, is smoking. Other factors include childhood exposure to air pollution, increased in patients with schizophrenia, and many socioeconomic factors. In addition, people with schizophrenia are less physically active than the general population. Also, antipsychotics may worsen respiratory diseases, mainly through weight can.

Oral Health in Schizophrenia

People with schizophrenia have poor dental health, among the poorest reported in the literature. Reports suggest that patients with schizophrenia brush their teeth irregularly, leading to functional difficulties such as difficulty with chewing and eating, in addition to increased risk for decay, infection, and inflammation.

MECHANISMS OF DISEASE

The previous sections have already shed some light on many of the reasons for the increased incidence of most major chronic physical disorders. Smoking, socioeconomic factors, psychological stress, and side effects of antipsychotics, particularly weight gain and metabolic changes, undoubtedly play essential roles. Patients with schizophrenia tend to have less insight into their illness and are less likely to seek medical care for physical complaints. When they do, health care professionals may dismiss their complaints as part of their mental disease. Even when diagnosed, patients with schizophrenia are less likely to receive optimal care, either due to their avoidance behaviors or owing to physician bias.

Apart from behavioral, social, and economic factors, schizophrenia may have direct physiologic effects that put patients more at risk for physical illnesses. For example, inflammation may have a role in schizophrenia and metabolic and other physical disorders. Some studies have found a correlation between markers of systemic inflammation (such as C-reactive protein and myeloperoxidase) and dyslipidemia in patients with schizophrenia.

Limited data suggest that increased activation of the hypothalamic–pituitary–adrenal (HPA) axis and the sympathetic nervous system can adversely affect the body. However, genetic factors may play a role. For example, one report found that 18% to 19% of individuals with schizophrenia had a family history of type 2 diabetes mellitus. In addition, some pharmacogenomic studies suggest that specific genetic variants that decrease the action of certain enzymes (such as methylenetetrahydrofolate reductase) are associated with an increased cardiovascular risk.

The physiologic effects are likely reciprocal as well. For example, some research suggests that metabolic dysfunction may directly affect brain structure and increase vulnerability to psychotic or other SMI.

Although research into possible direct physiologic effects is fascinating, it is preliminary. Even if more definitive studies follow, it remains likely that behavioral, lifestyle, and environmental factors offer the best explanation for why so many chronic physical illnesses are so common in patients with schizophrenia. This reality is perhaps good news, as we already have proven interventions to modify many of these risk factors. This chapter will

discuss those after considering some of the potentially modifiable risk factors.

INCREASED PREVALENCE OF MODIFIABLE RISK FACTORS IN PATIENTS WITH SCHIZOPHRENIA

Key risk factors for the most significant causes of morbidity and mortality are all more prevalent in schizophrenia. These include public health priorities such as obesity, smoking, hypertension, dyslipidemia, and hyperglycemia. Thus, successfully addressing the excess burden observed in persons with schizophrenia depends on primary and secondary prevention efforts targeting modifiable risk factors. Table 12.14–3 discusses some of the most common modifiable risk factors in schizophrenia.

Table 12.14–3.
Modifiable Risk Factors in Patients with Schizophrenia

Smoking
Substance abuse
Metabolic syndrome
▸ Overweight and obesity
▸ Hypertension
▸ Dyslipidemia
▸ Hyperglycemia
▸ Insulin resistance

Smoking and Substance Abuse

As we discuss throughout this chapter, cigarette smoking is a well-known risk factor, and it is associated with most of the diseases we have discussed. More than 16 million Americans are living with a smoking-related disease. Smokers die about 10 years earlier than nonsmokers, and smoking is responsible for more than 480,000 deaths every year in the United States, including more than 41,000 from secondhand smoke. This represents more than one in five deaths annually, of 1,300 deaths per day. Worldwide, tobacco use causes more than 7 million deaths per year. Although the prevalence of smoking has declined significantly, primarily due to public health campaigns and related cultural changes,

smoking remains the leading cause of preventable disease, disability, and death.

While the overall rate of current smoking in the United States declined during this time from 42% to 18%, it remains very prevalent among people with mental illness, and perhaps as many as 70% to 85% of people with schizophrenia smoke. Persons with mental illness who smoke also tend to smoke more cigarettes than other smokers. Smokeless tobacco is also becoming more popular. Tobacco use is most common in people with mental illness younger than 45, who have low education levels and live in poverty. Co-occurring substance use is another influential risk factor. Some experts speculate that the high smoking rates are because nicotine's stimulant effect can transiently improve some symptoms. However, quitting smoking also improves mood and quality of life in individuals with severe mental illness.

Besides nicotine, other substances are common for patients with schizophrenia, and perhaps half of patients with the disorder also suffer from a substance use disorder. The most common substances include alcohol, cannabis, and cocaine. The prevalence of each has an extensive range depending on the population studied and the methods used. However, it is about three times that of the general population for each of the drugs. In addition to the many health problems caused by these drugs, substance use can cause exacerbations of the user's substance disorder, poor adherence to treatment, and an overall functional decline.

The exact link between substance use and schizophrenia is unclear, and experts have advanced various theories, many of which have commonsense appeal despite little empirical support. For example, the diathesis–stress model posits an interaction between neurobiologic vulnerabilities and environmental stress leading to schizophrenia and substance use. The self-medication hypothesis suggests that patients with schizophrenia use substances to address their symptoms. Alternatively, the two disorders may share a common pathophysiology with overlapping brain pathways. For example, schizophrenia may cause a deficit in the reward pathway, for which patients attempt to use substances to compensate. Admittedly, the theories are not mutually exclusive. However, there is little evidence for self-medication as a primary explanation, whereas there is growing evidence that schizophrenia and substance use disorders share common disordered circuits.

Metabolic Syndrome

The metabolic syndrome is not a separate entity from the other risk factors discussed here but instead brings together a constellation of several abnormal clinical and metabolic findings. These include adiposity, insulin resistance, hypertension, elevated triglycerides, and low high-density lipoprotein (HDL) levels. The most widely accepted definition of metabolic syndrome is, from the third adult treatment panel (ATP III) of the National Cholesterol Education Program (NCEP) and the adapted adult treatment panel (ATP III-A) of the NCEP Program proposed by the American Heart Association. Table 12.14–4 lists the guidelines.

Table 12.14–4.
Definition of Metabolic Syndrome

		Cutoff		
Clinical/Lab Finding	Measure	ATP	ATP-III	IDF
Abdominal obesity	Waist Circumference (cm)	>102 (men) >88 (women)		>94 (men) >80 (women)
↑ Triglycerides	Plasma triglycerides (mg/dL)		≥150	
↓ HDL Cholesterol	Plasma HDL (mg/dL)		<40 (men) <50 (women)	
Hypertension	Blood pressure (mm Hg)		130/85	
Hyperglycemia	Fasting plasma glucose (mg/dL)	≥110	≥100	≥110

HDL, high-density lipoprotein.
Data from The National Cholesterol Education Program Third Adult Treatment Panel (ATP III), and Adapted Adult Treatment Panel (ATP III-A), and the International Diabetes Federation (IDF).

ATP III-A modified this slightly by decreasing the cutoff for fasting glucose, and the International Diabetes Federation (IDF) stressed the importance of waist circumference by modifying the parameters to a lower cutoff. The general population prevalence of metabolic syndrome is approximately 34% in U.S. adults, similar to other developed countries. Like other risk factors, it is on the rise, increasing from 25% in 1988. The groups with the highest risk were non-Hispanic black females, whereas non-Hispanic black males are less likely to have metabolic syndromes than are non-Hispanic white males. Lower education and older age are also associated with the syndrome.

The metabolic syndrome and the composite syndrome components are major risk factors for type 2 diabetes mellitus and CVD. In addition, as discussed, obesity, dyslipidemia, hypertension, and type 2 diabetes mellitus are all common in people with schizophrenia. Most relevant studies indicate that the prevalence of metabolic syndrome in patients with schizophrenia ranges from about 40% to over 50%.

Antipsychotic medications are associated with the risk of metabolic syndrome to differing degrees, again generally in proportion to their risk for weight gain. For example, pooled data from two 26-week randomized double-blinded studies, one comparing aripiprazole with placebo and the other comparing aripiprazole with olanzapine, showed incidences of metabolic syndrome of 19.2 ± 4.0% for olanzapine, 12.8 ± 4.5% for placebo, and 7.6 ± 2.3% for aripiprazole.

Overweight and Obesity. Increased adiposity is associated with increased morbidity and mortality from hypertension, dyslipidemia, type 2 diabetes mellitus, coronary artery disease, stroke, and certain cancers, including colon, breast, endometrial, and gallbladder cancer. We usually use the body mass index (BMI) to define the conditions, in which we calculate weight in kilograms divided by the square of height in meters (the latter being proportional to body surface area). Persons with a BMI greater than 25 kg/m^2 are considered overweight, and a BMI greater than 30 kg/m^2 generally defines obesity. As of 2019 (the most recent available CDC data), approximately 42% of adults in the United States are obese. Obesity is increasing—in 2000, the rate was 30%. During the same span, severe obesity increased from about 5% to 9%. This upward trend appears to continue, both nationally and worldwide. Obesity disproportionally affects certain groups, as non-Hispanic Black adults have the highest age-adjusted obesity (50%), followed by Hispanic adults (45%), non-Hispanic White adults (42%), and non-Hispanic Asian adults (17%). It peaks in adults aged 40 to 59 years, and the rate has a slight decrease after age 60. The role of socioeconomic factors is complex. However, on average, people with college degrees have a lower obesity prevalence than those with less education. For women, obesity is lowest in the highest-income group, whereas it is lowest in men's low- and high-income groups. The effect of income is modified by sex, race, and ethnicity, as income seems to have little effect for non-Hispanic Black women, and for non-Hispanic Black men, obesity is higher in the highest-income group than the lowest-income group. The estimated annual medical cost of obesity in the United States was 147 billion in 2008, and medical costs for people with obesity are more than $1,900 higher each year than for people with a healthy weight.

Obesity is about twice as prevalent in people with schizophrenia in comparison to the general population. Evidence from numerous studies

characterizes the problem. Substantial evidence suggests that treatment with psychotropic medications, particularly certain antipsychotic medications, increases body weight, and adiposity. Most antipsychotics lead to weight gain, although they differ in degree. Clozapine and olanzapine have the highest propensity, and haloperidol, lurasidone, and ziprasidone have the lowest. The mechanism of weight gain is varied, with histamine H1 receptors, D2 dopamine receptors, blockade of 5-hydroxytryptamine receptor 2C, and dysregulation of glucagon-like peptide-1 receptors all playing a role. Mood stabilizers, particularly sodium valproate, and, to a lesser degree, lithium can also increase weight. Carbamazepine has a lower propensity, and lamotrigine appears not to affect weight gain.

Hypertension. Schizophrenia patients are about twice as likely to have hypertension than members of the general population. Estimates of the rate of hypertension in schizophrenia patients range from 19% to roughly 47%. By comparison, approximately 15% of the general population has hypertension.

The mechanisms causing hypertension in patients with schizophrenia are multiple and include weight gain, insulin resistance, and increased sympathetic nervous system activity with resulting sodium retention. Again, many psychotropic medications put patients at risk for hypertension. Although the α_1-adrenoceptor antagonism associated with some medications can attenuate hypertension, the substantial weight gain overwhelms any protective effect. Cigarette smoking may also increase blood pressure both acutely due to the stimulant effects of nicotine and secondarily due to chronic smoking.

Dyslipidemia. Dyslipidemia is a term to describe abnormal lipid levels, such as increases in total or low-density lipoprotein (LDL) cholesterols and decreases in HDL cholesterols. It is responsible, at least in part, for as much as a third of ischemic heart disease and a fifth of cerebrovascular disease cases. In the United States, the prevalence of total cholesterol above 200 mg/dL is 38% higher in women (40%) than men (35%). In addition, about 29% of U.S. citizens have high levels of LDLs (at or above 130 mg/dL), with more men (30%) than women (27%).

Patients with schizophrenia are at even higher risk of dyslipidemia, and perhaps half of persons with schizophrenia have some measure of the

disorder. Despite this, the disorder is often untreated in this population.

Some antipsychotic medications are associated with clinically significant increases in serum lipid concentrations, generally, but not exclusively, in association with their propensity to produce weight gain. The medications causing the highest risk include such atypical antipsychotics as clozapine and olanzapine and low-potency conventional antipsychotics. Risperidone and quetiapine have a moderate risk, and ziprasidone, aripiprazole, and high-potency conventional antipsychotics have the lowest risk.

Insulin Resistance and Hyperglycemia. The prevalence of insulin resistance, variously defined, in patients with schizophrenia is about 1.5 to 2 times the prevalence in the general population. Hyperglycemia in schizophrenia (glucose >100 mg/dL) is common, affecting up to 20% of patients in pooled samples. If uncontrolled, it can progress to type 2 diabetes mellitus. Most evidence implicates antipsychotics as increasing the risk for insulin resistance and hyperglycemia in patients with schizophrenia, as opposed to the disease state. Lifestyle can undoubtedly affect outcomes, with poor diet, inactivity, smoking, and lack of exercise commonly associated with overweight and obesity and insulin resistance in untreated nonpsychiatric samples and treated patients.

Different antipsychotic medications are associated with different levels of risk for insulin resistance and hyperglycemia, generally proportional to their association with drug-induced weight gain, although additional adiposity-independent effects may contribute to risk with some medications. For example, antipsychotic agents such as clozapine and olanzapine achieve relatively high intracellular concentrations where they can interact with intracellular glucose transporter proteins. This effect reduces glucose transport from the extracellular to intracellular space, potentially contributing to insulin resistance. The result is an increased risk for hyperglycemia, independent of any weight or adiposity effects.

PRIMARY AND SECONDARY PREVENTION

Cardiovascular Events

In the general U.S. population during the past decade, most of the observed reductions in CVD mortality are attributable to improvements in the treatment of acute cardiovascular events and long-term secondary prevention. For example, the decrease in the fatality rate for hospitalized

MI is likely due to the acute utilization of aspirin, thrombolytics, β-blockers, and angiotensin-converting enzyme (ACE) inhibitors. Longer-term post-MI use of aspirin, β-blockers, ACE inhibitors, and statins, as well as therapeutic lifestyle changes, have made additional critical contributions to reductions in MI-related mortality. Unfortunately, patients with schizophrenia who experience an acute MI are significantly less likely than the general population to receive drug therapies of proven benefit, including thrombolytics, aspirin, β-blockers, and ACE inhibitors. Patients with schizophrenia are also significantly less likely than members of the general population to undergo cardiac catheterizations and receive emergency angioplasties or coronary artery bypass grafts.

Smoking

As we discussed, the general decline in smoking rates is not apparent for patients with schizophrenia. Many patients with schizophrenia rely on state programs such as Medicaid, however many states have only limited coverage for smoking cessation treatments. Furthermore, there are often barriers to receiving these smoking cessation treatments, including requiring prior authorization and copayments and limiting the number of courses of treatment, all of which create additional hurdles for disabled patients with fewer resources and fixed incomes.

Most research on smoking cessation treatment does not include patients with severe mental illness. However, the limited evidence suggests that the same interventions that can help the general population can also help patients with schizophrenia. For example, some studies show that bupropion can increase quitting rates without exacerbating psychiatric symptoms. Other studies show similar positive results for varenicline, and in one meta-analysis, the quitting rates were four times that of the placebo group. There is less evidence for other medications, such as nicotine replacement. There is also promising but limited evidence for behavioral options, with the best evidence being for face-to-face (versus online) interventions.

Metabolic Risk

Screening for metabolic risk occurs at very low rates in patients with schizophrenia. This phenomenon occurs even in the context of treatment with antipsychotic medications associated with risk for disturbances in glucose and lipid metabolism, despite recommendations by the American

Psychiatric Association, the American Diabetes Association, other groups, and FDA warnings. The frequency of baseline glucose and lipid monitoring varies from 8% to less than 30%, and follow-up assessments occur in only 8.8% of patients. The NCEP guidelines recommend that physicians treat patients with diabetes mellitus as aggressively as patients with prior MI or stroke. However, patients with diabetes and schizophrenia are less likely than nonmentally ill diabetes patients to receive standard-of-care treatments.

The American Diabetes Association, the American Psychiatric Association, the American Association of Clinical Endocrinologists, and the North American Association for the Study of Obesity published recommendations for monitoring patients with diabetes in 2004. Table 12.14–5 summarizes these recommendations. The recommendations are for routine assessment, and specific clinical situations may warrant closer monitoring or adding other measures such as glycosylated hemoglobin (HbA_{1C}). For patients with hypertension, for example, the NHLBI recommends monthly monitoring of blood pressure following the initiation of antihypertensive therapy, with follow-up every 3 to 6 months once stabilizing the blood pressure.

Table 12.14–5.
Recommended Monitoring for Patients Taking Atypical Antipsychotics

Baseline, every 4 weeks for 12 weeks, then quarterly
Weight and BMI
Baseline, 12 weeks, then annually
Blood pressure
Fasting blood glucose
Baseline, 12 weeks, every 5 years
Fasting lipid profile
Baseline then Annually
History (Personal, family)
Waist circumference

Data from American Diabetes Association; American Psychiatric Association; American Association of Clinical Endocrinologists; North American Association for the Study of Obesity. Consensus development conference on antipsychotic drugs and obesity and diabetes. *Obes Res*. 2004;12(2):362–368.

The most effective strategy for treating hyperglycemia and other metabolic factors is to switch the antipsychotic. In addition, behavioral interventions, particularly those discussed below to address weight gain and physical fitness, can significantly impact at least specific indices, such as fasting blood glucose levels.

However, if switching antipsychotics and behavioral interventions fail, we should appropriately treat the risk factors using appropriate guidelines. For dyslipidemia, the American College of Cardiology/American Heart Association has developed guidelines for the general population, and these should also be the first step for patients with schizophrenia. Such recommendations include statin therapy and possibly other nonstatin agents such as ezetimibe or a bile acid sequestrant. However, some evidence suggests that patients on antipsychotics do not respond as well as other patients to standard treatments, such as statins, and may require other strategies. Physicians may need to consider off-label strategies such as metformin more aggressively than they might for other patients.

For hyperglycemia, behavioral interventions and metformin have both shown efficacy in patients with schizophrenia, although the data are mixed. As with weight, lifestyle interventions focusing on diet and physical activity may have the most significant benefit.

Weight and Physical Fitness

The most effective treatment for weight gain and related cardiovascular risks appears to be an antipsychotic switch similar to treating metabolic risks. The available evidence supports the strategy of switching from an agent with a high weight gain risk to one with lower risk would help reduce weight.

In addition, behavioral therapy can be an effective method for overweight or obese patients with schizophrenia to manage weight gain. The most successful interventions combine both diet and exercise, showing positive improvements in BMI and waist circumference.

Until recently, medications for weight loss had at best a modest effect. However the introduction of the glucagon-like peptide-1 receptor agonists offers a promising alternative which is being explored. There are currently 7 randomized controlled trials, and a pooled analysis from gives preliminary support for the safety and efficacy of these options, although additional studies are needed.

Increasing evidence points to excessively low physical fitness in this population, representing another modifiable CVD risk factor and an intervention opportunity. Numerous studies support the use of physical exercise, and it has the benefit of improving cardiovascular fitness and improving some of the core symptoms of schizophrenia and overall quality of life. However, the studies vary in the magnitude and significance of their results. This variation likely relates to the length of the studies and the intensity of the intervention. In addition, research is ongoing to determine whether any particular approach (e.g., strength vs. aerobic training) is best. However, it seems likely that any program that the patient will accept can be helpful.

The Role of the Psychiatrist in Aiding Prevention

Although psychiatrists usually prefer to defer to a primary care physician for many of the treatments described here, the psychiatrist should remain involved to encourage the rest of the treatment team to pursue aggressive treatment and avoid the therapeutic nihilism that may accompany the care of mentally ill patients. Thus, psychiatrists should continue to play a role in the care, not to help avoid undertreatment but to guide the medical team regarding the unique challenges inherent in patients with a severe mental illness.

Improvements in primary and secondary prevention offer the most significant potential impact on medical mortality in schizophrenia patients. However, clinicians will need to learn more about the potential risks to achieve such improvements better. We will need careful attention and more research on the appropriate role of cardiometabolic risk assessments during psychiatric treatment. We should also focus on the role of adjunctive pharmacotherapies and behavioral and physical fitness interventions that might target excess weight, dyslipidemia, hypertension, hyperglycemia, and smoking in this population. Without a greater degree of collaboration in the future between primary health care providers, endocrinologists, cardiologists, and psychiatrists, the significant burden of avoidable premature mortality from CVD in patients with severe mental illness is likely to continue and increase in severity.

SUMMARY AND RECOMMENDATIONS

Schizophrenia patients have elevated rates of medical comorbidities such as heart disease, cancer, and diabetes, in addition to other prevalent concomitant complications such as substance use. These commodities account for much, if not most, of the morbidity and mortality affecting these patients. Therefore, addressing prevention, screening, referral, and treatment of medical comorbidities is essential to improving health outcomes among patients in this population. In addition, there is a need for strategies that can provide clear guidance to administrators and medical directors on incorporating changes into already existing medical and psychiatric systems.

Although the information on the interactions of schizophrenia and other medical disorders grow exponentially, we can do a better job at standardizing methods and approaches so that pooled data will be more helpful. Even better would be more extensive prospective studies from different countries targeting different racial and ethnic groups.

As care providers, we have a particular responsibility to the many components of medical risk that we cause through our treatments. The Institute of Medicine has suggested that all psychiatric and medical systems involved in the care of patients with schizophrenia, including mental health, substance abuse treatment, general health care, and other services, need to effectively collaborate to coordinate the care of their patients and eliminate gaps and redundancies in necessary services. This collaboration should include establishing structured and routine comorbidity risk assessments, in addition to scheduled monitoring of antipsychotic treatment for side effects and adherence issues. Most importantly, the medical comorbidities of schizophrenia should receive the same established interventions provided to the general population. Implementation of such screening before the initiation of antipsychotic treatment and during treatment will likely improve outcomes among individuals with schizophrenia.

Although there is likely no perfect model for health care delivery to the seriously mentally ill, one crucial model is the integrated clinic in which medical care providers are on-site, colocated with psychiatrists and other team members. Data from collaborative care programs suggest that such an approach can improve service delivery and medical outcomes without increasing total costs. Regardless of the exact model, the psychiatrist will need to play a central role in a schizophrenia patient's overall care. In many cases, the psychiatrist or other mental health team member has the

best therapeutic relationship with the patient. The team should use that relationship to help assure adherence to all aspects of care, not just psychiatric. The mental health team member's role may involve coordination of care with a patient's primary care physician. Case management can also help immensely and appears to be a crucial ingredient for comprehensive treatment in patients with SMI and medical comorbidities.

There has been some optimism about the potential role of the medical home. The Agency for Healthcare Research and Quality (AHRQ) defines the medical home as a model of care with five functions and attributes: Comprehensive care, a patient-centered approach, coordination of care, accessible services, and a commitment to quality improvement and safety. Although such an approach could provide the type of coordination needed to help patients with schizophrenia, in practice, many of the existing examples do not include treatment for SMI. Some of the barriers are practical—primary care providers are often already overwhelmed and do not have the needed time to provide the counseling and monitoring needed for chronically mentally ill patients. In addition, there remain financial obstacles, and current attempts at mental health parity continue to fall short of the mark. The AHRQ has recommended several central policy and programmatic shifts to incorporate mental health care into the medical home model. These include such essentials as normalizing mental health into the mainstream of medical practice, integrating reimbursement mechanisms so that mental is not financially "carved out" from the rest of the health care system, creating a coordinated road map and plan to address complex mental health problems and then disseminate these to primary care practitioners.

In the short term, the existing mental health care system will have to put forth a significant effort, reallocating existing resources to coordinate screening, interventions, including needed referrals and follow-up monitoring. In addition, mental health care providers and systems will need to improve working relationships with primary care and specialty collaborators, including proactive efforts to facilitate patient evaluation and follow-up. Finally, future collaborations between primary health care providers, medical specialists, and psychiatrists will be required to reduce the enormous burden of avoidable premature mortality in patients with schizophrenia and reduce health care disparities between schizophrenia patients and the general population.

Recommendations

Improve research on risk factors and interventions
- Standard protocols
- Standard measures
- More prospective studies
- Larger samples

Improve and coordinate care between primary care and mental health specialists

Screen for common medical comorbidities

When discovered, treat comorbidities aggressively
- Medication changes
- Education
- Pharmacologic interventions
- Behavioral interventions

Advocate for more resources for integrated care for the mentally ill.

ACKNOWLEDGMENTS

This chapter is a revision of the previous edition's chapter, authored by John W. Newcomer, M.D., Martin T. Strassnig, M.D., Peter A. Fahnestock, MD, and Michele L. Pergadia, Ph.D. The current chapter preserves much of their content and prose, and the author is indebted to the previous authors for their excellent scholarship and literary skill. Although much has happened since they wrote their chapter, and many facts and statistics are updated, the conclusions and recommendations of the prior authors remain essentially unchanged.

12.15 Recovery in Schizophrenia

Dina Hooshyar, M.D., M.P.H., Chacku Mathai, A.A.S., Drew Musa, C.P.S., and Mark Ragins, M.D.

DEFINING RECOVERY AND ITS EVOLUTION

By the 1980s and 1990s, severe problems were emerging in the public community mental health system, and the dream of deinstitutionalization was fading. Failures were often attributed to a lack of funding and political will, but suspicions also began to arise that the "medical model" itself was inadequate to meet the needs of community-based mental health services. Fueling the dissatisfaction were outcome studies that showed that, contrary to common knowledge and expectations, people with schizophrenia recovered to live reasonably full lives, free from seriously disabling symptoms about two-thirds of the time. Why were people settling for stabilization and isolation if recovery is not just possible but probable? Maybe the diagnosis of schizophrenia should not impose a destiny of life-long treatment, medication, disability, and dependence.

Alternative programs and approaches began to be developed to pursue better outcomes and lives:

- Ex-patient–controlled support groups, crisis respite, homeless outreach, and rights advocacy organizations, such as the Insane Liberation Front in Portland, Oregon, founded in 1970, the Mental Patients Liberation Project in New York City, and the Mental Patients Liberation Front in Boston (both founded in 1971), and the Network Against Psychiatric Assault in San Francisco in 1972 and other groups, demanded and obtained inclusion of their self-help initiatives in the National Institute of Mental Health's (NIMH) Community Support Program division conferences in the late '70s.
- Fountain House in New York, clubhouses, and psychosocial rehabilitation programs addressed people's loss of usefulness and meaningful, productive roles.

- Psychiatric rehabilitation championed at University of California at Los Angeles by R.P. Liberman and at Boston University by Bill Anthony used behavioral and medical rehabilitation techniques to build a variety of skills, including educational, employment, housing, and social skills.
- “Housing first” programs and “supported” programs with a variety of quality of life goals—for example, housing, employment, education, parenting, physical health care—emerged that focused on people learning by doing instead of being given treatments to prepare them to do things.
- Integrated dual diagnosis approaches for people with both mental illnesses and substance abuse ranged from Fred Osher’s early efforts at the NIMH to Ken Minkoff’s integrated systems of care to “harm reduction” and Miller and Rolnick’s “Motivational Interviewing.”
- Trauma-informed approaches were developed to reduce retraumatizing people while serving them and have been used to radically decrease seclusion and restraints in inpatient settings.
- Client choice, empowerment, and shared decision-making strategies were developed and used to enhance engagement with and participation in services.

Taken individually, each of these techniques adds to the “tool kit” of effective treatment approaches. More strikingly, however, was how they organically coalesced the Recovery Movement by the mid-1990s, no longer isolated “outsiders” but now part of a strong nationwide movement.

Previously within psychiatry, the concept of recovery had been used primarily within the context of substance-abuse recovery. Now “recovery” was being repurposed for serious mental illnesses.

The word “recovery” itself brings along with it a variety of traditions, histories, and values ranging from 12-step recovery to recovery from physical illness, to trauma recovery, to spiritual recoveries. This broad spectrum of grassroots, “bottom-up” influences gives the recovery movement impressive diversity and practicality and widespread appeal. It also makes it unwieldy. Even defining “recovery” has been difficult.

Two “consensus” approaches to defining recovery have been put forward by the Substance Abuse and Mental Health Services Administration (SAMHSA). The first, released in 2006, emphasized the “individual journey” aspect of recovery: “Mental Health Recovery is a journey of healing and transformation enabling a person with a mental health problem to live a meaningful life in a community of his or her choice

while striving to achieve his or her full potential." This approach emphasizes the individual's struggles and triumphs in overcoming mental illnesses and conceptualizes service providers as guides, coaches, and fellow travelers promoting recovery journeys.

The second approach is to define recovery as achieving a quality of life despite the burdens of mental illness. SAMHSA's 2011 "working definition" of recovery was: "A process of change through which individuals improve their health and wellness, live a self-directed life, and strive to reach their full potential." It goes on to define four domains to support a life in recovery: *Health:* overcoming or managing one's disease(s) as well as living in a physically and emotionally healthy way; *Home:* a stable and safe place to live; *Purpose:* meaningful daily activities, such as a job, school, volunteerism, family caretaking, or creative endeavors, and the independence, income and resources to participate in society; and *Community:* relationships and social networks that provide support, friendship, love, and hope.

JOURNEY OF RECOVERY

From an illness-centered point of view, the treatment of schizophrenia is based upon the course of the illness: It may begin with a prodromal phase before a "first break." There is often a period of untreated psychosis before multiple attempts to acutely stabilize the illness are undermined by relapses. Over time the illness may stabilize and go into a residual phase or even remission, though acute relapses can always recur.

From a person-centered point of view, the service needs to depend less upon the diagnosis or stage of the illness and more upon how the illness is impacting the person and how they are relating to it—for example, out of control and at high risk, ambivalently engaging with helpers, taking self-responsibility and building coping skills, incorporating the illness into a rebuilt self-identity, or adapting to reconnect to meaningful community roles.

There are perceptive autobiographies written by people who have worked hard to recover from schizophrenia that everyone can all learn from, ranging from Joanne Greenberg's fictionalized classic "I Never Promised You a Rose Garden," describing her relationship with her psychiatrist Frieda Fromm-Reichmann at Chestnut Lodge and her return to the community in the premedication, psychoanalytic era, to the more

contemporary “The Center Cannot Hold” describing Elyn Saks’ ongoing struggles with psychosis even as she has become a law school professor and associate dean at University of Southern California.

Patricia Deegan built her exemplary career promoting recovery practice upon her own experiences and her taped interviews of people describing their own recoveries. Based on these “lived experiences” of recovery, she created her “conspiracy of hope” promoting self-help “Coping with Voices” techniques and her “Common Ground” program promoting “personal medicine” and shared decision-making with psychiatrists. The approach of building strategies on personal stories and experiences has expanded to families in NAMI (National Alliance on Mental Illness) with their “In Our Own Voice” programs. Sharing personal experiences has proved a powerful tool for bridging differences and reducing antagonism to work effectively together.

The best way to learn about how someone’s brain functions is to ask them and then listen deeply. Their narratives tell us about important details of the recovery process and how to help people in their journeys while appreciating that everyone’s journey is unique. Listen deeply to the self-reflection and advice from one of our coauthors with lived experience of psychosis:

My name is Drew Musa. I'm a 27-year-old native New Yorker, and I've been diagnosed with schizophrenia. Due to my diagnosis, every day looks different. I can never expect what my mind is going to do every day. I experience auditory hallucinations where I hear things that others cannot. What I hear depends on where I am at that exact moment. I may hear voices through the TV, the radio, or just ambient sounds. My training as a peer specialist gave me the confidence to still have hope for the future regarding living with a diagnosis. It was through my Howie the Harp training that I learned to believe in myself again. Now thanks to the training, I know I can still live a normal life and not be ashamed of my diagnosis. When I first heard my diagnosis, I had no idea what it meant for me or if I would have a life worth living, but now I am no longer ashamed of my diagnosis. I see it as something I just live with.

The most challenging part of my recovery journey was the beginning. I was frustrated and scared that I was hearing things other people could not, which led to my first break. Fortunately, I've learned a lot since then. I've come a long way since my first hospitalization. The medication I take now is working for me. Now I always try to keep myself busy, whether it's playing games on my phone, cooking, or watching movies. I'm thankful I have such a great family who got me help as soon as possible. Thanks to my family, we found the OnTrack program (New York State's Office of Mental Health, Coordinated Specialty Care model for First Episode Psychosis). OnTrack is unlike any clinic I've been to. The program is based on peer-centered recovery, meaning there are no decisions made about me without me. The client is in the driver's seat, and the Ontrack staff is there to offer support and give their clients the tools to succeed. In addition, they helped me look for a job and offered me a music group that I go to regularly. I also speak with a therapist and a psychiatrist regularly as well. The coolest part of OnTrack is the way they treat me as a person. The biggest lesson I learned from OnTrack is to ask for help when I need it. I have great supports between OnTrack and my family, so I should utilize them as much as possible. I learned to be honest about what I'm experiencing and never be afraid to ask for help which is important because dealing with a mental health diagnosis on your own is difficult.

If I could go back in time and give myself advice, I'd say don't be afraid to ask for help, and things may seem bleak now, but things will get better. That's the type of support I wish someone would've given me when I was newly diagnosed. As a peer, I now get to support people the way I wish I was supported. I try to tell newly diagnosed clients to be proactive in their recovery. You shouldn't let people make decisions about your recovery without your consent, and don't be afraid to ask questions when you don't understand something like "what does the medication do exactly?" "What does that medical term mean?" and "Can we try a different medication?"

Elizabeth Kubler Ross made a groundbreaking shift by identifying five stages that a person goes through while dying (as opposed to stages the cancer illness goes through while it's spreading and killing someone). One of the authors, Mark Ragins, has analogously described four common stages people go through while recovering from serious illnesses or destruction of any kind in his short book *A Road to Recovery.*

- Hope: Recovery begins with hope. To be motivating, hope has to be more than just an ideal. Hope has to take form as an actual image of how things could be if they were to improve. It must be personally meaningful for them to pursue it as a goal, persisting despite inevitable setbacks.
- Empowerment: To move forward, people need to have a sense of their own capability, their own power. Their hope needs to be focused on things they can do rather than new cures or fixes someone else will discover or give to them. It is often needed for someone else to believe in them before they're strong enough to believe in themselves and to start focusing on their strengths instead of their losses. It also often takes some actual experience of success to really believe one can be successful. Waiting until someone is ready to move on can often be stagnating and disempowering because "readiness" often occurs only in retrospect after something has been done successfully.
- Self-Responsibility: At some point, most people who recover realize that no one else can do it for them, that they have to take charge of their Recoveries. People can be supported, but they can't be caretaken or protected into recovery. Taking one's own risks, setting one's own goals and path, and learning one's own lessons are essential parts of recovery.

- Meaningful Roles in Life: Ultimately, to recover, one must achieve some meaningful role apart from schizophrenia. Connectedness to other people, belonging, and feeling accepted, which may have for a while only been possible with others who have mental illnesses, within families, or with compassionate helpers, becomes possible in a variety of contexts. The isolation is increasingly broken, and life re-entered.

The journey of recovery should take place primarily in the community rather than in isolated islands of tolerance and asylum. The overarching social culture, as well as many local community cultures, often make a recovery difficult. Illness-centered, psychoeducational, antistigma efforts are likely less effective than relationship-based storytelling efforts. The overall goals are to increase community acceptance, inclusion, compassion, relationships, and belonging for people with schizophrenia. Since the middle ages, when a spiritual healing center for people with mental illnesses was established there, the small town of Gheel, Belgium, has maintained a pervasive counter-culture integrating people with severe mental illnesses within their families and community, proving it can be done.

Illness-Centered versus Person-Centered Recovery

The medical model conceptualizes the process of recovery as:

- The fundamental problem is the symptoms of their mental illness.
- Diagnosis, assessments, treatment, monitoring, and achieving success are focused on symptom reduction.
- Once the illness is treated, other services may be needed to help people deal with residual symptoms, keep symptoms away, and to rebuild lost functions or quality of life.
- Some fortunate people respond to treatment and other services to achieve recovery.

In contrast, the recovery model conceptualizes the process of recovery as:

- Mental illnesses are a highly individualized, complex personal reaction to a variety of biologic, emotional, developmental, traumatic, and social influences.
- Each person’s outcome is more dependent upon how they personally react, adapt, and cope than it is dependent upon the type or severity of

the symptoms themselves.

- Promoting positive personal reactions (e.g., maintaining hope, self-belief, managing risks, engaging and collaborating with helpers, taking self-responsibility, being motivated to build skills and supports, finding personal and social meanings, and avoiding isolation) throughout the course of each person's illness is crucial.
- Some fortunate people find enough inner strengths and resilience to make personal changes to achieve recovery.

These differences in conceptualization translate into three major transformations in service delivery: (1) from illness-centered to person-centered: *Recovery is something a person does, not what an illness does*. (2) From professionally driven to client-driven: *Recovery isn't something a professional can do to a person. It is a process they must engage in.* And (3) from deficit-based to strength-based: *Recovery doesn't happen when the person never has any more symptoms, even serious ones, but when they have the strength and resilience to handle whatever symptoms occur.*

Perhaps counterintuitively, this difference means that the recovery model is most important for people whose illnesses are most difficult to treat medically: traditionally, though perhaps not accurately, schizophrenia. The strength of the person is more relevant than the strength of their illness.

Within the medical model, persistent psychosis is viewed entirely as a reflection of brain abnormalities that lead to hallucinations, delusions, thought disorders, and often "negative symptoms" that must be addressed with antipsychotic medications. The recovery model is more likely to include the entire person in its conceptualization, leading to individualized, multidimensional personal formulations of the development and recovery from psychosis.

One of the author's current models is "The Psychosis Triangle" (Fig. 12.15–1).

The three interacting dimensions that lead people to have psychosis are as follows:

1. **Experiencing Reality**: There are changes in how they are experiencing "reality"—for example, hallucinations, delusions, paranoia, or spiritual experiences as well as changes in how they process reality, like making idiosyncratic connections or relying on irrational "primary process" thinking.

2. **Self-Identity**: There are changes in their internal processing and self-identity—for example, how they hold themselves together, balance rational and irrational portions, self-observation, or create their own stories. It can also include "anhedonia," the inability to feel joy or pleasure in life.
3. **Relationships**: There are changes in how they relate to other people—for example, disconnected, missing "normal" social signals, hard to relate to, socially anxious, avoidant, or even paranoid.

FIGURE 12.15–1. The Psychosis Triangle: Interacting dimensions of psychosis.

None of these dimensions falling apart on its own creates psychosis. All three of them must be seriously impaired for someone to become psychotic. Any of the three can act as the initial weak point, putting its neighboring dimensions at risk. Once two dimensions are compromised, the third dimension in the triangle is under severe strain, and if it also falls, psychosis is the result—or it could be a stronghold to rebuild the other two dimensions, leading to recovery. The "prodromal" period is usually a time when self-identity and relationships are deteriorating, making the person vulnerable to distortions in reality.

In contrast with the medical model that only focuses on the Experiencing Reality dimension, often sacrificing the other two dimensions along the way, the recovery model is open to all three dimensions.

Using all three dimensions allows us to integrate and appreciate not just biologic factors but also personal meaning, such as hope creation, role modeling, identity formation, and social factors, like structural racism, mentoring, and productive social integration.

One of our authors, Chacku Mathai, is a thoughtful peer advocate who effectively integrates all three dimensions (adapting to the unusual way he experiences reality including hearing voices, some of which are more

trustworthy than others, intersecting personal identities, and navigating relationships within a racial, immigrant context). In this section, he models synthesizing his unique personal journey and experiences with the overarching social and professional contexts that envelop all of us.

Understanding the experiences of people diagnosed with schizophrenia and/or other psychotic disorders, especially experiences of recovery, is an incredible challenge due to the wide heterogeneity of experience, even among those with the same diagnosis. To add to the challenge, the history of psychiatry, psychiatric diagnosis, and the evolving characterization and naming of mental illness, psychosis, and schizophrenia are inextricably linked to the social and political forces, such as racism, that marginalized and oppressed certain groups throughout our history.

Accordingly, the authors in this section intend to offer a more personal, narrative approach to engaging these concerns in order to support and encourage greater reflection on structural practices and competencies that might matter most in supporting recovery. This is in contrast to a less effective narrative-sharing approach to address “stigma,” which in this author’s view is an inadequate and even euphemistic term that obscures the path to understanding the true depth and impact of bias, discrimination, and oppression in people’s lives.

Our hope is that the reader will experience the start of a uniquely crafted path toward an ongoing reflection and analysis of recovery experiences, including the journey of meaning-making in psychosis, dynamic qualities of a recovery-oriented approach, and the role of psychiatry in addressing social and political determinants of health to eliminate the racial disparities and inequities that continue to persist in psychiatry.

A Journey of Sense-Making With Psychosis

I struggled with an inner world that no one would understand, eventually resulting in a suicide attempt and drug overdoses when I was 15. Even after several years of abstinence from any of the substances I used to quell the stormy experiences within, I was struggling with hearing troubling voices and other extreme states. I saw shadowy figures jumping around my room, one of them always trying to enter my body. The only way to stop her was to scream. I also struggled with a belief that my parents were conspiring with others to poison my food and get rid of me. I caught my mother watching me eat. It was then that a convincing voice told me what

she was doing. Although they denied it, I knew secrets about the family and broader society, including how teachers and schools were controlling people and our minds. Despite losing nearly a full year of high school to an intensive, long-term, outpatient day treatment program, I still managed to return and graduate high school with the advocacy and support of my family, although by a thin margin. Despite my suspicions and poor grades, I started some community college courses, only to then drop out in the middle of the semester.

The voices had finally convinced me that my father, and now the community college soccer coach, were conspiring against me. I struggled to find and keep work. Despite my limited income, I moved out of my parent's house to live with an older and supportive friend in his apartment. After volunteering a bit at a local animal shelter, I eventually found part-time work at a YMCA and took odd jobs swinging mops and delivering pizzas. I eventually found some full-time work in a local warehouse, loading trucks and shipping damaged or defective goods back to their manufacturers. My title was the Damaged and Defective (D and D) Clerk, and the irony of the narrative was not lost on me. As South Indian immigrants, my family and I did not plan for any of this. I felt like such a failure in our great experiment with life in America. I was supposed to be the first in my family to immigrate to the United States and study at a prominent university.

Through the mid to late 80s, I accepted my father's urging for me to check out a local teen recovery center he learned about from an acquaintance at his church. It was an old, renovated horse barn owned by a church across the parking lot from a high school. It was the first of its kind anywhere and was started by a group of families as a place for their teenage children to support each other as they returned to school and home from mental health and substance use treatment centers. I even surprised myself and my family as I discovered a peer community I could trust and a sense of purpose to pursue in this place we called "the Barn."

During that time, I managed to start some of the first-ever peer support meetings and advocacy groups in that region at treatment centers, group homes, and even the local psychiatric center. I was asked to deliver public presentations about mental health and substance use conditions at schools, treatment programs, and police departments, calling for changes in the way we were perceived and responded to. I organized and spoke at local hearings with Congressional representatives and state legislators. I

was even given an award by a local television station and the Junior League of Women Voters for my volunteer civic activities.

In 1990, as a 20-year-old local advocate with a personal psychiatric and substance use history, I attended a mental health fundraiser in my hometown. The guest speaker was Lionel Aldridge (February 14, 1941 to February 12, 1998). He was a Super Bowl Champion Defensive End for the Green Bay Packers, one of the pioneering Black men in the National Football League (NFL) in the 1960s, and a sports broadcaster in the 70s. He was also the first professional football player to share his story as a person diagnosed with paranoid schizophrenia as a mental health advocate.

Mr. Aldridge was speaking during the culmination of an era that strongly associated mental illness, substance use, and those of us who were Black, Indigenous, People of Color (BIPOC) with violence, crime, and poor moral character. I rushed to the front of the room after his presentation. Although his story was definitely inspiring on many levels, my hope was that he would answer some big questions that I was struggling with that whole year. Despite all the advocacy efforts, I still felt quite alone in my experience and perspective. I had no one left to ask. While I was aware of the family-run local and national mental health advocacy groups he was involved with, at the time, called the National Alliance for the Mentally Ill (NAMI), I was still just learning about other ex-patient–controlled groups that were organized around the country and would eventually be referred to as consumer/survivor/ex-patient advocacy groups. Until Mr. Aldridge, I had also yet to meet another person of color who spoke publicly about mental health and wondered why.

As the line of people waiting to speak with Mr. Aldridge grew longer behind me, I realized that I would only have his attention for one question. It was my turn next, and as I frantically tracked through my now racing thoughts, like a person trying to find a friend across a crowded room, one of my most trusted voices softly suggested, “Ask him about the cycles.”

She was referring to something my clinicians would say in our sessions and the various psychoeducation groups that my family and I attended. They explained what I was going through with illness-oriented language, such as decompensation, relapse, and remission. One of the main features of this explanatory model and approach to relapse prevention was that the course of mental illness was cyclical and deteriorating in nature and that if I could become aware of the early warning signs, I might

have a better chance of getting the help I needed to manage it before things got worse for me. While I certainly appreciated the idea of a proactive plan for when I might be struggling, I was terrified by the idea that I might have to go through repeating cycles and waves of my worst experiences, only to eventually drown and require more treatment as I struggled beneath them. I kept hearing this theme, especially as a way to explain why one of my friends was struggling, had to go to the emergency room, or get hospitalized against their will.

This also just didn't jive with my own observation of my experiences; however, I couldn't yet articulate my take on this, and there didn't seem to be anyone else who might understand. So, after introducing myself as a psychiatric survivor/ex-patient who was diagnosed with schizoaffective disorder and cooccurring substance use disorders, I asked Mr. Aldridge, "What do you think about this idea that we are in a remission cycle of illness that gets worse over time, and that will eventually repeat itself as a relapse? Is this true?"

Mr. Aldridge looked at me with deep kindness and empathy that I will never forget. I remember noticing during his speech that he seemed to be free in a way that I only hoped could be true for me. In this moment with me, it seemed as though he was reaching back to reflect on a time when he was battling when he wasn't so free. He had no hesitation and responded with full authority. He also seemed to be speaking to all of us who were in line, "No man, that's not how it goes. The people that say this are looking at us from the outside. It only looks like the same old thing to them. We know that we are growing. We grow up, we grow out, we grow sideways, we grow down." As he was talking, I was imagining a sphere of my experiences, each experience as a swirling revolution of growth in every direction. That made more sense to me. They were different experiences…every time. Of course, they would look like cycles to the outside observer, or even me, especially if all we noticed were my repeated and seemingly failing ways of dealing with them. I would eventually learn that if I could understand the cycles as revolutions of growth and catalysts for change, I could also discover the unique gifts within them and new ways of going through them with the outside world.

This was one of several life-changing milestones in my own journey of sense-making about my experiences and led me to discover even more healing strategies, communities, and resources to turn to over the years. Even my family, who struggled to understand what I was going through as

well, were willing to support my own strategies for recovery and reject the commonly held notions of the psychiatric system that I would be better off hospitalized, treated with psychiatric medications, and supported in the community with regular monitoring and supervision. Despite years of continuing conflict and my lack of trust in their motives, my parents still expressed their belief in me and supported my self-determination and choices.

What I Really Wanted

During my early treatment experiences, one of my therapists asked me if I could recall a time when I was happy. I remember thinking that this was one of the better questions she had asked. Although I still didn't answer her, my mind took flight toward a vivid memory that has never left me. Like a bird arriving at her favorite tree, I stood quietly as I watched myself, a 6-year-old boy, reach up to touch and gently hold the ear of the young elephant kneeling before me.

I was born in Kuwait. We had just started our life in the United States and were now on a visit to my parents' respective home villages in Kerala, India. At the time, elephants were used to clear the trees for farming and, noticing my delight at seeing them, my father asked one of the local handlers to let me sit on the elephant.

I pulled myself onto the elephant's back without hesitation. There was no question in my mind that this was where I belonged. As I ran my hands over the elephant's skin, I could feel him welcoming my touch. We were connected in a way that I didn't expect. As I looked up, I noticed my parents, uncles, aunts, cousins, local villagers, and the handler, all looking at me with pride and gratitude for my presence. They were seeing me and looking at me with great expectations. It was as if I was already doing something so immense that they couldn't wait to see what I would do next. What I could do next. There was a belief in me and what I was already offering to the world expressed in their eyes, by their gaze, that I will never forget; because this is what I really wanted but knew that I couldn't have in my life back in the United States.

A Structural Formulation of My Own: An Antiracist Approach to Recovery

Whenever I was asked to offer "my story" to various institutions as an advocate, I noticed that there were fundamental differences in how

people, even Mr. Lionel Aldridge, were telling their stories publicly and how I wanted to tell my story. Most people offered statements like, “When I first became sick,” “After I was diagnosed,” or “Following my psychiatric hospitalization.” They also seemed to erase any contextual, marginalizing experiences from their story. BIPOC survivors seemed to avoid any references to race or racism. My story, however, would begin with, “When we moved to the United States.” I would then describe the racial tensions of the time, including how my family and I were treated with hostility and violence as people of color or “foreigners,” blaming us for taking White people’s jobs and moving into their neighborhoods. This became my personal strategy for opening the doors to important conversations about recovery, rights, and antiracism as an integrated framework for support.

Opportunities to train and influence communities across the country led me to realize that most of the behavioral health professionals, administrators, policy makers, police, teachers, and the general public still held the false belief that schizophrenia is a deteriorating illness of the brain. This was despite the international, long-term follow-up studies discussed earlier in this chapter that found that a high proportion of people diagnosed with schizophrenia completely or significantly recovered. It also seemed that most people were also not aware of the diverse and international presence of consumer/survivor/ex-patient–led organizations and public disclosure by those of us diagnosed with schizophrenia and other psychotic disorders who successfully live, learn, work, and play meaningful roles in society.

Many also still believed the debunked myth that people diagnosed with psychotic disorders, especially schizophrenia, are violent. This also seemed embedded as a racial bias and attitude that was maintained as a racist attitude of mental health systems, rationalizing policies, and practices that perpetuate significant racial disparities and inequities for BIPOC communities. For example, studies demonstrated that doctors over-diagnosed schizophrenia in African American men four times as often as in white patients, despite what we already know about schizophrenia as a disorder that affects all ethnic groups at the same rate.

An antiracist approach to recovery calls for:

- Commitment to recovery equity in communities of BIPOC
- Transform how we evaluate and understand racial disparities and inequities in behavioral health

- Defining racism as the powerful collection of policies and practices that perpetuate racial inequities and antiracism as the policies and practices that reverse them
- Utilize practice approaches such as structural competence and formulation that recognize that “place matters” and address social determinants of health, such as racism, as factors in how our health is influenced by where we are born, live, learn, work, and play.

Recovery Model Service Delivery

The challenges of both the medical model and recovery model services are the same. We can both work with people at any stage of illness or recovery, but truly integrating person-centered, client-driven, and strengths-based values while focusing on all three dimensions of psychosis leads to very different program designs and emphasis within each stage (Table 12.15–1).

Table 12.15–1. Many of the programs in the below table will be discussed later in the chapter. References are given for further exploration.

The most common “positive” outcomes from illness-centered treatment are someone with repressed psychotic symptoms but limited self-identity, roles, community integration, resilience, and protective factors, leaving them dependent on medications, vulnerable to relapses under stress, and with poor long-term health outcomes. The most common “positive” outcomes from person-centered approaches are someone who may have to continue to deal with psychotic symptoms while rebuilding a self-identity, purpose, relationships, and roles, either with ongoing medications (like Elyn Saks and Fred Frese) or without ongoing medications (like Dan Fisher and Mark Vonnegut).

Table 12.15–1.
Characteristics of the Medical Compared to the Recovery Model

	Medical Model (focus on experiencing reality only)	**Recovery Model** (includes focus on self-identity and relationships)
Public Health	Mental Health First Aid: Teaches people to recognize early signs of mental illness, destigmatize, and promote professional treatment	Emotional CPR: Teaches empathic listening and empowering relationships to help people build their own growth responses to emotional crisis
Individual Prevention	Preemptive antipsychotic medications for people with a family history of schizophrenia, “ultra-high risk”	Headspace: enhances social skills, relationships, and personal emotional skills for youth
Early Intervention “First break”	RAISE: Rapid medication stabilization, using hospitalizations if needed, psychoeducation into the chronic nature of illness and patient role, early rehabilitation to rebuild functioning	Open Dialogue: Intensive work with the natural social network to preserve relationships and roles while the person deals with unusual experiences
Intensive Ongoing Support	ACT: “hospital without walls,” multidisciplinary, community-based team insuring medication treatment and life supports	Full-Service Partnerships: Multidisciplinary, community-based team including specialists that support a wide variety of people’s quality of life goals through collaborative, growth-oriented partnerships building increasing personal self-responsibility
Crisis	Police, urgent care,	Soteria model crisis residential,

Response	Psychiatric Emergency Rooms, and involuntary hospitalizations designed to avoid the risk of danger and control people, usually with medications	peer respite programs designed to give space for people to regain self-control and learn what changes to make to stop suffering
Recovery	Illness Management Recovery: Focusing on chronic illness management	Clubhouse, Voice Hearers: Focusing on building positive personal roles and relationships

RECOVERY OUTCOMES

"Schizophrenia is a chronic disabling illness affecting approximately 1% of the U.S. population" is a familiar introduction to schizophrenia in the medical literature. The pessimistic tone of this introduction does not take into account the heterogeneity of outcomes associated with recovery in this population. Existing challenges to objectively measuring the longitudinal progress of people with schizophrenia include: (1) evolving, nonuniform definitions of schizophrenia across the world; (2) lacking universally accepted criteria for measuring recovery and rather measuring the nonexistence of symptoms associated with schizophrenia; and (3) having self-reinforcing conclusion (i.e., the bias of researcher/clinician that worst outcomes are typical based on the historical, mainstream medical society's perception).

Although Emil Kraepelin's intent was to advance the understanding of psychiatric conditions through the categorization of symptoms into manic depression and dementia praecox, a result was dementia praecox (i.e., schizophrenia) became associated with poor outcomes while manic depression with good outcomes. However, 17% and 8% to 13% of dementia praecox cases demonstrated long-term clinical improvement and long-term recovery, respectively. Eugen Bleuler, who coined the word "schizophrenia," also propagated this sentiment when he revised his initial more optimistic assessment to one never associated with a "full restitutio ad integrum."

In the 1970s, published studies contested the dogma that schizophrenia equals poor outcomes. The 1987 findings of the Vermont Longitudinal Research Project, which had a more rigorous study design as compared to some of the 1970s studies, supported the findings of these earlier studies. One-half to two-thirds of the Vermont study participants attained considerable improvement or recovery 20 to 30 years post completion of a comprehensive rehabilitation program and planned deinstitutionalization (Table 12.15–1). Vermont Longitudinal Research Project's cohort consisted of clients residing in Vermont State Hospital (*n* = 269) between January 1955 to December 1960 who were considered the most chronically mentally ill among the Vermont State Hospital's client population. They had not responded to chlorpromazine (Thorazine) treatment and had been referred to a comprehensive rehabilitation and community placement program sponsored by the Vermont State Hospital and Vocational Rehabilitation Division of the Vermont State Department of Education.

Despite the evidence that recovery occurs in schizophrenia, the concept that schizophrenia is a progressive disease and associated psychosis may be deleterious to the brain assisted in program development for minimizing the duration of untreated psychosis among young people experiencing a first episode of psychosis. PACE (Personal Assessment and Crisis Evaluation) Clinic was established in 1994 as the first clinical and research clinic in the world designed to prevent or delay the onset of psychosis among persons aged 14 to 25 years old with prodromal symptoms, brief self-resolving psychotic episodes, and a significant decrease in functioning in the past year. A meta-analysis of long-term outcome studies among first-episode psychosis in adults found remission over a mean follow-up of 5.5 years occurred in 58% of participants, and recovery over a mean follow-up of 7.2 years occurred in 38% of participants. This meta-analysis defined remission when symptoms were mild or absent and/or functional improvement occurred for at least greater than 6 months, while its definition of recovery required improvements to be sustained for at least 2 years. Predictors of treatment nonresponse among patients in their early stage of psychosis include lower premorbid functioning, lower level of education, negative symptoms from first psychotic episode, comorbid substance use, younger age at onset, lack of early response, non-adherence to treatment, and longer duration of

untreated psychosis. Currently, a clear association between the duration of untreated psychosis and direct neurotoxicity does not exist.

Not all people with schizophrenia require continuous antipsychotic treatment for the remainder of their lives. Their characteristics include better premorbid developmental conditions, less vulnerability to anxiety and psychosis, and better neurocognitive skills. Another predictor of outcome is country of residence. A World Health Organization study found participants living in East Asia experienced the highest clinical remission rate at 84.4%; however, participants living in North America experienced the highest functional remission rate at 35.0%. Environmental factors associated with recovery include repeated opportunities for rehabilitation, positive expectations, and relationships, family psychoeducation, and access to good-quality mental health care (i.e., therapeutic alliance with clinician, satisfaction with antipsychotics, general medical condition care, assistance in managing deficits in resources, and responsiveness to needs and services).

The principle that schizophrenia is not uniformly synonymous with a chronic disabling illness was not a prevalent view during the *Diagnostic and Statistical Manual of Mental Disorders* (DSM)-III era. DSM-III described schizophrenia as “a complete return to premorbid level of functioning in individuals is so rare as to cast doubt upon the accuracy of the diagnosis.” However, DSM-5 reads: “course and outcome may not be reliably predicted. The course appears to be favorable in about 20% of those with schizophrenia, and a small number of individuals are reported to recover completely. However, most individuals with schizophrenia still require formal or informal daily living supports, and many remain chronically ill, with exacerbations and remissions of active symptoms, while others have a course of progressive deterioration.” As an appreciation of recovery being possible grows, a question naturally arises regarding what are the meaningful outcomes that should be evaluated to establish a practice as being a *recovery evidence-based practice*, especially given the majority of existing peer-reviewed literature analyzes symptoms rather than functional, everyday life task improvement.

EVIDENCE-BASED PRACTICES

The presented practices are a sampling of recovery evidence-based practices. More exhaustive lists can be found at such sites as the U.S.

Department of Health and Human Service's SAMHSA's Evidence-Based Practices Resource Center.

Pharmacotherapy

Pharmacotherapy is the mainstay of evidence-based treatments for schizophrenia. Yet, findings from a cohort of nearly 30,000 patients living with schizophrenia who were prescribed antipsychotics found that 43.7% were rehospitalized, and 71.7% experienced treatment failure over the observation period of approximately 7 years. These negative outcomes were the least among those prescribed clozapine and long-acting injections of antipsychotics. Neither first- nor second-generation antipsychotics effectively treat primary negative symptoms or cognitive impairments; second-generation antipsychotics are associated with minimal cognitive gains that are not associated with functional improvements. Antipsychotics improve functional impairment as a consequence of reducing positive symptoms; however, the main causes of functional impairment are negative symptoms and cognitive impairment. Clinical Antipsychotic Trials of Intervention Effectiveness found that before 18 months of antipsychotic treatment, 74% of the study's population discontinued their antipsychotic due to such factors as inefficacy or intolerable side effects. This finding stresses the importance of the inclusion of nonpharmacologic therapies in tandem with pharmacotherapy in the recovery process for people with schizophrenia.

Assertive Community Treatment (ACT)

ACT is a comprehensive, individualized approach to delivering care for people whose functional impairments traditionally from chronic psychosis prevent them from effectively navigating their lives and health care systems in less intensive care models. ACT's fundamental principles include integration of services, team approach (i.e., shared caseloads and daily team meetings), low client–staff ratios (i.e., 10:1 ratio, which varies depending on the severity of clients' functional impairment), point-of-contact care delivery in the community, medication management, focus on everyday concerns, rapid access, assertive outreach (i.e., being persistent in offering services to clients who are not engaging in their care), and individualized services. Two original components of ACT have been revised: (1) time-unlimited services have been replaced with policies and practices that support encouraging graduation; (2) the multidisciplinary

staff concept has been replaced with the concept that team members should continuously learn new competencies. ACT is one of the most researched treatment models and is associated with numerous beneficial outcomes (Table 12.15–2). However, critics view ACT as not being a recovery-orientated practice due to its "assertive outreach" model of repeatedly contacting clients who have repeatedly declined this service, its medication management component, some of its fidelity standards are clinician rather than client preference based, and utilization of behavioral contracts, outpatient commitments, and representative payeeship.

Table 12.15–2.
Illness-Centered Versus Person-Centered Prescribing

Illness-Centered Prescribing	Person-Centered Prescribing
1. Take a history and collect objective signs and symptoms. 2. Make a diagnosis. 3. Obtain informed consent (may include family psychoeducation). 4. Prescribe medications. 5. Assess the impact on target signs and symptoms of diagnosis and creation of undesirable side effects. 6. Adjust medications until effect maximized. 7. Continue effective medications to avoid relapse and deterioration. 8. If medications have been effective and the patient is motivated, they may add rehabilitation to overcome disabilities and recovery services to enhance the quality of life.	1. Engage the person in the process, building a trusting relationship. 2. Find out their goals to motivate them and build hope for positive change. 3. Create a shared story of their lives, a "formulation" that stands up to self-reflection and makes them feel understood. 4. Work together, using shared experience and decision-making, to learn how they can use medications and other tools to achieve their goals, change, and recover. 5. Support adaptations to their changed perceptions of reality and develop a recovery narrative. 6. Help them internalize the meaning of their changes, so they can be self-sustaining.

Supported Employment (SE)

SE's core principles include obtaining competitive employment rather than a sheltered workshop or transitional work participation, being available to all clients living with psychosis who are interested in competitive employment, designing job searches based on client employment preferences, engaging in rapid job search, integrating mental health and employment services, and providing individualized job supports and benefits counseling. Study findings favor SE with a large effect size in job acquisition, total weeks worked, and job tenure as compared to non-SE vocational programs. This employment has been associated with improved quality of life and well-being with mixed effects on clinical functioning.

Cognitive-Behavioral Therapy (CBT)

Findings from randomized controlled trials with CBT developed specifically for people with psychosis include no difference in psychotic symptom reduction or social function improvement as compared to an antipsychotic medication treatment-only control group; however, two people in the CBT group versus none in the antipsychotic medication group were hospitalized during the study period. Core components of CBT used in these trials included normalizing interpretation of events, examining the advantages/disadvantages of interpretations and responses, exploring causes of these events or interpretations, using behavioral experiments to test interpretations, considering alternative explanations, and developing coping strategies.

Housing First (HF)

HF's foundation is that permanent housing is a basic human right to be provided in tandem with a psychiatric rehabilitation approach that values client choice. "Continuum of Care," the traditional model, requires clients to complete a progressive housing program model starting from outreach to transitional housing to end with permanent housing. Given its progressive nature, if clients are unable to meet the "housing readiness" expectations for each step, such as maintaining sobriety or adhering to prescribed medications, then clients do not advance to permanent housing and/or potentially return to homelessness. Studies have shown that clients of HF, as compared to Continuum of Care, are more likely to

experience fewer emergency department visits and hospitalizations, spend less time hospitalized, spend more days housed, and obtain housing earlier. No difference in substance use has been demonstrated.

Wellness Recovery Action Planning (WRAP)

WRAP is a peer-led, self-management intervention program for chronic mental health conditions. Unlike traditional medical models, WRAP does not depend on clients obtaining formal mental health care. WRAP also fosters an environment that empowers clients to build a life worth living, rather than simply managing symptoms, through emphasizing holistic health, wellness, strengths, and social support. WRAP intervention has been associated with a reduction in psychiatric symptoms and self-reported need for and use of formal mental health services and improvement in physical health, quality of life measures, and recovery-orientated perspectives such as hopefulness.

Motivational Interviewing (MI)

MI's aim is to resolve ambivalence as the means to stimulate behavioral change. Its elements include rapport building, reflective listening, assessing the client's motivation for change through the use of open-ended questions, highlighting the client's change-related statements and efforts, demonstrating the gap between baseline and desired behaviors, soliciting permission prior to providing assessment or recommendations, utilizing resistance as prompt to alter approach, bolstering client's self-efficacy for change, and creating an action plan that client verbalizes willingness to follow. Utilizing MI when providing treatment to people living with schizophrenia is associated with reducing symptom severity and rehospitalization and improving medication adherence, functioning, and insight into illness and/or treatment over a 6-month follow-up period.

Electroconvulsive Therapy (ECT)

ECT is indicated for the treatment of schizophrenia when antipsychotic therapy has not been associated with a beneficial response.

Low-Frequency Repetitive Transcranial Magnetic Stimulation (rTMS)

rTMS on the left temporoparietal cortex appears to be a valid treatment for auditory hallucinations in refractory schizophrenia.

EXEMPLARY PRACTICES

Among expert clinicians, the trend is to define practices as being the "gold standards" if they are "evidence-based." This paradigm does not address the challenges of creating evidence-based practices. Specifically, are the populations being enrolled in studies, which are the bases for evidence-based practices, truly representative of the general population living with mental health conditions who do not participate in these studies? Do these studies' questions, hypotheses, study design, and outcome measures take into consideration the perspective of people living with mental health conditions? This lack of representation limits the scope of evidence-based practices. Actions that might bridge this gap include active recruitment of people with mental health conditions into mental health fields given this level of training is required to appreciate the nuances of evidence-based practice creation and evaluation, self-disclosure by current mental health practitioners of their mental health conditions as a means to demonstrate that mental health policy and research decisions are not being created in isolation from clients, and awareness by mental health practitioners of practices that do not have the needed body of literature to determine if they are evidence-based practices but are associated with preliminary data to suggest beneficial outcomes. The presented practices are a sampling of recovery practices that do not have the needed body of literature to determine if they are "evidenced-based," but preliminary data suggest beneficial outcomes.

Crisis Intervention Team (CIT) Model

The number of people with serious mental illness in prisons and jails surpasses the number in state psychiatric hospitals by 10-fold. CIT's goal is to divert people with serious mental illness from the criminal justice system to services, if appropriate, through a collaborative approach between law enforcement and mental health systems. The main components of CIT include (1) 40 hours of mental health-related training for CIT officers; (2) training for call dispatchers to recognize calls potentially involving persons with serious mental illness and assigning them to CIT officers; (3) central designated psychiatric emergency drop-off site that accepts all people CIT officers bring for assessment. Initial findings suggest that CIT programs are associated with improved officer-level outcomes (officer satisfaction and self-perception of reduced use of

force) and increased prebooking diversion from jails to psychiatric facilities. Peer-reviewed literature contains little evidence of CIT's impact on objective measures of arrests, officer injury, citizen injury, or use of force. Rogers Mental health advocates also question the effectiveness of CIT approaches, especially for BIPOC communities. CIT training does not include any content on racism or implicit bias for police to address.

Mental Health Courts (MHC)

MHC was created to address the over-representation and disproportionate jail stays of inmates with mental health illnesses; the U.S. jail system incarcerates approximately 2 million adults with serious mental illness annually and retains them 2.5 to 8 times longer than adults without mental health illnesses. MHC's goal is to divert people with mental illness from the criminal justice system to community treatment while maintaining public safety. Participation in MHCs is voluntary, given this decision is usually accompanied by a mandatory guilty plea; however, some courts expunge guilty pleas upon successful completion. Generally, clients are required to sign a written contract pledging their commitment to MHC's mandates, such as clients taking their prescribed medications. Penalties for nonadherence to this contract include increased supervision and reincarceration. Evidence suggests that important components of effective mental health courts include care managers or access to vocational and housing services. Long participation in MHCs has been associated with reduced recidivism rates without consistent findings that access to behavioral health services or psychiatric functions improves. This discrepancy then questions the criminalization hypothesis that mental illness causes criminal behavior. There are concerns about the impact of such long periods of involvement with MHCs on participants, as well as the disparities between the extensive length of involvement in MHC and traditional criminal court, leading to concerns that MHCs actually extend state control over individuals with serious mental illness rather than divert them.

Hearing Voices Network (HVN)

Collaborating with people who hear voices, social psychiatrist Marius Romme and researcher Sandra Escher promoted an approach that developed into HVN. The pillars of this approach emphasize accepting and making sense of these voices, being recovery orientated, and

understanding the role of psychosocial adversity in voice onset and maintenance. A key part of this international network is supporting self-help groups called hearing voices groups (HVG). The aim of HVG includes providing psychologically safe environments to share the experience of hearing voices, promoting coping strategies, and cultivating a positive identity as people who hear voices. HVG consider the persons who hear voices as the experts in their experience, and as such, all perspectives about the existence of these voices are considered valid. Given that HVN does not consider hearing voices as pathologic, success is measured not by voice cessation but by understanding and accepting the experience of hearing voices and forming productive relationships with them. HVG members report an increased sense of social support, acceptance, and empowerment, along with improved coping strategies and quality of life. Critics of HVN also inaccurately perceive HVN as devaluing the benefits associated with antipsychotic treatment. HVN is not antipsychiatry, and members of HVN welcome and support each other to consider all pathways for addressing and making sense of their experiences, including the use of medications and psychiatry.

Open Dialogue

In 1984, the inpatient admission practices performed in a Finnish psychiatric hospital were changed to include patients and their family members in treatment-planning conversations. Open Dialogue has its origins in this transparency and includes seven principles: immediate help; social network perspective; flexibility and mobility; responsibility; psychological continuity; tolerance of uncertainty; and dialogue. Using this framework, Dialogic Practice promotes creating equal space for different points of view and thus reduces the gap between the identified “sick” and “well.” This equal footing dynamic increases the potential for people to be heard. In addition to relying on the personal ways therapists respond to people, Dialogic Practice has twelve key fidelity elements: having two (or more) therapists in the team meeting; having family and network participation; using open-ended questions; responding to clients’ utterances; emphasizing the present moment; eliciting multiple viewpoints; using a relational focus in the dialogue; responding to problem discourse or behavior in a matter-of-fact style and being attentive to meanings; emphasizing the clients’ own words and stories, not symptoms; having a conversation amongst professionals (reflections) in the treatment

meetings; being transparent, and tolerating uncertainty. Olson Studies suggest that Open Dialogue decreases chronicity and disability associated with schizophrenia by half and is highly cost-effective as compared with geographic and historic controls. Critics of the available research on Open Dialogue grade it as very low quality.

Soteria

From 1969 to 1971, the original Soteria-California research project was conducted. Meaning “deliverance” in Greek, Soteria was the name of a 1915-vintage, 12-room house located in the Bay Area used as the location for the research’s experimental arm. The core principles of the Soteria paradigm include: creating a small, community-based therapeutic milieu; having a significant proportion of staff be lay staff; preserving personal power, social networks, and communal responsibilities; understanding and hence giving meaning to a person’s subjective psychotic experience by “being with” and “doing with,” having empathetic relationships and engaging in meaningful shared activities with clients, respectively; utilizing no or low-dose antipsychotic medications where clients take medications by choice and without coercion. This antipsychotic medication viewpoint stems from antipsychotic medications not being a cure-all for psychosis and from the desire to avoid unnecessary antipsychotic medication-associated side effects. The limited existing data suggests Soteria treatment produces comparable psychotic symptoms reduction with significantly lower doses of medications as compared to conventional hospital treatment, and clients strongly prefer it over conventional hospital treatment. The most controversial aspect of Soteria treatment is the concept that the therapeutic milieu in itself could be enough to treat acute psychosis. This hypothesis is based on the “affect-logic” theory that contends marked increase in affective tension in vulnerable people triggers psychosis. Thus, the sustained emotional relaxation cultivated in the Soteria therapeutic milieu causes symptom remission.

Trauma-Informed Approach

Causes of trauma include violence, abuse, neglect, loss, disaster, war, and other emotionally harmful events. Exposure to traumatic events is high. For example, among an online survey of U.S. adults, 89.7% reported exposure to a traumatic event. Addressing trauma is increasingly considered a vital health care component because traumatic exposure is

almost ubiquitous and can have lasting adverse effects on people's functioning and mental, physical, social, emotional, and spiritual well-being. A trauma-informed approach includes all people at all levels of the organization or system realizing how trauma impacts groups and individuals, recognizing the signs of trauma, responding with a trauma-informed approach in all their interactions, and resisting retraumatization of both staff and clients. The six key principles of a trauma-informed approach include safety (staff and clients feel physically and psychologically safe throughout the organization); trustworthiness and transparency (the organization is transparent in its decisions with clients, family, and staff); peer support (people with lived experiences of trauma promote recovery through sharing their life experiences); collaboration and mutuality (power differences between staff and clients and among staff are leveled as the organization values everyone's contributions in providing a trauma-informed approach); empowerment, voice, and choice (the organization supports clients' shared decision-making, choice, and goal setting and provides needed supports for staff to do their work); cultural, historical, and gender issues (the organization addresses biases and offers responsive services). Inconsistent definitions of trauma-informed approaches and limited available information about measurement development processes limit the rigorous evaluation of determining the effectiveness of the trauma-informed approach.

ROLE OF PSYCHIATRIST

Psychiatrists are important staff members in a person's recovery despite the profound shortages of psychiatrists and limited time available because, all too often, they are the only staff. This situation is due to the crucial importance of medications and hospitalizations within the current system, both usually under direct psychiatrist control. There are important tools psychiatrists can incorporate into their practice.

The recovery model has frequently been presented to psychiatrists as either an antipsychiatry, antimedications movement that interferes with treatment and encourages people to get off their medications or as a useful supplement to psychiatric treatment, including a range of rehabilitative, supportive, self-help, and clubhouse services, especially useful once illnesses are successfully controlled. Instead, it can be a revolutionary paradigm, emphasizing person-centered, client-driven,

strengths-based perspectives that transform our entire mental health system, including our daily prescribing practices, as was recommended by the President's New Freedom Commission on Mental Health back in 2003. Consider Table 12.15–2, which contrasts our usual prescribing practices with a transformed practice:

Once we free ourselves from the constraints of the medical model, we can find lots of collaborative uses for medications. Here are some examples of medication usage within various formulations from our journeys:

- The pills strengthen you mentally, so you can handle the stress you're under without fragmenting as much. They help "glue" you together. They also keep your sleep/wake cycle and basic functions under better control.
- The pills help your mind filter the amazing range of stimuli, including physical stimuli from your body, and internal thoughts that bombard it, so you can think more clearly and more linearly and have an easier time maintaining your personal balance and homeostasis, but this might make you feel less creative.
- The pills slow down your ability to jump rapidly between various thoughts and mental associations, so your thinking will be more grounded and normal and less ethereal and idiosyncratic. This may help you feel less lost, confused, and alone and help you be more productive.
- The pills help strengthen your rational, conscious mind so that your unconscious mind is more under control in both your sleep and waking hours.
- The pills help you stay in reality, so you're better able to deal with it instead of escaping into your imagination.
- The pills help strengthen your personal boundaries, so you won't pick up on other people's feelings as much as you walk by, and they won't impact you as much. This may make you less intuitive and lonelier but will make you more emotionally grounded and independent. This also makes it harder for other people to influence your mind outside of your personal control, regardless of the way they're trying to do it.
- The pills help make the "spiritual waters" you're swimming in shallower, so you won't drown as easily, but you also may not have as much contact with the immensity of the spiritual world, at least until you learn more about how to "swim" in these "deep waters."

- The pills help strengthen you, so the devil can't fool you or bully you as easily.
- The pills decrease the ability of voices to impact your self-consciousness and take over more of your mind.
- The pills partially counteract the disorganizing influence of drugs, alcohol, seizures, and other medical and neurologic conditions.

These aren't clever ways of manipulating people into taking medications who don't have insight into their psychiatric illness. They are authentic hypotheses for mechanisms of action for how these pills actually work. Remember that the classes of medications we now use have been named to correspond to the illness-centered model that corresponds to their FDA approval and their marketing campaign. For example, "antipsychotics" were originally "major tranquilizers" when the goal was to sedate institutionalized patients (or sometimes housewives), and now they've been rebranded as "mood stabilizers" so they can be marketed to people with major depression and bipolar disorder without psychosis. These class names aren't really any more legitimate than these psychological descriptions. These pills are all so complex neurochemically that there isn't a clear correlation between their biochemical actions and their psychological impacts. These descriptions haven't been studied, not because they're outlandish but because the medical model is narrow-minded and controls all the pharmaceutical research funding.

Keep in mind that medications aren't the only tool available. For example, some people might improve with better sleep, coping skills, cognitive reframing, using fewer drugs, talking with friends, relaxation, less isolation, etc. A package can be put together through shared trial-and-error for each person.

Taking Strengths Seriously and Building Resilience

- Building Social Determinants of Health: Often, the outcome of treatment depends more upon the social characteristics of the person than upon their illness itself. Integrating poverty services with mental health services without saying "that's not my job" will likely improve outcomes. Political and community activism supporting social policies that promote improved social determinants of health will also likely improve outcomes.

- Building protective factors: Protective factors have been shown to prevent risk factors from becoming predictive. For people experiencing repeated mental health crises, it may be more effective to build protective factors to prevent further mental health crises than to treat each crisis after it occurs.
- Building self-efficacy: The more someone believes and has experienced that what they do makes a difference in their life, the more likely they are to take self-responsible action to recover. Examples of self-efficacy include: Increasing the ability to affect inner states directly, increasing one's role in their own life instead of relying on others, developing specific goal-driven skills to achieve personal growth, making developmental progress through life's stages, building interpersonal and community-based efficacy, and increasing spirituality.
- Building resilience by finding strengths in struggles: Sometimes, the process of struggling helps people discover and develop strengths inside of themselves they didn't know they had, receive gifts from their wounds, and figure out what's really important in life. Examples of these strengths include internal qualities, external resources, meaning-making, and enhanced connectedness and belonging.

This example illustrates how the psychiatrist–patient relationship keeps evolving to meet the needs of each stage of the recovery journey. Notice the variety of interventions used by the team and the psychiatrist. Notice also how the three dimensions of the Psychosis Triangle (Experiencing Reality, Self-Identity, and Relationships) evolve in intertwined ways along the way, impacting each other positively and negatively.

Martha had suffered a great deal by the time I met her. She grew up in a small town in Missouri, the fourth of eight children. She had only a ninth-grade education and could barely read and write. When she was 15 years old, Martha's father left for St Louis to find work and her mother struggled to take care of the family even with his financial help. Martha started spending more time reading her Bible and began believing that God was telling her what to do. Unfortunately, the instructions included spending her day trying to hail down cars on the highway to teach people about the Bible and taking off all of her clothes in church to prove she was pure. After trying to deal with her for several years, Martha's family took her to a psychiatric hospital when she was standing over her mother with a knife one night. She was repeatedly put into seclusion and sedated for disrobing in the hospital. One day, she reported being raped by another patient, but the staff didn't believe Martha. After 2 weeks, she was discharged back home with a prescription she threw away because it drugged her. After 5 more years of psychosis, fighting with her family, never going to the clinic in the next town, police being called repeatedly on her, and several hospitalizations and jailings, she ran away to Los Angeles, where she arrived without any funds or friends. She was huddled in the corner, mumbling to herself, disheveled, holding tight to her Bible.

Help Them Trust Us

In a recovery-based treatment, clients do not trust their psychiatrist just because of their ability to treat them. They also trust their psychiatrist to personally care enough to create a relationship where they can find strengths in themselves to use their treatments and rebuild their lives.

Martha was wary of psychiatrists because she was afraid of being locked up, so staff arranged for me to meet her a few times informally, eating lunch at our client-run Deli. We talked about my memories of St Louis from medical school and about how she had helped raise her younger siblings. We shared family pictures from our wallets. I told Martha about a couple of other young women we'd met who came to Los Angeles all alone and how, even though it is hard, I thought she had the strength to make it. The third time, I helped Martha with forms to get welfare payments and a discount bus pass and offered to help her get social security income (SSI) if she came in for a full assessment. We let Martha use our showers and got her some clean clothes from our donations.

Help Them Regain Control of Their Lives

In a recovery-based treatment, the focus isn't on the psychiatrist taking care of them and helping them feel better. It is on them to take control of their own life so they can take care of themselves and function even if they're not always feeling well.

Martha enrolled in our program. We asked her what her goals were, and she said she wanted a place to stay of her own, someone to talk to and feel normal with, and to go to church. We introduced Martha to another member who was a little older and further on in her recovery, and they became friends even though Martha is hard to understand sometimes and still talked to voices. We loaned Martha money against her pending back check from SSI to get a cheap weekly hotel room. In return, she had to come to the Village and do some light office work for us for 1 hour a day. Martha's favorite job was helping to decorate the office for Christmas, but it made her miss her family. We helped Martha call them and tell them she was safe, and she sent off a box of presents for them. I showed her the award I'd gotten from the local Baptist church for community service and told her that although it isn't my job to help find business for churches, I could give her a list of local churches to try. She got dressed up to try the church her friend went to that caters to homeless people. As she was feeling stronger, she asked to meet our teacher to learn to read better. She became attached to him as a surrogate father figure, but mostly she was shocked and pleased with herself that she could learn to read when no one was yelling at her and hitting her when she made a mistake.

Help Them Rebuild Their Life

In a recovery-based treatment, the goal is not just to treat a mental illness. The goal is to help someone with a mental illness have a better life.

My report helped Martha get SSI, and we gave her the money for a deposit for her own apartment. Several staff and clients went to Martha's housewarming party. I brought diet soda and chocolate. She said she was having trouble sleeping and wondered if I had any medications that might help. She noticed that other clients weren't being drugged up here at the Village and had grown to trust me. I asked Martha about what was keeping her awake, and we ended up talking about how she was tormented by demons which she hated, as well as hearing God, which was a blessing. We talked about how the demons took advantage of her when she felt weak and vulnerable, and maybe medications could strengthen her to keep them away. We decided together that she would try taking low-dosage antipsychotic medications at bedtime, and I encouraged more nightly prayers to prepare her to sleep safely. She started coming to regular appointments with me in my office. As she felt stronger, she wanted to earn some money to donate to the church, and we helped Martha get a part-time training job at our Deli. She enjoyed preparing my daily salad the way I like it, without any carrots.

Help Them Heal

In a recovery-based treatment, healing isn't just from the illness. Healing is also from the destruction and the rejection.

She was proud to share her success with her mother and younger brother, but she also began to realize how much she'd hurt them over the last few years. We began talking about her regrets more in our sessions than her medications, and she began to accept what she'd done enough to write a letter asking her mother for forgiveness. She never sent it, but she felt a weight lifted nonetheless. When our teacher left to take another job, she was devastated. She started isolating herself and stopped taking her medications, and the demons returned with a vengeance.

Take the Long View

In a recovery-based treatment, psychiatrists don't just assess and treat illnesses as detached professionals. Psychiatrist and patient walk together, sharing the joys and sufferings of recovery.

> We resisted the impulse to hospitalize Martha and get her back on her medications, even though it was heartbreaking to see Martha deteriorate again because we didn't want to push her away. She lost her job at the Deli. She wouldn't respond to repeated phone calls, so I went with Martha's caseworker to Martha's apartment to reach out to her. She opened the door and broke into tears. As we talked, we realized together that the loss of our school teacher had reactivated the feelings of abandonment and betrayal she'd felt when Martha's father had left them. We talked about how she was older and stronger now and could handle this departure. She agreed to take the bottle of pills I'd brought in my pocket.

Help Them Move On

Even though many serious mental disorders persist indefinitely, a recovery-based treatment can prepare them to deal with whatever happens and keep going with their lives without needing to be in treatment forever.

> After Martha rebuilt her life again, she enrolled in a WRAP group to develop better tools besides giving up and isolation to deal with life's inevitable losses in the future. And she'd have to do it without me coming to her home to help rescue her. I started spending less and less time helping her, and she spent more time mentoring new clients. The next Christmas, she saved money to take a bus back to Missouri, and this time did ask her mother for forgiveness which her mother gave her. After she returned to Los Angeles, she realized that Missouri really was her home, and we made arrangements for her to return home, including a phone call and letter from me so she could get medication from the clinic there. At our farewell party, she gave me a poster she'd made with her friend, as she was leaving, for my office wall that said, "The Village opens a door for us to have a better life. It's up to us to walk through it."

PEER SUPPORT SPECIALIST

Peer support is emotional support offered by a person with a mental health condition(s) to another who has a similar mental health condition(s) and works toward minimizing the inherent power imbalances between clients and providers. Peer Support Specialists (PSS) are people who are active in their recovery and potentially have obtained a PSS certificate. Over 30,000 PSS are working in the United States alone. Although fluctuating in its prominence in the history of psychiatry, the role of PSS can trace its roots to at least the “moral treatment era,” an 18th-century concept whose aim was to treat people with mental health disorders humanely. In 1935, Alcoholics Anonymous formed and utilized the peer support concept of a “sponsor.” During the 1970s, Mental Health Recovery Movement advocated for more inclusion of people with mental health disorders in their mental health care, and as such, the concept of incorporating people with mental health disorders into mental health treatment teams further emerged. In the early 1990s, the current version of PSS developed; however, their roles and responsibilities were limited as compared to today’s PSS.

Early roles for PSS generally included fewer clinical activities or activities that non-PSS clinicians were too busy to perform, such as driving clients to their appointments, filing, and answering phone calls. PSS initially did not participate in treatment planning given their marginalized, unclear clinical role. With time, PSS’ roles have become more clinical in nature to include assisting in identifying goals, teaching new skills, advocating, job coaching, providing counseling, and leading groups along with documenting these clinical interactions in the client’s medical records. One of the main roles of PSS is to disclose their mental health conditions to clients as a means to serve as a role model. This disclosure also potentially makes them more approachable to clients due to this acknowledged shared similar mental health-related experiences. These shared experiences can lay the foundation for engagement with clients whom non-PSS clinicians have been unable to reach. Another important role of PSS is to educate non-PSS clinicians about what methods might assist clients based on the PSS’ past experience with similar experiences and model engagement based on what matters most to clients.

SAMHSA considers the role of PSS as evidence-based practice in the context that “there is a need to identify specific attitudes, knowledge, and skills that are essential for peer support and effective operation of these services and programs.” Studies have shown that PSS is effective in engaging people in care, reducing emergency visits and hospital admissions, and improving social functioning. If PSS provides positive self-disclosure and role modeling to clients, these actions increase the clients’ self-care ability, decrease clients’ depression and psychosis, and increase clients’ sense of hope, control, ability to effect changes, community belonging, and life satisfaction. However, conclusions from limited meta-analytic reviews are PSS has a limited impact on measured outcomes.

Challenges faced by PSS include hiring officials at times being hesitant about hiring PSS for multiple reasons. One reason is concern that job-related stressors will disproportionately negatively impact PSS compared to non-PSS clinicians. As a result, “stability” eligibility criteria are sometimes utilized in hiring practices, such as a time requirement since last mental health hospitalization or length of sobriety. These eligibility restrictions are not based on any evidence-based predictive findings and potentially constitute discrimination based on disability rights legislation. Another concern is PSS might break clients’ confidentiality; however, like other clinicians, PSS has national practice guidelines that emphasize confidentiality and privacy and should be provided with on-the-job training and supervision, which also emphasize these topics. Yet another concern is that PSS will make the supervisor’s work harder. Initially, PSS might benefit from more supervision time to acclimate to working in their new environment than non-PSS clinicians; however, long-term benefits of improved client engagement and associated outcomes generally outweigh this time investment.

PSS do encounter unique on-the-job challenges that non-PSS clinicians do not encounter. The identification of therapeutic boundaries might be more challenging, given their past experiences and their role of being the more relatable people in the treatment team. For example, in the past, PSS could have been hospitalized with a client and, as such, has a preexisting relationship with this client as a client. Another unique challenge is clients often view PSS as reaching the pinnacle of success and, as such, are viewed as role models whom they overtly idolize. Simultaneously, some clients may be concerned about a possible relapse

of the PSS, impugning the reputation of recovering persons as being able to perform in a competent manner. These challenges can usually be effectively dealt with in supervision with PSS' clinical supervisor either in individual or group meetings with other PSS and through structured training. In addition to challenges, the role of PSS often brings personal growth to both PSS and the other members of the treatment team. The PSS benefits from the experience of having fulfilling employment. The non-PSS clinicians are able to interact with people with openly disclosed mental health conditions who are contributing to their team's mission, challenging misconceptions about the abilities of people living with mental health conditions.

12.16 Psychosis as a Defining Dimension in Schizophrenia

Elena I. Ivleva, M.D., Ph.D., and Carol A. Tamminga, M.D.

DSM-5: DEFINITION OF PSYCHOSIS

In the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and its text revision (DSM-5-TR), the psychosis syndrome is incorporated into a broad range of diagnoses, including schizophrenia, schizoaffective disorder, other psychotic disorders (e.g., delusional disorder, psychosis due to substance use or general medical condition), as well as attenuated psychosis syndrome and schizotypal personality disorder. The key symptom domains comprising “psychosis” include delusions, hallucinations, disorganized thought process (formal thought disorder), and disorganized or abnormal motor behavior (including catatonia). Despite the absence of unique pathognomonic psychosis features for each diagnosis, that is, any type of psychotic symptoms can occur in any diagnosis, DSM-5-TR emphasizes that some aspects of psychosis manifestations are characteristic for various psychosis diagnoses. In schizophrenia spectrum disorders (e.g., schizophrenia, schizoaffective disorder, schizophreniform disorder), psychotic symptoms are typically comprised of prominent hallucinations and/or delusions as well as formal thought disorder leading to rather severe behavioral manifestations (e.g., disorganized, bizarre, or catatonic behavior). In

psychotic disorders due to general medical conditions, as well as in substance-induced psychotic disorders, psychosis refers to delusions and/or hallucinations temporally overlapping with the presumably causative event (medical illness, substance use), which do not occur exclusively during the course of a delirium. In such rare psychotic diagnoses as delusional disorder and shared psychotic disorder, psychosis is essentially equivalent to isolated persistent delusions. Importantly, only disorders grouped under the “Schizophrenia spectrum and other psychotic disorders” section of DSM-5 are conventionally characterized by psychotic symptoms as the key defining feature comprising the clinical “core” of the diagnosis. Nevertheless, multiple other psychiatric disorders, such as affective disorders, neurodevelopmental disorders, dementias, and some personality disorders (besides schizotypal type), may also manifest with psychotic symptoms as associated (“secondary”) diagnostic features.

In schizophrenia, psychosis presents in its most severe form, frequently with bizarre delusions and hallucinations leading to prominent behavioral and functional changes. Although any of five senses may be affected by hallucinatory experiences, the most common hallucinations in schizophrenia are auditory, with multiple voices conversing among themselves, commenting on the patient’s life or behavior, or talking directly to the patient. Visual hallucinations are rather common, whereas tactile, olfactory, and gustatory hallucinations are less typical and should alert the clinician to look for underlying neurologic or medical conditions that mimic psychotic disorder. Delusions in schizophrenia vary broadly in content with most classic examples including paranoid/persecutory delusions, ideas of reference, or spiritual/religious delusions. Although not entirely specific for schizophrenia, such delusions as being influenced or controlled by an outside entity or force (delusions of passivity or control), phenomena of thought insertion, withdrawal or broadcasting, and delusional preoccupation with esoteric, symbolic, abstract, or philosophical ideas are more typical for patients with schizophrenia than for other psychotic disorders. Importantly, Schneiderian psychotic features (i.e., presence of bizarre delusions or hallucinations consisting of a voice that keeps a running commentary on the person’s behavior or thoughts or multiple voices conversing with one another) have been de-emphasized in DSM-5 leaving criterion A to a broader range of symptoms including (any)

delusions, (any) hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and negative symptoms.

Although delusions and hallucinations are commonly perceived as core symptoms of schizophrenic psychosis, they are not an obligate component of the formal diagnosis of schizophrenia. According to DSM-5, since at least two Criterion A symptoms are required to fulfill the diagnosis, patients without either hallucinations or delusions could receive a diagnosis of schizophrenia; however, in these cases, other psychotic symptoms are required such as thought disorder (e.g., looseness of associations, thought blocking, derailment, tangentiality, circumstantiality, neologisms, verbigeration, echolalia, global incoherence), grossly disorganized behavior or catatonic symptoms. Although the phenomena of a gross impairment in reality testing and a loss of ego boundaries are not included in formal psychosis definitions, they are commonly seen in patients with schizophrenia, especially during acute psychotic states. These clinical entities describe the lack of a clear sense of where the patient's own mind or body ends and where those of other people or inanimate objects begin. In the most severe manifestations, the patients may have experiences that they mentally or physically disintegrated or fused with an outside object or with the entire universe. These components of psychosis may be poorly verbalized by schizophrenia patients due to the complexity of the experiences; however, they can manifest in peculiar, impulsive, or dangerous behavior, and therefore, these symptoms should be carefully evaluated.

Schizophrenic psychosis is usually characterized by a chronic course with either continuous psychotic symptoms or intermittent periods of disease exacerbations and remissions. Course types with a single (or few) episodes followed by a long-term stable remission or full functional recovery are uncommon. However, in other psychotic disorders, the lifetime course of psychosis can be intermittent or fleeting, with relatively short episodes of hallucinations and delusions manifesting at the peak of severe depression or mania, decompensated medical conditions, or induced by substance exposure or medication. In the course of schizophrenia, psychotic symptoms tend to become less severe with time, whereas a decline in cognitive functioning and negative symptoms become more apparent. A further deterioration in the patient's baseline functioning can follow each relapse of schizophrenic psychosis. This failure to return to baseline functioning after each relapse is commonly

taken as the major distinction between schizophrenia and psychotic mood disorders, although recent studies report that about 20% to 25% of patients with affective disorders show considerable long-term impairment in psychosocial and basic daily functioning. Without treatment, psychosis in schizophrenia and related disorders is frequently incapacitating and contributes, along with negative symptoms and cognitive decline, to an overall poor prognosis of the illness.

CATEGORICAL AND DIMENSIONAL DIAGNOSTIC APPROACHES IN SCHIZOPHRENIA

The symptoms comprising DSM-5 criteria for schizophrenia do not define a diagnosis-specific syndrome and reflect substantial clinical heterogeneity of the illness. No single clinical sign is pathognomonic for schizophrenia; every symptom observed in schizophrenia can occur in different psychiatric disorders. The current categorical concept of schizophrenia (and other psychiatric diagnoses) is based on having a number of different combinations of symptoms, such that many variations of the defining and associated symptoms and symptom domains are possible. The phenomenology-driven diagnostic systems, while serving the purpose of clinical utility, have critical limitations resulting in classifications that are heterogeneous, lack clear boundaries, and, most importantly, neither map on emerging experimental biomarker constructs nor reflect causal biologic disease mechanisms. Despite considerable progress in understanding neurobiologic bases of psychiatric disorders, at this point, it is not possible to propose a biologically based diagnostic system due to a lack of defining knowledge about the neurophysiologic and molecular mechanisms of psychiatric disorders. One of the alternative diagnostic approaches espoused to reduce the clinical heterogeneity of psychiatric diagnoses is the identification of psychopathologic illness dimensions (such as psychosis) with a research and clinical focus on underlying disease neurobiology. Such symptom dimensions are comprised of groups of symptoms that resemble one another, occur together, and are, hypothetically, based on interrelated pathophysiologic and molecular mechanisms.

Three major symptom dimensions have been identified in schizophrenia: Psychosis, disorganization, and negative symptoms. The psychosis dimension includes distortions or exaggerations of inferential

thinking (delusions) and perceptual disturbances (hallucinations). The disorganization domain manifests as illogical disorganized thought process and/or grossly disorganized behavior. Although schizophrenic disorganization is commonly perceived as one of the accompanying features of acute psychotic state which tend to improve as severity of psychosis diminishes, disorganized features are phenomenologically unique, and are specifically associated with poor prognosis, especially in cases of chronic presentation. Therefore, disorganization has been recognized as a distinct clinical domain of schizophrenia, not just a subtype of psychotic symptoms. Negative symptoms dimension includes restrictions in the range and intensity of emotional expression (affective flattening), in the fluency and productivity of thoughts and speech (alogia), and in the initiation of goal-directed behavior (avolition). Recently, a broader dimensional model of schizophrenia has been proposed, including cognitive dysfunction (i.e., deficits in general intelligence level, various aspects of memory, executive function, global processing speed, and attention) as well as affect dysregulation and mood symptoms (Fig. 12.16–1). Although neither is yet a part of the current DSM-5 diagnostic definition, cognitive dysfunction is known to be one of the defining features of the illness which frequently manifests long before first-break psychosis and is a strong predictor of functional outcome and overall prognosis.

Comparative studies contrasting dimensional composites with traditional diagnostic categories have shown that the dimensional approach may be superior in predicting course, demand for psychiatric care, treatment outcome, social adaptation, and global prognosis of illness. Originally, the dimensional models were developed to aid diagnostic classification. However, more recently these dimensional constructs have been targeted in various research paradigms, including genetic and disease biomarker studies, as well as in identifying clinical targets for novel drug development. Dimensional components within the schizophrenia diagnosis may be characterized by unique underlying neurobiologic mechanisms and appear to be, at least partially, pharmacologically independent. To date, effective treatments are available for only a few of these symptom dimensions. Psychotic symptoms may be satisfactorily controlled with the arsenal of first- and second-generation antipsychotic medications, although treatment-refractory cases are not uncommon. Affective symptoms are typically alleviated by

antidepressants, mood stabilizers, and some antipsychotic agents. However, no effective treatments exist either for cognitive deficits or negative symptoms, although treatment development is evolving in these areas. Clinical experience, as well as well-controlled treatment trials, suggests that psychosis across many diagnostic categories, including such diagnoses as schizophrenia, bipolar disorder, psychotic depression, substance-induced psychoses, and various organic psychoses, show a similar pharmacologic treatment response. One of the current foci in drug development for schizophrenia is treatment for cognitive dysfunction, with hypothetical pharmacologic targets focused on glutamatergic, cholinergic, and serotoninergic neurotransmitter systems, as well as nonpharmacologic interventions (i.e., neuromodulation).

FIGURE 12.16–1. Symptom dimensions of schizophrenia.

PSYCHOSIS SPECTRUM DISORDERS: DOES PSYCHOSIS CUT ACROSS THE FORMAL DIAGNOSTIC CATEGORIES?

Among the clinical manifestations of psychiatric illnesses, psychosis represents perhaps the most dramatic and clinically captivating phenomenon. Historically, in early German and French schools of psychiatry in the 18th and early 19th centuries, psychosis was described

as a single clinical entity and often was the hallmark of mental illness. Since 1896, when Emil Kraepelin demarcated “dementia praecox” from “manic depressive insanity,” the nosologic (categorical) mode of thinking and classification has been predominant in psychiatry worldwide. This is despite the fact that Kraepelin’s concept underwent a complex evolution that led him to a considerable personal uncertainty about making clear distinctions among psychosis spectrum disorders, such as dementia praecox, manic depressive psychosis, intermediate conditions, and paranoid disorders. In the current psychiatric classification, psychosis is acknowledged as a clinical phenotype within numerous psychiatric disorders, including schizophrenia, mood disorders, substance use disorders, cognitive and neurodevelopmental disorders, and disorders related to general medical conditions, although it is not an obligate component of their formal diagnoses (Fig. 12.16–2).

Large-scale research studies that utilized multivariate factor analytic approaches applied to samples spanning various categorical diagnoses suggest that psychosis represents a distinct clinical domain overlapping a broad spectrum of psychiatric disorders. The strategy of breaking down phenomena into distinct dimensions has been routinely used in many fields of medicine. But, at the present time, there is not a full consensus on how to subclassify various psychosis spectrum disorders into meaningful, biologically based dimensions. In recent studies of patients with psychotic disorders (schizophrenia, schizoaffective disorder, psychotic mood disorders, and other functional psychoses) and their biologic relatives, five distinct symptom domains spanning these diagnoses were described, including reality distortion (psychosis), disorganization, mania, depression, and negative symptoms commonly referred to as the “pentagonal model” of psychotic disorders. Different diagnostic categories showed distinct dimensional profiles, with schizophrenic persons scoring highest in the reality distortion, negative, and disorganized symptoms, and affective diagnoses scoring highest in manic and depressive dimensions and lower in the psychosis and negative symptoms. Interestingly, the mania factor is considered to be the best discriminator between schizophrenia and mood disorder diagnoses, while psychosis turned out to be a domain of overlap between these diagnostic categories. In all dimensional constructs, schizophrenia patients typically show higher variability compared to patients with mood disorders, suggesting that bipolar disorder diagnosis may signify a better-

defined phenomenologic construct than schizophrenia, which is known to be highly heterogeneous. However, multiple questions remain, including whether or not the phenomenologic structure of psychosis is the same across diagnoses, what is the extent of similarities and uniqueness of underlying genetic and pathophysiologic mechanisms of psychosis is, and whether various psychosis spectrum disorders show the same molecular basis, treatment response, and functional outcomes.

FIGURE 12.16–2. DSM-5 diagnoses overlapping the psychosis dimension. GMC, general medical conditions.

BIOLOGIC FACTORS IN PSYCHOSIS: EVIDENCE FROM TRANSLATIONAL NEUROSCIENCE INVESTIGATIONS

Genetic Studies

Psychotic illnesses are broadly heterogeneous disorders, not caused by a single etiologic factor, but rather due to a complex interplay of various endogenous and environmental influences. There is consistent evidence that a genetic component contributes to the etiology of psychosis; however, little is known for certain about particular genomic regions or individual risk genes. Recent findings from large-scale whole genome studies provide evidence for contribution of numerous genes, each of a very small effect, to ethiopathogenesis of schizophrenia. Moreover, a substantial overlap in genetic susceptibility across a broad spectrum of psychiatric disorders, for example, schizophrenia, bipolar disorder, and

autism, has been observed. Some of the identified candidate genes show strong associations with dimensional constructs, such as psychosis or mood symptoms, that are not projected directly onto categorical diagnoses. Hypothetically (not yet well-established) genes or sets of genes, interacting with epigenetic and environmental factors, may predetermine vulnerability to psychosis and other clinical disease manifestations. Depending on genetic influence and other endogenous (e.g., neurodevelopmental) and/or environmental interactions, psychosis may coexist with different clinical phenotypes (e.g., mood symptoms or cognitive dysfunction), composing epiphenomenal categorical diagnoses, such as schizophrenia. This conceptualization of psychosis draws preliminary support from epidemiologic and molecular genetic studies.

Family Studies. Family studies of schizophrenia and affective psychoses have established that psychosis strongly aggregates in families. Based on current knowledge, having a relative with schizophrenia or bipolar disorder is the single most powerful risk factor for developing psychosis. The lifetime risk for developing schizophrenia increases approximately 8- to 12-folds in first-degree biologic relatives of schizophrenic probands. Although the results of genetic studies in affective psychoses are less consistent, the familial aggregation of bipolar disorder and major depressive disorder is well-established. First-degree relatives of individuals with bipolar I disorder have elevated rates of bipolar I disorder (4% to 24%), bipolar II disorder (1% to 5%), and major depressive disorder (4% to 24%). While it was originally thought that schizophrenia and affective psychoses are inevitably segregated, recent reports challenge this. Family studies show that schizophrenia and affective psychoses frequently co-occur in the same families, suggesting shared familial risk. For example, a large epidemiologic study, using a genetically homogeneous population isolate in north-eastern Finland, reported that 16% of siblings of schizophrenic probands carried a lifetime diagnosis of psychotic disorder, including schizophrenia (0.5%), schizoaffective disorder (3.3%), bipolar I disorder (1.1%), major depressive disorder with psychotic features (2.2%), alcohol-induced (2.2%), and other substance-induced (1.1%) psychoses, delusional disorder (1.6%), and psychotic disorder, not otherwise specified (4.4%). Over half of the siblings (54%) in this study had a lifetime diagnosis of any mental illness, with major depressive disorder (15.3%) and anxiety

disorders (12%) leading among nonpsychotic diagnoses. Numerous reports confirmed that the increased risk for psychotic illness in relatives of individuals with schizophrenia does not appear to be confined to schizophrenia alone. Likewise, bipolar illness has been associated with an increased risk of schizophrenia in relatives. In one of the recent family studies, it was reported that relatives of women with early onset of bipolar disorder had the highest morbid risks for both bipolar illness and schizophrenia. The presence of more than one patient with bipolar disorder in a family increased the risk for schizophrenia nearly fourfold. In a different study, it was shown that affective disorders were more frequently inherited from the same parental side of the family as schizophrenia psychosis, suggesting that the same genetic factors could contribute to susceptibility to both schizophrenic and affective psychoses. Several studies showed that, in fact, parents of schizophrenic probands suffer from affective disorders (especially, major depressive disorder) more often than from schizophrenia. Schizoaffective disorder occurs at similarly increased rates both in families of probands with schizophrenia and bipolar disorder. Likewise, schizophrenia and bipolar disorder have been shown to occur at increased rates in relatives of probands with schizoaffective disorder.

Further, there is growing evidence that certain clinical phenotypes and symptom dimensions may predict familial risk of psychosis across categorical diagnoses. For example, in a large family study from the Netherlands, a syndrome, characterized by bizarre behavior, inappropriate affect, catatonia, and poor rapport, predicted psychosis in biologic relatives of schizophrenic probands. The syndrome characterized by affective blunting and insidious early onset of illness predicted psychosis in the first-degree relatives of probands with various types of functional psychoses. A lifetime history of mania specifically predicted affective psychosis in the relatives of probands with various psychotic disorders. Similarly, in a recent study, conducted in a sample of psychotic inpatients and their 2,987 first-degree relatives in Spain, severe primary negative symptoms in probands were related to familial liability for schizophrenia, whereas familial morbid risk of mood disorders was predicted by mania, depression, and catatonia syndromes in probands. Importantly, this familial association pattern was completely independent of the probands' diagnosis of schizophrenia or major mood disorder. These studies provide evidence that familial liability for psychosis clearly overlaps DSM

categories of schizophrenia and mood disorder. From a dimensional perspective, psychosis may represent a shared phenotype with unique genetic etiologies, running through family generations.

Twin Studies. Twin studies show that the concordance rate for schizophrenia is higher in monozygotic twins (47% to 56%) than in dizygotic twins (12% to 16%), suggesting a strong heritability component for the illness. It has been reported that the more severe the schizophrenia manifestations, the more likely it is for the twins to be concordant for the disorder. Some European studies have reported a concordance rate for monozygotic twins of over 80% in cases of severe schizophrenia with typical core symptoms. These observations suggest that the schizophrenia diagnosis includes clinically and etiologically heterogeneous subgroups with potentially distinct underlying genetic backgrounds. Further, twin studies suggest that a schizophrenia diagnosis in one twin equally increases the risk for schizophrenia and affective disorders in the co-twin. A substantial overlap in genetic risk for schizophrenia, schizoaffective, and manic phenotypes was reported in a sample of 77 monozygotic and 89 same-sex dizygotic twin pairs, ascertained from the Maudsley Twin Register in London. In this study, if one member of a monozygotic twin pair had schizophrenia, there was about an 8% chance of schizoaffective disorder diagnosis in the co-twin and an 8% risk of mania. Another report, based on the Maudsley twin series, showed that the maximum monozygotic/dizygotic concordance ratio was produced by a combination of schizophrenia, affective disorder with mood-incongruent psychotic features, schizotypal personality disorder, and atypical psychosis, suggesting that these psychosis spectrum disorders share a common genetic background.

Genetic Linkage Studies. Genetic linkage studies have identified several chromosomal regions showing linkage to both schizophrenia and affective psychosis, including 1q32, 10p11-15, 13q32, 18p11.2, and 22q11-13. In one study, significant linkage to psychotic bipolar disorder was obtained on chromosomes 9q31 and 8p21. Several other chromosomal sites were supportive of linkage with psychosis in bipolar pedigrees, including 5q, 6q, 8p, 13q, 15q, 17p, and 18q, which are also implicated in schizophrenia. A recent genome-wide linkage scan in schizoaffective disorder, using British and Irish pedigrees with at least one member diagnosed with schizoaffective disorder, bipolar type, confirmed

the existence of loci that influence susceptibility across the functional psychosis spectrum. This study demonstrated genome-wide significant linkage at chromosome 1q42 and suggestive linkages at 22q11 and 19p13. The evidence for these linkages was equally contributed by schizophrenia pedigrees (where schizophrenia was predominant among relatives in addition to schizoaffective disorder) and bipolar disorder pedigrees (with higher proportion of affective psychosis). Noteworthy, two candidate genes, *DISC1* (disrupted in schizophrenia 1) and *COMT* (catechol-O-methyltransferase), which have been consistently implicated in schizophrenia and, more recently, in bipolar disorder, map to 1q42 and 22q11, respectively.

Studies of Individual Genes and Genome-Wide Association Studies. Studies of individual genes also support the evidence of overlap between schizophrenia and different psychotic disorders. In most studies, the candidate genes were first tested in schizophrenia, but a growing number of reports suggest that some of these genes may also be involved in etiologies of affective psychoses and even broader psychopathology, for example, autism spectrum disorders and epilepsy. In particular, recent genetic studies have shown increasing evidence for an overlap in genetic susceptibility across the traditional classification categories, including association findings at *DISC1*, *COMT*, *DAOA* (G72)/G30), (D-amino acid oxidase activator [G72]/G30), dysbindin (dystrobrevin-binding protein 1), *BDNF* (brain-derived neurotrophic factor), *NRG1* (neuregulin 1), and *RGS4* (regulator of G protein signaling 4). For instance, *NRG1* has been consistently implicated in schizophrenia; more recently, its relationship to bipolar disorder as a candidate susceptibility gene has also been reported. A recent study found the association of *NRG1* with a clinical phenotype of bipolar disorder with mood-incongruent psychotic symptoms, as well as with schizophrenia with lifetime manic episodes, suggesting that *NRG1* may confer susceptibility to a specific clinical phenotype with combined features of psychosis and mania. A number of independent genetic linkage and association studies in diverse populations support that variation in *DISC1* gene influences susceptibility to disorders of the psychosis spectrum, including schizophrenia, schizoaffective disorder, bipolar disorder, and major depressive disorder. Although this gene has been named “disrupted in schizophrenia,” in fact, the family in which the *DISC1* translocation was originally observed

included cases of both psychosis and mood disorder. Recently several independent research groups have implicated the association of *DISC1* with bipolar disorder, and in one study, the strongest association was observed with schizoaffective disorder, suggesting that *DISC1* may influence susceptibility to a mixed psychosis–mood phenotype that cuts across the traditional schizophrenia/bipolar divide. *Dysbindin* is another example of a candidate gene that was initially implicated in schizophrenia. Nevertheless, recent reports have also demonstrated an association between a set of polymorphisms in this gene and a clinical subtype of bipolar disorder with recurrent psychotic episodes, specifically psychotic mania. Overall, these findings support variations in *NRG1*, *DISC1*, and dysbindin as potential genetic effects contributing (along with many other genetic and environmental factors) to susceptibility for psychosis or a mixed phenotype with features of both psychosis and mood symptoms rather than to the DSM “schizophrenia” construct, although these genetic markers were indeed originally tested as schizophrenia candidate risk genes.

Polymorphisms in *G72 (DAOA)/G30* have been broadly linked to both schizophrenia and bipolar disorder. Furthermore, a recent study from the United Kingdom, conducted with a large sample of schizophrenia and bipolar disorder cases, implicated several genetic variations in *G72 (DAOA)/G30* as specific risk markers for major mood episodes across the bipolar and schizophrenia diagnoses. Thus, although this locus was originally described as a schizophrenia risk gene, this large-scale report suggests that G72 (DAOA)/G30 appears to be more strongly associated with the mood symptoms domain, not psychosis, within the schizophrenia–bipolar diagnostic continuum.

Epidemiologic and molecular genetic studies support the hypothesis that psychosis is a clinical phenotype with multifactorial etiologies, including convincing heritability and genetic contributions. Family studies of schizophrenia and affective psychoses have established that psychosis aggregates in families. Twin studies have suggested high heritability estimates of psychosis with a complex mode of transmission. Recent whole genome linkage studies have identified a number of chromosomal loci that appear to influence susceptibility to psychosis, independently of diagnostic categories. Furthermore, studies identified several putative candidate genes that appear to be involved in genetic etiologies of schizophrenia and affective psychoses. Since schizophrenia is a relatively

rare illness with presumably multiple small and/or very small genetic effects involved in its etiology, the majority of available to date genetic studies are still statistically underpowered. Geneticists suggest that tens of thousands of cases and controls may be needed to define firm associations. For example, the Schizophrenia Psychiatric Genome-Wide Association Consortium recently conducted a multistage genome-wide association study (GWAS) including 36,989 schizophrenia cases and 113,075 controls and identified 108 loci associated with schizophrenia at a genome-wide significance level. Examination of specific candidate genes at these loci suggested the involvement of dopaminergic regulation (*DRD2* gene), multiple genes involved in glutamatergic neurotransmission and synaptic plasticity (e.g., *GRM3, GRIN2A, SRR, GRIA1*), as well as neuronal calcium signaling (e.g., *CACNA1C, CACNB2*, *CACNA11*). Independent of genes expressed in the brain, associations were enriched among genes expressed in tissue that play an important role in immunity (in particular, relevant to B-lymphocyte lineages involved in acquired immunity), providing support for the hypothesized link between the immunologic effects and schizophrenia. In addition to polygenic, complex inheritance observed in schizophrenia and other psychotic disorders, there is also a strong indication that in some patients a deletion or insertion of a larger chromosomal region, so-called copy number variation (CNV), plays a crucial role in the disease pathogenesis. This could be specifically important in sporadic cases of schizophrenia since a higher frequency of *de novo* mutations has been associated with CNVs. Noteworthy, CNV markers linked to schizophrenia show substantial overlap with neurodevelopmental disorders, such as intellectual disability and autism spectrum disorders, providing support for partially overlapping etiologies underlying these clinical phenotypes.

Current clinical targets available for genetic studies, for example, “schizophrenia” or “bipolar disorder,” are highly heterogeneous and do not clearly map onto molecular or neurophysiologic disease models. Understanding the biologic effect of genetic risk markers is undoubtedly complex. Although several such candidate markers have been implicated, the associating variations are likely different in different disease subtypes and symptom clusters, and it is, therefore, difficult to determine the specific biologic effect of each risk gene characteristic for specific disease components. Various epigenetic factors, although insufficiently investigated so far, add to the complexity of the picture. In addition,

environmental factors, perhaps interacting with risk genes, are likely to contribute and further complicate endogenous and environmental factors interplay. Although originally, the candidate risk genes were implicated in schizophrenia, recent findings provide evidence that they show the strongest associations with symptom dimensions, such as psychosis (e.g., *NRG1*, *DISC1*, and *dysbindin*) or mood symptoms (e.g., *G72/G30, BDNF*), across the schizophrenia–mood disorder continuum. Furthermore, recent GWAS studies support much broader genetic overlaps, from psychotic disorders to autism spectrum disorders, to epilepsy and neurodegenerative disorders, and to medical conditions (e.g., autoimmune disorders). Although intriguing, these observations are still preliminary and should be treated with caution, given the difficulties in establishing and defining evidence for genetic etiologies in complex, polygenetic disorders. Future genetic studies derived from large samples, targeting more homogeneous disease components (e.g., symptom dimensions) and/or biomarker-derived constructs underlying clinical phenomenology, are needed.

Emerging Brain-Based Biomarkers for Psychosis

Despite considerable progress in epidemiologic and molecular genetics of psychiatric syndromes made in the past decades, clinical phenotypes, such as schizophrenia or bipolar disorder, when directly applied in genetic studies, generally fail to generate consistent findings. Although multiple genome-wide “hotspots” and associated candidate genes have been implicated, the causative “psychosis genes” have not been identified. Even less is known about specific pathways and brain circuits through which these genetic effects may contribute to symptom manifestations of psychotic disorders. The inconsistent genetic findings may be, in part, explained by the presumed complexity of the pathophysiologic mechanisms of psychiatric disorders, resulting from a multicomponent interplay of genetic/epigenetic, endogenous, and environmental factors. In addition, the phenomenologic heterogeneity of psychotic disorders, as well as the lack of biologically based definitions and clear boundaries in the existing diagnostic categories, contribute to the limited success in identifying causative genetic etiologies. Based on these kinds of considerations, the focus of genetic and translational studies has recently shifted toward disease “intermediate phenotypes.” Intermediate phenotypes (often interchangeably called disease biomarkers) are

specific, measurable alterations in brain function or structure or abnormalities in peripheral systems (e.g., inflammatory or endocrine effects) capturing components of disease pathogenesis which are thought to be “intermediate” between the aberrant genes and the clinical manifestations of the disease. These alterations are frequently referred to as “disease biomarkers” and can be assessed by objective neurophysiologic, neuroanatomical, or behavioral measures. An ideal intermediate phenotype for an illness would be a measure that is associated with the clinical syndrome, heritable and state-independent. In addition, it cosegregates in families while being expressed in unaffected family members and may serve as an informative predictor or risk marker observed long before full disease manifestations. Intermediate phenotypes are a promising area of study in the search for genetic factors in psychosis which may provide more direct clues to the genetic underpinnings than the clinical syndrome itself. On the other end, dimensions of illness, such as psychosis, may be particularly useful in identifying the underlying intermediate phenotypes, as dimensions provide less heterogeneous clinical constructs.

Biomarker-focused studies in psychotic disorders have led to the recognition of an array of putative disease biomarkers. These include oculomotor abnormalities (smooth pursuit and saccadic eye movement alterations); deficits in sensorimotor gating, measured with electroencephalography-based event-related potential (ERP) and prepulse inhibition (PPI) of startle response paradigms; abnormal neurocognitive performance; as well as structural and functional brain abnormalities captured with various neuroimaging methodologies. In contrast to the considerable amount of data on schizophrenia, much less is known about intermediate phenotypes of other psychotic disorders, although selected candidate biomarkers have recently begun to be explored in disorders of neurodevelopmental and affective spectrum. Similar to overlapping clinical symptom manifestations, the three most common psychotic disorders, schizophrenia, schizoaffective disorder, and bipolar disorder, appear to share common etiologic determinants and biomarker signatures (Fig. 12.16–3). Within the array of neurophysiologic, anatomic, and cognitive measures, there are specific elements that can be targeted as candidate psychosis biomarkers.

Oculomotor Alterations in Psychotic Disorders. Similar abnormalities in smooth pursuit eye movement (i.e., inability to closely follow a moving target) and saccadic eye movement disinhibition have been observed in schizophrenic and psychotic bipolar disorder patients, as well as in their first-degree relatives and persons with schizotypal personality disorder. These oculomotor phenotypes are thought to be mediated by the frontal cortex and associated circuits and have been linked to working visual–spatial memory function as well as deficits of inhibitory control. These oculomotor deficits are stable, trait-like characteristics observed in both acute (psychosis, acute mania) and remission disease phases and appear to be minimally influenced by medications. Recent genetic studies of oculomotor biomarkers suggested a linkage of smooth pursuit eye movement alterations to chromosome 6p21 in schizophrenia families. Other studies using fMRI simultaneously with eye tracking during the imaging sessions have reported that schizophrenic patients tend to activate different brain regions in order to maintain smooth visual tracking compared to healthy subjects. Patients showed reduced activation in frontal and, specifically, supplemental eye-field regions, medial superior temporal, and anterior cingulate cortices. Interestingly, activation in the medial occipitotemporal cortex was increased in patients compared to healthy individuals, perhaps, reflecting the recruitment of different brain regions in order to compensate for primary prefrontal deficits underlying smooth pursuit eye movement system dysfunction in schizophrenia.

FIGURE 12.16–3. Clinical, biomarker, and genetic components in the schizophrenia–bipolar disorder continuum. Schizophrenia, schizoaffective disorder, and bipolar disorder are the three main psychiatric diagnoses overlapping the psychosis dimension. In addition, other symptom dimensions, such as cognitive dysfunction, disorganization, negative and affective symptoms, are variably presented in these diagnoses. These symptom manifestations are thought to result from a complex interplay of environmental and biologic factors, expressed in disease biomarkers such as altered brain anatomy, cognitive or neurophysiologic abnormalities, captured with electroencephalography, brain imaging, and other objective measurements. Some, though not all, of these biomarkers may be heritable and subserved by genetic and epigenetic effects.

Sensory and Sensory-Motor Gating Deficits in Psychotic Disorders. Sensory/sensory-motor gating is a neurophysiologic function of a normal brain that allows one to “filter out” irrelevant and/or excessive environmental stimuli. It has long been observed that patients with evolving psychosis and mania display hypersensitivity to environmental stimuli as well as aberrant stimuli attributions, thought to be mediated by altered sensory and sensory-motor gating mechanisms. These phenomena are typically measured by various electroencephalography (EEG) ERP paradigms as well as electromyography (EMG), for example, PPI paradigms.

Auditory Paired Stimuli ERPs. An overall pattern of gating deficits characteristic for psychosis is a reduced sensory, and sensory-motor gating function thought to capture neural “hypersensitivity” to environmental stimuli. In the standard auditory “paired stimuli” paradigm, the so-called “P50” response amplitude (i.e., the largest EEG wave within 50 ms after the stimulus presentation) is measured in response to each of two auditory “clicks.” In healthy individuals, the P50 wave following the second stimulus is lower than that of the first stimulus, reflecting normal sensory gating function. In contrast, both schizophrenia and bipolar patients (specifically, patients with acute mania) show diminished suppression of P50 ERP to the second stimulus, that is, insufficient sensory gating. These sensory gating deficits are thought to be stable “trait” measures largely independent of the current severity of psychotic or mood symptoms or treatment effects. Some studies report more prominent P50 abnormalities in patients with disorganized schizophrenia. In addition, associations between disrupted P50 and negative symptoms have been reported. An intriguing observation suggesting that sensory gating deficits may represent a unique psychosis biomarker has been recently reported in patients with bipolar disorder. Persons with bipolar I disorder and a lifetime history of psychosis and those with schizoaffective disorder showed P50 deficits similar to those observed in schizophrenia, whereas bipolar patients with no history of psychosis exhibited normal P50 suppression. “Schizophrenia-like” P50 suppression deficits are also observed in people with schizotypal personality disorder as well as in individuals at high risk for developing psychosis, such as subjects originating from high genetic density families (i.e., those with several psychotic family members) and individuals with schizophrenia prodrome. Evidence for a linkage between disrupted P50 gating and chromosome 15q14 has been reported in several studies, specifically to the promoter region of the α-7 nicotinic cholinergic receptor subunit gene, in both individuals with schizophrenia and their biologic relatives.

Odd Ball Paradigm and P300 ERP. P300 is typically measured in auditory or visual “oddball” paradigms where frequently presented stimuli (“targets”) are interleaved with infrequent and unexpected atypical (“oddball”) stimuli and refers to a positive EEG wave occurring within 300 ms following an “oddball” stimulus. Several large meta-analyses reported reduced P300 ERP amplitude and delayed P300 latency in probands with

schizophrenia and their biologic relatives, as well as in “mild psychosis phenotypes” such as schizophrenia prodrome and schizotypy. Recently studies of P300 ERP have been extended to bipolar disorder and suggested similar “schizophrenia-like” alterations in P300 amplitude and latency in individuals with psychotic bipolar disorder and their relatives, albeit less consistently across different studies. In several studies, a frontal subcomponent of P300 ERP was reported to correlate with the severity of hallucinations in patients with schizophrenia, perhaps due to the shifting of attentional resources from external to internal (psychotic) stimuli. Similarly, patients with psychotic bipolar disorder showed reductions in frontal lobe P300 voltage, suggesting a component of overlapping neural substrate for dysfunction in both schizophrenia and affective psychosis. Diminished P300 amplitude and increased latency have also been linked to the severity of negative symptoms, illness duration, and early age at psychosis onset, as well as cognitive dysfunctions, that is, deficits in attention. Several studies conducted on healthy twin pairs suggested moderate heritability estimates for the P300 ERP biomarker. Interestingly, the P300 heritability in females appeared to be lower (45% compared to 56% in males), suggesting that endogenous or environmental factors may have a stronger modifying influence on this ERP biomarker in females. Genetic association studies linked P300 alterations to *COMT* and *NRG1* polymorphisms in patients with schizophrenia.

Sensorimotor Gating Deficits in Psychosis: Prepulse Inhibition. PPI paradigms measure inhibition of the startle reflex. In healthy individuals, a weaker “prepulse” stimulus leads to an inhibition of a response magnitude to a startle (“pulse”) stimulus, used as an index of sensorimotor gating. In individuals with psychotic disorders, insufficient PPI reflecting an exaggerated startle response is commonly observed. Diminished PPI has been reported in patients with schizophrenia, schizotypal personality disorder, and both affected and unaffected biologic relatives of schizophrenia probands. Similar findings have been noted in persons with bipolar disorder, especially during the acute manic phase, although the studies on bipolar disorder are few and less consistent. Several studies reported associations between PPI deficits and florid psychotic symptoms, such as disorganized thought processes and behavior, greater distractibility, and bizarre psychotic behavior. However, at least a few

studies in schizophrenia observed disrupted PPI even in remission phases, supporting this candidate biomarker as a stable “trait” measure. Likewise, individuals with acute psychotic mania show significantly reduced PPI and less startle habituation, along with a significant reverse correlation between PPI sensorimotor gating and the severity of psychotic symptoms. In contrast, euthymic bipolar patients failed to demonstrate abnormalities in PPI. These observations of similar PPI deficits in schizophrenia and psychotic mania suggest that abnormal sensorimotor gating may represent one of the putative biomarkers subserving psychosis as a unique clinical dimension.

Cognitive Dysfunction as a Candidate Psychosis Biomarker. Cognitive dysfunction has recently drawn interest as a distinctive dimension across psychotic disorders, as well as a potential treatment target. The presence of specific cognitive deficits is not yet part of the diagnostic DSM-5 criteria for schizophrenia; nonetheless, it is recognized as a common feature of the disorder. Extensive cognition studies have shown stable, trait-like deficits in the domains of working memory, verbal episodic memory, attention, processing speed, problem-solving, and executive function in individuals with schizophrenia. Patients with bipolar disorder manifest deficits in overlapping cognitive domains, with attention, working memory, and verbal memory difficulties being among the most prominent, albeit generally less severe, than those found in schizophrenia. A considerable clinical heterogeneity of the bipolar phenotype correlates with variable presentations of cognitive deficits, with some patients manifesting more severe “schizophrenia-like” abnormalities and others showing little or no alterations in cognitive function. Studies demonstrate that a lifetime history of psychosis, a higher number of past manic episodes, a longer overall duration of illness, and a higher number of past hospitalizations are associated with more severe cognitive deficits in bipolar disorder. Moreover, bipolar patients with a lifetime history of psychosis appear to have a different profile of neurocognitive deficits than those without a history of psychosis, manifesting more severe impairment on measures of executive function and spatial working memory. More severe bipolar patients, especially those with psychosis, begin to resemble schizophrenia patients with regard to the level and profile of neurocognitive deficits. One of the commonly reported cognitive features that may help to disambiguate schizophrenia and bipolar disorder is a

general intelligence level, especially premorbid intellectual functioning, with lower scores typically observed in patients with schizophrenia but normal/near normal general intelligence levels in bipolar disorder. Extensive research work has been done in an attempt to discover genetic associations for cognitive dysfunction in schizophrenia and related psychotic disorders, with most consistent findings supporting links for *COMT* and executive function, *DISC1* and verbal declarative and working memory deficits in schizophrenia, and less consistently, bipolar probands, and their biologic relatives.

Anatomical Brain Alterations in Psychotic Disorders. Anatomical brain changes have been examined as candidate psychosis biomarkers across schizophrenia and related psychotic disorders. Studies in schizophrenia have consistently shown a modest but measurable reduction in whole brain volume, particularly in gray matter (averaging 2% to 8% for various brain structures, based on meta-analyses), as well as an increase in ventricular size. Multiple areas of the brain have been reported to demonstrate volumetric changes, typically with the largest effect sizes in the frontotemporal regions but also in the parietal cortex and several subcortical structures (e.g., thalamus, basal ganglia). Several meta-analyses of volume change in schizophrenia reported whole brain and, particularly, frontotemporal gray matter volume reductions in individuals at the time of their first psychotic break, preceding any treatments.

The structural findings in psychotic mood disorders are less consistent, ranging from decreased, to normal, to increased gray and white matter volumes in various brain regions. Recent large-scale psychosis-focused studies report regionally overlapping but more localized and lesser in magnitude gray matter volume reductions in psychotic bipolar disorder compared to schizophrenia and schizoaffective disorder. The most reproducible regional volume reductions in psychotic bipolar disorder are typically localized to anterior limbic regions, that is, orbitofrontal, anterior cingulate, insular cortex, as well as amygdala and anterior temporal cortex. However, volume increases in the amygdala have also been reported. Some studies comparing individuals across the psychosis dimension find no abnormalities in gray matter volume, while volume deficits of white matter were evident throughout the neocortex and brainstem, with similar regions of white matter loss found in individuals with schizophrenia and bipolar disorder.

The question of whether volume loss is progressive during the lifetime course of psychosis has been explored. Measurable gray matter volume and cortical thickness changes are already observed in individuals near psychosis onset, progress with illness duration (more aggressively during the initial years of illness in some cases), and ultimately result in characteristic gray matter alterations found in chronic psychosis samples. Data from relatives with psychosis spectrum disorders (e.g., schizotypal personality disorder) demonstrate milder but similar gray matter volume reductions suggesting a heritable link between psychosis manifestations and brain structure alterations. Moreover, recent large-scale reports demonstrate overlapping gray matter volume reductions in the psychosis probands (including schizophrenia, schizoaffective disorder, and psychotic bipolar disorder) and their first-degree relatives with psychosis spectrum disorders, but normal gray matter characteristics in relatives unaffected by lifetime psychosis, even in those relatives with clear nonpsychotic diagnoses (e.g., mood disorders, anxiety disorders). These gray matter alterations may capture lifetime “psychosis burden,” from extensive reductions in probands where psychosis is fully manifested to similarly distributed but milder alterations in relatives with mild psychosis phenotypes (e.g., schizophrenia spectrum personality disorders), to normal gray matter in relatives without lifetime psychosis. Moreover, associations between lifetime duration of psychosis and gray matter volume, with more loss observed as the illness progresses, have been reported in schizophrenia and schizoaffective probands in the frontal, temporal cortex, basal ganglia, and thalamus, the regions long implicated in psychosis in both early-course and chronic samples.

The exact mechanisms underlying these brain structure changes are unknown but can be interpreted in the context of available postmortem findings of cellular neocortical pathology in psychotic disorders. Histologic examination of schizophrenia cases indicates absence of neuronal loss, yet altered neuronal cell packing, presumably due to reduced interstitial neuropil, resulting in higher neuronal density and overall decreased cortical thickness. In contrast, analyses from bipolar cases show decreased neuronal and glial density but normal overall cortical thickness. Dendritic spine loss, as well as reduced dendritic length in dorsolateral prefrontal cortex, has been observed in both schizophrenia and bipolar postmortem tissue samples. These postmortem findings suggest both overlapping and unique anatomical underpinnings for schizophrenia and

bipolar disorder, providing plausible cellular correlates for the structural brain changes captured with imaging techniques.

Furthermore, longitudinal studies provide support for the measurable effect of various psychotropic medications on brain structure. Long-term treatment with first-generation antipsychotics has been linked to increased gray matter volume in basal ganglia. Both first- and second-generation antipsychotics are associated with decreased gray and white matter volume in the frontotemporal regions. Lithium has been linked to higher gray matter volume/density in diffuse neocortical regions as well as a larger volume of specific subcortical structures, that is, the amygdala, in psychosis and mood disorder samples. Given that the majority of psychotic and mood disorder patients undergo years of treatment with various psychotropic agents, it is possible that the gray matter deficits consistently reported in patients with schizophrenia, and schizoaffective disorder are, at least in part, accounted for by the effect of a lifetime antipsychotics use, whereas a relative gray matter volume preservation in bipolar patients could be secondary to a medication effect (i.e., chronic treatment with lithium) and that, even if a “primary” disease-associated loss of neocortical volume exists in these patients, it could be obscured by a volume-enhancing effect of chronic lithium use. Disentangling “primary” disease and medication effects on brain structure presents considerable difficulty and requires carefully designed longitudinal research protocols.

Some, though not all studies, have reported associations between brain anatomy changes and clinical manifestations in schizophrenia and related disorders. In particular, reductions in the frontotemporal volume have been linked to severity of positive symptoms in schizophrenia and schizoaffective disorder; reductions in various structures within the medial temporal lobe have been shown to correlate with the severity of delusions. Additionally, volume reductions in the medial temporal lobe have been linked to declarative memory dysfunction in first-degree relatives of schizophrenic probands. Subsequent data suggest that the various subgroups within bipolar disorder may have different structural brain characteristics, depending on whether they have psychosis. The majority of studies report similar brain structure changes in persons with schizophrenia and psychotic bipolar disorder, perhaps as one of the overlapping intermediate phenotypes indicative of psychosis liability.

Biomarker-Based Approaches to Psychosis Dimension: Challenges and Future Directions. Disease biomarkers (sometimes referred to as “intermediate phenotypes”) represent smaller, homogeneous, measurable units of illness that are thought to be more proximal to the pathogenesis of illness and/or genetic etiologies than the global diagnosis constructs. At first, the intermediate phenotype/biomarker-focused approaches were used in schizophrenia research and resulted in the recognition of several reproducible cognitive, neurophysiologic, and neuroanatomical markers. More recently, these same candidate biomarkers have been used to explore different psychotic disorders in the hope of developing valid, objectively defined psychosis biomarkers. As reviewed above, among the variety of biomarker measures, there are specific elements that appear to be promising as indicators of the “psychosis dimension” cutting across DSM-based psychosis diagnoses. Further progress in psychosis research can move the field past early “proof of concept” biomarker studies. Parsing complex brain disorders, such as psychosis, based on biomarker approaches within and across psychiatric syndromes can provide more precise diagnostic algorithms and paths for the development of targeted treatments.

However, many challenges will need to be addressed in order to move the field toward successful translational and clinical implementation of biomarkers. To date, the majority of psychosis biomarker studies have focused on a single biomarker, for example, cognition or EEG. While it is unlikely that such single biomarker measures can adequately capture the complexity of brain alterations underlying psychosis, comprehensive biomarker batteries are lacking. It remains unknown which combination(s) of specific measures would represent the most parsimonious “psychosis biomarker battery.” There is a critical need for large-scale psychosis studies that incorporate multimodal biomarkers and link biomarker batteries to clinical manifestations. A few biomarker-focused psychosis consortia (e.g., the Bipolar-Schizophrenia Network for Intermediate Phenotypes [B-SNIP]) have made progress, but more studies—including biomarker replication in large independent samples—are needed.

Furthermore, little is known about specific functional, anatomical, and molecular features underlying current “psychosis biomarker” constructs. Unlike biomarkers in medicine, for example, glucose levels or Hemoglobin A1C for diabetes, currently available candidate biomarkers in psychiatry

fail to capture specific mechanistic elements of complex brain disorders. Further basic neuroscience and translational work are urgently needed in order to link human *in vivo* brain-based biomarkers to potential molecular targets, for example, via animal models or live cell studies. In parallel, efforts are also needed to parse the biologic heterogeneity of psychiatric syndromes to guide successful clinical translation. Additionally, longitudinal studies are needed to investigate the prognostic value of psychosis biomarkers. Furthermore, pharmacologic target studies and clinical trials incorporating biomarker measures will be critical for capturing specific aspects of disease mechanisms and generating “actionable” biomarkers in psychiatry. Cumulatively, these strategies may move the field closer to elucidating disease mechanisms and exploiting mechanistically informed therapeutic targets—the bases for successful clinical translation.

At present, the clinical utility of the “psychosis biomarker” constructs is unclear. In contrast to many other fields of medicine where objective tools are the cornerstone of diagnostic algorithms, biomarker measures are not available to support the vast majority of psychiatric diagnoses. Experimental research biomarker batteries are complex and costly and require substantial technical and analytic expertise as well as further development in automatic quantification tools. It remains unclear which specific biomarkers (and/or biomarker batteries) are useful in informing clinical diagnostic algorithms and predicting treatment response and, thus, represent suitable candidates for implementation into clinical practice. Substantial work is needed to bridge the gap between research and clinical practice in order to demonstrate the translational applicability of biomarker findings in psychiatry.

Ultimately, to successfully address the challenging task of establishing clinical utility, the field will have to bring brain-based biomarkers to an individual patient level. This calls for sophisticated computational approaches, which would allow biomarker characterization and “biotyping” in individual patients, in real-time, with subsequent application of these biomarkers as a means to guide clinical decision-making. Changes in psychiatric training and in insurance policies, so they will support objective brain measures as part of routine clinical workups, are examples of challenging tasks lying ahead.

To conclude, significant challenges remain for direct clinical translation of biomarkers in psychiatry, though none are insurmountable in light of

fast progress in other fields of medicine towards similar translational goals. The developing field of neurobiologic psychiatry offers unique paths to tackle these challenges via multidisciplinary efforts that bridge research and clinical practice. If successful, these efforts may generate stronger diagnostic algorithms and offer novel therapeutic targets for psychiatric disorders.

PSYCHOSIS AS A CLINICAL CONTINUUM: FROM ATTENUATED PSYCHOSIS PHENOTYPES TO FRANK PSYCHOTIC DISORDERS

Psychosis manifestations include a broad array of symptoms of various severities, which appear to lay on a continuum from mild subthreshold psychotic phenomena to frank and florid psychosis. Mild sporadic psychotic symptoms, such as illusions, mild hallucinations (e.g., undifferentiated noises or calling a person's name), ideas of reference, magical thinking, unusual beliefs, and perceptual experiences, and the like are fairly common in otherwise healthy individuals who don't carry any diagnosis of psychiatric illness. Although these symptoms are psychotic by nature, they are considered to be below the threshold for a formal psychosis diagnosis. It appears that there may be no discrete demarcations between frank psychosis and minor subclinical psychotic symptoms other than severity, breadth, and persistence; rather, psychosis represents a clinical continuum with multiple subtypes and grades of symptom manifestations.

Large longitudinal studies evaluated the frequency of mild psychotic symptoms in the general population and found that subclinical psychotic experiences are not uncommon. For example, the large community sample study using the British National Psychiatric Morbidity Survey data showed that 4.4% of the general population reported incident psychotic symptoms over an 18-month period. The vast majority of individuals who reported such psychotic symptoms did not meet the full diagnostic criteria for any psychiatric disorder. These observations may indicate the presence of latent continuum-like psychopathology in the general population. Moreover, they are consistent with a multifactorial etiologic model of schizophrenia where many different genes of small effect interact with one another and with environmental factors to result in the illness. Depending on a complex interplay of genetic and environmental

influences, the manifestations of psychosis can vary from mild episodic experiences (e.g., déjà vu, infrequent thought blocking, or visual illusions) to moderate psychotic-like symptoms (e.g., magical thinking, ideas of reference, bodily illusion, or out-of-body experiences), or to severe and persistent frank psychosis, fulfilling DSM criteria (e.g., delusions or hallucinations). From the psychosis continuum perspective, subthreshold psychotic symptoms are considered indicators of proneness to psychosis, with clinical psychosis emerging perhaps when a critical genetic threshold is reached, accompanied by modifying or triggering epigenetic and environmental factors (Fig. 12.16–4).

Clinically, the continuum nature of psychosis is well illustrated by premorbid and prodromal symptoms in individuals with schizophrenia and affective psychoses, psychopathology in biologic relatives of psychotic probands, as well as by certain types of personality disorders, displaying a wide range of psychotic symptoms, varying from very mild psychotic-like phenomena to frank psychosis during decompensation phases.

Premorbid and Prodromal Signs and Symptoms in Schizophrenia and Affective Psychoses

The course of schizophrenia is generally conceptualized as starting with premorbid (preprodromal) signs and symptoms and then a prodromal phase of illness, leading to typical clinical manifestations as the illness evolves. However, it is not always possible to clearly demarcate these periods due to the presence of schizophrenia spectrum personality disorders and traits characteristic for a proportion of individuals who subsequently develop schizophrenia, as well as minor psychotic, affective, and behavioral symptoms that sometimes appear long before the debut of schizophrenia. In the typical, although not invariable, premorbid history of schizophrenia, patients have had schizoid or schizotypal personality features and are characterized as quiet, passive, introverted, emotionally aloof, and reclusive. Other characteristics, more typical for schizoid personality, include a low need for emotional bonds: In childhood, these individuals have few friends. By the adolescent period, they may show no interest in dating and avoid school sports and competitions. Instead, they prefer solitary activities and seem content by themselves. When schizotypal features are predominant, thinking, perception, and behavior appear to be odd or peculiar. Various psychotic-like symptoms, such as magical thinking, peculiar beliefs, ideas of reference, perceptual illusions,

odd fantasies, or derealization–depersonalization symptoms, are commonly present. Especially during the adolescent period, peers may exclude them from group activities or tease them, as schizotypal individuals have poor communication skills and distorted social judgment. This often leads to increased anxiety, feelings of “not fitting in,” and further withdrawal from the social group. Although different types of personalities (including paranoid, avoidant, obsessive-compulsive, and, less commonly, borderline) are also seen in the premorbid period in individuals with schizophrenia, schizoid and schizotypal personality traits are believed to be the most common. Still, the presence of these premorbid and prodromal symptoms does not inevitably result in conversion to schizophrenia or other psychotic disorder.

Although the first hospitalization is often taken to be the beginning of the illness, in many cases, premorbid and prodromal signs and symptoms may have been present for months or years prior. The majority of schizophrenia cases are characterized by an insidious, gradual onset of psychosis with no clear date of its first manifestation. The prodromal symptoms may start with somatic complaints, such as headaches, digestive problems, autonomic symptoms, fatigue, and generalized weakness. Family and friends commonly notice that the person has changed, become withdrawn and isolated, and is no longer functioning well in occupational, personal, and social settings. Deterioration in personal hygiene and grooming decreased appetite, and peculiar eating habits are also common. During this stage, a patient may begin to develop new, unusual interests in abstract ideas, philosophy, occult, or religious topics. Gradually, although acute onset may also occur, subthreshold psychotic symptoms, such as unusual speech, strange perceptual experiences and bodily illusions, bizarre ideas, and markedly peculiar behavior, build up and subsequently progress to the level of frank psychosis in the form of hallucinations, delusions, typical thought and speech disorders, and/or grossly disorganized behavior.

FIGURE 12.16–4. Threshold model of psychosis. In the general population, considerable evidence indicates the presence of fleeting psychotic symptoms without any functional impact. When more severe or persistent, psychotic symptoms appear at subthreshold of formal psychosis diagnosis and manifest in entities like schizophrenia prodrome and schizophrenia spectrum personality disorders, as well as are frequently seen in biologic relatives of probands with psychotic illnesses. In a proportion of these individuals, psychosis may reach the level of florid clinical manifestations severe enough to fulfill criteria for DSM diagnosis. Genetic, epigenetic, other biologic, and environmental factors can protect against or advance psychosis. Examples of propsychotic risk factors include obstetrical complications, drug abuse, specifically, adolescent cannabis use, and psychosocial stressors. Less is known about antipsychotic resilience factors, though high premorbid functioning, structured environment, and cognitive remediation administered early in the course of evolving psychosis appear to have protective effects. •, candidate psychosis genes; P-Relatives, psychotic relatives of probands with psychotic disorder; SSPD, schizophrenia spectrum personality disorders (cluster A: Schizoid, paranoid, schizotypal); BPD, borderline personality disorders; SZ, schizophrenia; SAD, schizoaffective disorder; BD, bipolar disorder with psychotic features; MDD, major depressive disorder with psychotic features; SFD, schizophreniform disorder; SIP, substance-induced psychosis; P-GMC, psychosis due to general medical conditions; other Psy, other psychotic disorders.

The validity of the prodromal syndrome is uncertain, since symptoms are frequently recognized only after the diagnosis of schizophrenia has been made. During the prodromal phase, patients usually lack insight regarding their developing symptoms, although some verbalize feeling as

if they have changed. Once schizophrenia is diagnosed, the retrospective remembrance and the patient's subjective report of early signs and symptoms may be affected, therefore obtaining the information about the early (prodromal) period of illness from the patient's family may be of significant help in building a diagnosis.

The presence of prodromal symptoms in affective psychoses is unclear. Although clinical observations suggest that such symptoms as mood lability, impulsivity, destructibility, and physical hyperactivity are often present long before the development of affective psychosis, the phenomenology of bipolar prodrome is not well characterized. One of the recent studies conducted with early onset bipolar I disordered individuals showed that there may be unique prodromal characteristics in patients with and without subsequent bipolar phenotype that manifests as psychotic mania. In this study, attenuated psychotic symptoms emerging late in the prodrome and increased energy and goal-directed activity were more common in individuals with later psychotic mania. Studies comparing prodromal symptoms in schizophrenia and affective psychosis revealed considerable overlap; for example, such symptoms as suspiciousness, subthreshold hallucinatory experiences, anxiety, insomnia, and impaired school or work functioning were frequently present during the prodromal period in both psychoses. On the other hand, depressed mood, suicidality, mood lability, difficulty thinking/communicating clearly, tiredness/lack of energy, obsessions/compulsions, and physical agitation were more specific for bipolar than schizophrenia prodrome.

Recently, substantial research and clinical efforts have focused on psychosis prodrome and other "clinically high risk" states, with overarching goals of identifying (i) clinical subgroups within highly heterogeneous prodromal states, (ii) predictive factors (including biomarkers) for conversion to fully manifested psychosis, and (iii) developing interventions that could prevent or, at least, delay conversion to psychosis. Recent studies have demonstrated that premorbid and prodromal symptoms, clinically well accepted as a phase in the course of schizophrenia, are not necessarily pathognomonic of schizophrenia psychosis. For example, in a study by the Melbourne group, high-risk individuals with either a family history of psychotic disorder, schizotypal personality disorder, subthreshold psychotic symptoms, or brief transient psychotic symptoms were followed for a 12-month period. In that group,

40.8% of the high-risk individuals subsequently developed psychosis; however, diagnoses ranged between schizophrenia, schizoaffective disorder, bipolar disorder, and major depression with psychosis. Other large-scale studies in this field suggest that approximately one-third of “at risk” individuals eventually convert to psychosis, one-third will continue to experience stable chronic mild psychotic phenomena without a full conversion to DSM-level psychotic illness, and one-third will improve over time, some to the level of full recovery. These results indicate that although early signs and symptoms, including prodromal psychotic-like phenomena, can be predictive of conversion to a spectrum of psychotic disorder, they do not indicate the exact type of psychosis, and the long-term outcomes are highly variable, ranging from fully manifested psychotic disorders to full recovery. Given these research outcomes, in DSM-5, a new diagnostic category, “Attenuated psychosis syndrome,” has been introduced. It refers to a broadly defined syndrome characterized by psychotic-like phenomena that are below a threshold for full psychosis, for example, the symptoms that are less severe and more transient and frequently accompanied by a relatively preserved insight. This diagnostic category is appropriate for some (but not all) individuals with prodromal or subthreshold symptoms and calls for a clinician’s judgment on where to draw the line for mild psychotic-like presentations that do not deserve DSM diagnosis and where it is appropriate to introduce this diagnosis.

Psychosis Manifestations as a Component of Personality Disorders

The occurrence of brief psychotic symptoms is common in individuals with personality disorders. Typically, psychotic experiences in these people are triggered by psychological (e.g., change in employment, loss of a relationship) or physiologic (e.g., medical illness) stressors, or substance use, when compensatory mechanisms weaken. Certain types of personality disorders are especially predisposed to psychosis, including cluster A and borderline personality disorders. In DSM-5, cluster A personality disorders include paranoid, schizoid, and schizotypal types. These personality disorders are also called *schizophrenia spectrum personality disorders* because their core features resemble symptoms of schizophrenia, albeit in a milder manifestation. In addition, evidence demonstrates the familial aggregation of these personality disorders in biologic relatives of probands with schizophrenia and other psychotic disorders.

Schizotypal Personality Disorder. Schizotypal personality disorder is described under the DSM-5-TR category of “Schizophrenia Spectrum and Other Psychotic Disorders,” emphasizing the long-acknowledged biologic link between this particular cluster A personality disorder and schizophrenia. Schizotypal personality disorder is characterized by cognitive and perceptual distortions, eccentric behavior, as well as a persistent pattern of social and interpersonal deficits. Mild psychotic symptoms, such as magical thinking, perceptual alterations, bizarre rituals, ideas of reference, paranoid ideation, derealization/depersonalization, idiosyncratic speech, and odd or eccentric behavior, are core features of schizotypal personality disorder. In response to stress, schizotypal individuals may decompensate and display frank psychotic symptoms (e.g., hallucinations, delusions, disorganization of thought process, and behavior); however, these episodes are generally brief and fragmentary. Usually, these psychotic symptoms are insufficient in duration and/or severity to draw an additional diagnosis of a psychotic disorder. Nevertheless, in some cases, clinically significant psychotic symptoms may develop that ultimately meet the criteria for brief psychotic disorder, schizophreniform disorder, delusional disorder, or evolve into schizophrenia. In these cases, a schizotypal personality disorder may be indicated in the diagnosis as a premorbid personality disorder, in parallel with a diagnosis of psychotic illness.

Evidence from research demonstrates that among cluster A personality disorders, schizotypy is most intimately related to schizophrenia and other psychoses. There is a higher density of schizotypal personality disorder cases in the biologic relatives of schizophrenia probands than in controls. Although schizotypal personality disorder occurs in 0.3% to 3% of the general population, studies have reported rates of 0.8% to 4.7% in the biologic relatives of psychotic patients. Recent genome-wide studies in schizophrenia and schizotypal personality disorder, conducted with a large sample of high-density schizophrenia families, have suggested that at least a subset of candidate schizophrenia susceptibility genes is also involved in the etiology of schizotypy in nonpsychotic relatives of schizophrenic probands.

In the large epidemiologic study called the Roscommon Family Study, which collected 534 probands with psychotic and affective disorders and 2,043 of their biologic relatives, schizotypal personality disorder showed a strong familial relationship not only with schizophrenia but also with the

other major psychotic disorders. Further factor analysis from this research sample showed that schizotypy is a complex, multidimensional clinical construct whose various dimensions differ widely in the specificity with which they reflect the familial liability to psychosis. In this study, seven schizotypal dimensions were described, among which subpsychotic thought disorder, negative schizotypal signs, such as poor rapport and odd behavior, deficient occupational functioning, and social isolation/avoidance best disambiguated relatives of schizophrenic probands from relatives of matched controls. Different studies reported that the disorganization dimension of schizotypy was common to relatives of both schizophrenia and psychotic bipolar disorders but not in the relatives of nonpsychotic bipolar probands. Interestingly, schizotypal disorganization symptoms were suggested as a unique clinical phenotype associated with an increased familial risk for both schizophrenia and affective psychoses. From this perspective, schizotypy represents a subthreshold psychosis phenotype that cuts across the categorical diagnosis of schizophrenia and bipolar disorder.

Paranoid Personality Disorder. The essential feature of paranoid personality disorder is a pattern of long-standing suspiciousness and mistrust of people in general, such that their motives are interpreted as malevolent. Subthreshold psychotic symptoms are not uncommon in persons with paranoid personality disorder, of which ideas of reference and associated verbal and visual illusions are seen most often. Under stressful conditions, specifically in a situation naturally provoking paranoid feelings (e.g., when these patients are being criticized or disagreed with, relocating, or facing a new professional environment), they may decompensate and experience psychotic episodes. Among frank psychotic symptoms, paranoid and persecutory delusions are the most common, although brief visual and auditory hallucinations may also occur.

There is evidence of a genetic association between paranoid personality disorder and psychosis spectrum conditions. For example, in some instances, paranoid personality disorder may appear as the premorbid antecedent of schizophrenia or delusional disorder. An increased incidence of major depressive disorder with psychotic features has also been reported in patients with paranoid personality disorder. There have been few controlled studies of the familial risk of paranoid personality disorder based on direct interviews of relatives blind to

proband's diagnosis. However, there is substantial evidence for a familial relationship between paranoid personality disorder and psychotic disorders, with reports of a higher prevalence of paranoid personality disorder among first-degree relatives of schizophrenic, schizoaffective, and psychotic bipolar probands ranging from 1.7% to 8.6% in different studies (compared to 0.5% to 2.5% in the general population). In contrast to schizotypal personality disorder, paranoid personality disorder is less common in relatives of probands with affective psychoses, although one study reported an increased familial risk of paranoid personality disorder for unipolar depression (2.9%), which was higher than for relatives of schizophrenia patients (1.7%).

Schizoid Personality Disorder. Individuals with schizoid personality disorder are characterized by a pervasive pattern of detachment from social relationships and a restricted range of emotional expressions. This behavioral pattern begins in childhood and is usually clinically obvious by early adulthood, appearing in a variety of contexts. Although subclinical psychotic symptoms are not uncommon in persons with different cluster A personality disorders, individuals with a schizoid personality disorder do not show many unusual perceptual experiences, distorted thinking processes, or bizarre behavioral patterns. Although they appear self-absorbed, detached, and emotionally aloof, they have a normal capacity to recognize reality. On rare occasions, particularly in response to social or interpersonal stressful circumstances, individuals with this disorder may experience very brief psychotic episodes (typically lasting minutes to hours). The content of psychotic symptoms may vary but is usually limited to delusions of reference, paranoid or persecutory delusions, and brief visual and auditory hallucinations relevant to the social or interpersonal stressors.

Although a genetic association between schizoid personality disorder and functional psychoses has been suggested, the data to support this are contradictory. Some studies (e.g., the Roscommon Family Study, B-SNIP) have reported that schizoid personality disorder has significantly increased prevalence in the relatives of individuals with schizophrenia (1.2% to 3.4%), although this association is modest compared to schizotypal personality disorder. In contrast, several studies showed that the rate of schizoid personality disorder among biologic relatives of schizophrenic probands is not any higher than in the general population

(reports vary between 0.3% to 0.7%). Similarly, reports of schizoid personality disorder cosegregated in families with affective psychoses are uncommon. One of the difficulties is that people with isolated schizoid personality disorder are not commonly seen in clinical settings, and the prevalence of this personality disorder in the general population is not clearly established. Schizoid personality disorder may appear as the premorbid precursor of schizophrenia; however, the proportion of patients who eventually convert to schizophrenia is unknown. Schizoid personality disorder most often co-occurs with schizotypal and paranoid personality disorders, as well as with avoidant personality disorders, which have also been reported to be associated with schizophrenia.

Borderline Personality Disorder. The crucial feature of borderline personality disorder is a pervasive pattern of instability of self-image, interpersonal relationships, and affective reactions, as well as marked impulsivity and self-damaging behavior. Borderline personality disorder is clinically perceived as a condition “on the border” of psychotic functioning; therefore, historically, in the psychoanalytic literature, it has been called “ambulatory schizophrenia” (a term introduced by Helene Deutsch) and “psychotic character disorder” (described by John Frosch). Individuals with borderline personality disorder are prone to transient psychotic episodes that occur most frequently during periods of stress, specifically in response to a real or imagined abandonment. In fact, psychotic-like symptoms are included as diagnostic criteria for borderline personality disorder (criterion 9: Transient, stress-related paranoid ideation or severe dissociative symptoms). Other broadly defined psychotic symptoms are also often reported, including ideas of reference, hypnagogic phenomena, and body-image distortions. More severe psychotic symptoms, including frank hallucinations and delusions, occur less frequently. Typically, the symptoms tend to be transient, lasting minutes to hours. However, one study by a Cornell group reported that 27% of the patients with borderline personality disorder had psychotic episodes lasting for weeks which were not attributed to comorbid affective or substance use disorders.

It is noteworthy that in some cases, psychotic symptoms in persons with borderline personality disorder may be of a factitious nature (e.g., Canadian studies report up to 13% of factitious psychotic symptoms in inpatients with borderline personality disorder). Thus a thorough psychiatric history, observation of the patient’s behavior, and objective

information obtained from the family members are crucial. In some cases, the psychotic symptoms of borderline personality disorder respond well to external structuring and situational changes (e.g., the real or perceived return of subjectively valuable person or caregiver may result in the remission of the transient psychosis). However, in more severe cases, antipsychotic medications are warranted.

Borderline personality disorder shows a strong familial pattern. For example, the risk of acquiring borderline personality disorder for first-degree biologic relatives of those with the disorder is about five times greater than in the general population. There is also an increased familial association of borderline personality disorder with mood disorders, antisocial personality disorder, substance-related disorders, and eating disorders. Although considerable co-occurrence of borderline personality disorder with schizotypal personality disorder has been reported, as well as the occurrence of premorbid borderline personality features in persons with schizophrenia, the majority of studies do not support a familial link between borderline personality disorder and schizophrenia. The large-scale epidemiologic studies of schizophrenia-related personality disorders in relatives (e.g., the Roscommon Family Study) reported that borderline personality disorder was rare among first-degree relatives of schizophrenic probands but showed a modest clustering of cases in relatives of patients with psychotic and nonpsychotic affective disorders. Recent findings from a large multisite consortium in biomarkers of psychosis, B-SNIP, demonstrated that 1.3% of first-degree relatives of schizophrenia patients met rigorous DSM-IV-TR criteria for borderline personality disorder, whereas 4.1% and 3.2% of relatives of patients with schizoaffective disorder and psychotic bipolar I disorder, respectively, met such criteria. Family studies of borderline personality disorder have also indicated increased rates of mood disorders in the relatives of borderline probands compared with healthy controls. Recent studies have suggested that borderline personality disorder and bipolar disorder may exist on a spectrum and, perhaps, share partially overlapping pathogenesis and may be rooted in the same genetic etiology, similar to cluster A personality disorders and schizophrenia. However, the question of whether borderline personality disorder is related specifically to psychotic bipolar disorder and to psychosis, in general, remains open. Pilot studies suggest that persons who have borderline personality disorder with a history of psychotic-like symptoms show distinct eye-tracking abnormalities similar to those in

patients with schizophrenia. This may suggest that borderline personality disorder with psychotic symptoms may fall into the psychosis spectrum disorders continuum and share some endophenotypic and genetic markers underlying psychosis. Psychotic-like symptoms and narrowly defined psychosis appears to be a promising target dimension for future research in borderline personality disorder.

In summary, clinical and research evidence suggests that psychosis is best conceived of as a clinical continuum with multiple subtypes and grades of symptoms, similar to hypertension or congestive heart failure. In fact, there appears to be no clear demarcation between frank, clinically significant psychosis and mild psychotic-like symptoms other than severity and duration. Large epidemiologic studies suggest that fleeting psychotic symptoms are common in the general population. The majority of individuals who have these psychotic experiences show no functional impairment and are considered to be free of any formal psychiatric diagnosis. These observations suggest that psychosis can manifest in mild forms long before its manifestation to a clinically significant level. Moreover, many of the individuals with such subthreshold symptoms will remain stable for years without further progression into a full psychosis phenotype. Only a modest proportion of them will convert to a psychotic illness in the future. These “at risk” individuals, while rarely evaluated in psychiatrists’ offices, represent a valuable population for studying proneness to psychosis as well as for exploring propsychotic risk factors and individual resilience against psychosis.

In more severe and persistent presentations, psychotic symptoms appear at the border of formal psychosis diagnosis and manifest in entities like schizophrenia prodrome and cluster A personality disorders, frequently seen in biologic relatives of probands with psychotic illnesses. Although cluster A personality disorders (in particular, schizotypy) are generally thought to be biologically related to schizophrenia, recent family and whole genome linkage studies have shown that schizotypal personality disorder may present a unique phenotype associated with an increased familial risk for psychosis in general, independent of the categorical diagnosis. Similarly, prodromal symptoms, which are classically conceptualized as a phase in the course of schizophrenia, appear to be not unique to schizophrenia psychosis. Instead, they signify a risk for a spectrum of functional psychoses but not the exact diagnosis that will emerge.

From the disease continuum perspective, the final diagnosis of a psychotic disorder is the end point of a longitudinal pathway from asymptomatic, to subthreshold psychotic experiences, to frank but infrequent psychotic symptoms, to the development of persistent psychosis. It is possible that this pathway is based on a dynamic matrix of genetic, gene expression, and epigenetic influences, which are in a complex interplay with environmental factors, with frank psychosis emerging when a critical genetic effects threshold is reached, accompanied by modifying or triggering epigenetic, individual biologic and/or environmental factors. Although subthreshold manifestations of psychosis are considered indicators of proneness to schizophrenia and other functional psychoses, they do not signify an inevitable conversion to psychosis. Whether or not an individual at risk will traverse this pathway may depend on the interaction between propsychotic factors (e.g., individual biologic vulnerability, obstetrical complications, maternal/in-utero immune stimulation, adolescent cannabis use, childhood trauma) and protective resilience factors (e.g., high premorbid functioning, stable social environment).

12.17 Other Psychotic Disorders

Ramin Mojtabai, M.D., Ph.D., M.P.H., Laura J. Fochtmann, M.D., M.B.I., and Evelyn J. Bromet, Ph.D.

This section describes disorders included in the section on other psychotic disorders in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and its text revision (DSM-5-TR). It also describes the 11th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-11) category of acute and transient psychotic disorder. The disorders discussed in this section occur less frequently and are less well understood than schizophrenia or mood disorders with psychotic features. Nevertheless, they can have profound consequences for affected individuals and are important to identify and treat.

ACUTE AND TRANSIENT PSYCHOTIC DISORDER AND BRIEF PSYCHOTIC DISORDER

History

Descriptions of psychotic disorders with an acute onset and transient course have a long history in psychiatry. Along with the classic syndromes of schizophrenia and affective psychoses, Emil Kraepelin (1856–1926) mentioned amentia, a psychotic disorder with a remitting course and favorable outcome, originally described by Theodor Meynert (1833–1898). Similar psychotic syndromes were described by other 19th- and 20th-century European psychiatrists under various terms such as “cycloid psychosis,” “bouffée délirante,” “reactive psychosis,” and others, as briefly described in Table 12.17–1. At the same time, investigators reported a high prevalence of

acute psychotic episodes with a benign course in Africa, the Caribbean islands, and India.

The descriptions of these psychotic syndromes are rather similar, a remarkable observation since these descriptions grew out of different psychiatric traditions separated by cultural and linguistic boundaries. Although all portray a psychotic condition with acute onset and remitting course, the multiplicity of descriptions and labels has been a major impediment to better understanding and classifying these psychoses. In recent years, attempts have been made to surpass this barrier by defining a syndrome based on the common features of the traditional descriptions. In this context, an important step was the introduction of the acute and transient psychotic disorder in ICD-10 and its successor, the ICD-11. Many of these cases would be classified under the category of brief psychotic disorder in DSM-5-TR. Some would be categorized under schizophreniform and other schizophrenia spectrum disorders, as well as other psychotic disorders in the DSM-5-TR.

The historical roots of the DSM-5-TR diagnosis of brief psychotic disorder and the ICD-11 diagnosis of acute and transient psychotic disorder can be found in European psychiatry. The Scandinavian concept of reactive or psychogenic psychosis was especially influential in the formulation of the DSM-III brief reactive psychosis diagnosis, which was the forerunner of the DSM-5-TR brief psychotic disorder. Brief reactive psychosis was defined as a psychotic condition lasting less than 2 weeks that followed a significant psychosocial stressor, involved emotional turmoil, and was manifested by loosening of associations, delusions, hallucinations, or disorganized or catatonic behavior. This diagnosis was maintained in the DSM-III-R, but the allowable duration of symptoms was extended to 1 month. In DSM-IV and DSM-IV-TR, the diagnosis of brief reactive psychosis was replaced by brief psychotic disorder, eliminating an identifiable psychosocial stressor as a diagnostic criterion. The change was partly motivated by the observation that many cases of brief psychosis are not precipitated by a marked stressor and hence cannot be labeled as “reactive.” Furthermore, the DSM-III and DSM-III-R criterion of emotional turmoil was removed

from the DSM-IV and DSM-IV-TR criteria for brief psychotic disorder. The aim of these revisions in later editions of the DSM was to broaden the scope of the diagnosis of brief psychotic disorder. Nonetheless, DSM-IV and DSM-IV-TR distinguished between brief psychotic disorder with and without marked stressors and indicated that the former group is equivalent to the brief reactive psychosis. There were few changes in the definition and characterization of brief psychotic disorder between the DSM-IV-TR and the DSM-5. The DSM-5 requires that one of the criteria be the presence of delusions, hallucinations, or disorganized speech. The DSM-5 also includes a “with catatonia” specifier and ratings of the current severity of symptoms on a scale ranging from not present to present and severe.

Comparative Nosology

Acute and transient psychotic disorder is defined by ICD-11 as a psychotic disorder characterized by acute onset of psychotic symptoms without a prodrome. The symptoms reach their maximum severity within 2 weeks and commonly last from a few days to 1 month but not more than 3 months. In addition to delusions, hallucinations, and disorganized thoughts, perplexity or confusion may also be present, as well as disturbances of mood. Furthermore, in some cases, catatonia-like psychomotor disturbances may be present. The symptoms and their severity typically change rapidly from day to day or even within a day. Brief psychotic disorder is defined by DSM-5-TR as a psychotic condition that involves the onset of psychotic symptoms that last 1 day or more but less than 1 month. Remission is full, and patients return to their premorbid level of functioning. Thus, most individuals diagnosed with brief psychotic disorder under DSM-5-TR would be classified as having acute and transient psychotic disorder under ICD-11.

There is no specific section for acute and transient psychotic disorder in the DSM-5-TR. As a result, patients who meet these ICD-11 criteria are classified under a number of different diagnostic categories in the DSM-5-TR. The large majority would meet the

DSM-5-TR criteria for brief psychotic disorder, schizophreniform disorder or other specified schizophrenia spectrum, and other psychotic disorder, although the actual proportion receiving each diagnosis varies considerably across studies. In a study from Germany, 62% of patients with ICD-10 acute and transient psychotic disorder also met the DSM-IV criteria for brief psychotic disorder, 31% for schizophreniform disorder, and 5% for psychotic disorder not otherwise specified (NOS).

By including a specifier for “with peripartum onset,” DSM-5-TR allows many cases of postpartum psychosis to be categorized under the brief psychotic disorder category. ICD-11, on the other hand, categorizes cases that start within about 6 weeks after delivery under the category of “mental or behavioral disorders associated with pregnancy, childbirth or the puerperium, with psychotic symptoms.” ICD-11 also requires that a diagnosis of a specific mental disorder be additionally assigned if the criteria for that disorder are met.

Table 12.17–1.
Partial Listing of the Classic Descriptions of Acute and Transient Psychotic Disorders

Diagnosis	Publications	Description
Amentia	Meynert T. Amentia, die Verwirrtheit. *Jahrb Psychiatr Neurol*. 1889;9:1.	A psychotic illness with acute onset characterized by confusion and perplexity, agitation, rapidly changing vivid hallucinations and delusions, misidentification phenomena, anxiety and apprehension, first introduced by Theodore Meynert (1833–1898). An association with physical illness and exhaustion was noted in some patients. Full recovery occurs in a few weeks or months. Although somewhat influential at its time, amentia never produced much interest in later years.
Cycloid psychosis	Kleist K. über zykloide, paranoide und epileptoide Psychosen und über die Frage der Degenerations-	A psychotic disorder with acute onset and good prognosis but frequent recurrences, characterized by

psychosen. *Schweizer Arch Neurol Psychiat*. 1928;23:1.

Leonhard K. Cycloid psychoses-endogenous psychoses which are neither schizophrenic nor manic depressive. *J Ment Sci*. 1961;107:632.

Perris C, Brockington IF. Cycloid psychoses and their relation to the major psychoses. In: Perris C, Struwe G, Jansson B, eds. *Biological Psychiatry*. Elsevier; 1981:447.

confusion, mood incongruent delusions, hallucinations, overwhelming anxiety, deep feelings of happiness or ecstasy, motility disturbances of akinetic or hyperkinetic type, a particular concern with death, mood swings, rapid change in symptoms within an episode. Two variants of the disorder were first described by Karl Kleist (1879–1960): confusional insanity characterized by contrasting phases of confused excitement and stupor and motility psychosis characterized by contrasting phases of hyperkinesis and akineses. A third variant, anxiety-elation psychosis was introduced by

		Karl Leonhard (1904–1988). The diagnosis of cycloid psychosis is still used by German, Scandinavian, and other European psychiatrists and was influential for the formulation of acute and transient psychotic disorders in ICD-10. Carlo Perris and Ian Brockington introduced a set of explicit criteria for the diagnosis of cycloid psychosis in 1981.
Bouffée délirante	Magnan V, Legrain M. *Les Dégénérés* (*Etat Mental et Syndromes Episodiques*). Rueff et Cie; 1895. Pull CB, Pull MC, Pichot P. Nosological position of schizoaffective psychoses in France. *Psychiatr Clin*. 1983;16:141.	A psychotic disorder with acute onset in a person without previous psychiatric history. The episode remits completely with no residual symptoms. The episodes are characterized by delusions, hallucinations, depersonalization and derealization, confusion, mood

change, and changing symptoms during the course of episode. Episodes are not due to organic or substance use. The syndrome was introduced by Valentin Magnan (1835–1916) and Paul-Maurice Legrain (1860–1939) in 1895 and was said to be caused by degeneration, a 19th-century view that attributed mental illness to the spread of modern civilization and urban life. Although this etiologic formulation is no longer accepted, the diagnosis is still used by French-speaking clinicians in Europe, West Africa, and the Caribbean. The concept of bouffée délirante was influential in formulating the ICD-

		10 acute and transient psychotic disorders. Due to its common occurrence in Africa and the Caribbean, it is also categorized as a culture-bound syndrome in the DSM-IV-TR. Charles Pull and colleagues proposed a set of explicit diagnostic criteria for bouffée délirante in 1983.
Psychogenic or reactive psychosis	Wimmer A. *Psykogene Sindssygdomsformer*. St. Hans Hospitals Jubilæumsskrift; 1916.	A psychotic disorder with acute onset following external stress. Compared to schizophrenia, the onset is more likely to be acute and to be later in life. Premorbid adjustment tends to be better than in schizophrenia. There are more affective and confusional symptoms and less bizarre symptoms, and there is less family history of

		schizophrenia. Prognosis is better than schizophrenia. Diagnoses of psychogenic or reactive psychoses were popular among Scandinavian psychiatrists in the early part of the 20th century and continued to be used throughout the past century but found limited use outside of these countries.
Schizophreniform psychosis or disorder	Langfeldt G. *The Schizophreniform States.* Ejnar Munksgaard; 1939. American Psychiatric Association. *Diagnostic and Statistical Manual*. 3rd ed. American Psychiatric Press; 1980.	The Norwegian psychiatrist Gabriel Langfeldt (1937–1966) introduced the concept of schizophreniform psychosis as a condition with a good outcome that had a sudden onset following an identifiable precipitating factor in an individual with well-adjusted premorbid personality. Patients

		often present with disturbance of mood and clouding of consciousness. The term, but not the concept, was adopted by the DSM-III as a nonaffective psychotic syndrome with schizophrenic symptoms, which is distinguished from schizophrenia by a duration of less than 6 months. The concept of schizophreniform disorder in the latter sense was perpetuated in the later editions of the DSM.
Oneirophrenia	Meduna LJ. *Oneirophrenia: The Confusional State*. University of Illinois Press; 1950.	Ladislas von Meduna (1896–1964) described oneirophrenia in 1939 as a syndrome characterized by acute onset of confusion, nightmare, or dream-like quality of all perceptions (hence the term

		“oneirophrenia”), extreme fear and anxiety, delusions, and visual hallucinations. The prognosis is generally good with full recovery. Meduna proposed an endocrinologic explanation for the syndrome.
Hysterical psychosis	Hollander MH, Hirsch SJ. Hysterical psychosis. *Am J Psychiatry*. 1964;120:1066.	Although the term hysterical psychoses had been in use since the early 20th century, Marc Hollander and Steven Hirsch presented the first formal description of the syndrome in 1964. These authors described a psychotic episode with sudden and dramatic onset related to a profoundly upsetting event in the context of a “hysterical” personality. Symptoms include hallucinations,

	delusions, depersonalization, and disorganized behavior. The episode seldom lasts longer than 1–3 weeks.

Epidemiology

Acute and transient psychotic disorder is rare, especially in industrialized countries. As a result, data on its incidence or prevalence are limited. Much of the current knowledge of this disorder has come from clinical samples, but the brief duration of this condition means that many individuals with acute and transient psychotic disorder will never come to the attention of mental health services. Additional information about the epidemiology of this condition derives from international studies in developing and industrialized countries in the 1980s and 1990s. For example, a first-episode psychosis study from Nottingham, England, estimated the incidence rate of cases that remained diagnostically stable for 3 years to be 1.36 per 100,000 (0.74 per 100,000 for men and 1.99 for women). Another epidemiologic study reported a substantially higher incidence in developing countries compared with industrialized countries. These psychoses comprised 35% of all first-contact nonaffective psychoses in developing countries compared to only 6% in industrialized countries. The age of onset was also younger (the mid-20s) in developing than industrialized (mid-20s to 30s) countries.

Brief psychotic disorder is perhaps even less common than acute and transient psychotic disorder, although, as noted, the two disorders overlap considerably. In a sample of over 1,000 patients with nonorganic psychotic or major affective disorder hospitalized in Germany, individuals with brief psychotic disorder comprised only 2.5% of the cases. Similarly, in the Suffolk County, New York, first-admission cohort, a primary diagnosis of brief psychotic disorder was

found in only 2% of the cohort sample. The incidence may be higher in first-onset samples compared to first-admission samples because some of these cases may remit before clinical attention is sought. A study of U.S. Air Force recruits during basic training reported a 6-week incidence rate of 1.43 cases of DSM-III-R brief reactive psychosis per 100,000 recruits. However, this number may be an overestimate of general population rates because basic training is a particularly stressful period.

Similar to acute and transient psychotic disorders, brief psychotic disorder is more common among women than men. Also similar to acute and transient psychotic disorders, the age of onset of brief psychotic disorder in industrialized countries appears to be older than in developing countries.

Etiology

Little is known about the etiology of acute and transient psychotic disorders, and even less is known about brief psychotic disorder. The available evidence for acute and transient psychotic disorders points to both biologic and sociocultural factors, including stress, as underlying risk factors. In one study from India, for example, a history of antecedent fever was reported in 47% of individuals with an acute and transient psychotic disorder. In almost all cases, the fever was of high grade, requiring medical attention or hospitalization. In all patients, the fever had resolved before the onset of psychotic symptoms, making it unlikely that the psychosis was the direct consequence of an acute infection. Similar reports from other low-income country settings and classic European psychiatric literature also note high rates of febrile illness prior to the development of acute and transient psychotic disorders, which may, in part, explain the higher incidence of these disorders in low-income countries where infectious diseases are more common than in high-income countries. A more recent study from India identified elevated levels of proinflammatory markers in a group of patients with acute and transient psychotic disorder compared with healthy controls.

Information on the biochemical, physiologic, and anatomical correlates of these disorders is limited, and the available data do not reveal any distinctive abnormalities that would suggest a specific etiology. A recent MRI study from Hungary identified reductions in the volume of the caudal/rostral middle frontal cortex and superior frontal cortex in patients with brief psychotic disorder compared to controls. These abnormalities were more pronounced in patients with multiple lifetime episodes. Researchers from Japan have noted hypothalamic–pituitary axis abnormalities in subsets of female patients with recurrent atypical psychoses who are more likely to experience episodes at the time of menstruation and parturition; however, the relevance of these findings to other patients with acute and transient psychotic disorders is unclear. Most available evidence on biologic correlates of these conditions is based on work involving patients with cycloid psychosis, which overlaps with ICD-11 acute transient psychotic disorder and DSM-5-TR brief psychotic disorder. Auditory evoked potential studies in patients with cycloid psychosis recorded P300 peaks over the left hemisphere, similar to normal controls, but patients with cycloid psychosis had a higher P300 amplitude than normal controls, suggesting a higher level of arousal. This finding is consistent with a regional cerebral blood flow study of cycloid psychosis that recorded increased hemispheric blood flow during the psychotic episode that was directly related to symptom severity and that returned to a normal level after remission.

No genetic studies and few family studies of ICD-11 acute and transient psychotic disorders or DSM-5-TR brief psychotic disorder have been conducted. A study from India reported a higher risk of acute transient psychotic disorder and a lower risk of schizophrenia and mood disorders in the first-degree relatives of probands compared with schizophrenia probands. Similar results were obtained in family studies of cycloid psychosis and reactive psychosis in other settings.

The high incidence rate of acute and transient psychotic disorder in low-income countries has also led to speculations about the role of sociocultural factors in the etiology of these syndromes. It has been suggested that rapid cultural change and modernization in low-

income countries expose individuals to loss of status and stress arising from role confusion, making individuals vulnerable to psychotic reactions.

Acute stress (within about 2 weeks of onset of psychosis) was noted by ICD-10 as a feature of illness in some individuals with acute and transient psychotic disorder. However, the actual proportion of patients who experience acute stress in this time frame varies considerably across studies, ranging from 10% to 69%. Assessment of acute stress is also complicated by lack of a clear definition of such stress and the possible impact of recall bias. Furthermore, the stressors likely vary according to social and cultural context. For example, in one study from India, departure from or return to their parental village was a major stressor among women, whereas job-related problems were the main stressor among men. Association with social stressors is not limited to low-income countries and tentative links between the stress-associated social and economic consequences of COVID-19 epidemic and incident cases of brief psychotic disorder have been noted in a case series from Italy.

The specifiers “with” or “without marked stressor(s)” are noted in the DSM-5-TR criteria of brief psychotic disorder. DSM-5-TR also notes that these events “would be markedly stressful to almost anyone in similar circumstances in the individual’s culture.” However, there are few reliable data on the proportion of cases of brief psychotic disorder that are preceded by such stressors.

Clinical lore suggests that pre-existing personality disorders and psychoticism traits are associated with acute and transient psychotic disorder as well as brief psychotic disorder. However, reliable assessment of premorbid personality disorders in patients with psychotic conditions is often difficult and may be affected by recall bias or residual psychotic symptoms. This point was highlighted in a Danish study of acute and transient psychotic disorder in which the majority of patients were diagnosed with a pre-existing personality disorder shortly after recovery from psychosis, whereas a year later, only a minority received such a diagnosis. Similarly, a study from Germany did not find significant differences with regard to premorbid adjustment or the “big five” personality dimensions (neuroticism,

extraversion, openness to experience, agreeableness, and conscientiousness) measured by self-report between patients who had recovered from an acute transient psychotic episode and normal controls.

A psychodynamic formulation of brief reactive psychosis links this condition to deficient ego strength. According to this formulation, psychosis occurs in response to an intense emotionally stressful event that, in the absence of support in the environment, overwhelms the individual's ego defense mechanisms.

Diagnosis and Clinical Features

Acute and Transient Psychotic Disorder. Recognition of acute and transient psychotic disorder early in its course is difficult. In the first few weeks of the illness, there are often few specific indicators that would distinguish acute and transient psychotic disorder from other nonaffective psychotic disorders with acute onset. Furthermore, even in retrospect, it is often difficult to assess the duration of a psychotic episode or distinguish spontaneous remission from remission due to antipsychotic medication treatment. Therefore, a definitive diagnosis of acute and transient psychotic disorder is often only possible retrospectively and when extensive information on the patient's history is available.

Some of the features of acute and transient psychotic disorder in ICD-11 are helpful in differential diagnosis: (a) acute onset of psychotic symptoms that emerge without a prodrome and reach their maximal severity within 2 weeks; (b) presence of perplexity or confusion; and (c) rapid change in the symptoms and their intensity, from day to day, or even within a day (sometimes referred to as "polymorphic symptomatology").

A diagnosis of acute and transient psychotic disorder requires ruling out another medical condition (e.g., a brain tumor) and the effect of a substance or medication on the central nervous system (CNS) (e.g., corticosteroids) or withdrawal from substances (e.g., alcohol withdrawal).

DSM-5-TR Brief Psychotic Disorder. The diagnosis of brief psychotic disorder in DSM-5-TR is based on the presence of one or more of the following psychotic symptoms for a period of at least 1 day but less than 1 month: (1) delusions, (2) hallucinations, (3) thought disorder as evidenced by disorganized speech, and (4) disorganized or catatonic behavior. DSM-5-TR specifies that one of the first three symptoms must be present for the diagnosis to be made. DSM-5-TR criteria for brief psychotic disorder allow for specifiers indicating the presence or absence of a marked stressor or stressors. These are defined as events that would be "markedly stressful to almost anyone in similar circumstances in the individual's culture." The manual does not specify stressors that would qualify as marked stressors, but examples reported in the literature include serious surgery or medical illness, immigration, war and other mass violence, torture, and even intensive training programs such as military training.

Although in some cases the temporal order of stressor and psychotic episode is clear, it is not always easy to determine whether a specific stressor was a precipitant or consequence of the illness. Other sources of information, such as information from spouse or friends about the level of functioning before the onset of episode, as well as history of response to similar stressors in the past, would be helpful in determining the order of events. The DSM-5-TR criteria for brief psychotic disorder also allow for a "with peripartum onset" specifier for episodes starting during pregnancy or within 4 weeks of giving birth. Comorbid catatonia can be identified by a "with catatonia" specifier and the additional diagnostic codes 293.89 (F06.1). Similar to other psychotic disorders in the DSM-5-TR, the current severity of psychotic symptoms can be optionally specified using a 5-point rating scale.

"Emotional turmoil" and "confusion" are not among the diagnostic criteria for brief psychotic disorder in DSM-5-TR. However, they are noted as typical experiences in the text of the manual. The text also notes rapid shifts from one intense affect to another in some individuals. A study of brief reactive psychosis from Swaziland, South Africa, also notes that the clinical presentation in that setting is

characterized more by volatile affect and behavior, altered states of consciousness, and dissociative experiences than by clear-cut psychotic symptoms.

Differential Diagnosis

A definitive diagnosis of acute and transient psychotic disorder or brief psychotic disorder early in the first episode of illness is difficult if not impossible. Unless the psychosis has fully remitted, the duration of an episode of illness cannot be determined. Therefore, during the first few days or weeks of an episode, the diagnosis is usually provisional.

Many aspects of the differential diagnosis of ICD-11 acute and transient psychotic disorders relate to symptom duration. A provisional diagnosis of acute psychotic disorder would be changed to ICD-11 schizophrenia or other psychotic disorders if the illness lasts more than 3 months.

Similar considerations apply to DSM-5-TR brief psychotic disorder, in which the duration of an episode is defined as less than 1 month. If the duration of illness (from prodrome through recovery) exceeds 1 month, the diagnosis would need to change depending on other symptoms and the duration of the illness. A remission of psychotic symptoms within 1 month as a result of successful treatment also makes it difficult to distinguish brief psychotic disorder from other longer-lasting disorders. In such instances, the presence of continued residual symptoms or impairment may be helpful in ruling out a diagnosis of brief psychotic disorder. In many cases, however, only the long-term course of illness can resolve diagnostic uncertainties.

Perhaps the most critical differential diagnostic issue for both acute and transient psychotic disorder and brief psychotic disorder is to rule out delirium, psychotic disorder due to another medical condition, substance/medication-induced psychotic disorder, and drug or alcohol intoxication or withdrawal. Careful physical and laboratory examination is often indicated. Toxicologic screens and imaging studies may also be necessary. A positive drug or alcohol

screen does not necessarily rule out a diagnosis of acute and transient psychotic disorder or brief psychotic disorder. Some patients with acute and transient psychotic disorder or brief psychotic disorder may use substances in an attempt to ameliorate their symptoms. The temporal relationship between onset of psychosis and the pattern of substance abuse may be helpful in determining if a psychotic disorder is substance or medication induced. Symptoms that persist for many days after all traces of the substance are eliminated from blood and urine would support a diagnosis of acute and transient psychotic disorder or brief psychotic disorder.

Both ICD-11 acute and transient psychotic disorder and DSM-5-TR brief psychotic disorder may be associated with confusion and perplexity, making it difficult to distinguish these disorders from delirium or medical causes of psychosis. Diurnal variation in consciousness, which is a characteristic of delirium, may also be confused with variable “polymorphic” psychotic symptoms seen in acute and transient psychotic disorder. However, compared with delirium, changes in consciousness in acute and transient psychotic disorder are generally less severe and less persistent. Furthermore, a medical cause of delirium can often be identified through history, physical examination, laboratory tests, or imaging studies.

Acute psychotic episodes have been reported in a number of medical conditions, including head trauma, cerebral anoxia, epilepsy, and endocrine disorders such as hyper- or hypothyroidism. Many of these episodes are associated with disturbances of consciousness. Differential diagnosis is often based on a thorough medical history and physical examination as well as laboratory investigations.

Good prognosis of brief psychotic disorder and of acute and transient psychotic disorder, variability of symptoms, and the presence of mood symptoms sometimes make it difficult to differentiate these diagnoses from mood disorders. The presence of a full-mood syndrome that meets the criteria for a manic or a depressive episode excludes a diagnosis of brief psychotic disorder.

Patients with personality disorders, especially borderline personality disorder, sometimes experience psychotic symptoms under stressful life circumstances. These symptoms are generally

transient and do not require a separate diagnosis. If the symptoms last more than 1 day, an additional diagnosis of brief psychotic disorder may be warranted.

Finally, a number of “culture-bound” syndromes with acute onset of psychotic and dissociative symptoms have been described in various cultural settings. Many of these syndromes are transient and resolve spontaneously without antipsychotic medication treatment. The nosologic relationship of these conditions to acute and transient psychotic disorders or brief psychotic disorder remains unresolved.

Course and Prognosis

Acute and transient psychotic disorder has a favorable early course by definition. Full remission within 3 months is a diagnostic criterion for this disorder in the ICD-11. Although there are few first-admission studies that allow for reliable assessment of course and outcome, the available evidence indicates that most of the recovered patients remain well in ensuing years, and even among those who experience further episodes, these episodes are transient, and the outcome is generally favorable. ICD-11 includes specifiers for “first episode” and “multiple episodes.” Recurrence rates of 39% to 47% have been reported in first-admission samples followed for 3 to 4 years, but full recovery between episodes is common. Only about 6% to 18% of patients have any residual symptoms at a later point in time, although some studies have shown that the duration of nonaffective psychoses with acute onset and remitting course may extend up to 6 months. A 12-year follow-up study from India also reported favorable long-term outcomes. There is a paucity of data on the long-term course and outcome of acute and transient psychotic disorders in industrialized countries. In a prospective study from Latvia, 40% of a group of first-admission patients with a diagnosis of acute and transient psychotic disorder were readmitted in a 26-month follow-up.

A number of studies from various countries have assessed the diagnostic stability of the ICD-10 acute and transient psychotic disorders. In studies from India, Denmark, Spain, and Latvia,

between 27% and 48% of patients had a different diagnosis 1 to 3 years after their index episodes. Some studies have found that diagnostic stability was associated with the patients' clinical features. Polymorphic symptoms are associated with greater stability of diagnosis; whereas, presence of schizophrenia symptoms was associated with change of diagnosis at follow-up. The diagnostic stability of an acute and transient psychotic disorder may also vary according to the patient's gender. In a British study, the diagnoses of acute and transient psychotic disorder remained unchanged in 73% of women but only 14% of men at 3-year follow-up. Most changes were in the schizophrenia or mood disorder categories.

Brief psychotic disorder also has a benign early course by definition. Full remission within 1 month is a DSM-5-TR criterion for this diagnosis. Some individuals, however, experience relapses. In a study of consecutive admissions for psychosis in Germany, 83% of the patients initially diagnosed with brief psychotic disorder maintained this diagnosis when re-evaluated 2 years later, and 70% experienced relapses during the 2-year follow-up. Because changes in diagnosis are more likely to occur in the early course of psychotic conditions and the German study used cross-sectional diagnosis at the time of follow-up, the rates of diagnostic change and of relapse would likely be higher than in a first-admission or first-episode sample. Nevertheless, the social functioning of these individuals was much better than individuals with schizophrenia; over 90% were living independently, and over half were employed.

Several other studies have also examined the stability of the brief psychotic disorder diagnosis. In a prospective epidemiologic study of a first-admission cohort from Suffolk County, New York, only 27% of those receiving a consensus research diagnosis of brief psychotic disorder at 6-month follow-up maintained this diagnosis when re-evaluated at the 24-month follow-up, with 9% rediagnosed with schizophreniform disorder and 18% with psychotic disorder NOS, a residual diagnostic category in DSM-IV. The remaining individuals were rediagnosed with mood disorders (27%), schizophrenia (9%), or other conditions (9%). A Brazilian study of first-episode patients admitted to an emergency psychiatric unit also found that only about

23% of patients with a clinical discharge diagnosis of brief psychotic disorder maintained this diagnosis 1 year later. These findings suggest that assessment of the prognosis of brief psychotic disorder is confounded by the diagnostic instability of the disorder.

SCHIZOPHRENIFORM DISORDER

History

The concept of schizophreniform disorder was introduced in 1939 by the Norwegian psychiatrist Gabriel Langfeldt. He divided a group of patients who had initial symptom profiles consistent with schizophrenia into two groups based on their subsequent course. One group had a poor course and was referred to as "typical schizophrenia," whereas the "schizophreniform" group had a sudden onset, associated mood symptoms, and clouding of consciousness with a more benign course.

Forty years later, schizophreniform disorder was officially included in the DSM-III in the section on psychotic disorders not elsewhere classified. However, the term was used to describe patients with a different set of characteristics from those identified by Langfeldt. In fact, when the charts of 55 of Langfeldt's original patients diagnosed with schizophreniform psychosis were re-evaluated, most patients met the DSM-III-R criteria for a mood disorder. In contrast, DSM-III described a condition that was identical to schizophrenia except with regard to its duration, with the prodromal, active, and residual phases of schizophreniform disorder lasting more than 2 weeks but less than 6 months.

DSM-III-R added the requirement that a patient given a diagnosis of schizophreniform disorder should not meet the criteria for brief reactive psychosis (i.e., the duration of symptoms should not be less than a month). In addition, the presence or absence of a series of good prognostic features was added as a specifier in order to more closely approximate Langfeldt's original conception of the disorder. DSM-III-R also dropped the criterion B of schizophrenia (impairment in functioning) from the diagnostic criteria of schizophreniform

disorder and noted that the diagnosis should be made provisionally if recovery had not yet occurred. Additional changes in the diagnostic criteria for schizophreniform disorder reflect changes to the underlying diagnostic criteria for schizophrenia between DSM-III and DSM-III-R (i.e., differences in the specific psychotic symptoms needed to establish a diagnosis, removal of the requirement for an age of onset of fewer than 45 years). In DSM-IV and DSM-IV-TR, the diagnostic criteria for schizophreniform disorder were maintained with little change. DSM-5 introduced a few changes consistent with changes in the A criterion for schizophrenia and specifiers added to virtually all psychotic disorder diagnoses. In addition, in keeping with the other psychotic disorder diagnoses, the DSM-5 diagnosis for schizophreniform disorder allows for a "with catatonia" specifier and ratings of current severity of symptoms.

The A criterion for schizophrenia in DSM-5 removed the higher weight given in prior editions of DSM to bizarre delusions, auditory hallucinations keeping up a running commentary on the person's behavior or thoughts, and auditory hallucinations of two or more voices conversing with each other. In DSM-III-R, DSM-IV, and DSM-IV-TR, presence of one of these symptoms was enough to meet the A criterion requirement; whereas, at least two symptoms were required for diagnosis if none of these highly weighted symptoms were present. In contrast, the DSM-5 gives equal weight to symptoms included under the A criterion. However, it requires that one of the symptoms be a delusion, hallucination, or disorganized speech.

Comparative Nosology

The nosology of schizophreniform disorder and, in particular, its relationship to the schizophrenia diagnosis has changed little in successive editions of the DSM. Similar to previous editions of the DSM, in DSM-5-TR, schizophreniform disorder is conceptualized as a variant of schizophrenia (Table 12.17–2). Thus, the first criterion specifically requires that a patient meet the A criterion for schizophrenia. The criteria further specify the minimum and

maximum duration at least 1 month but less than 6 months, that the patient does not meet criteria for schizoaffective or mood disorder with psychotic features, and that the disorder is not due to the physiologic effects of a substance or another medical condition. With a similar constellation of symptoms but a duration of less than 1 month, a diagnosis of brief psychotic disorder would be made. If the duration of illness extended beyond 6 months and there is associated functional impairment, a diagnosis of schizophrenia would be warranted.

A comparable category of schizophreniform disorder does not exist in ICD-11. However, the duration of schizophrenia in ICD-11 is 1 month or longer. As such, many cases of DSM-5 schizophreniform disorder will be classified as schizophrenia in ICD-11.

Table 12.17–2.
DSM-5 Diagnostic Criteria for Schizophreniform Disorder

Diagnostic Criteria

295.40 (F20.81)

A. Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be (1), (2), or (3):
   1. Delusions.
   2. Hallucinations.
   3. Disorganized speech (e.g., frequent derailment or incoherence).
   4. Grossly disorganized or catatonic behavior.
   5. Negative symptoms (i.e., diminished emotional expression or avolition).

B. An episode of the disorder lasts at least 1 month but less than 6 months. When the diagnosis must be made without waiting for recovery, it should be qualified as “provisional.”

C. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms, or (2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.

D. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, and a medication) or another medical condition.

Specify if:

With good prognostic features: This specifier requires the presence of at least two of the following features: onset of prominent psychotic symptoms within 4 weeks of the first noticeable change in usual behavior or functioning, confusion or perplexity, good premorbid social and occupational functioning, and absence of blunted or flat affect.

Without good prognostic features: This specifier is applied if two or more of the above features have not been present.

Specify if:

With catatonia (refer to the criteria for catatonia associated with another mental disorder, pp. 119–120, for definition).

Coding note: Use additional code 293.89 (F06.1) catatonia associated with schizophreniform disorder to indicate the presence of the comorbid catatonia.

Specify current severity:

Severity is rated by a quantitative assessment of the primary symptoms of psychosis, including delusions, hallucinations, disorganized speech, abnormal psychomotor behavior, and negative symptoms. Each of these symptoms may be rated for its current severity (most severe in the last 7 days) on a 5-point scale ranging from 0 (not present) to 4 (present and severe). (See Clinician-Rated Dimensions of Psychosis Symptom Severity in the chapter "Assessment Measures.")

Note: Diagnosis of schizophreniform disorder can be made without using this severity specifier.

Reprinted with permission American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:111, 112.

Epidemiology

Data on the prevalence of schizophreniform disorder are limited. One study of DSM-IV schizophreniform disorder in the Finnish general population found a lifetime prevalence of 0.07% overall with a fivefold greater rate in men than in women. Somewhat higher estimates were noted in a systematic review of the literature, which found a 1-year prevalence of 0.09% and a lifetime prevalence of 0.11%, although a great deal of heterogeneity in the data was observed. In one study from Suffolk County, New York, approximately 5% of patients with a first-admission psychotic disorder met the diagnostic criteria of schizophreniform disorder on admission.

Etiology

The etiology of schizophreniform disorder remains unclear. Studies of risk factors for psychotic illness have typically combined results from individuals with schizophreniform disorder with those from individuals with schizophrenia, making it difficult to delineate risk factors for the development of schizophreniform disorder separate from schizophrenia. The heterogeneity in the course and outcome of schizophreniform disorder further complicates etiologic research. As currently conceptualized, this diagnostic category includes both individuals with schizophrenia in the early course of illness who are given the diagnosis of schizophreniform disorder provisionally and whose diagnosis would switch to schizophrenia in follow-up, as well as individuals with a remitting psychotic illness who would not meet the criteria for schizophrenia in future.

Nevertheless, available research supports the role of genetic factors in the etiology of schizophreniform disorder. One meta-analysis found that rates of schizophrenia and of mood disorder in relatives of schizophreniform probands did not differ from those rates in the relatives of probands with schizophrenia or mood disorders, respectively. A subsequent study showed an excess risk of schizophrenia spectrum illness in relatives of schizophreniform probands but no increase in the risk of mood disorder in family members. However, a third study of patients with schizophreniform disorders with “good prognostic features” showed an increased likelihood of mood disorder in first-degree relatives of probands. Despite this variability in the findings of family studies, there does seem to be an increase in the rates of other psychiatric illnesses among family members of those with schizophreniform disorder, suggesting that genetic factors may be playing a role in some patients.

Studies using brain imaging to look for abnormalities in individuals with schizophreniform disorder have had mixed results. One large study that examined hippocampal and amygdala volumes found no difference between patients with schizophreniform disorder and controls. Studies of ventricular enlargement in patients with schizophreniform disorder have produced mixed results. In one study, left ventricular enlargement was correlated with a progression

of illness to schizophrenia or schizoaffective disorder. Although two studies showed no progressive increases in ventricular size over 2 to 7 years of follow-up for the schizophreniform patient group as a whole, outcomes were poorer in patients with initially enlarged ventricles than in those without ventricular enlargement. A more recent study found that hippocampal volume deficits were related to the prognosis of illness. These deficits were apparent at baseline only among patients whose illness persisted and whose diagnosis was changed to schizophrenia at 2-year follow-up, but not among those whose illness remitted and maintained a diagnosis of schizophreniform disorder.

Diagnostic and Clinical Features

The mode of onset of schizophreniform disorder is similar to that of schizophrenia. Although many patients with schizophreniform disorder may experience functional impairment during an episode, they are unlikely to report a progressive decline in social and occupational functioning. The initial symptom profile is the same as that of schizophrenia in that two or more psychotic symptoms (hallucinations, delusions, disorganized speech, grossly disorganized or catatonic behavior, and negative symptoms) must be present. There is an increased likelihood of emotional turmoil and confusion or perplexity, the presence of which may indicate a good prognosis. Although negative symptoms may be present, they are relatively uncommon in schizophreniform disorder and are considered poor prognostic features. By definition, patients with schizophreniform disorder return to their baseline state within 6 months. Otherwise, the provisional diagnosis of schizophreniform disorder needs to be changed to schizophrenia. In some individuals, schizophreniform disorder is episodic with more than one episode occurring after long periods of full remission.

Differential Diagnosis

It is important to first differentiate schizophreniform disorder from psychoses that can arise from medical conditions or use of

substances. This is accomplished by taking a detailed history and physical examination, and where indicated, performing laboratory tests or imaging studies. Although it is not always possible to distinguish substance-induced psychosis from other psychotic disorders cross-sectionally, a rapid onset of psychotic symptoms in a patient with a significant substance history should raise the suspicion of a substance/medication-induced psychotic disorder. Because individuals with schizophreniform disorder also may have an acute onset of psychotic symptoms, longitudinal assessment is often crucial in distinguishing a substance/medication-induced psychotic disorder from schizophreniform disorder with incidental substance use. A detailed history of medication use, including over-the-counter medications and herbal products, is essential because such therapies may produce an acute psychosis. A substance-use history and toxicologic screen are also important for identifying substance-related psychosis and developing an appropriate treatment plan in an individual with a new onset of psychosis.

The duration of psychotic symptoms is one of the features that distinguishes schizophreniform disorder from other syndromes. Schizophrenia is diagnosed if the duration of illness lasts more than 6 months, whereas symptoms that occur for less than 1 month indicate a brief psychotic disorder. One of the difficulties in making a diagnosis of schizophreniform disorder involves dating the onset of a psychotic episode that evolves insidiously. Without a distinct symptom onset, it becomes difficult to decide whether the illness has actually lasted less than 6 months. In the event that the diagnosis is made before 6 months have elapsed, the diagnosis of schizophreniform disorder is considered provisional. For some patients, prolonged observation will be needed before the duration of symptomatology can be established with certainty, particularly if the patient has received antipsychotic treatment.

It is sometimes difficult to distinguish mood disorders with psychotic features from schizophreniform disorder. The acute onset of symptoms may resemble the onset of mood disorder episodes. In addition, mood symptoms such as loss of interest and pleasure may be difficult to distinguish from negative symptoms, avolition, and

anhedonia. A thorough longitudinal history is important in elucidating the diagnosis since the presence of psychotic symptoms exclusively during periods of mood disturbance is an indication of a primary mood disorder.

Course and Prognosis

The course and prognosis of schizophreniform disorder are variable and depend largely on whether the diagnosis remains schizophreniform disorder or whether the provisional diagnosis of schizophreniform disorder changes over the course of longitudinal follow-up. There are conflicting data on the diagnostic stability of schizophreniform disorder. One small study found that all patients in a first-episode cohort who were initially diagnosed with schizophreniform disorder were subsequently diagnosed with schizophrenia or schizoaffective disorder at 2-year follow-up. However, most studies have found that 45% to 75% of patients who receive a diagnosis of schizophreniform disorder will have a subsequent change in diagnosis to schizophrenia or schizoaffective disorder with longitudinal assessment. Evolution of schizophreniform disorder to a mood disorder was less common, occurring in about 5% to 15% of patients in most studies with a maximal rate of 35% in a single study. Based on data from one study, greater rates of progression to a mood disorder may be seen in individuals with schizophreniform disorder who have good prognostic features. Only about 20% to 40% of patients maintained the diagnosis of schizophreniform disorder over follow-up periods of several years. With longer periods of follow-up, the proportion of individuals who retain the diagnosis of schizophreniform disorder is even smaller. In the Suffolk County, New York, first-admission sample, less than 5% of those who initially received a diagnosis of schizophreniform disorder retained that diagnosis at the time of the 10-year follow-up assessment. These findings underscore the importance of regarding the diagnosis of schizophreniform disorder as provisional when it is made cross-sectionally.

For individuals whose diagnosis remains schizophreniform disorder after longitudinal follow-up, the illness course is usually benign. In general, these patients will have met criteria for “good prognostic features” upon first presentation.

Individuals classified as “without good prognostic features” often have a course that resembles that of patients initially diagnosed with schizophrenia. For many of these patients, their diagnosis indeed changes to schizophrenia over time.

DELUSIONAL DISORDER

History

Delusional disorders, which were once referred to as paranoid disorders or paranoia, have been recognized since the time of the ancient Greeks. In the early 19th century, Johann Heinroth and later Jean Esquirol described a disorder that influenced the intellect in which irrational ideas and actions appeared to develop through plausible and logical reasoning. In 1863, Karl Kahlbaum, who referred to the syndrome as “diastrephia,” made the important observation that personality is preserved during the course of the illness. Late in the 19th century, Valentin Magnan described a chronic systematized delusional disorder in which delusional ideas were well circumscribed and highly structured.

Kraepelin described paranoia as a third form of psychosis, distinct from both schizophrenia and mood disorder and consisting of chronic, nonbizarre, well-systematized delusions without the typical deterioration of dementia praecox. He noted that “One invariably observes the insidious development of a permanent unshakable delusional system from inner causes in which clarity and order of thinking, willing and action are completely preserved.” In the sixth edition of his textbook, Kraepelin also introduced the concept of paranoia in the older adults, which would later be termed paraphrenia.

The distinction between paranoid disorder and paranoid schizophrenia was maintained by Eugen Bleuler. However, Kurt

Kolle reassessed Kraepelin's patients at a later time and showed that their pattern of deterioration was similar to that of patients with dementia praecox. This view was expressed in DSM-II in which paranoid states were regarded as possible variants of schizophrenia.

Beginning with the third edition, the DSM adopted the Kraepelinian concept of paranoia as consisting of nonbizarre delusions without prominent hallucinations. DSM-III-R changed the name of the disorder to delusional disorder for clarity and to encompass other types of delusion in addition to persecutory delusions. The DSM-IV and DSM-IV-TR also acknowledged that delusions may show varying levels of conviction and that delusional beliefs may be partially responsive to evidence or reason. The major change between DSM-5 and prior editions of the DSM in the definition of delusional disorder is the removal of the requirement that the delusions be nonbizarre. Furthermore, in DSM-5, a specifier for delusions "with bizarre content" was added if the delusions are clearly implausible, not understandable, and not derived from ordinary life experiences. The example of bizarre delusion provided in the manual is the delusional belief that the person's internal organs have been replaced with someone else's organs without leaving any wounds or scars. The DSM-5 further added course specifiers and current severity specifiers to the criteria (Table 12.17–3).

Comparative Nosology

In the DSM-5-TR criteria for delusional disorder, the emphasis is on the presence of one or more delusions lasting for more than a month, in the absence of other criterion A symptoms of schizophrenia. Hallucinations, if present, are not prominent and are related to the content of delusions.

The ICD-11 description of delusional disorder is similar to the DSM-5-TR description except that the minimum duration is 3 months.

Notwithstanding these differences, delusional disorder is typically chronic in nature, and both systems of classification will most likely

include similar patients. Similar to DSM-5-TR, the ICD-11 allows for the presence of transient and nonprominent perceptual disturbances, including hallucinations, illusions, and misidentifications of persons that are thematically related to the delusional content.

Epidemiology

Studies of the epidemiology of delusional disorders have been difficult to conduct because the condition occurs infrequently. However, in a general population study from Finland, the lifetime prevalence of DSM-IV delusional disorder was 0.18%. In clinical studies, individuals with delusional disorder represent from 1% to 4% of psychiatric admissions. The persecutory type is the most common type of delusional disorder. Other than the jealous type that appears to be more common in men, delusional disorders appear to be equally common in the two genders.

Etiology

The etiology of delusional disorder is not known and its infrequent occurrence limits the ability to examine genetic or other risk factors. However, small family studies have failed to identify strong genetic links between delusional disorder and schizophrenia. Abnormalities in grey matter volume and cortical surface have been noted in a number of imaging studies. Interestingly, the specific patterns of these deficits appear to vary according to the content of delusions. For example, lower gray matter volume in thalamic, striatal (putamen), insular, and medial prefrontal brain regions were found in delusional parasitosis (a form of somatic delusion); whereas, patients with nonsomatic delusional disorder showed lower gray matter volume in temporal cortical regions.

Table 12.17–3.
DSM-5 Diagnostic Criteria for Delusional Disorder

Diagnostic Criteria

297.1 (F22)

1. The presence of one (or more) delusions with a duration of 1 month or longer.
2. Criterion A for schizophrenia has never been met.

   Note: Hallucinations, if present, are not prominent and are related to the delusional theme (e.g., the sensation of being infested with insects associated with delusions of infestation).
3. Apart from the impact of the delusion(s) or its ramifications, functioning is not markedly impaired, and behavior is not obviously bizarre or odd.
4. If manic or major depressive episodes have occurred, these have been brief relative to the duration of the delusional periods.
5. The disturbance is not attributable to the physiological effects of a substance or another medical condition and is not better explained by another mental disorder, such as body dysmorphic disorder or obsessive–compulsive disorder.

Specify whether:

Erotomanic type: This subtype applies when the central theme of the delusion is that another person is in love with the individual.

Grandiose type: This subtype applies when the central theme of the delusion is the conviction of having some great (but unrecognized) talent or insight or having made some important discovery.

Jealous type: This subtype applies when the central theme of the individual's delusion is that his or her spouse or lover is unfaithful.

Persecutory type: This subtype applies when the central theme of the delusion involves the individual's belief that he or she is being conspired against, cheated, spied on, followed, poisoned or drugged, maliciously maligned, harassed, or obstructed in the pursuit of long-term goals.

Somatic type: This subtype applies when the central theme of the delusion involves bodily functions or sensations.

Mixed type: This subtype applies when no one delusional theme predominates.

Unspecified type: This subtype applies when the dominant delusional belief cannot be clearly determined or is not described in the specific types (e.g., referential delusions without a prominent persecutory or grandiose component).

Specify if:

With bizarre content: Delusions are deemed bizarre if they are clearly implausible, not understandable, and not derived from ordinary life experiences (e.g., an individual's belief that a stranger has removed his or her internal organs and replaced them with someone else's organs without leaving any wounds or scars).

Specify if:

The following course specifiers are only to be used after a 1-year duration of the disorder:

First episode, currently in acute episode: First manifestation of the disorder meeting the defining diagnostic symptom and time criteria. An *acute episode* is a time period in which the symptom criteria are fulfilled.

First episode, currently in partial remission: *Partial remission* is a time period during which an improvement after a previous episode is maintained and in which the defining criteria of the disorder are only partially fulfilled.

First episode, currently in full remission: *Full remission* is a period of time after a previous episode during which no disorder-specific symptoms are present.

Multiple episodes, currently in acute episode

Multiple episodes, currently in partial remission

Multiple episodes, currently in full remission

Continuous: Symptoms fulfilling the diagnostic symptom criteria of the disorder are remaining for the majority of the

illness course, with subthreshold symptom periods being very brief relative to the overall course.

Unspecified

Specify current severity:

Severity is rated by a quantitative assessment of the primary symptoms of psychosis, including delusions, hallucinations, disorganized speech, abnormal psychomotor behavior, and negative symptoms. Each of these symptoms may be rated for its current severity (most severe in the last 7 days) on a 5-point scale ranging from 0 (not present) to 4 (present and severe). (See Clinician-Rated Dimensions of Psychosis Symptom Severity in the chapter "Assessment Measures.")

Note: Diagnosis of delusional disorder can be made without using this severity specifier.

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:104–106.

Psychodynamic theories hypothesize that persecutory delusions, such as those found in delusional disorder, are a protective psychological response to stresses or conflicts that represent a profound threat to the self (e.g., fear of the unknown and adjustment to immigration). In responding to the threat, there is an affective withdrawal from intimate ties and an intense effort to retain the appearance of normalcy through defensive mechanisms such as projection. At its extreme, the paranoid defense fails to relieve anxiety and escalates to a distinct maladaptive state, which is postulated to result in the development of a delusional disorder.

Another theory of the etiology of delusional disorder is based on research by cognitive and experimental psychologists and suggests that persons with persecutory delusions selectively attend to threatening information, jump to conclusions on the basis of insufficient information, attribute negative events to external personal causes, and have difficulty in envisaging others' intention and

motivations. Preferential recall of threatening episodes has also been postulated as a mechanism for reinforcing the delusional belief.

Diagnostic and Clinical Features

The DSM-5-TR lists five specific subtypes of delusional disorder based on their content: persecutory, jealous, somatic, grandiose, and erotomanic. It also allows for mixed and unspecified types.

Persecutory Type. The persecutory type is the best-recognized type of delusional disorder in which the individual is convinced that they (or someone to whom the person is close) are being malevolently treated or harmed in some way. These persecutory beliefs are often associated with querulousness, irritability, anger, and at times aggressive or even homicidal behavior. The individual may also become preoccupied with formal litigation. In contrast to the persecutory delusions of schizophrenia, the delusions in delusional disorder are systematized and coherent. With the exception of impairments related to the delusion itself, social functioning is not compromised. In some of these individuals, the demarcation between normality, pathologic behavior, overvalued ideas, and delusion may not be very clear.

Jealous Type. Feelings of jealousy can fall on a continuum from normal jealousy to pathologic jealousy and to jealousy that is delusional in nature, with the thresholds for abnormal jealousy being, in part, socially determined.

The most common delusion of jealousy is the belief that one's spouse or partner is unfaithful. In some instances, some degree of infidelity may actually be occurring, yet the magnitude of the jealous response and the "evidence" accumulated to support accusations of unfaithfulness may take on a delusional quality. Jealousy is dangerous, for it not only evokes anger but also arms jealous individuals with a sense of righteous indignation to justify their acts of aggression. Jealousy focuses primarily on the partner and can sometimes lead the partner or others to be harmed or even murdered.

Erotomanic Type. In the erotomanic type of delusional disorder, which has also been referred to as De Clerambault syndrome or *psychose passionelle*, the patient has the delusional conviction that another person, usually of higher status, is in love with them. Patients will generally describe the love object as having fallen in love with them first and as having made the first advances. Patients also describe elaborate rationalizations when the love object ignores or rejects their contacts and communications. Patients who develop erotomania often tend to be solitary, withdrawn, dependent, and sexually inhibited and have low levels of social or occupational functioning. Symptoms typically have an acute onset and become chronic.

Erotomanic symptoms may also occur in the context of other psychiatric disorders. In fact, the majority of patients with erotomanic symptoms will have a diagnosis other than delusional disorder.

Stalking may be observed in individuals with the erotomanic type of delusional disorder, although most stalkers do not meet the criteria for erotomania. Stalkers most often persecute their targets through unwanted communications that consist of frequent telephone calls, letters, emails, text or social media messages, or mail packages. Typically, stalkers will also follow their target and make unwelcome or intrusive and unexpected appearances in their target's public domain. Along with this pattern of intrusive behavior is an implicit or explicit threat, which leads the stalking target to experience considerable fear. In some circumstances, the violence may escalate until the stalker actually physically attacks the target or individuals associated with the target.

Somatic Type. The somatic type of delusional disorder is the only one of the five specific types that was not included in Kraepelin's original description of paranoia. It is diagnosed when the central themes of the delusional beliefs are of a hypochondriacal or somatic nature. As a result, in the older literature, this type of delusional disorder is sometimes referred to as monosymptomatic hypochondriasis. As with other subtypes of delusional disorder, the patient must have a clear sensorium and the symptoms may not

result from an underlying general medical condition or another psychiatric disorder.

In the somatic type of delusional disorder, the onset of symptoms may be gradual or sudden. In most patients, the illness is unremitting, although the severity of the delusion may fluctuate. Anxiety and hyperalertness also characterize patients with this subtype. Some themes recur, such as concerns about infestation in delusional parasitosis, preoccupation with body features with dysmorphic delusions, and delusional concerns about body odor, which are sometimes referred to as “bromosis.” In delusional parasitosis, tactile sensory phenomena are often linked to the delusional beliefs.

Patients with the somatic type of delusional disorder rarely present for psychiatric evaluation, and when they do, it is usually in the context of a psychiatric consultation. Instead, these patients generally present to a specific medical specialist for evaluation. Thus, these individuals are more often encountered by dermatologists, plastic surgeons, urologists, and other medical specialists, including dentists.

Grandiose Type. The grandiose type of delusional disorder was included in Kraepelin’s original description of paranoia. However, it is relatively rare to encounter a patient who has grandiose delusions alone without associated symptoms of mania that would suggest a diagnosis of bipolar disorder with psychotic features, or other psychotic symptoms that would indicate a diagnosis of schizophrenia. The content of delusions in some other delusional disorder types may include elements of grandiosity. For example, an individual with a persecutory delusion may attribute the persecution to their own special qualities. However, these grandiose elements are rarely elaborated into a full-blown delusion.

Mixed Type. The mixed type of delusional disorder includes individuals who exhibit more than one of the preceding types simultaneously. These delusions may be bizarre in nature. Of note, under DSM-IV-TR, the presence of a bizarre delusion would have

satisfied criterion A for schizophrenia or schizophreniform disorder and ruled out a diagnosis of delusional disorder. However, under DSM-5-TR, at least two of the criterion A symptoms need to be met for a diagnosis of schizophrenia or schizophreniform disorder, and delusional disorder can be diagnosed even if the delusions are bizarre.

Unspecified Type. Although the preceding themes are the most common themes observed among individuals with delusional disorder, other delusions may occur as well. One example is the Cotard syndrome, in which individuals report that they have lost all of their possessions and status as well as their entire being and even their internal organs. Other examples include the misidentification syndromes such as the Fregoli syndrome, in which strangers are misidentified as a single persecutor wearing different disguises, and the Capgras syndrome, in which the individual believes that their family members or other familiar people have been replaced by identical-looking imposters. Individuals experiencing misidentification delusions may act violently toward the presumed imposter, believing that the imposter is doing harm to the individual or a loved one.

Differential Diagnosis

The first step in the clinical assessment is establishing whether a delusion exists. Some statements that initially seem to be delusional may, in fact, be true. In contrast, reports of circumstances that initially seem believable may only be clearly identified as delusions as the symptoms worsen, the delusion becomes less encapsulated, or more information comes to light. At times, having multiple sources of information is helpful in deciding the delusional nature of a belief.

Certain behavioral features such as hypersensitivity, guardedness, evasiveness, secretiveness, litigiousness, overly detailed descriptions, hostility, and humorlessness are characteristic of the delusional patient yet are not pathognomonic. The patient may also be secretive, vague, and not voluntarily provide the clinician with necessary details. At other times, the patient may see no need to

convey information, believing that the interviewer is part of the "conspiracy" and already knowledgeable about its specifics. For example, the patient may view the interview as a staged game where both parties know the hidden meanings behind the overt text. As a result, certain phrases are commonly heard from individuals with persecutory ideas in the context of delusional disorder (e.g., "Don't play games with me," "You know what 'they' have been doing").

Characteristic observations or reports about the patient's behavior (e.g., checking for microphones in persecutory delusions and checking the spouse's clothes in delusions of jealousy) may also lend support to the diagnosis. Even with such observations, it is sometimes difficult to distinguish between a true situation, an overvalued idea, or a delusion. Confabulation may, at times, be difficult to distinguish from delusions, although delusions are usually more systematized. Often, the inappropriateness of the patient's behavior or emotional response, rather than the simple truth or falsity of the belief, will indicate its delusional nature. Consequently, when evaluating individuals with possible delusional disorder, the most sensible approach is to gather as much data as possible from many sources and then utilize clinical judgment in determining whether a threshold indicating psychopathologic disturbance has been passed.

In making a diagnosis of delusional disorder, the first step is to eliminate general medical conditions as potential causes of delusions. Many general medical conditions may be associated with the development of delusions, and delusion may, at times, accompany a delirious state.

Metabolic conditions and disorders affecting the limbic system and basal ganglia are most often associated with the emergence of delusional beliefs. Complex delusions occur more frequently in patients with subcortical pathology. In Huntington disease and in individuals with idiopathic basal ganglia calcifications, for example, more than 50% of patients demonstrate delusions at some point in their illness. Anosognosia (i.e., nonrecognition of disability) and reduplicative paramnesia (i.e., individuals believing they are in different places at the same time) that accompany right-side cerebral

infarctions may seem like delusional beliefs. Capgras syndrome has been observed in a number of medical disorders, including CNS lesions, vitamin B12 deficiency, hepatic encephalopathy, diabetes, and hypothyroidism. Focal lesions associated with such misidentification delusions have more often involved the right than the left hemisphere. Delusions of infestation, lycanthropy (i.e., the false belief that the patient is an animal, often a wolf or werewolf), and erotomania have been reported in small numbers of patients with epilepsy, CNS lesions, or toxic–metabolic disorders. In such cases, a diagnosis of psychotic disorder due to another medical condition is appropriate.

In dementia syndromes of all types, 15% to 50% of individuals experience delusions. Most of these delusions are simple, although a minority of patients may have complex, well-systematized delusions. Persecutory delusions are particularly common in early dementia and may be the first manifestation of a dementing illness in some individuals.

Once general medical conditions, delirium, and dementia have been eliminated as possible diagnoses, substance use and medications must be explored as possible causes. Among the substances of abuse, amphetamines and cocaine are most likely to result in delusional beliefs, which are typically persecutory in nature. Prescribed substances, over-the-counter medications, and herbal products such as ephedra may also be associated with the development of delusions. Delusional beliefs clearly linked to a substance of abuse or medication are categorized as substance/medication-induced psychotic disorder.

In differentiating delusional disorder from other psychotic disorders, a number of factors need to be taken into consideration. Individuals with schizophrenia will often have hallucinations or disorganized thoughts or behaviors that are not present in delusional disorder. In addition, prominent negative symptoms or deterioration in function from previous premorbid levels would suggest a diagnosis of schizophrenia. Functional impairment in delusional disorder is a consequence of the delusions themselves (e.g., being fired from

work after harassing the boss in the context of an erotomanic delusion).

Mood disorders are also important in the differential diagnosis of delusional disorder. Mood symptoms are highly prevalent in delusional disorders. Symptoms of depression may seem to be an understandable response to the perceived delusional experiences (e.g., feeling overwhelmed and demoralized over “harassment” by neighbors or coworkers). In addition, given the prevalence of mood disorders, many individuals who present with a delusional disorder will be found to have had a history of depression. Somatic, grandiose, or persecutory delusions that are similar to those observed in patients with delusional disorder may also be seen in individuals with psychotic mood disorders. In distinguishing mood disorders with psychotic features from delusional disorder, it is therefore important to determine whether a full mood syndrome (manic, depressed, or mixed episode) is present or whether milder mood symptoms that do not meet the criteria for a mood disorder are present. It is also important to consider the temporal pattern of symptom onset and progression, recognizing that the boundaries between mood disorder and delusional disorder will generally become clear over time. If mood disorders have occurred concurrently with the delusions, their duration should have been brief relative to the duration of the delusions.

Perhaps the most difficult in terms of differential diagnosis is differentiating between an overvalued idea, an obsession with a lack of insight, and a delusion. For example, the somatic type of delusional disorder may be easily confused with illness anxiety disorder (hypochondriasis). In illness anxiety disorder, there is a preoccupation with fears or ideas of having a serious disease, and these concerns are based on the person’s misinterpretation of bodily symptoms. In addition, the somatic preoccupation persists despite appropriate medical evaluation and reassurance. Although the patient may be briefly relieved and begin to doubt their ideas of having an illness for a short while after each evaluation, the fear generally emerges again. Although many individuals with illness anxiety disorder have some realization of the excessive nature of

their fears, some individuals may lack insight, which makes differential diagnosis difficult. In most individuals with illness anxiety disorder, however, there is a long pattern of being preoccupied with physical symptoms, and the preoccupations usually involve more than one symptom or organ system. Furthermore, somatic delusions are generally more bizarre than the health concerns in illness anxiety disorder.

In body dysmorphic disorder, there is a preoccupation with a slight or imagined defect in appearance. These individuals may recognize that their view of their appearance is distorted, yet a significant proportion of individuals with body dysmorphic disorder will hold their beliefs with delusional intensity. In these cases, a diagnosis of body dysmorphic disorder, with “absent insight/delusional beliefs” specifier is appropriate.

Similarly, reality testing may be poor in some individuals with obsessive–compulsive disorder (OCD). The DSM-5 diagnosis of OCD requires that the individual must recognize that the obsessions or compulsions are excessive or unreasonable at some time. DSM-5-TR includes a specifier for the degree of insight. In practice, patients show varying degrees of insight into the validity of their beliefs and some individuals do not recognize that their symptoms are unreasonable. If the obsession reaches “delusional proportions,” DSM-5-TR suggests that a diagnosis of OCD with the “absent insight/delusional beliefs” specifier is the appropriate diagnosis.

When persecutory ideas are present and patients are guarded about sharing full details of their delusional beliefs, it may be particularly difficult to differentiate delusional disorder from a paranoid personality disorder. In these cases, the longitudinal history will be important in establishing a diagnosis of a personality disorder and also in determining whether delusions are superimposed on the individual’s premorbid personality. If a patient met the criteria for a paranoid personality disorder prior to the onset of psychosis and continues to meet these criteria after the psychosis has subsided, such individuals would be given a diagnosis of delusional disorder as well as a diagnosis of paranoid personality disorder.

Course and Prognosis

The course of delusional disorder has been difficult to study for a number of reasons, including the relatively low prevalence, the unstable nature of the diagnosis, and the tendency for patients with delusional disorder to avoid treatment by medical professionals in general and by psychiatrists in particular. The age of onset of delusional disorder is generally in the mid- to late-30s, with the vast majority of individuals having an insidious onset of symptoms. In addition, delusional disorder is generally associated with less deterioration in functioning over time than schizophrenia or schizoaffective disorder. Although the specific delusions may persist and remain fixed, they are generally stable. Functioning tends to be preserved and negative outcomes from the disorder typically occur when individuals are unable to refrain from acting on their delusional beliefs. The impact of age of onset on the course is unclear, with some studies showing a more favorable prognosis with earlier age of onset and others showing no effect of age of onset on course. In some studies, the presence of precipitating factors has been associated with better outcomes, along with female sex and being married. The presence of co-occurring diagnoses, particularly depression, may be an additional factor that negatively influences the course of the disorder.

SCHIZOAFFECTIVE DISORDER

History

Kraepelin divided the psychoses into dementia praecox characterized by progressive deterioration and manic-depressive illness characterized by a remitting course; however, his rich clinical examples included many patients with features of both disorders. In the early 20th century, Lange, Bowman, and Dunton also described intermittent forms of dementia praecox that presented with periods of excitement or depression along with gradual deterioration in functioning. Bleuler believed that the existence of mood and

schizophrenic symptoms during the same episode did not alter the diagnosis of schizophrenia and pointed out the need for prolonged observation to correctly differentiate schizophrenia from manic-depressive psychosis.

Jacob Kasanin, in a 1933 paper, was the first to coin the term schizoaffective psychosis to identify patients with characteristics of both schizophrenia and mood disorders. He based his observation on a distinct subgroup of nine young patients with good premorbid functioning, a sudden onset of both schizophrenic and mood symptoms, and good outcome. However, a review of his detailed case histories shows that all of these individuals could have been diagnosed as having a mood disorder with psychotic features under the DSM classification.

DSM-I described a schizoaffective type of schizophrenia reaction diagnosed in individuals “showing significant admixtures of schizophrenic and affective reactions.” The manual also noted that “The mental content may be predominantly schizophrenic, with pronounced elation or depression. Cases may show predominantly affective changes with schizophrenic-like thinking or bizarre behavior.” However, the long-term course of these individuals was said to be “basically schizophrenic in nature.” DSM-II maintained the diagnosis of schizophrenia, schizoaffective type, and further divided the category into excited and depressed subtypes.

Under DSM-III, disorders involving full affective syndromes with schizophrenia-like symptoms were classified as mood disorders with mood-incongruent psychotic symptoms. As long as the schizophrenic symptoms occurred at the same time as the mood disturbance, the patient was considered to have a mood disorder. The DSM-III relegated schizoaffective disorder to the psychotic disorders not elsewhere classified, reserved for cases that did not clearly meet the diagnostic criteria for schizophrenia or mood disorders. In the DSM-III-R, schizoaffective disorder became more clearly defined with the specification that “there have been delusions or hallucinations for at least 2 weeks, but no prominent mood symptoms” and that “the duration of all episodes of a mood syndrome has not been brief relative to the total duration of the

psychotic disturbance." DSM-IV and DSM-IV-TR incorporated the stricter time frame of 1-month duration of schizophrenia symptoms (as part of criterion A). DSM-5 and DSM-5-TR further elaborated on the duration of mood symptoms by requiring that the symptoms for a major mood episode should be present for the majority of the total duration of the active and residual portions of the illness.

Comparative Nosology

Both the DSM-5-TR and ICD-11 criteria for schizoaffective disorder require that there be a period of concurrent psychosis and disturbance of mood (Table 12.17–4).

DSM-5-TR specifically requires "An uninterrupted period of illness during which there is a major mood episode (major depressive or manic) concurrent with Criterion A of Schizophrenia."

ICD-11 similarly requires that "diagnostic requirements of schizophrenia and a manic, mixed, or moderate or severe depressive episode are met within the same episode of illness, either simultaneously or within a few days of each other." However, DSM-5-TR requires a period of at least 2 weeks during the lifetime duration of illness in which delusions or hallucinations occur in the absence of a major mood episode. In addition, DSM-5-TR requires that "Symptoms that meet criteria for a mood episode are present for the majority of the total duration of the active and residual portions of the illness." In contrast, ICD-11 requires that mood and psychotic symptoms both be a prominent part of the clinical picture.

DSM-5-TR schizoaffective disorder is further divided into two subtypes based on whether or not manic episodes are present with or without major depressive episodes (bipolar type) or the mood episodes are limited to the major depressive episodes (depressive type).

Epidemiology

Few studies have examined the prevalence of schizoaffective disorder in general population samples. A general population study

in Finland using DSM-IV criteria found a lifetime rate of schizoaffective disorder of 0.32%.

Table 12.17–4.
DSM-5 Diagnostic Criteria for Schizoaffective Disorder

Diagnostic Criteria

1. An uninterrupted period of illness during which there is a major mood episode (major depressive or manic) concurrent with Criterion A of schizophrenia.

   Note: The major depressive episode must include Criterion A1: Depressed mood.
2. Delusions or hallucinations for 2 or more weeks in the absence of a major mood episode (depressive or manic) during the lifetime duration of the illness.
3. Symptoms that meet criteria for a major mood episode are present for the majority of the total duration of the active and residual portions of the illness.
4. The disturbance is not attributable to the effects of a substance (e.g., a drug of abuse and a medication) or another medical condition.

Specify whether:

295.70 (F25.0) Bipolar type: This subtype applies if a manic episode is part of the presentation. Major depressive episodes may also occur.

295.70 (F25.1) Depressive type: This subtype applies if only major depressive episodes are part of the presentation.

Specify if:

With catatonia (refer to the criteria for catatonia associated with another mental disorder, pp. 119–120, for definition).

Coding note: Use additional code 293.89 (F06.1) catatonia associated with schizoaffective disorder to indicate the presence of the comorbid catatonia.

Specify if:

The following course specifiers are only to be used after a 1-year duration of the disorder and if they are not in contradiction to the diagnostic course criteria.

First episode, currently in acute episode: First manifestation of the disorder meeting the defining diagnostic symptom and

time criteria. An *acute episode* is a time period in which the symptom criteria are fulfilled.

First episode, currently in partial remission: *Partial remission* is a time period during which an improvement after a previous episode is maintained and in which the defining criteria of the disorder are only partially fulfilled.

First episode, currently in full remission: *Full remission* is a period of time after a previous episode during which no disorder-specific symptoms are present.

Multiple episodes, currently in acute episode: Multiple episodes may be determined after a minimum of two episodes (i.e., after a first episode, a remission and a minimum of one relapse).

Multiple episodes, currently in partial remission

Multiple episodes, currently in full remission

Continuous: Symptoms fulfilling the diagnostic symptom criteria of the disorder are remaining for the majority of the illness course, with subthreshold symptom periods being very brief relative to the overall course.

Unspecified

Specify current severity:

Severity is rated by a quantitative assessment of the primary symptoms of psychosis, including delusions, hallucinations, disorganized speech, abnormal psychomotor behavior, and negative symptoms. Each of these symptoms may be rated for its current severity (most severe in the last 7 days) on a 5-point scale ranging from 0 (not present) to 4 (present and severe). (See Clinician-Rated Dimensions of Psychosis Symptom Severity in the chapter “Assessment Measures.”)

Note: Diagnosis of schizoaffective disorder can be made without using this severity specifier.

Note: For additional information on Development and Course (age-related factors). Risk and Prognostic Factors (environmental risk factors), Culture-Related Diagnostic Issues, and Gender-Related Diagnostic Issues, see the corresponding sections in schizophrenia, bipolar I and II

disorders, and major depressive disorder in their respective chapters.

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:121, 122.

Gender differences in the rates of schizoaffective disorder in clinical samples generally parallel gender differences seen in mood disorders, with approximately equal numbers of men and women who have the bipolar subtype and a more than twofold female-to-male predominance among individuals with the depressed subtype of schizoaffective disorder. Individuals with schizoaffective disorder are more likely to be married or employed than individuals with schizophrenia but less likely than those with bipolar disorder. Other sociodemographic risk factors have not been well studied.

Etiology

In etiologic research, analyses have typically combined individuals with schizoaffective disorder and those with schizophrenia into a single category. As a result, little is known about the distinctive etiologic factors associated with schizoaffective disorder. However, genetic factors may play a role because relatives of probands with schizoaffective disorder have higher rates of mood disorder than relatives of probands with schizophrenia and higher rates of schizophrenia than relatives of probands with a mood disorder. Studies of the *disrupted-in-schizophrenia 1* (*DISC1*) gene, located on chromosome 1q42, suggest its possible involvement in schizoaffective disorder as well as schizophrenia and bipolar disorder.

Diagnostic and Clinical Features

According to the DSM-5-TR, a diagnosis of schizoaffective disorder is based on the presence of both criteria A for schizophrenia (i.e., delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and negative symptoms) and presence of

concurrent symptoms meeting the criteria for a depressive or a manic episode. To distinguish depressive symptoms from negative symptoms of schizophrenia, the DSM-5-TR criteria for schizoaffective disorder, depressed type, emphasize that the A1 criterion of a major depressive episode must be fulfilled (i.e., the presence of “depressed mood” and not simply anhedonia and/or loss of interest).

Determining whether an individual fulfills the DSM-5-TR criteria for schizoaffective disorder also requires that the clinician take a detailed temporal history of the onset and cessation of mood and psychotic symptoms. To accomplish this, the patient must be able to clearly distinguish when mood and psychotic symptoms started and stopped. Because retrospective reporting is inherently unreliable and both types of symptoms can begin or end insidiously, this is not always a simple task for either the clinician or the patient. Without sufficient information about the length of psychosis and mood symptoms, it is difficult to know whether the group A criteria (psychotic symptoms of at least 1 month’s duration), the group B criteria (psychotic symptoms in the absence of the mood syndrome), and the group C criteria (mood symptoms occurring for the majority of the total duration of the active and residual portions of the illness) are fully met. It is particularly difficult to make retrospective estimates of the duration of these criteria. In a series of approximately 700 first-admission patients with psychotic features, 6% received a diagnosis of schizoaffective disorder at hospital discharge, but only half of these (3% of the total) met DSM-III-R criteria for schizoaffective disorder upon review by the research psychiatrists. Two years later, only one-third of those initially diagnosed with schizoaffective disorder were again diagnosed with this disorder, one-third were diagnosed with schizophrenia, and another third with an affective disorder. Recent phenomenologic research has failed to support the validity of the 2-week cutoff for duration of psychotic symptoms in the absence of mood episode for distinguishing schizoaffective disorder from other disorders with concurrent mood and psychotic symptoms.

In clinical practice, the diagnosis of schizoaffective disorder is more commonly made than justified by strict application of DSM-5-

TR criteria. Individuals with a chronic longitudinal course of illness and elements of psychosis and mood disturbance are sometimes erroneously classified as cases of schizoaffective disorder, as are some individuals who have psychosis in the absence of mood symptoms and prominent mood episodes but who do not fulfill criteria for mood episodes during a significant portion of the illness. Schizoaffective disorder has also been mistakenly viewed as a compromise between the diagnoses of schizophrenia and mood disorder when the exact diagnosis is unclear.

Differential Diagnosis

A critical step in differential diagnosis is determining whether a substance use disorder or a general medical condition could account for the patient's symptoms. A substance/medication-induced mood or psychotic disorder is diagnosed when there is evidence from the history, physical examination, or laboratory tests indicating that the symptoms are the direct physiologic consequence of a specific substance or medication. A number of prescribed and over-the-counter medications and substances of abuse may produce mood change and psychosis either with chronic use, acute intoxication, or withdrawal. For example, acute or chronic use of alcohol can produce hallucinosis and can also predispose the patient to a depressive state. The chronic use of cannabis may precipitate psychosis and can also lead to an anergic state, which shares many features with depression (amotivational syndrome). Chronic cocaine use may similarly be associated with psychosis as well as changes in mood. Thus, careful screening for general medical conditions and substance misuse is an essential aspect in the differential diagnosis of schizoaffective disorder. Similarly, mood or psychotic disorder due to another medical condition is diagnosed when there is evidence from the history, physical examination, or laboratory tests indicating that the symptoms are the direct consequence of another medical condition. A wide range of medical etiologies including neurologic disorders, infectious diseases, metabolic abnormalities, and

endocrinopathies may result in a combination of psychosis and mood change that may resemble schizoaffective disorder.

In distinguishing between schizoaffective disorder and mood disorder with psychotic features, several elements should be taken into consideration. Many clinicians fail to assess the relative persistence of psychotic and mood symptoms between acute episodes, and others expand the definition of schizoaffective disorder to include chronic psychosis with a few prominent mood symptoms or mood disorders with an acute and severe psychotic presentation. Patients often view depression as more understandable or socially acceptable than psychosis and may retrospectively emphasize the duration of depressive symptoms in their illness. It is also difficult to disentangle negative symptoms from depressive symptoms by history alone. Without a clear history of a euphoric mood, retrospectively assessed manic episodes may be viewed as episodes of acute psychosis associated with agitation or irritability. Thus, it is important to take a thorough history using information from as many informants as possible to delineate whether criteria were met for both a mood episode and for schizophrenia. Obtaining a thorough temporal history can also be useful in distinguishing a mood disorder, typically depression that is superimposed on schizophrenia. Even with a detailed history, the diagnosis of schizoaffective disorder may only become clear over time.

Course and Prognosis

Although the course and prognosis of schizoaffective disorder may vary, the outcome is generally poorer than in mood disorders but somewhat better than schizophrenia. In the Suffolk County, New York, first-admission series, 75% of patients with this disorder did not remit fully over the first 2 years of follow-up, compared to 87% of patients with schizophrenia and 22% and 40% of those with bipolar disorder with psychotic features or major depressive disorder with psychotic features, respectively. Individuals with schizoaffective disorder may also have levels of neurocognitive impairment and

deficits in social and occupational functioning that are greater than those of individuals with bipolar disorder. In one European study, the death rate of schizoaffective disorder due to unnatural causes was comparable to the death rate of bipolar disorder and greater than schizophrenia.

SUBSTANCE/MEDICATION-INDUCED PSYCHOTIC DISORDER

History

Psychotic symptoms in alcoholics and in opioid or hashish intoxication have been known for many years. In the DSM-I, these disorders were introduced under the rubrics of acute or chronic brain syndromes associated with alcohol intoxication, with drug or poison intoxication. However, the DSM-I did not distinguish between psychotic symptoms that occur in the context of delirium and those that occur in clear sensorium. These syndromes continued to be classified under organic brain syndromes in DSM-II. However, the DSM-II also introduced the categories of other alcoholic hallucinosis characterized by accusatory or threatening auditory hallucinations in a state of relatively clear consciousness and alcohol-paranoid state (alcoholic paranoia) that develops in chronic alcoholics and is characterized by excessive jealousy and delusions of infidelity by the spouse. The DSM-IV and DSM-IV-TR combined the organic hallucinosis and delusional syndromes into a single category of substance-induced psychotic disorders in the section on schizophrenia and other psychotic disorders and introduced specifiers for onset during intoxication and onset during withdrawal. This approach to classification of these disorders was maintained in the DSM-5 and DSM-5-TR, although the name of the disorder was changed to substance/medication-induced psychotic disorder.

Diagnostic and Clinical Features

According to the DSM-5-TR, substance/medication-induced psychotic disorder is characterized by the presence of delusions and/or hallucinations that have developed during intoxication or withdrawal from a medication or substance or soon after exposure to it. The substance or medication involved is one that is known to produce psychotic symptoms. Furthermore, the symptoms are not better explained by an independent psychotic disorder, such as schizophrenia. DSM-5-TR presents some features of the disorder that could be helpful in the differential diagnosis of an independent psychotic disorder, including psychotic symptoms that preceded substance/medication use, recurrent episodes of the disorder, or symptoms that last for a long period of time (1 month or longer) after withdrawal or intoxication symptoms are resolved, all suggesting an independent psychotic disorder.

Symptoms that occur exclusively during the course of delirium should not be diagnosed as a substance/medication-induced psychotic disorder. Also, in the context of intoxication or withdrawal, a diagnosis of substance/medication-induced psychotic disorder can only be made when the psychotic symptoms predominate the clinical picture and are sufficiently severe to need clinical attention. Specifiers “with onset during intoxication” and “with onset during withdrawal” can be used to signal association with intoxication or withdrawal, respectively, and to indicate that the diagnostic criteria for intoxication or withdrawal are met.

Comparative Nosology

Corresponding diagnoses are included in the ICD-11 under disorders due to each substance separately, including alcohol; cannabis; synthetic cannabinoids; opioids; sedatives, hypnotics, or anxiolytics; cocaine, stimulants including amphetamines, methamphetamine, or methcathinone; synthetic cathinones; hallucinogens; volatile inhalants, 3,4-methylenedioxymethamphetamine (MDMA), and 3,4-methylenedioxyamphetamine (MDA); and dissociative drugs including ketamine and phencyclidine (PCP). In addition, categories are included for psychotic disorder induced by other specified

psychoactive substance, psychotic disorder induced by multiple specified psychoactive substances, and psychotic disorder induced by unknown or unspecified psychoactive substance. Alcohol- and stimulant-induced psychotic disorders include the subcategories with hallucinations, delusions, and mixed psychotic symptoms.

Epidemiology

The prevalence of substance/medication-induced psychotic disorder likely varies according to the distribution of substance and medication use in the population. In the Lundby study, the prevalence of substance-induced psychotic disorders was about six times more common among males than females with a lifetime prevalence of 0.59% in a sample of over 3,500 participants in rural communities in Sweden who were followed over a period of 50 years. In a study of 544 young people presenting with a first-episode psychosis in Australia, 10.3% (N = 56) were diagnosed with a substance-induced psychotic disorder. More than a third (35.6%) of those initially diagnosed with a substance-induced psychosis had a change of diagnosis to a primary schizophrenia spectrum or bipolar disorder after a median of 84 weeks. The prevalence of substance/medication-induced psychotic disorder is expectedly higher among individuals with concurrent psychosis and substance use. In a study of 400 New York City emergency department patients with psychosis in conjunction with substance use, 44% were diagnosed as cases of substance-induced psychotic disorder. When these patients were re-evaluated a year later, 25% of cases initially diagnosed as substance-induced were rediagnosed as cases of psychotic disorders not related to substances.

The substances involved are likely different in different age groups. Substances of abuse may be a more common cause of substance/medication-induced psychotic disorder in the younger age group; whereas medications in the context of treatment for multiple health conditions are a more common cause in the older age group—a distribution that follows the pattern of substance and medication use in these age groups.

Etiology

A broad range of substances have been implicated in cases of substance/medication-induced psychotic disorder. Withdrawal from alcohol, sedative–hypnotics, and anxiolytic drugs has also been associated with psychotic symptoms.

A number of common medication groups are associated with psychotic symptoms, including nonsteroidal anti-inflammatory medications, other over-the-counter medications (e.g., phenylephrine and pseudoephedrine), corticosteroids, gastrointestinal medications, muscle relaxants antihistamines, antihypertensive and cardiovascular medications, antimicrobial medications, and chemotherapeutic agents (e.g., cyclosporine and procarbazine). The list includes medications commonly used in psychiatry and neurology, anticonvulsants, antiparkinsonian medications, and disulfiram. In addition, some toxins commonly used in agriculture or industry have been reported to induce psychotic symptoms, including organophosphate insecticides, carbon monoxide, carbon dioxide, and volatile substances such as fuel or paint.

Diagnostic and Clinical Features

Prominent delusions and/or hallucinations that are judged to be due to the physiologic effects of a substance/medication are the core features of the diagnosis of substance/medication-induced psychotic disorder. The DSM-5-TR states that if reality testing remains intact, meaning that a person experiences a distorted perception but recognizes them as false and does not act on them, the disorder would be diagnosed as substance intoxication or substance withdrawal with the accompanying specifier “with perceptual disturbances.” The manual also notes that the psychotic symptoms are required to have developed during or soon after substance intoxication or withdrawal, as identified by specifiers “with onset during intoxication” and “with onset during withdrawal.” The diagnosis is recorded along with the name of the substance and, in the case of substances of abuse, the presence of a substance

disorder if appropriate (e.g., cocaine-induced psychotic disorder with onset during intoxication, with severe cocaine use disorders).

Differential Diagnosis

A major differential diagnosis is between substance/medication-induced psychosis and an independent psychotic disorder that is not substance induced. The DSM-5-TR provides a few guidelines for differential diagnosis of nonsubstance/medication-induced psychotic disorders, including temporal order of symptom onset, course of psychotic symptoms, and past history. If the psychotic symptoms preceded the onset of the substance/medication use or the symptoms persist for a substantial period of time (e.g., about 1 month) after the acute withdrawal or severe intoxication, then the psychotic symptoms are more likely to be related to a primary psychotic disorder. A history of a recurrent primary psychotic disorder also argues against substance/medication-induced psychosis. Nevertheless, information about the temporal order of symptoms and substance use and past history are not always clear. Furthermore, a past history of psychotic disorder unrelated to substances does not rule out a current diagnosis of substance/medication-induced psychotic disorder.

Specific features of the disorder, such as atypical age of onset (e.g., the first onset of delusions in a person older than 35 years without a known history of a primary psychotic disorder) or the nature of symptoms, may provide some guidance in differentiating substance/medication-induced psychotic disorder from primary psychotic disorders. Certain types of psychotic symptoms and accompanying symptoms are more common with certain substances. For example, the tactile hallucination of bugs crawling under the skin (formication) is more common in cocaine-induced psychosis, whereas cannabis-induced psychotic disorder developing shortly after high-dose cannabis use usually involves persecutory delusions, anxiety, emotional lability, and depersonalization experiences. Alcohol-induced psychotic disorder with hallucinations often presents with auditory hallucinations after prolonged and heavy

use of alcohol. Evidence of substance use from the history and physical examination or laboratory tests for substances that can be detected using such tests may be helpful in solidifying a diagnosis.

Research comparing the characteristics of patients with substance-induced psychosis and patients with primary psychosis and concurrent substance abuse has produced few consistent results. In a study from Australia among patients with first-episode psychosis, those with substance-induced psychosis were more likely to be male, unemployed, and have a comorbid substance use disorder. Patients with substance-induced psychosis were not different from those with primary psychotic disorders with regard to duration of untreated psychosis, severity of psychotic symptoms, time to remission, or rates of relapse. A review of six studies comparing substance-induced psychotic disorders with primary psychotic disorders found that compared to those with primary psychotic disorders, patients with substance-induced psychosis had less family history of psychotic disorders, a greater degree of insight, fewer positive and negative symptoms, more depression (only in cannabis-induced psychotic disorders), and more anxiety.

Assessment of cognitive and mood symptoms is vital for differential diagnosis from delirium and mood disorders. Hallucinations are relatively common in the context of delirium associated with substance intoxication or withdrawal and do not justify a separate diagnosis of substance/medication-induced psychotic disorder. Similarly, delusions in the context of dementia or mild neurocognitive disorder should be coded as major or mild neurocognitive disorder, with behavioral disturbance.

The DSM-5-TR clearly states that if the individual recognizes that the hallucinations are the result of substance or medication use and does not act on them, then these experiences should not count toward a diagnosis of substance/medication-induced psychosis. Some individuals who are intoxicated with stimulants, hallucinogens, or PCP, or withdrawing from alcohol or sedatives may experience altered perceptions that they recognize as such. In these cases, the appropriate diagnoses are substance intoxication or substance withdrawal with perceptual disturbances.

Prolonged use of hallucinogens is sometimes associated with recurrent hallucinations long after stopping the use of these drugs. Reality testing remains intact, and the person is aware that these experiences are related to drug effects. Such “flashbacks” should be diagnosed as hallucinogen-persisting perception disorder.

A difficult differential diagnosis is to separate the effects of medications from the effects of underlying medical or mental disorder for which the medication is prescribed. The clinical history, course of illness, and the nature and course of treatments may provide clues to this differential diagnosis. At times medication substitution or discontinuation may be the only way to definitively establish a causal link between medication use and psychosis. If the disturbance is deemed to be related to both a medical condition and substance/medication use, both diagnoses should be made (e.g., psychotic disorder due to systemic lupus erythematosus and steroid-induced psychotic disorder).

Course and Prognosis

The course and prognosis of substance/medication-induced psychotic disorder is generally favorable, and psychosis typically remits after the removal of the offending agent. However, there have been reports of continuing psychotic symptoms for weeks or months after stopping stimulants, cocaine, or PCP. Treatment with antipsychotic medications may be needed in cases of severe substance/medication-induced psychotic disorder associated with agitation, suicidal/homicidal ideation, or other life-threatening behavior. Hospitalization may be needed for the safety of the patient or others in some of these cases.

PSYCHOTIC DISORDER DUE TO ANOTHER MEDICAL CONDITION

History

An association between mental and physical illness has been noted since antiquity. The concept of “sympathetic insanity” that became popular in the 19th century hypothesized an association in normal and abnormal functioning between all body organs that leads to severe mental illness among individuals with sicknesses in other organs. In DSM-I, these disorders were introduced under the rubric of “acute brain disorders,” which included acute brain disorders associated with infections, trauma, circulatory disturbances, metabolic disturbances, convulsive disorder, and neoplasms. However, the DSM-I did not distinguish between psychotic symptoms that occur in the context of delirium and those that occur in conjunction with clear sensorium. The DSM-III introduced two categories of “organic delusional disorder” and “organic hallucinosis” that presented with psychotic symptoms in the absence of clouding of consciousness, as in delirium. The DSM-IV and DSM-IV-TR combined the two categories into one category of “psychotic disorder due to…[the general medical condition] and introduced specifiers: “with delusions” and “with hallucinations” to identify the predominant symptoms.” This approach to the classification of these disorders was maintained in the DSM-5 and DSM-5-TR.

Comparative Nosology

Corresponding diagnoses are included in the ICD-11 secondary psychotic syndrome under the overall category of “Secondary mental or behavioral syndromes associated with disorders or diseases classified elsewhere.” Similar to DSM-5-TR, the secondary psychotic syndrome in ICD-11 includes specifiers “with hallucinations,” “with delusions,” as well as “with hallucinations and delusions.” The clinician is instructed to code the causing medical condition.

Epidemiology

There are few studies on the population prevalence of “psychotic disorder due to another medical condition.” The prevalence of this disorder likely varies across different communities and, over time, corresponds to the prevalence of the common underlying disorders.

In the Lundby study, the prevalence of psychotic disorders related to a general medical condition did not vary across genders and was 0.76% over the lifetime in a sample of over 3,500 participants in rural communities in Sweden who were followed over a period of 50 years. The prevalence is likely higher in the old age group, reflecting the prevalence of the underlying disorders. The nature of medical disorders giving rise to psychotic symptoms may also change across the lifespan, with epilepsy, head trauma, and autoimmune diseases being more common causes earlier in life and stroke, anoxic events, and cardiovascular diseases more common later in life. There are growing reports of psychotic episodes linked to Covid-19 infection. However, these reports are based on case reports and case series. Possible causal links need to be investigated in future epidemiologic studies.

Etiology

The list of medical conditions associated with psychotic symptoms is quite long, including neurologic conditions (e.g., head trauma, neoplasms, cerebrovascular disease, Huntington disease, multiple sclerosis, epilepsy, visual nerve injury, deafness, migraine, and CNS infections), endocrine disorders (e.g., hyper- and hypothyroidism, hyper- and hypoparathyroidism, hyper- and hypoadrenocorticism), metabolic conditions (e.g., hypoxia, hypercarbia, hypoglycemia), fluid or electrolyte imbalances, hepatic insufficiency, kidney failure, and autoimmune disorders with CNS involvement (e.g., systemic lupus erythematosus, anti-NMDA receptor antibody encephalitis). Among these conditions, endocrine, metabolic, and autoimmune disorders are the most common contributors to psychotic disorder due to another medical condition. Psychotic symptoms are also observed in 2% to 7% of epilepsy patients and are specifically associated with the postictal phase of temporal lobe epilepsy. Table 12.17–5 provides a partial listing of medical conditions associated with psychotic symptoms.

Diagnostic and Clinical Features

The essential feature of psychotic disorder due to another medical condition is the existence of prominent delusions or hallucinations that are judged to be directly caused by another medical condition as evidenced by clinical history, physical examination findings, or laboratory data including neuropsychological testing and imaging studies. The psychotic symptoms are not better explained by another mental disorder, such as a mood disorder with psychotic features or schizophrenia and do not occur only in the course of a delirium. The DSM-5-TR criteria also require that the psychotic symptoms be associated with significant distress or impairment in functioning. The DSM-5-TR allows the clinician to identify the predominant psychotic symptoms by using specifiers “with delusions” or “with hallucinations” and to specify the severity of psychotic symptoms.

Although hallucinations in psychotic disorder due to another medical condition can occur in any sensory modality, certain types of hallucinations are suggestive of specific etiologies. For example, olfactory hallucinations are suggestive of temporal lobe epilepsy. Furthermore, visual hallucinations and hallucinations in more than one sensory modality may be more common in psychotic disorder due to another medical condition than in schizophrenia. Psychotic disorder due to another medical condition is generally not diagnosed if reality testing is preserved and the individual recognizes that the hallucinations result from the medical condition. When delusions are due to another medical condition, they are most commonly persecutory. The association between the content of delusions and particular medical conditions appears to be less specific than is the case for hallucinations.

Table 12.17–5.
A Partial List of Medical Disorders that May Cause a Psychotic Disorder due to Another Medical Condition

Neurodegenerative disorders	Huntington disease, basal ganglia calcification, multiple sclerosis, metachromatic leukodystrophy
Other CNS disorders	Brain tumors, especially temporal lobe and deep hemispheric tumors; epilepsy, especially complex partial seizure disorder; head trauma, anoxic brain injury, migraine
Vascular disease	Atherosclerotic vascular disease, especially when associated with diffuse, temporoparietal, or subcortical lesions; hypertensive encephalopathy; subarachnoid hemorrhage; subdural hematoma; fat embolism
Infectious disease	HIV/AIDS, encephalitis lethargica, Creutzfeldt–Jakob disease, syphilis, malaria, acute viral encephalitis
Metabolic disorder	Hypercalcemia, hyponatremia, hypoglycemia, uremia, hepatic encephalopathy, pancreatic encephalopathy, porphyria
Endocrinopathies	Addison disease, Cushing disease, hyper- or hypothyroidism, hyper or hypoparathyroidism, panhypopituitarism
Vitamin deficiencies	Vitamin B_{12} deficiency, folate deficiency, thiamine deficiency, niacin deficiency
Autoimmune diseases	Systemic lupus erythematosus, temporal arteritis, anti-NMDA receptor antibody encephalitis

AIDS, acquired immunodeficiency syndrome; CNS, central nervous system; HIV, human immunodeficiency virus; NMDA, *N*-methyl-D-aspartate.

Psychotic disorder due to another medical condition is coded in DSM-5-TR by recording the name of the medical condition (e.g., psychotic disorder due to malignant lung neoplasm, with delusions).

Differential Diagnosis

Psychotic disorder due to another medical condition must be distinguished from delirium, which is common in many acute medical conditions and may be associated with hallucinations and delusions. A separate diagnosis of psychotic disorder due to another medical condition is not justified if the psychotic symptoms only occur in the context of delirium. Delusions in the context of a neurocognitive disorder (e.g., dementia) would be diagnosed as a neurocognitive disorder with behavioral disturbance.

Severe medical conditions can be extremely stressful, especially if they lead to serious disability or prolonged hospitalization. Distinguishing between a psychologically mediated brief psychotic disorder with marked stressor and a psychotic disorder due to another medical condition is especially difficult in the absence of other information regarding past history, including information about the course of medical illness and psychosis.

Many patients with medical conditions also use medications. If there is evidence of recent (within 4 weeks) use of medications or substances of abuse, a substance/medication-induced psychotic disorder should be considered as part of the differential diagnosis. If the disturbance is judged to be due to both a medical condition and substance use, both diagnoses (i.e., psychotic disorder due to another medical condition and substance/medication-induced psychotic disorder) can be given.

Psychotic disorder due to another medical condition must be distinguished from other psychotic disorders including schizophrenia, delusional disorder, schizoaffective disorder, and/or mood disorders with psychotic features. The presence of features such as later age at onset or presence of visual or olfactory hallucinations may suggest psychotic disorder due to another medical condition or a substance/medication-induced psychotic disorder.

Course and Outcome

The course and outcome of psychotic disorder due to another medical condition depend on the course and outcome of the underlying medical illness. With appropriate management of the underlying medical disorder, the psychotic symptoms generally remit. Most cases are transient and very rarely do the psychotic symptoms continue after remission of the underlying medical disease.

CATATONIA

History

Catatonia was originally described by the German psychiatrist Karl Kahlbaum in the 1870s as a distinct mental disorder with psychiatric, motor, and behavioral symptoms. Although originally, Kahlbaum considered catatonia to have an overall benign course, reports of chronic catatonia led later psychiatrists, including Kraepelin, to reconsider and view catatonia as a chronic disorder similar to hebephrenia. This view of catatonia contributed to Kraepelin's proposal that catatonia be viewed as a subtype of dementia praecox. While Kraepelin recognized that catatonic symptoms could occur in mood and organic disorders, he distinguished between catatonic dementia praecox and catatonic symptoms occurring in other disorders.

This view of catatonia as a distinct subtype of schizophrenia dominated modern classification systems, including the DSM and ICD. Multiple editions of DSM through DSM-IV-TR and ICD-10 discussed catatonia as a subtype of schizophrenia. DSM-III-R introduced the catatonic features specifier for mood disorders when the clinical picture of a mood disorder episode is dominated by two or more catatonic symptoms. The category of catatonic disorder due to a general medical condition was introduced in DSM-IV. Furthermore, the ICD-10 recognized a category of organic catatonic disorder in addition to catatonic schizophrenia.

In a clear break from the Kraepelinian conception of catatonia as a subtype of schizophrenia, DSM-5 and ICD-11 introduced a separate rubric for catatonia. This change was motivated by evidence regarding the occurrence of catatonia in a number of other psychiatric and medical disorders besides schizophrenia and mood disorders and evidence of the underrecognition of catatonia in current psychiatric practice. DSM-5 and DSM-5-TR recognize three types of catatonia: (1) catatonia associated with another mental disorder, (2) catatonic disorder due to another medical condition, and (3) unspecified catatonia. Similarly, ICD-11 identifies catatonia associated with another mental disorder, catatonia induced by substances or medications, and an unspecified category of catatonia.

Epidemiology

Epidemiologic research on the prevalence, incidence, and correlates of catatonia has been hampered by differences in the definition and method of assessment of catatonia. A review of 20th-century studies found that catatonia was reported in 7% to 17% of patients hospitalized with acute psychotic disorders and 13% to 31% of patients with mood disorders. A more recent review of 74 prevalence studies in clinical samples conducted between 1935 and 2017 reported that catatonia was present in 9% of patients. There is some evidence that the prevalence of the catatonic type of schizophrenia may have declined over the 20th century and that catatonia may be more common in developing countries than in industrialized countries. However, overall, the prevalence of catatonia syndrome does not appear to have changed markedly over time. Catatonia may be seen in individuals of all ages, including children and adolescents. Gender and age distributions of patients with catatonia likely reflect the epidemiology of the underlying disorder.

Etiology

The etiology of catatonia is unknown. The long and growing list of medical conditions associated with catatonia underscores the

potential heterogeneity in the etiology of catatonia. The list includes major neurologic disorders such as epilepsy, encephalitis, and trauma; endocrine disorders including thyroid disease; metabolic disturbances such as uremia and hypercalcemia; paraneoplastic disorders; and autoimmune diseases. Catatonia can also occur in the context of a number of mental disorders, including psychotic and mood disorders, and neurodevelopmental disorders, including autism spectrum disorder.

Imaging studies among patients with hypokinetic catatonia in the context of psychotic disorders indicate increased activity in premotor areas which may be due to corticocortical inhibition or increased activity of inhibitory corticobasal projections. The favorable response of the disorder to GABAergic treatments (e.g., benzodiazepines) points to a role of the GABA system in catatonia. There is also a growing interest in the role of the NMDA receptors in catatonia based on numerous case reports associating anti-NMDA receptor antibody encephalitis with catatonic symptoms.

Diagnostic and Clinical Features

The essential feature of catatonia is a psychomotor disturbance that may involve decreased engagement with the interviewer during clinical interview or physical examination, decreased motor activity, or excessive and peculiar motor activity. The psychomotor disturbance may range from marked unresponsiveness to environmental stimuli (stupor) to marked agitation. In some cases, the individual's symptoms may quickly switch between decreased motor activity and excessive motor activity, making the diagnosis difficult. Some of the peculiar motor and verbal symptoms such as catalepsy (holding a posture induced by the examiner), posturing (active adoption of often awkward postures by the patient), waxy flexibility (slight resistance when the examiner tries to position the patient's body parts), mannerism (odd or caricature-like mimicking of normal actions), grimacing, echolalia, and echopraxia (mimicking another person's speech or behavior) are more pathognomonic and helpful for the diagnosis of a catatonic syndrome. Self-inflicted

injuries and harm to others can also occur, particularly during periods of increased activity.

The DSM-5-TR diagnosis of catatonia requires that the clinical picture be dominated by at least 3 of the 12 characteristic symptoms, including stupor, catalepsy, waxy flexibility, mutism, negativism, posturing, mannerism, stereotypy, agitation, grimacing, echolalia, and echopraxia. The diagnosis of catatonia associated with another medical condition also requires evidence from clinical history, physical examination, or laboratory examinations findings (including imaging studies) that the catatonic symptoms are caused by another medical condition, that they are not better explained by another mental disorder and do not occur exclusively during the course of delirium, and that the symptoms cause significant distress or impairment in social or occupational functioning.

In coding catatonia associated with another mental disorder or medical disorder, the name of the associated mental or medical disorder is recorded first, followed by the specifiers “catatonia associated with…” in the case of mental disorders (e.g., “major depressive disorder; catatonia associated with major depressive disorder”) or “catatonic disorder due to…” in the case of medical conditions (e.g., “hypothyroidism; catatonic disorder due to hypothyroidism”).

The residual category of unspecified catatonia is reserved for situations in which the catatonic symptoms are present and cause clinically significant distress or impairment. However, either the number of symptoms does not reach the minimum required of three symptoms, the underlying medical or mental disorder is not clear, or there is insufficient information regarding the underlying cause (e.g., in the emergency department settings).

Differential Diagnosis

Movement disturbances are common during the course of delirium or neuroleptic malignant syndrome, and a separate diagnosis of catatonic disorder due to another medical condition is not justified in these cases. Catatonia-like symptoms are not uncommon among

patients treated with antipsychotic medication (e.g., neuroleptic-induced acute dystonia). History of recent exposure to medications, especially first-generation antipsychotic medications, may help in distinguishing these diagnostic possibilities. Generalized rigidity is a cardinal feature of neuroleptic malignant syndrome, in which significant increases in creatine kinase levels are common. Autonomic instability and increases in temperature can be seen in individuals with catatonia, but these findings are typically more severe in neuroleptic malignant syndrome and can be potentially life-threatening.

Course and Prognosis

Catatonic symptoms sometimes remit with the management of the underlying psychiatric or medical condition. However, many individuals will also require specific treatment of the catatonic syndrome and early identification of catatonia is essential. Although a rare type of remitting and relapsing catatonia, known as “periodic catatonia” has been described in classic European literature, the majority of cases of catatonia do not have a recurring course.

Catatonic symptoms are especially responsive to treatment with high doses of benzodiazepines and electroconvulsive therapy (ECT), which may be indicated as the main or adjunctive treatment in the acute management of psychiatric patients presenting with severe catatonic symptoms. On the other hand, outcomes may be worsened by use of antipsychotic medications, particularly high-potency first-generation antipsychotic medications. During severe stages of immobility or increased activity, the individual may need careful supervision and intervention to prevent dehydration, malnutrition, exhaustion, hyperpyrexia, aspiration, embolic events, decubiti, or contractures of extremities.

OTHER SPECIFIED SCHIZOPHRENIA SPECTRUM AND OTHER PSYCHOTIC DISORDER AND

UNSPECIFIED SCHIZOPHRENIA SPECTRUM AND OTHER PSYCHOTIC DISORDER

History

The concept of “unspecified psychosis” was introduced in DSM-II but was specifically noted to be “for librarians and statisticians to use in coding incomplete diagnoses” rather than for use by clinicians. However, in DSM-III, the diagnosis of “atypical psychosis” was introduced as “a residual category for cases in which there are psychotic symptoms … that do not meet the criteria for any specific mental disorder.” DSM-III-R changed the name of the diagnosis to psychotic disorder NOS (atypical psychosis) and eliminated mention of the diagnosis as a “residual category.” Instead, it emphasized the use of the diagnosis for “Disorders in which there are psychotic symptoms (delusions, hallucinations, incoherence, marked loosening of associations, catatonic excitement or stupor, or grossly disorganized behavior) that do not meet the criteria for any other nonorganic psychotic disorder.” It also noted that the diagnosis of psychotic disorder NOS was preferable to deferring a diagnosis in individuals for whom there was inadequate information to make a specific diagnosis.

The concept of psychotic disorder NOS persisted in DSM-IV, although the references to atypical psychosis and nonorganic psychotic disorders were dropped. As in prior editions of DSM, there were no specific diagnostic criteria for this category. However, it was now defined as including psychotic symptoms “about which there is inadequate information to make a specific diagnosis or about which there is contradictory information, or disorders with psychotic symptoms that do not meet the criteria for any specific Psychotic Disorder.”

The DSM-5 divided the DSM-IV category of psychotic disorder NOS into two distinct categories of “other specified schizophrenia spectrum and other psychotic disorder” and “unspecified schizophrenia spectrum and other psychotic disorder” to underscore the reason why the disorder could not be classified as one of the

specific schizophrenia spectrum disorders. DSM-5-TR maintained this approach.

While in the other specified schizophrenia spectrum and other psychotic disorders the characteristics of the condition clearly do not meet the criteria for a specific disorder, in the unspecified schizophrenia spectrum and other psychotic disorder there is inadequate information to make a more specific diagnosis. The latter diagnosis may thus be appropriate for acute care and emergency department settings where there is insufficient information available. Similar categories of “other specified primary psychotic disorder” and “schizophrenia or other primary psychotic disorder, unspecified” were included in ICD-11.

DSM-5-TR provided four examples of other specified schizophrenia spectrum and other psychotic disorder: (1) persistent auditory hallucinations, (2) delusions with significant overlapping mood episodes, (3) attenuated psychosis syndrome, and (4) delusional symptoms in a partner of an individual with delusional disorder. The last example, variously called “shared delusional disorder,” “shared psychotic disorder,” “induced psychosis,” and “folie à deux,” was discussed as a specific psychotic disorder in the previous edition of DSM and in ICD-10. The new category of attenuated psychosis syndrome was a new category in the DSM-5, and its introduction was associated with some controversy. These two categories are discussed in some detail later in the chapter.

Epidemiology

There is minimal information about the prevalence of other specified schizophrenia spectrum and other psychotic disorder and unspecified schizophrenia spectrum and other psychotic disorder in the community. In clinical practice, the psychotic disorder NOS diagnosis has been often used in first-admission or emergency psychiatric patients when there is inadequate information to make a diagnosis.

Etiology

Given the heterogeneity of the other specified and unspecified schizophrenia spectrum and other psychotic disorder diagnoses, it is not surprising that there has been minimal investigation into the etiologies of these disorders. However, one family study has examined the occurrence of other psychotic illnesses in relatives of probands with psychotic disorder NOS according to prior editions of the DSM and found a substantially elevated risk of schizophrenia and schizophrenia spectrum disorders in these family members but not mood disorders.

Diagnostic and Clinical Features

The diagnostic category of other specified schizophrenia spectrum and other psychotic disorder includes cases with psychotic symptoms and clinically significant distress or impairment that do not conform to diagnostic criteria for specific schizophrenia spectrum and other psychotic disorders. The specific presentation can be recorded as well. For example, for a patient who presents to the hospital with persistent auditory hallucinations that are not accompanied by mood disturbance and that are not consistent with symptom criteria for schizophrenia or any other DSM-5-TR category, a diagnosis of “other specified schizophrenia spectrum and other psychotic disorder, persistent auditory hallucinations” may be recorded. Other examples include psychotic symptoms that are below the threshold for a full psychotic episode (attenuated psychosis syndrome), delusional beliefs in partners of individuals with a primary delusional disorder, and persistent delusions with periods of overlapping mood symptoms that have been present for a substantial portion of the delusional disturbance.

A diagnosis of unspecified schizophrenia spectrum and other psychotic disorder may be appropriate for a patient presenting with psychotic symptoms causing clinically significant distress or impairment but where information regarding symptoms and history is not sufficient to make a diagnosis of a specific schizophrenia spectrum and other psychotic disorder. For example, the clinician may not be able to determine whether the psychosis is primary, due

to a general medical condition, or the result of a substance or medication use. Such distinctions can be difficult to make, especially when adequate clinical history is not available (e.g., in the emergency department settings).

Differential Diagnosis

Because other specified and unspecified schizophrenia spectrum and other psychotic disorder are diagnoses of exclusion, the differential diagnosis includes other possible diagnoses with psychotic symptoms. Co-occurring substance misuse is one of the most frequent confounding factors in establishing a specific diagnosis, because substance use can be found in more than half of hospitalized patients with psychotic symptoms. Furthermore, the possibility that a general medical condition may be causing the psychotic symptoms must always be kept in mind.

If mood symptoms are present, the differential diagnosis will include major depressive disorder with psychotic features or bipolar disorder with psychotic features, depending on the type of mood change that is present. Schizoaffective disorder is also possible if the temporal requirements for the psychotic symptoms and mood changes are met.

If no mood symptoms are present and substance, medication, and medical disease can be ruled out as causes of psychotic symptoms, the differential diagnosis will include schizophrenia, schizophreniform disorder, brief psychotic disorder, and delusional disorder, depending on the duration and type of psychotic symptoms.

Course and Prognosis

The course and prognosis are highly variable as other specified and unspecified schizophrenia spectrum and other psychotic disorder are heterogeneous. Furthermore, the diagnosis of unspecified schizophrenia spectrum and other psychotic disorder is often a provisional diagnosis by design that would be changed upon gathering more information. In the first-admission study in Suffolk County, New York, 12% of individuals were diagnosed by the

research team with psychotic disorder NOS at the time of their first admission, but only 4.8% received this diagnosis by the 6-month follow-up, and by 24-month follow-up, the rate was 3.9%. Of 25 individuals with a diagnosis of psychotic disorder NOS at 6-month follow-up, only 11 maintained this diagnosis by 24-month follow-up, a stability rate of 44%. Eight of the 25 subjects with psychotic disorder NOS had met the criteria for schizophrenia or schizoaffective disorder.

ATTENUATED PSYCHOSIS SYNDROME

The introduction of the new category of attenuated psychosis syndrome in the DSM-5 was subject to some controversy. While prodromal symptoms of schizophrenia have long been recognized by psychiatric investigators, earlier classifications did not include a specific category for these symptoms. Introduction of these symptoms in the diagnostic system was motivated by efforts over the past two decades to improve early detection of schizophrenia and to implement early treatment with the aim of reducing chronicity and long-term disability often associated with schizophrenia. In recognition of this aim, the category was initially labeled the "psychosis risk syndrome." The name change to attenuated psychosis syndrome was intended to highlight the importance of current symptoms and the associated distress and disability as a focus of clinical attention rather than the future risk of a full-blown psychotic disorder.

The DSM-5-TR provides few guidelines and no discrete criteria for the diagnosis of attenuated psychosis syndrome. The manual mentions symptoms that are of lower severity are more transient or are associated with relatively intact insight as examples of attenuated psychosis syndrome. Although the definition specifies "psychotic-like symptoms that are below a threshold for full psychosis," no cutoffs for the severity or duration of symptoms are given. Like other conditions included under other specified schizophrenia spectrum and other psychotic disorders, attenuated psychosis syndrome is associated with "clinically significant distress

or impairment in social, occupational, or other important areas of functioning."

In a study from Switzerland, prevalence of attenuated psychosis syndrome in adolescents and young adults aged 15 to 40 years was estimated at 0.3%. Attenuated psychotic syndrome is associated with comorbid depressive disorder, suicidality, and functional impairment. The syndrome may be more common in males than females.

Etiology of attenuated psychosis syndrome remains unknown. Genetic risk, such as history of psychotic disorders in first-degree relatives, is a criterion in some alternative definitions of attenuated psychosis risk. Structural imaging studies of attenuated psychosis syndrome cases have produced mixed results. Some functional imaging studies have suggested abnormalities in dopamine and glutamate systems.

The future risk of a full-blown psychotic disorder among individuals with attenuated psychosis syndrome has been a major focus of research. In one meta-analysis of short-term studies, less than 40% developed a full-blown psychotic illness in a 3-year period. However, the risk of transition remained elevated beyond 3 years and was as high as 65% to 79% in a long-term study. In a more recent meta-analysis of 23 cohort studies, the risk of transition was 11% at 6 months, 15% at 12 months, 20% at 24 months, and 23% at 36 months.

There are few guidelines regarding the management of attenuated psychosis. Given that the majority of individuals with attenuated psychosis syndrome would not experience a full-blown psychotic illness in near future, treatment with antipsychotic medication may not be indicated for self-limited symptoms. In many cases, careful assessment and frequent monitoring may be appropriate.

DELUSIONAL SYMPTOMS IN PARTNER OF INDIVIDUAL WITH DELUSIONAL DISORDER

The category of “delusional symptoms in partner of individuals with delusional disorder” was first described in 1860 by Jules Baillarger, who called the syndrome “folie à communiquée,” and again described in 1877 by Charles Lasègue and Jean Pierre Falret who gave the syndrome the commonly used name, “folie à deux.” Over the years, many other names including shared psychotic disorder, shared delusional disorder, and induced psychotic disorder have been used to describe this syndrome in which two individuals with a close and generally long-term relationship share the same delusional belief. Shared paranoid disorder was introduced in DSM-III in the section on paranoid disorders and the persecutory nature of the shared delusions was emphasized. In DSM-III-R and later, DSM-IV and DSM-IV-TR, the content of the shared delusion was broadened to include all types of delusional beliefs. DSM-5-TR included this condition in the category of other specified schizophrenia spectrum and other psychotic disorder. Due to the rarity of cases that present to clinical settings, there is no information about the prevalence of delusional symptoms in the partners of individuals with delusional disorder.

Etiologic theories regarding delusional symptoms in the partner of an individual with delusional disorder are primarily based on family and interpersonal dynamics. In general, individuals who develop a shared delusion will tend to have had a submissive role in the relationship with the partner who was first to develop a delusional disorder. The person who develops the shared delusional symptoms may be particularly impressionable due to personality factors or intellectual limitations. Social isolation, poverty, language difficulties, and geographical isolation may also contribute to the development of the condition. In some cases, the shared delusion may involve more than two individuals and even the entire family unit. Persecutory delusional beliefs are most commonly seen in shared psychotic disorder, comprising about 70% of patients in one study; however, religious, grandiose, and somatic delusions may also be observed. Because of the relative rarity of shared delusional disorder, its clinical course and prognosis are unclear, although some reports of successful treatment are present in the literature.

Mood Disorders

13.1 Mood Disorders: Historical Introduction and Conceptual Overview

ROBERT J. BOLAND, M.D.

CLINICAL AND PUBLIC HEALTH SCOPE OF MOOD DISORDERS

Epidemiology

Research on the epidemiology of depression, both in the United States and worldwide, has considerably broadened our understanding of the disorder. We have discovered that depression is much more common than once thought. It is also one of the more debilitating disorders known to humanity, as it often affects individuals during what should be their most productive years. Hence, the depressive disorders are one of the most costly disorders in society.

Measuring the true incidence of major depressive disorder (MDD) is complicated and highly dependent on the methods used to collect the sample, definitions of the disorder, and the particular instruments used to measure depression. For example, studies that use self-assessment tend to report higher incidences than studies using clinician-rated instruments. The timing of a study likely affects the results as well. As depressive illness become less stigmatized, persons may be more willing to endorse

symptoms of the disorder to the well-meaning strangers who knock at their door, call their phone, or email them and identify themselves as researchers.

In a reasonably recent meta-analysis, which included 90 studies from 30 countries done from 1994 to 2014, with combined data on more than 1 million participants, the point prevalence for depression was 12.9%, the 1-year prevalence was 7.2%, and the lifetime prevalence was 10.8%. There was significant heterogeneity among the different studies.

In the United States, the most recent epidemiologic data is from the National Survey on Drug Use and Health (NSDUH), sponsored by the Substance Abuse and Mental Health Services Administration (SAMHSA). Using a definition of a major depressive episode based on *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), they found the overall 1-year prevalence of a major depressive episode to be 7.1%; hence, very similar to the international data.

Concepts of Mood Disorders

The broader rubric of affective disorder (which subsumes mood and anxiety disorders) has been conceptualized along two influential schools in the European tradition. Aubrey Lewis and his followers from the Maudsley school have promoted a continuum model—from anxiety disorders to mild neurotic depressions to severe endogenous and psychotic depressions. The Newcastle school, led by Martin Roth, has sharply demarcated those conditions from one another. Although vestiges of both approaches are still influential in clinical and basic research, European studies in German-speaking countries that subdivide mood disorders based on polarity now overshadow that approach. That sharp demarcation, in part supported by studies in the United States, has served as the basis for much recent research into the biology, treatment, and classification of mood disorders and is reflected in the fifth edition of the DSM-5 and the tenth revision and eleventh revisions of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10 and 11). Despite such official sanctions, many authorities continue to see considerable continuity between recurrent depressive and bipolar disorders. This inconsistency has led to widespread discussion and debate about the bipolar spectrum (BPS), which incorporates classic bipolar disorder, bipolar II, and recurrent depressions.

Childhood bipolarity, too, is receiving increasing clinical attention, thanks to the seminal work of Elizabeth Weller and colleagues, conducted initially at Ohio State University. In addition, clinical observations at the University of Tennessee on the juvenile offspring of adult patients with bipolar disorder have led to a greater appreciation of the bipolar nature of complex clinical presentations of affective illness in the juvenile offspring and kin of adult bipolar probands. More recent work by Biederman's group at Harvard suggests intriguing links between pediatric bipolar disorder and attention-deficit/hyperactivity disorder (ADHD).

Current concepts of mood disorders in the United States embrace a broad spectrum, including many conditions previously diagnosed as schizophrenia, personality disorder, or neurosis. The diagnostic shift occurred in part as a result of the U.S.–U.K. Diagnostic Project, which demonstrated that we often diagnosed schizophrenia at the expense of mood disorders. The availability of new and effective treatments and the unacceptable risk for tardive dyskinesia and suicide in persons with misdiagnosed mood disorders further broadened the conceptual boundaries. More generally, current research interest in mood disorders in the United States emanated from a landmark 1969 NIMH conference on the psychobiology of affective illnesses. The NIMH Collaborative Depression Study—a long-term prospective project deriving directly from recommendations made at the conference—has legitimatized the broader perspective.

Morbidity and Mortality

Unfortunately, findings published by Martin Keller and colleagues in the 1980s documenting gross undertreatment of mood disorders continue to describe the current treatment landscape worldwide. Whatever changes have occurred in diagnostic practice do not appear to have significantly affected the morbidity and mortality of mood disorders. This depressing news is all the more concerning given that the 1990s saw new classes of user-friendly antidepressant and mood-stabilizing agents, as well as depression-specific psychotherapies. Thus, the state of affairs results, in part, from the fact that clinical exposure to mood disorders in specialized (psychiatric) and primary care training is suboptimal. As highly prevalent and lethal disorders, mood disorders must command a more significant share in the clinical curriculum of both psychiatrists and general medical practitioners. Because most mood disorders are chronic and relapsing,

long-term exposure to patients with these disorders in mood or bipolar clinics should be part of a young doctor's core knowledge. Unfortunately, few academic centers have appropriate clinics for this training, and those with the resources often devote them primarily to research. The primary goal of these clinics is the execution of research protocols rather than the acquisition of clinical experience in caring for such patients.

Nearly half of all cases of depression, just like those with adult-onset diabetes, remain undetected for years or inadequately controlled—both of which seem to lag behind hypertension, in which early detection and treatment have significantly reduced complications such as stroke. Efforts by patient-advocacy organizations—often in concert with national psychiatric organizations and governmental mental health agencies—appear to be increasing public and government awareness of mood disorders. Ultimately, however, the challenge is to provide all primary care physicians with the requisite hands-on experience in this prevalent group of disorders. User-friendly tools to detect suicidal patients in the general medical sector would further enhance preventive efforts. These would require significant changes in health care structure, including, but not limited to, the greater participation of nurses and social workers as liaisons in primary mental health and continuity of care for depressed or suicidal patients.

Because mood disorders underlie 50% to 70% of all suicides, effective treatment of these disorders on a national level should, in principle, drastically reduce this significant complication of mood disorders. That depressed older adult patients, often with medical comorbidity, constitute the highest-risk group for suicide yet escape clinical detection and treatment is particularly problematic for public health. In addition, clinical findings in recurrent mood disorders have shown the value of lithium prophylaxis for preventing suicide and overall mortality. Emerging data suggest that such benefits may accrue from all efficacious treatments for mood disorders. Suicide prevention at the national level, attributed to the widespread use of selective serotonin reuptake inhibitors (SSRIs) and primary care physician education has been achieved in many but not all European countries. Such prevention does not have a tradition in the United States, and, as mentioned earlier, suicide rates have increased in the United States.

DEFINITIONS

Mood disorders encompass many psychiatric disorders in which pathologic moods and related vegetative and psychomotor disturbances dominate the clinical picture. Known in previous editions of DSM as *affective disorders*, we prefer *mood disorders* because it refers to sustained emotional states, not merely to the present emotional state's external (affective) expression. Mood disorders are more syndromes than discrete diseases, with a cluster of signs and symptoms sustained over weeks to months. The symptoms represent a marked departure from a person's habitual functioning and tend to recur, often periodically or cyclically.

Major Depressive Disorder and Bipolar Disorder

MDD (unipolar depression) is the most common mood disorder. It may manifest as a single episode or as recurrent episodes. The course may be somewhat protracted—up to 2 years or longer—in those with the single-episode form. Whereas the prognosis for recovery from an acute episode is good for most patients with MDD, three of four patients experience recurrences throughout life and have varying degrees of residual symptoms between episodes. *Bipolar disorders* (previously called *manic-depressive psychosis*) consist of at least one hypomanic, manic, or mixed episode. *Mixed episodes* represent a simultaneous mixture of depressive and manic or hypomanic manifestations. Although a minority of patients experience only manic episodes, most bipolar disorder patients experience episodes of both polarities. Manias predominate in men, depression, and mixed states in women. Bipolar II disorder, which is not always easily discernible from recurrent MDD, illustrates the need for more research to elucidate the relationship between bipolar disorder and MDD.

The border with schizophrenia continues to be fuzzy. Modern research challenges the Kraepelinian dichotomy between dementia praecox and manic-depressive illness in favor of a spectrum concept that goes beyond mood-incongruent mood episodes and might spill over into "good-prognosis" schizophrenia.

Dysthymia and Cyclothymia

Clinically, major depressive episodes often arise from a low-grade, intermittent, and protracted depressive substrate known as *dysthymic disorder* (called persistent depressive disorder in DSM-5, but the terms

are interchangeable). Likewise, many instances of bipolar disorders, especially ambulatory forms, represent episodes of mood disorder superimposed on a cyclothymic background, which is a biphasic alternating pattern of numerous brief periods of hypomania and numerous brief periods of depression. Dysthymic and cyclothymic disorders represent the two prevalent subthreshold mood conditions roughly corresponding to the basic temperamental dysregulations described by Emil Kraepelin and Ernst Kretschmer as predisposing to affective illness.

It is not always easy to demarcate full-blown syndromal episodes of depression and mania from their subthreshold counterparts commonly observed during the interepisodic periods. The subthreshold conditions appear to be fertile terrain for interpersonal conflicts and postaffective pathologic character developments that may ravage the lives of patients and their families. In North America and some Western European countries, clinicians often label such patients as a *borderline personality disorder*, which, unfortunately, often tends to obscure the affective origin of the presenting psychopathology.

Cyclothymic and dysthymic conditions also exist in the community without progression to full-blown mood episodes. As such, they are best considered, respectively, as trait bipolar and trait depressive conditions. Understanding the factors that mediate the transition from trait to clinical state is essential for preventing manic and major depressive episodes.

A fascinating development related to these temperaments pertains to the “positive” attributes of the depressive and related temperaments in subserving sensitivity to human suffering, thereby playing a role in altruistic behavior. The more tempestuous cyclothymic, based on recent data from different centers, appears to be the temperament involved in poetry, the arts, architecture, and other forms of creative human endeavor. In other words, the “dilute” forms of affective illness may have evolved as traits of fundamental importance for human culture.

Other Subthreshold Mood States

Epidemiologic studies in Europe and North America have also revealed other subsyndromal conditions with depressive and hypomanic manifestations with few symptoms (oligosymptomatic mood states) and short duration (brief episodes). Variously referred to as *minor*, *subsyndromal*, *brief*, or *intermittent*, these descriptions do not merely represent an arbitrary lowering of diagnostic thresholds. However, they

also herald increasing realization of their importance in the early detection of at-risk individuals, as has happened in other medical fields (e.g., diabetes mellitus and essential hypertension). If disabling mood disorders afflict 5% to 8% of the general population (Epidemiologic catchment area [ECA] study), milder but still clinically significant mood disorders would raise lifetime rates to 17% (National Comorbidity Study [NCS]). If we add subclinical mood states, the figure doubles to involve one-third of the general population (as reported, e.g., by Kenneth Kendler and colleagues). New evidence from both Europe and the United States has shown that BPS conditions (bipolar I, bipolar II, and unspecified bipolar disorder in diagnostic manuals such as the DSM-5 and the ICD-10) may account for at least 50% of all mood disorders in the community and psychiatric practice.

Comorbidity in mood disorders involves considerable overlap with anxiety disorders. As summarized in an NIMH monograph, anxiety disorders can occur during an episode of depression, perhaps as a precursor to the depressive episode, and, less commonly, during the future course of a mood disorder. Those findings suggest that at least some depressive disorders share a common diathesis with certain anxiety disorders. More recent clinical experience suggests intriguing comorbidity patterns between bipolar II disorder on one hand and panic, obsessive-compulsive, and social phobic states on the other.

Furthermore, bipolar I and II disorders are particularly likely to be complicated by alcohol, stimulants, or both. In some cases, the alcohol or substance abuse represents attempts at “self-treatment” of the depression and associated anxiety or insomnia (or both) and attempts to maintain or enhance the positive moods in the case of mania and hypomania energy. Finally, physical illness—both systemic and cerebral—occurs in association with depressive disorders with a greater frequency than expected by chance alone. Unless properly treated, such depression negatively affects the prognosis of the physical disorder. More provocatively, there is current reawakening of the contribution of cerebral and cardiovascular factors to the origin of late-onset psychotic depressions (previously classified as *involutional melancholia*).

An integrated framework of pathogenesis is necessary for understanding psychopharmacologic, somatic, and psychotherapeutic approaches in the clinical management of patients with mood disorders. A

historical perspective on current developments is also a valuable lesson in the study of mood disorders.

ANCIENT GREEK AND ROMAN DESCRIPTIONS

The Greeks and Romans described much of our current concepts of mood disorders, and we can trace much of our modern thinking to their descriptions. They coined the terms *melancholia* and *mania* and noted their relation. The ancients also hypothesized a temperamental origin for those disorders.

Melancholia

Hippocrates (460 to 357 BCE) described melancholia ("black bile") as a state of "aversion to food, despondency, sleeplessness, irritability, and restlessness." Thus, in choosing the condition's name, Greek physicians (who likely borrowed the concept from ancient Egyptians) postulated the earliest biochemical formulation of any mental disorder. They believed that the illness often arose from the substrate of the somber, melancholic temperament, which, under the influence of the planet Saturn, made the spleen secrete black bile, ultimately leading to mood darkening through its influence on the brain.

One Hippocratic aphorism recognized the close link between anxiety and depressive states: "Patients with fear or depression of long-standing are subject to melancholia." Hippocrates, who described the first historical case of melancholia, may have also been the first to describe a depressive mixed state, an activated form of depression:

> *A woman of Thasos became morose because of justifiable grief, and although she did not take to her bed, she had insomnia, loss of appetite . . . she complained of fears and talked much; she showed despondency and . . . talked at random and used foul language . . . many intense and continuous pains . . . she leapt up and could not be restrained.* [Hippocrates.]

According to Galen (131 to 210 CE), melancholia manifested in "fear and depression, discontent with life, and hatred of all persons." A few hundred years later, another Roman, Aurelianus, citing the now-lost works of Soranus of Ephesus, amplified the role of aggression in melancholia (and its link to suicide) and described how the illness assumed delusional coloring:

Animosity toward members of the household, sometimes a desire to live and at other times a longing for death, suspicion on the part of the patient that a plot is being hatched against him.

In addition to natural melancholia, which, presumably, arose from an innate predisposition to overproduce the dark humor and led to a more severe form of the malady, ancient medicine recognized such environmental contributions to melancholia as immoderate consumption of wine, perturbations of the soul due to the passions (e.g., love), and disturbed sleep cycles. Autumn was considered the season most disposing to melancholy.

Mania

The ancient Greeks noted a state of raving madness with exalted mood, although it referred to a somewhat broader group of excited psychoses than that in modern nosology. Its relation to melancholia was probably noted as early as the first century BCE, but, according to Aurelianus, Soranus discounted it. Nonetheless, Soranus had observed the coexistence of manic and melancholic features during the same episode, consisting of continual wakefulness and fluctuating states of anger and merriment and, sometimes, of sadness and futility. Thus, Soranus seemed to have described what today are called *mixed episodes.* Natural melancholy was generally considered a chronic disorder, but Soranus noted the tendency for attacks to alternate with periods of remission.

Although others before him hinted at it, many credit Aretaeus of Cappadocia (ca. 150) for making the connection between the two major mood states: “It appears to me that melancholy is the commencement and a part of mania.” He described the cardinal manifestations of mania as it is known today:

There are infinite forms of mania, but the disease is one of them. If mania is associated with joy, the patient may laugh, play, dance night and day, and go to the market crowned as if a victor in some contest of skill. The ideas the patients have are infinite. They believe they are experts in astronomy, philosophy, or poetry.

Aretaeus described the extreme psychotic excitement that could complicate the clinical picture of mania:

The patient may become excitable, suspicious, and irritable; hearing may become sharp . . . [and they might] get noises and buzzing in the ears; or may have visual hallucinations; bad dreams and his sexual desires may get uncontrollable; aroused to

anger, he may become wholly mad and run unrestrainedly, roar aloud; kill his keepers, and lay violent hands upon himself.

Noting the fluctuating nature of symptoms in the affectively ill, Aretaeus commented:

They are prone to change their mind readily; to become base, mean-spirited, illiberal, and in a little time extravagant, munificent, not from any virtue of the soul, but from the changeableness of the disease.

Aretaeus was keenly aware of the characterologic distortions so commonly manifested during the different phases of cyclical mood disorders.

Finally, consolidating the knowledge of several centuries, Aretaeus described mania as a disease of adolescent and young men given intermittently to "active habits, drunkenness, lechery" and an immoderate lifestyle (what today might be called *cyclothymic disorder*). Exacerbations were most likely to occur in the spring.

Affective Temperaments

The concept of health and disease in ancient medicine was based on harmony and balance of the four humors, of which the ancients deemed sanguine humor the healthiest. Even desirable humor, however, such as blood, which made persons habitually active, amiable, and prone to jest, could, in excess, lead to the pathologic state of mania. The melancholic temperament, dominated by black bile and predisposed to pathologic melancholia, was described as lethargic, sullen, and given to brooding or contemplation; its modern counterpart might be persistent depressive disorder as defined in DSM-5. A long tradition dating back to Aristotle (384 to 322 BCE) attributed creative qualities to the otherwise tortured melancholic temperament in philosophy, the arts, poetry, and politics. The remaining two temperaments—choleric and phlegmatic—were less desirable, in that yellow bile made persons choleric (irritable, hostile, and given to rage), and phlegm made them phlegmatic (indolent, irresolute, and timid). The choleric and phlegmatic temperaments would probably be recognized today as borderline personality disorder and avoidant or schizoid personality disorder, respectively.

Many of the original Greek texts on melancholia were transmitted to posterity through medieval Arabic texts written by such scholars as Ishaq Ibn Imran and Abu Ali al-Hussain ibn Abdallah ibn Sina (known in the

West as Avicenna), and their Latin renditions by Constantinus Africanus. In describing different affective states, Avicenna developed the theory of the temperaments to its fullest. He speculated that a particular form of melancholia supervened "if black bile is mixed with phlegm," when the illness was "coupled with inertia, lack of movement, and quiet." Furthermore, mania was not necessarily linked to the sanguine (what today is termed *hyperthymic*) temperament, in that many forms of excited madness were believed to represent a mixture of black and yellow bile.

Avicenna further observed that the mixture of anger and restlessness in melancholia indicated that the disease was manic in nature and that the appearance of such signs and symptoms with violence heralded the transition from melancholia to mania. Those elaborations on Galen's temperamental types might be considered the forerunners of current personality dimensions, deriving mood states from various mixtures of neuroticism and introversion–extroversion. (What both the ICD-10 and the DSM-5 describe as *cyclothymic disorder* represents the intense mood lability of high neuroticism coupled with cyclic alternation between extroversion and introversion.) Speculation on how we can understand diverse depressive phenomena as a mix of humors anticipated modern multiple-transmitter hypotheses of depression. Ishaq Ibn Imran summarized the existing knowledge of melancholia by considering the interaction of genetic factors ("injured prenatally as the result of the father's sperm having been damaged") with an exceptional temperament given to "mental overexertion"—although not necessarily physical overactivity—that, in turn, was associated with "disruption of the correct rhythms of sleeping and waking." Those views, too, have a very modern ring to them.

MODERN ERA

The first English text (Fig. 13.1–1) entirely devoted to affective illness was Robert Burton's *Anatomy of Melancholy*, published in 1621. A scholarly review of medical and philosophical wisdom accumulated in past centuries also anticipated many modern developments. The concept of affective disorder endorsed by Burton was rather broad (as it always has been in the United Kingdom), embracing mood disorders and many disorders that are today considered somatoform disorders, including hypochondriasis. Although he described "causeless" melancholia, Burton

also categorized the various forms of love, melancholy, and grief. Particularly impressive was his catalog of causes, culminating in a grand conceptualization:

FIGURE 13.1–1. Frontispiece of Robert Burton's *Anatomy of Melancholy* (1621).

Such as have the moon, Saturn, Mercury misaffected in their genitures … such as are born of melancholy parents; as offend in those six non-natural things … are of a high sanguine complexion … are solitary by nature, great students, given to much contemplation, lead a life out of action, are most subject to melancholy. Of sexes both, but men more often … Of seasons of the year, the autumn is most melancholy … Jubertus excepts neither young nor old.

Burton's six non-natural things referred to such environmental factors as diet, alcohol, biologic rhythms, and perturbations induced by passions such as intense love. Burton did not definitively indicate age prevalences. Like nearly all of his predecessors, he favored male (rather than the currently reported female) preponderance.

Finally, Burton considered both the melancholic (contemplative) and the sanguine (hot-blooded) temperaments to be substrates of melancholia. Burton's work thus linked certain forms of depression with the softer expressions of the manic disposition, or bipolar II disorder, from which he appears to have suffered.

The 18th and 19th centuries introduced humane hospital care of the mentally ill, thereby permitting systematic clinical observation of the psychopathology and outcome of mood disorders.

Concept of Affective Disorder

Although Celsus (ca. 30CE) had described "forms of madness that go no further than sadness," the French alienist Jean-Philippe Esquirol (1840) may have been the first psychiatrist in modern times to suggest that a primary disturbance of mood might underlie many forms of depression and related paranoid psychoses. Until Esquirol's work, physicians considered melancholia a form of insanity (i.e., ascribed to deranged reasoning or thought disturbance). Esquirol's observations on melancholic patients led him to postulate that their insanity was partial (dominated by one delusion, a monomania) and that "the symptoms were the expression of the disorder of the affections. The source of the evil is in the passions." He coined the term *lypemania* (from the Greek, "sorrowful insanity") to give nosologic status to a subgroup of melancholic disorders that were affectively based. Esquirol cited Benjamin Rush (1745 to 1813), the father of American psychiatry, who had earlier described *tristimania*, a form of melancholia in which sadness predominated.

Esquirol's influence led other European psychiatrists to propose milder states of melancholia without delusions, which were eventually

categorized as simple melancholia and, ultimately, as primary depressions. Such descriptions culminated in the Anglo-Saxon psychiatric term *affective disorder*, coined by Henry Maudsley (1835 to 1918), the renowned British psychiatrist commemorated by the eponymous London hospital.

Manic-Depressive Illness and the Question of Psychogenic Depressions

Since it was described two millennia ago, the connection between mania and depression has sporadically been rediscovered. However, two of Esquirol's disciples did the clinical work establishing the illness as a discrete nosologic entity in the 1850s. Jean-Pierre Falret called it *circular insanity*, and Jules Baillarger used the term *folie à double forme.* That accomplishment built on Philippe Pinel's reforms, which championed humane treatment of the mentally ill in Paris around the turn of the 18th century and emphasized systematic clinical observations of patients and detailed case records. French alienists made longitudinal observations on the same patient from one psychotic attack into another.

Furthermore, Esquirol had introduced the practice of chronicling events in statistical tables. Thus, French alienists applied the Hippocratic approach to defining a particular case by its onset, circumstances, course, and outcome to the affectedly ill. The humanitarian reforms introduced in the 19th century ensured that general health and nutrition standards would improve the outlook for the mentally ill—especially those with potentially reversible disorders such as affective disorders. By segregating the nondeteriorating mood disorders from other types of insanity, the French school then paved the way for the Kraepelinian system.

Kraepelin's (1856 to 1926) unique contribution was not so much his grouping together of all the forms of melancholia and mania, but his methodology and painstaking longitudinal observations, which established manic-depressive illness as a nosologic entity and (he hoped) a disease entity. He based his rationale on the following: (1) the various forms had common heredity measured as a function of familial aggregation of manic and depressive cases, (2) frequent transitions from one to the other occurred during longitudinal follow-up of patients, (3) a recurrent course with illness-free intervals characterized most cases, (4) the superimposed episodes were commonly opposite to the patient's habitual temperament —that is, mania on a depressive temperament and depression on a

hypomanic temperament—and (5) both depressive and manic features could occur during the same episode (mixed states). Kraepelin developed his synthesis as early as the sixth (1899) edition of his *Lehrbuch der Psychiatrie* and most explicitly stated in the opening passages of the section on manic-depressive psychosis in the eighth edition (published in four volumes, 1909 to 1915):

> *Manic-depressive insanity … includes on the one hand the whole domain of so-called periodic and circular insanity, on the other hand simple mania, the greater part of the morbid states termed melancholia and also a not inconsiderable number of cases of confusional insanity. Lastly, we include here certain slight and slightest colorings of mood, some of them periodic, some of them continuously morbid, which on the one hand are to be regarded as the rudiment of more severe disorders, on the other hand, pass over without boundary into the domain of personal predisposition.* (Prof. Emil Kraepelin, Manic-depressive Insanity and Paranoia; translated by R. Mary Barclay, M.A., M.B.; edited by George M. Robertson, M.D., F.R.C.P. Edin. Edinburgh: E & S Livingstone; 1921.)

For Kraepelin, the core pathology of clinical depression consisted of lowered mood and slowed (retarded) physical and mental processes. In mania, by contrast, the mood was elated and physical and mental activity was accelerated. His earlier observations on what he termed *involutional melancholia* (referring to 40- to 65-year-old patients with extreme anxiety, irritability, agitation, and delusions) had led him to separate that entity from the broader manic-depressive rubric. In the eighth edition of *Lehrbuch der Psychiatrie,* however, he united melancholia with the manic-depressive group, with the justification that it was a unique form of mixed state and that follow-up conducted by his pupil Dreyfus had demonstrated unmistakable excited phases.

The classification of mood disorders is still evolving. Karl Leonhard in 1957, Jules Angst in 1966, Carlo Perris in 1966, and George Winokur, Paula Clayton, and Theodore Reich in 1969, working independently in four different countries, proposed that depressive disorders without manic or hypomanic episodes (unipolar depressive disorder) that appear in middle age and later are distinct from depressive episodes that begin at earlier ages and alternate with manic or hypomanic episodes (bipolar disorder). The main difference between the two affective subtypes is the more significant familial loading, especially for bipolar disorder among bipolar disorder probands.

Kraepelin had conceded the occurrence of psychogenic states of depression occasioned by situational misfortune. However, he believed

that manic-depressive illness was hereditary, although he could not document postmortem anatomopathologic findings in the brains of manic-depressive patients. Therefore, manic-depression had to be considered a functional mental disorder in which they presumed that the brain disturbances lie in altered physiologic functions. Such biologic factors were deemed absent in the psychogenic depressions. Thus, Kraepelin's classification of mood disorders is both dualistic and unitary. It is dualistic to the extent that he designated them as either psychologically occasioned or somatically caused. It is unitary concerning disorders in the latter group, termed *endogenous affective disorders* (i.e., internal biologic causes). In other words, Kraepelin restricted the concept of clinical depression to what the DSM-5 terms *major depressive disorder with melancholic features*. Moreover, he postulated a continuum between that condition and what the DSM-5 and the ICD-10 and -11 now term *bipolar disorders*.

Cartesian thinking in 17th-century France conceptually separated mind from body, thereby providing physicians autonomy over the somatic sphere, free from interference by the Church. The dichotomous paradigm ensured that the complexities of mind–body interactions would not confound the study of the two aspects of the human organism. That is one reason Kraepelin's descriptive observations have proved valuable to subsequent generations of clinicians. Furthermore, his approach exemplifies the best tradition of scientific humanism in medicine: description and diagnostic categorization of an individual patient are necessary for the physician to apply the knowledge gained from past observation of similarly described and diagnosed patients. One limitation of the Kraepelinian approach is that it is not sufficiently articulate to account for mind–body interactions in the genesis of mental disorders because of its biologic reductionism.

Depressions as Psychobiologic Affective Reaction Types

It was the ambition of Swiss-born Adolf Meyer (1866 to 1950) to bridge the divide between psyche and soma. Meyer, who dominated psychiatry from his chair at Johns Hopkins University during the first half of the 20th century, coined the term *psychobiology* to emphasize that both psychological and biologic factors could enter into the causation of depressive and other mental disorders. Because of the nascent state of brain science during Meyer's time, he was more adept at biography than

biology and paid greater attention to psychosocial causation. Meyer preferred the term *depression* (pressed down) to *melancholia* because of its lack of biologic connotation. He conceived of depressive states in terms of unspecified constitutional or biologic factors interacting with a series of life situations beginning at birth or even at conception. From that viewpoint arose the unique importance accorded personal history in depressive reactions to life events.

Meyer's terminologic revision left a somewhat confusing legacy in that we now use the term *depression* for a broad range of affective phenomena, ranging from sadness and adjustment disorders to clinical depression and bipolar disorders. Nosologic nuances to which Meyerians paid little attention, such as the difference between melancholic depression and more mundane depressions, are not just a matter of semantics. To the extent that those two forms of depression occur in different clinical settings, hypotheses based on one population may not apply to the other. For instance, uncontrollable traumatic events may have taught study participants to feel helpless or view the world negatively, but that does not equate with clinical depression. Nor does the process appear to be specific to depression. The failure to make such nosologic distinctions complicated trials that attempt to compare psychotherapy and pharmacotherapy for depressive disorders.

On the other hand, the Meyerian emphasis on biographical factors for the patient represented a more practical approach to depth psychology. Meyer's work also influenced recent sociologic interpretations of depression. In the final analysis, however, the Meyerian concern for the uniqueness of the individual has proved heuristically sterile. It de-emphasizes what is diagnostically common to different individuals, thereby obscuring the relevance of accrued clinical wisdom for the index patient. For that reason, the Meyerian approach, after enjoying clinical popularity for several decades in North America, has given way to neo-Kraepelinian rigor. However, the psychobiologic vision of bridging biology and psychology, one of the central preoccupations of psychiatric thought and research today, owes much to Meyer's legacy.

CONTEMPORARY MODELS OF DEPRESSION

Aggression-Turned-Inward Model

Sigmund Freud was initially interested in a psychoneural project for all mental phenomena. Limitations of the brain sciences of the day led him to adopt instead a model that relied on a concept of mental function borrowed from physics. Freud's disciple, Karl Abraham, initially suggested that depressed affect might derive from one's aggressive impulses directed against an ambivalently loved internalized object, and Freud later elaborated this idea. Abraham and Freud hypothesized that turned-inward anger was intended as punishment for the love object that had thwarted the depressed patient's need for dependency and love. Because the patient internalizes the object, they become the target of their own thanatotic impulses. A central element in those psychic operations was the depressed patient's ambivalence toward the object, which the patient perceived as a frustrating parent. Aggression directed at a loved object (parent) would then cause considerable guilt. In the extreme, such ambivalence, guilt, and retroflexed anger could lead to suicidal behavior.

Thus, this model implies that depression is an epiphenomenon of the transduction of thanatotic energy. Freud's earlier writings had similarly portrayed anxiety as being derived from the transformation of dammed-up sexual libido. Freud had hoped that these psychoanalytic constructs would eventually be localized neuroanatomically. However, we understand that the concepts are metaphors.

The concept of emotional behavior as an arena of incompatible forces confined to a psyche that is relatively impervious to current outside influences is the primary liability of the aggression-turned-inward model and, perhaps, of orthodox psychoanalysis itself. Although modern psychoanalysts have discarded the sexual-energy-transduction hypothesis of anxiety, they continue to use the aggression-turned-inward model clinically in modified versions. The lingering popularity of the model may be due, in part, to its compatibility with the clinical observation that many depressed patients suffer from a lack of assertion and outwardly directed aggressiveness. However, we encounter a substantial number of hostile, depressed patients in clinical practice (indeed, "depression with anger attacks" has been recently described), and clinical improvement in most patients typically leads to decreased, not increased, hostility. Such observations shed doubt on the aggression-turned-inward mechanism as a universal explanation for depressive behavior. Finally, little evidence supports the contention that outward expression of anger has therapeutic value in clinical depression.

Outwardly directed hostility in depression is not a new clinical observation; in fact, ancient Greek and Roman physicians had noted it. Hostility is best considered a manifestation rather than a cause of a depressive disorder, especially when mixed bipolar features attend the disorder. We can also understand the hostility of the depressed patient as an exaggerated reaction to frustrating love objects, as secondary to self-referential attribution, or simply as nonspecific irritability of an ego in affective turmoil. The latter could, in part, be a function of a concurrent personality disorder. Such commonsense explanations that do not invoke unobservable phenomena have greater appeal from heuristic and clinical perspectives.

Object Loss and Depression

Object loss refers to traumatic separation from significant objects of attachment. Ego psychology reformulations of the Abraham–Freud model focus on how these losses affect the ego, de-emphasizing other more abstract aspects. The depressant effect of separation events often resides in their symbolic meaning for a person and is difficult to measure objectively. However, love loss, bereavement, and other exits from the social scene, as defined by the London psychiatrist Eugene Paykel, are presently the concepts most commonly used in practice and research.

Although poets previously described love and melancholy, Freud first considered these systematically in his 1917 paper on mourning and melancholia. It appears that the transition from grief to pathologic depression occurs in no more than 10% of adults and 20% of children. These figures suggest that this transition occurs mainly in persons predisposed to mood disorders.

John Bowlby of the Tavistock Clinic, London, did a comprehensive clinical investigation of the child's attachment with the mother or mother substitutes during development, a bond considered the prototype for all subsequent bonds with other objects. Like many psychoanalytic explanations of adult symptom formation, the object loss model proposes a two-step hypothesis. The first step consists of early breaks in affectional bonds, which provide the behavioral predisposition to depression. The second involves adult losses, which revive the traumatic childhood loss and precipitate depressive episodes. However, the role of proximate separations in provoking depressive reactions rests on more solid clinical evidence than the hypothesized sensitization resulting from

developmental object loss. Realizing this, Bowlby regarded childhood sensitization from early deprivation as a generic characterologic vulnerability, leading to many possible disorders.

Compared with aggression turned inward, object loss is more directly relevant to clinical depression, yet it is still pertinent to question whether it is an etiologic factor. Studies at the Wisconsin Primate Center indicated that individuals achieve optimal homeostasis with the environment most readily when securely attached to significant others. The dissolution of such ties appears to be relevant to the emergence of a broad range of psychopathologic disturbances than depression per se. A related methodologic question is whether object loss operates independently of other etiologic factors. For instance, a history of early breaks in attachment may reflect that one or both of the patient's parents had a mood disorder, resultant separation, divorce, or suicide.

On balance, the ego-psychological object loss model is conceptually superior to its id-psychological counterpart. In postulating an open system of exchange between a person and the environment, the model permits consideration of etiologic factors other than separation, such as heredity, character structure, and adequacy of social support—all of which might modulate the depressant effect of adult separation events. Conceptualizing the origin of depression along those lines is mainstream of current adaptation, homeostasis, and disease ideas. A vital treatment implication is the value of social support in preventing relapse and mitigating the chronicity of depression. That is, indeed, an ingredient in the interpersonal psychotherapy of depression, which can be conceptualized as a form of brief, focused, and practical psychodynamic therapy.

Loss of Self-Esteem and Depression

Reformulating the dynamics of depression as the ego suffering a collapse of self-esteem represents an additional conceptual break with the original Abraham–Freud formulation. Depression is said to originate from the ego's inability to give up unattainable goals and ideals. The model further posits internalized values of the ego (rather than thanatotic energy turned inward) impose the narcissistic injury that crushes the depressed patient's self-esteem. Because the ego construct is rooted in social and cultural reality, loss of self-esteem may result from symbolic losses involving power, status, roles, identity, values, and purpose for existence. This

approach provides the clinician with a more flexible and pragmatic tool for understanding depressed persons than the classical model. This newer approach represents one of the first attempts to formulate depression in terms that subsequent psychological theory and research could operationalize in a more testable form.

Self-esteem is part of the habitual core of the individual and, hence, is integral to the personality structure. Indeed, low self-esteem conceived as a trait is a primary defining attribute of the depressive (melancholic) personality. Although understandably, environmental adversity can quickly sink such individuals into melancholia, it is not apparent why persons with higher self-esteem also succumb. To explain such cases, one must invoke an underlying instability in the system of self-esteem that renders it vulnerable to depression. The opposite is also known to occur; that is, manic episodes may develop from a baseline of low self-esteem, as in bipolar disorder patients with antecedent traits of shyness, insecurity, and dysthymia.

These considerations suggest that the fluctuations of self-esteem most central to the model of depression as loss of self-esteem represent a more fundamental mood dysregulation. Classic psychoanalysis considers this dysregulation to be of constitutional origin. Except for the idea that mania could be a way to deny painful affect, most psychoanalytic explanations for bipolar oscillations have not progressed beyond metapsychological jargon.

Cognitive Model

The cognitive model, developed by Aaron Beck at the University of Pennsylvania, hypothesizes that thinking along negative lines (e.g., thinking that one is helpless, unworthy, or useless) is the hallmark of clinical depression. Beck redefines depression as a cognitive triad. Patients think of themselves as powerless, interpret most events unfavorably vis-à-vis the self, and believe the future to be hopeless. More recent academic psychology formulations characterize these cognitions as a negative attributional style that is global, internal, and stable and exists in the form of latent mental schemata that generate biased interpretations of life events.

Because the cognitive model derives from retrospective observations of already depressed persons, proving causality is virtually impossible. Whether the negative mental schemata cause depression or are the result

is difficult to know. The theoretical importance of the cognitive model lies in the conceptual bridge it provides between ego-psychological and behavioral models of depression. Most importantly, it has also lead to a popular psychotherapy method that addresses these negative attributions.

Therefore, the cognitive model has the cardinal virtue of focusing on critical reversible clinical dimensions of depressive illness, such as helplessness, hopelessness, and suicidal ideation, while providing a testable and practical psychotherapeutic approach. That approach, however, is less likely to succeed in patients with the full-blown melancholic manifestations of a depressive disorder. It is doubtful that negative cognitions alone could account for the profound disturbances in sleep, appetite, and autonomic and psychomotor functions encountered in melancholic depressions. Furthermore, conceptualizing a multifaceted disorder such as depression primarily or solely as a function of distorted cognitive processes is reminiscent of pre-Esquirolian notions that emphasized impaired reasoning in the development of depression. Finally, the extension of modified cognitive and cognitive-behavioral therapy to treat virtually all emotional disorders—even schizophrenia—reminds us of earlier grandiose claims made by psychoanalysts.

Learned Helplessness Model

The learned helplessness model is, in some ways, an experimental analog of the cognitive model. The model proposes that one learns the depressive posture from past situations in which one cannot avoid undesirable contingencies. The basis for this model is the research performed on dogs, which the researchers prevented from taking adaptive action to avoid unpleasant electrical shock. These dogs subsequently showed no motivation to escape such aversive stimuli, even when escape avenues were readily available. Armed with evidence from many such experiments, University of Pennsylvania psychologist Martin Seligman postulated a trait of learned helplessness formed from the accumulation of past episodes of uncontrollable helplessness. He defined learned helplessness as a belief that it is futile to initiate personal action to reverse aversive circumstances.

The learned helplessness paradigm is a general one and refers to a broader mental disposition than depression. Thus, it is potentially helpful in understanding such diverse conditions as social powerlessness, defeat in sporting events, and post-traumatic stress disorder (PTSD). In addition,

past events might shape a characterologic cluster—consisting of passivity, lack of hostility, and self-blame—relevant to certain depressive phenomena. This paradigm may explain the low hostility observed in some patients during clinical depression. Learned helplessness could thereby provide plausible links between aspects of personal biography and clinical phenomenology in depressive disorders. Cognitive therapies capitalize on the concept and focus on developing new cognitive strategies geared to modifying expectations of uncontrollability. We can thus use experimental insights to inform our treatments.

Nonetheless, the clinician should be wary of unwarranted clinical extrapolations. For example, some therapists have argued that the depressed patient's passivity is "manipulative," serving to obtain interpersonal rewards. This dynamic may be significant in the development of the depressive character. That interpretation appears more relevant to selected aspects of depression than to the totality of the disorder. Depressive behavior and verbalizations have a powerful interpersonal impact, but casting depression as merely a masochistic lifestyle developed to secure interpersonal advantages represents a mechanistic circular argument that is disrespectful of the clinical agony of patients with mood disorders. Finally, although most formulations focusing on helplessness have emphasized acquisition through learning, recent experimental research in animals tends to implicate genetic factors in the vulnerability of learning to behave helplessly. The value of the helplessness paradigm may reside in its utility in predicting a variety of subthreshold affective disturbances generic to civilian reactions to adversity and trauma.

Depression and Reinforcement

Other behavioral investigators, such as the psychologist Peter Lewinsohn, developed clinical formulations of depression hinging on specific deficits in reinforcement mechanisms. According to the reinforcement model, depressive behavior may result from a lack of appropriate rewards, such as noncontingent rewards. The model identifies several contributory mechanisms. Some environments may consistently deprive persons of rewarding opportunities, thereby placing them in a chronic state of boredom, pleasurelessness, and, ultimately, despair. That reasoning, however, may offer more insight into social misery than clinical depression. A more plausible postulated mechanism is the provision of

rewards that are not in response to the recipient's actions; in other words, the gratis provision of what a person considers undeserved rewards may lower self-esteem. Inadequate social skills may predispose to depression, as they decrease a person's chances of responding to potentially rewarding contingencies in the environment. Indeed, recent research on the relationship between personality and depression suggests that such deficits might underlie certain depressive states. Therefore, psychotherapeutic approaches designed to enlarge a patient's repertoire of social skills may prove valuable in preventing some types of depression.

The concepts of depression that have been derived from behavioral methodology and developed in the last several decades are scientifically articulate and, therefore, testable approaches to clinical depression. However, the critical distinction between depression on self-report inventories and clinical depression tends to be overlooked in investigations testing the reinforcement paradigm. Furthermore, the behavioral model does not address the distinct possibility that reinforcement deficits may, in part, represent the psychomotor deficits of depressive illness. Nevertheless, the behavioral model provides a conceptual bridge between purely psychological and emerging biologic conceptualizations of depression by focusing on reward mechanisms.

Biogenic Amine Imbalance

The formulation of sophisticated biologic explanations of mood disorders had to await the development of neurobiologic techniques that could probe the parts of the brain involved in emotions. Although we cannot directly observe the complex physiology of the limbic-diencephalic centers of emotional behavior, we have learned much from animal work. The limbic cortex links with the neocortex, the midbrain, and lower brain centers. The midbrain subserves higher symbolic functions, and the midbrain and lower brain centers control autonomic functions, hormonal production, sleep, and wakefulness. Thus, the limbic cortex influences all aspects of the body and mind. Norepinephrine-containing neurons influence many functions that are profoundly disturbed in melancholia, including mood, arousal, appetite, reward, and drives. Other biogenic amine neurotransmitters mediating such processes are the catecholamine dopamine and indoleamine serotonin. Dopamine is crucial for drive, pleasure, sex, and psychomotor activity, and serotonin regulates affects,

aggression, sleep, and appetite. Cholinergic neurons, secreting acetylcholine at their dendritic terminals, are usually antagonistic to catecholaminergic neurons.

Although the opioid system might, on experimental and theoretical grounds, also serve as one of the neurochemical substrates for mood regulation, no cogent model of mood disorders involving that system has appeared. Likewise, biochemical formulations of mood disorders have paid relatively little attention to the major excitatory brain neurotransmitter glutamate and the inhibitory neurotransmitter γ-aminobutyric acid (GABA).

Biogenic Amine Hypotheses. Joseph Schildkraut at Harvard University and William Bunney and John Davis at NIMH published the first formal hypothesis connecting depletion or imbalance of biogenic amines (specifically norepinephrine) and clinical depression. Alec Coppen in England and I. P. Lapin and G. F. Oxenkrug in Russia emphasized the serotonin counterpart of the model. Both catecholamine and indoleamine hypotheses are essentially derived from two sets of pharmacologic observations. First, reserpine, which decreases blood pressure by depleting biogenic amine stores, precipitates clinical depression in some patients. Second, antidepressant medications, which alleviate clinical depression, raise the functional capacity of the biogenic amines in the brain. This thinking style is known as the *pharmacologic bridge*, extrapolating from evidence on the mechanism of drug action to the neurotransmitter pathologies presumed to underlie a given psychiatric disorder. Such pharmacologic strategies have been of heuristic value in developing research methods to investigate mood disorders and schizophrenia. Indeed, the research methodology developed by the relatively few investigators working in this area during the last half-century is among the most elegant in the history of psychiatry.

Variations of the biogenic amine model assign somewhat different relative weights to the biogenic amines norepinephrine and serotonin in the development of pathologic mood states. Arthur Prange and colleagues at the University of North Carolina formulated a permissive biogenic amine hypothesis in which serotonin deficits permit the expression of catecholamine-mediated depressive or manic states. Subsequent animal research showing that an intact serotonin system is necessary for the optimal functioning of noradrenergic neurons supported this hypothesis. Omission of tryptophan from the diet of antidepressant-responsive

depressed patients may annul the efficacy of the antidepressant; among healthy volunteers, that special diet also induces sleep electroencephalographic characteristics of clinical depression. Although such findings are provocative, the precursor-loading strategy to increase the brain stores of serotonin (e.g., with l-tryptophan) has not been unequivocally successful in reversing clinical depression. Dietary loading with catecholamine precursors has fared even worse than serotonin-precursor loading in the treatment of depression.

The cholinergic–noradrenergic imbalance hypothesis proposed by David Janowsky and colleagues is another attempt to understand the roles of biogenic amines. This hypothesis, along with the related cholinergic supersensitivity hypothesis developed by J. Christian Gillin, has been tested extensively at the University of California at San Diego. Subsequent formulations by Larry Siever and Kenneth Davis at the Mount Sinai Hospital in New York have refocused on noradrenergic dysregulation. The model assumes oscillation from one output mode to the other at different phases of depressive illness. In a provocative extrapolation from that model, bipolar depression would have low noradrenergic output. However, many instances of MDD, as with some anxiety disorders, could be biochemically conceptualized as high-output conditions.

Despite more than four decades of extensive research and indirect evidence, researchers have not demonstrated deficiencies or excesses of biogenic amines in specific brain structures that are necessary or sufficient for the occurrence of mood disorders. It has not been possible to confirm the putative role of central norepinephrine in depression or discard it altogether. The role of dopamine as formulated, among others, by the Italian pharmacologist Gian Luigi Cessa, although studied less extensively than norepinephrine, deserves greater recognition in that it might have relevance to atypical and bipolar depression or to mania.

Preliminary data from a small brain imaging study has shown blunted serotonin responsivity in prefrontal and temporoparietal areas in unmedicated patients with MDD. Such data, considered in the context of the overall serotonin literature in depression, are provocative but not conclusive and illustrate that the case for serotonergic disturbance in depression continues to be indirect. Moreover, the putative permissive role of serotonin is more evident in aggressive suicide attempts. Serotonergic dysfunction might subserve other conditions characterized

by lack of inhibitory control, such as obsessive-compulsive disorder (OCD), panic disorders, bulimia nervosa, certain forms of insomnia, alcoholism (alcohol use disorder), and impulse-ridden personality disorders. Such considerations have led Dutch psychiatrist Herman van Praag and colleagues to postulate a dimensional neurochemical disturbance generic to a large group of disorders within the traditional nosology. We could interpret this hypothesis as a challenge to psychiatric nosology or a statement of the need to supplement clinical classification with biochemical parameters. Both interpretations are in line with clinical observations during the last two decades, testifying to the high prevalence of comorbidity in depressive, other emotional disorders, and certain impulse-control disorders.

By implication, the preceding postulated biochemical faults are genetically determined. Although biogenic amine models of mood disorders were developed retrospectively from the pharmacologic action of antidepressant and thymoleptic agents, they have stimulated the development of new classes of antidepressants with more selective action on specific neurotransmitter receptors. Their introduction has virtually revolutionized the treatment of depression. Yet, the fundamental biochemistry of mood disorders is still far from being understood. Curiously, although selective in action, the new compounds working on the serotonin system have broad effectiveness for various mood-related conditions, such as dysthymic disorder, PTSD, OCD, panic disorder, social phobia, bulimia nervosa, and borderline personality disorder. Such data indirectly favor the hypothesis of an underlying biologic commonality to several of these disorders. In turn, the preceding considerations led to a provocative formulation of an increasingly prevalent “social syndrome” in populations experiencing social disruption, immigration, and abuse. This syndrome includes symptoms of anxiety, depression, violence-proneness, impulsivity, and suicidality. This formulation suggests a perturbation of the serotonin system, the most basic brain structure involved in human socialization and territoriality, coping with stress, danger, and survival.

New antidepressants with dual action on both serotonergic and noradrenergic receptors and emerging data on their possible greater efficacy in melancholic depressions suggest that the biochemistry of mood disorders is more complex than a single-neurotransmitter hypothesis can imply. The work of George Henninger and colleagues at Yale University indicates further that monoamines better explain how antidepressants

facilitate recovery from depression than their being the fundamental causes of depression. Moreover, emerging biochemical paradigms are moving away from distal biochemical lesions to focus on molecular perturbations closest to the putative genetic underpinnings of mood disorders. The initial work focused on mood stabilizers' mechanisms in bipolar disorder. However, researchers are now exploring second messenger systems, phosphorylation G proteins, signal transduction, DNA transcription, and messenger RNA translation. Again, such a search for molecular mechanisms represents "backward logic" from the putative mechanism of action of selected thymoleptic agents.

The same is true for Frederick Petty's GABAergic and Shih-Jen Tsai's brain-derived neurotrophic factor (BDNF) hypothesis of the origin of bipolar disorder. BDNF is responsible for the ongoing maintenance of neurons in the brain and disruption of it causes a reduction in neuronal number and size. It is challenging to measure BDNF in living subjects, but postmortem studies have suggested that deficits in BDNF may correlate with psychopathology. For example, some studies have found that in postmortem examination of persons who died from suicide, the average BDNF in the prefrontal cortex and hippocampus was lower than for control subjects. Indirect studies in live patients, looking at BDNF in plasma rather than the brain (the correlation between the two is not clear), found increases in serum BDNF in depressed patients who responded to antidepressants.

Neuroendocrine Links. Functionally inadequate mobilization of neurotransmitters in the face of continued or repeated stress, indirectly reflected in the pathologic modification of noradrenergic and serotonergic receptor function, could represent neurochemical final common pathways of homeostatic failure. Such mechanisms could also provide links with psychoendocrine dysfunction; the hypothesized neurotransmitter deficits may underlie the disinhibition of the hypothalamic–pituitary–adrenal axis, characterized by steroidal overproduction, the most widely studied endocrine disturbance in depressive illness. When challenged with dexamethasone, the altered axis resists suppression, which offered Bernard Carroll's team (then at the University of Michigan) the possibility of developing the dexamethasone-suppression "test" (DST) for melancholia. This procedure is of uncertain specificity for depressive illness and is unsuitable to serve as a diagnostic test. However, that line of

research has been helpful in pathogenetic understanding. For instance, it led to the demonstration by Charles Nemeroff (then at Emory University) of increased concentrations of corticotropin-releasing factor (CRF) in the cerebrospinal fluid (CSF) of patients with MDD. CRF also appears relevant to the pathophysiology of anxiety disorders, such as panic disorder and PTSD. The research of Florian Holsboer's group at Munich's Max Planck Institute has shown impaired glucocorticoid and mineralocorticoid receptor function in these disorders, with relevant pathophysiologic and therapeutic implications.

Another neuroendocrine index of noradrenergic dysregulation, blunted growth hormone response to the α_2-adrenergic receptor agonist clonidine, likewise points to limbic–diencephalic disturbance. However, studies performed in the United States suggest that it is positive in endogenous depression and severe anxiety disorder (panic disorder). Thyroid-stimulating hormone (TSH) blunting on thyrotropin stimulation, another common neuroendocrine disturbance in depression, also shows limited specificity.

However, what is remarkable is that the DST, clonidine, and thyrotropin challenge data, in aggregate, identify most persons with clinical depression. Such evidence of midbrain disturbance argues for considering clinical depression to be a legitimate disease. The disease concept of depression is further buttressed by computed tomography (CT) scans showing enlarged pituitary and adrenal glands, a state marker of depressive illness.

Stress and Depression. The concept of a pharmacologic bridge implies two-way traffic. The hypothesized chemical aberrations may be primary or genetically based. However, we should provide for the likelihood that psychological events that precipitate clinical depression might initiate or exacerbate neurochemical imbalance in vulnerable subjects. Support for this suggestion includes studies in animals in which early separation from peers and inescapable frustration profoundly alters the turnover of biogenic amines and postsynaptic receptor sensitivity. Thus, in genetically predisposed persons, environmental stressors might more easily lead to perturbations of limbic–diencephalic neurotransmitter balance. Finally, in vulnerable individuals, especially during the formative years of childhood, psychological mechanisms might more easily perturb midbrain neurochemistry. Traumatic experiences appear particularly

potent in this regard. The hippocampus has been the subject of intense recent research as the possible neuroanatomical substrate linking such loss and trauma to adult depression. Ongoing ingenious experimental paradigms in primates and rodents continue to explore the role of early experience and stress in subsequent depressive-like behaviors in these animals. In humans, a new provocative finding indicates that a polymorphism of the serotonin transporter gene would identify who among traumatized children would develop adult depression. Likewise, a polymorphism of the monoamine oxidase (MAO) gene plays a significant role in determining who among battered children grows into an adult sociopath. Animal models of mania are sparse and problematic.

Neurophysiologic Approaches

Neuronal Hyperexcitability. Lithium is known to replace intracellular sodium and hyperpolarize the neuronal membrane, thereby decreasing neuronal excitability. Abnormalities in neuronal electrolyte balance (an excess of residual sodium, defined by radioisotope techniques) and hypothesized secondary neurophysiologic disturbances were the focus of British investigations by Alec Coppen and colleagues in the early 1960s. The data appear compatible with the hypothesized movement of excess sodium into the neuron during an episode of mood disorder and redistribution toward the preillness electrolyte balance across the neuronal membrane during recovery. Intraneuronal sodium leakage is postulated in both depressive and manic disorders but is deemed more extreme in the latter. Because the harmonious activity of the neuronal cell and, by implication, that of a group of neurons, depends on the electrical gradient maintained across its membrane by differential distribution of sodium, abnormalities in sodium concentrations and transport are hypothetically relevant to the production of an unstable state of neurophysiologic hyperexcitability. In formulating their thesis of neurophysiologic arousal in melancholic states, Joseph Mendels and Peter Whybrow (both of whom have worked at the University of Pennsylvania) have capitalized on the previous electrolyte disturbances. The view that mania represents a more extreme electrophysiologic dysfunction in the same direction as depression violates the commonsense notion of symptomatologic “opposition” between the two kinds of disorder. Yet, in part, it may account for the existence of mixed states in which symptoms of depression and mania coexist. The NIMH team led by Frederick Goodwin first showed

that a substantial minority of depressed patients with a bipolar substrate respond to lithium salts, which further supports the concept of a common neurophysiologic denominator to mania and depression. Perturbations of calcium metabolism also appear relevant to bipolar patients. Therapeutic implications of this observation (e.g., the use of calcium channel inhibitors in bipolar I disorder) have not yielded consistent results. Finally, rubidium, another alkali metal, has been explored in the depressive phase of bipolar disorders, again with inconclusive results.

Immunologic Disturbance. Depressive disorders are associated with several immunologic abnormalities, including decreased lymphocyte proliferation in response to mitogens and other forms of impaired cellular immunity. These lymphocytes produce neuromodulators, such as CRF and cytokines, peptides known as interleukins. There appears to be an association with clinical severity, hypercortisolism, and immune dysfunction, and the cytokine interleukin-1 may induce gene activity for glucocorticoid synthesis.

Circadian Rhythms. It has long been understood that depression is associated with a premature loss of deep (slow-wave) sleep and an increase in nocturnal arousal. Four types of disturbance reflect the latter: (1) an increase in nocturnal awakenings, (2) a reduction in total sleep time, (3) increased phasic rapid eye movement (REM) sleep, and (4) increased core body temperature. The combination of increased REM drive and decreased slow-wave sleep results in a significant reduction in the first period of non-REM (NREM) sleep, a phenomenon referred to as reduced REM latency. Blunted secretion of growth hormone may cause this reduction in latency, which usually increases with sleep onset. It is very persistent, often lasting beyond recovery from depression. Some patients manifesting a characteristically abnormal sleep profile are less responsive to psychotherapy and have a higher risk of relapse or recurrence, and may benefit preferentially from pharmacotherapy.

Shortened REM latency, which David Kupfer and colleagues have extensively studied at the University of Pittsburgh, has been proposed as another laboratory “test” for depressive disorder. Shortened REM latency may serve as a trait marker for depression because it occurs in dysthymia and so-called borderline personality and among the clinically “well” offspring of adults with major depression.

Formulations of circadian rhythms by Thomas Wehr and Norman Rosenthal, working at NIMH, have focused on abnormalities in brain regulation of temperature, activity, and sleep cycles. Others have investigated the role of the pineal hormone melatonin in mood disorders without achieving consistent results. Applying circadian rhythm research concepts to women with mood disorders has also led to innovative methods, but, again, without definitive characterization of the neurophysiologic faults.

At a basic level, instrumental REM sleep deprivation in neonatal rats leads to adult “depression-like” behaviors. In human studies, sleep deprivation and exposure to bright white light correct phase disturbances and thereby terminate depressive episodes, especially in subjects with periodic and seasonal depressions. The average modern person is light-deprived, and phototherapy can benefit even those without clear-cut seasonal patterns. Unfortunately, except for their use in mild seasonal depressions and suppression of sleep deprivation to prevent hypomania in bipolar disorder, the preceding circadian studies have not had a tangible impact on practice. Their application in the large segment of mood-disordered patients remains cumbersome, if not elusive. Their effect can be better assessed at the level of theory. Although the specificity and efficacy of these neurophysiologic indices and manipulations for clinical depression and bipolar disorder require additional investigation, cumulatively, they point to midbrain dysregulation as the likely common neurophysiologic substrate of affective disorders. The preceding considerations further suggest that the ancient Greeks, who ascribed melancholia to malignant geophysical influences, did not indulge in mere poetic metaphor. The ancients had observed the disturbed circadian patterns and advocated their readjustment to restore euthymia.

Affective Dysregulation. A significant challenge for research in mood disorders is to characterize the fundamental molecular mechanisms that underlie the neurophysiologic rhythmopathies, which, in turn, might account for the recurrent nature of the affective pathology as envisioned by Kraepelin. For the most typical recurrent forms of the disorders, the constitutional foundations (manifested as cyclothymic and dysthymic traits or a broad range of emotional disequilibrium covered by the rubric of “neuroticism”) are so unstable that the illness may run its entire course more or less autonomously, with the environment mainly serving to turn on

and off the more florid phases (episodes). Parisian psychiatrist Jean Delay, a pioneer in psychopharmacology in the 1950s, also emphasized affective dysregulation as the fundamental pathology in the spectrum of mood disorders. Robert Post, at NIMH, hypothesized that the electrophysiologic substrates could be so kindled that an infrequent and episodic disorder initially triggered by environmental stressors could assume an autonomous and recurrent course. He hypothesized that this phenomenon might occur because neuronal perturbations brought about by stressors in the early course of mood disorders get incorporated into the DNA. However, this fascinating kindling hypothesis does not seem to pertain to garden-variety mood disorders but those with extreme cyclicity. The monograph on manic-depressive illness by Fred Goodwin and Kay Jamison presents in-depth arguments for this cyclical paradigm of thymopathy.

Through its connection with the serotonin transporter, the amygdala appears to play a crucial role in the dysregulation of the emotional life of affectively ill patients. Data indicate that the dysregulation is both in function and anatomic structure.

THEORETICAL SYNTHESIS

Pathophysiologic Understanding

Modern psychobiology attempts to link experience and behavior to the central nervous system (CNS). Building conceptual bridges between the psychological and biologic approaches to mood disorders require sophisticated strategies beyond the Cartesian notion of limited mind–body interactions or the pineal gland and the generalizations of the Meyerian school.

William McKinney and Hagop Akiskal, in 1973, developed a conceptual framework that considers the affective syndromes as the final common pathway of various psychological and biologic processes. The overarching hypothesis is that psychological and biologic–etiologic factors converge in reversible deficits in the diencephalic substrates of pleasure and reward. Those areas of the brain subserve the functions that are disturbed in melancholia and mania. The integrative model links the central chemistry and physiology of reward mechanisms with the object loss and behavioral models of depression, both of which give singular importance to the depressant role of loss of rewarding interpersonal bonds. A vital element

of the model is the circadian disturbances observed since ancient times in depressive and manic syndromes. Both syndromes are conceptualized as clinical manifestations of a disordered limbic system with its subcortical and prefrontal extensions. Brain imaging studies in melancholic patients by Wayne Drevets, originally at Washington University, have visualized limbic disturbances extending into subcortical structures and occurring primarily in patients with a familial diathesis for depression; the amygdala appears to be the focal limbic structure in the latter studies. Clinical experience and research data suggest that multiple factors described in the following subsections combine to produce or exacerbate dysregulation in these brain regions, leading to the final common pathway of clinical depression. The data on mania is more tentative and is mentioned when relevant.

Pathologic Findings from Brain Imaging Studies. The most consistent structural abnormality observed in depressive disorders is the increased frequency of abnormal hyperintensities in subcortical regions, such as periventricular regions, the basal ganglia, and the thalamus. More common among older adults, these hyperintensities appear to reflect the deleterious neurodegenerative effects of recurrent affective episodes. Ventricular enlargement, cortical atrophy, and sulcal widening also have been reported in some studies. Some depressed patients also may have reduced hippocampal or caudate nucleus volumes, or both, suggesting more focal defects in relevant neurobehavioral systems. Diffuse and focal areas of atrophy are associated with increased illness severity, bipolarity, and increased cortisol levels.

Also, specific structures appear reduced in volume in patients with depression, for example, the hippocampus. This reduction may be due to neuronal loss due to the neurotoxic effects of the increased cortisol found in depressed patients. Although many brain areas are susceptible to this toxic effect, the hippocampus is particularly vulnerable as it is rich in glutaminergic neurons. Other areas with reported brain loss include the prefrontal cortex, cingulate gyrus, and cerebellum.

The most widely replicated positron emission tomography (PET) finding in depression is decreased anterior brain metabolism, which is generally more pronounced on the left side. From a different vantage point, depression may cause a relative increase in nondominant hemispheric activity. Furthermore, a reversal of hypofrontality occurs after shifts from

depression into hypomania, such that higher left hemisphere reductions occur in depression compared with more significant right hemisphere reductions in mania. Other studies have observed more specific reductions of reduced cerebral blood flow or metabolism, or both, in the dopaminergically innervated tracts of the mesocortical and mesolimbic systems in depression. Evidence suggests that antidepressants at least partially normalize these changes.

In addition to a global reduction of anterior cerebral metabolism, increased glucose metabolism occurs in several limbic regions, particularly among patients with relatively severe recurrent depression and a family history of mood disorder. During episodes of depression, increased glucose metabolism correlates with intrusive ruminations.

One meta-analysis found three consistent differences when comparing fMRI studies of depressed patients with healthy controls. They found activation of the pulvinar nucleus of the thalamus, a more significant response to negative stimuli in the amygdala, insula, and anterior cingulate, and a lesser response in the dorsal striatum and dorsal lateral prefrontal cortex.

Heredity. Numerous family, adoption, and twin studies have long documented the heritability of mood disorders. Recently, however, the primary focus of genetic studies has been to identify specific susceptibility genes using molecular genetic methods.

Depression aggregates within families, and meta-analytic studies suggest that first-degree relatives of persons with MDD have an increased odds ratio of 2.84. Only limited adoption studies have been done, of varying quality and mixed results and most of what we know about the genetic contribution to the disorder comes from twin studies, which estimate the heritability to be 37%. It appears that this heritability is higher in women. The twin studies also concluded that shared environmental factors did not play a significant role in the familial aggregation of the disorder.

Genome-wide association studies have not found significant associations. Although there are various explanations for the lack of replicated findings, it likely relates to the fact that GWAS is powered to detect common variants and that the genes relevant to depression risk are rare.

Candidate gene studies, which focus on specific genes of interest, have resulted in many reported findings. However, few of these are replicated. The most considerable focus has been on genes that might have a role in the proposed mechanism of depression, such as the gene involved in the encoding of serotonin (HTR1A), the serotonin transporter (5HTTP/SLC6A4), or the dopamine receptor (DRD4) and transporter (SLC6A3). Although some have replicated the most significant associations for these genes (most often for the 5HTTP/SLC6A4 gene), the effects sizes are small, and the sample sizes are smaller than those using GWAS, leading some experts to question whether these are false-negative findings. Suppose some or all of the candidate gene studies are significant. In that case, the most likely interpretation of available findings is that much, or most of, the genetic heritability for depression results from many genes, each contributing a small effect, which only becomes meaningful when combined across thousands of genes. It is also possible, however, that there is some rare, still undetected genetic variant.

Developmental Predisposition. Parents with mood disorders are often in conflict, leading to separation, divorce, and suicide. Heredity often determines the type of environment into which the child predisposed to mood disorder is born. Although not involved explicitly in causing mood disorder, developmental object loss might modify the expression of the illness, possibly by leading to earlier onset, more severe episodes, and an increased likelihood of personality disorder and suicide attempts. The serotonin transporter polymorphism mentioned earlier appears to mediate the relationship between early trauma and depression. Likewise, this polymorphism appears relevant to neuroticism and suicide attempts.

Temperament. Since ancient times, doctors have described persons prone to mania and melancholia as possessing specific temperamental attributes, representing variations on a theme now subsumed under cyclothymic, dysthymic, and anxious-inhibited temperaments, as well as the traits of high neuroticism describing emotionality. Many monozygotic twins discordant for full-blown mood disorders, studied by Aksel Bertelsen's Danish research team, exhibited affective instability with temperamental moodiness, which strongly suggests a genetic basis for these attributes. Research conducted by Kendler's team at the Medical College of Virginia further suggests that several temperamental attributes are transmitted as part of the genetic liability to mood disorders. Research

has also identified such temperaments in the prepubertal offspring of parents with bipolar I disorders, suggesting that they precede by years to decades the overt onset of major mood disorder episodes. The atmosphere of high expressed emotion and the negative critical remarks by relatives and affectively unstable patients documented in the recent psychological literature on mood disorders often reflect the interpersonal clashes between patients and their temperamentally intense relatives. Thus, temperaments appear to be intimately involved in generating much interpersonal friction, emotional arousal, and sleep loss (just to cite common perturbations), thereby eliciting many of the life stressors that precipitate affective episodes. The use of stimulant drugs to self-treat lethargy or enhance hypomanic traits could further contribute to episode precipitation. As for the depressive disposition, the work of Maria Kovacs at the University of Pittsburgh has shown that dysthymia in children evolves into major depressive episodes postpubertally, of which a proportion switch to bipolar states. These data cohere with the work conducted at the University of Tennessee, Memphis, showing shortened REM latency in early-onset dysthymic subjects. The familial bipolar diathesis revealed in the Tennessee work and its tendency to switch to hypomania suggests commonalities between depressive and bipolar II disorders.

Life Events. Most individuals do not develop clinical depression when exposed to environmental adversity. Such adversity seems to play a pathogenic role primarily in those with an affective diathesis. The work of Kendler at the Medical College of Virginia indicates that genetic factors might underlie depressive disorder patients' susceptibility to life events. Furthermore, current data suggest that social stressors in the onset of depression relate more to the first few episodes of the illness. The evidence of this is less convincing for mania. At any rate, stressful events often appear to be triggered by the temperamental instability that precedes clinical episodes. Interpersonal losses are common events in the lives of individuals with intense temperaments. The arousal and sleep loss associated with such events can precipitate both depressive and manic states.

A recent study by Peter McGuffin's team at the Institute of Psychiatry, London, raised the possibility that one mechanism by which heredity produces depression is by creating environmental adversities in the lives

of individuals predisposed to this illness. Independent groups of investigators have replicated this work. Whatever the origin of environmental adversity, it is a common clinical experience that loss represents an important, perhaps even central, theme in clinical depression. Variables that seem to modulate the effect of adult losses include concurrent life events, resultant changes in lifestyle, lack of interpersonal support, deficient social skills, and the symbolic meaning of the putative loss. The research program of George Brown and his followers in London capitalizes on the preceding considerations, particularly the importance of early and proximate losses in socioeconomically disadvantaged women who lack supportive relationships. However, that conceptualization downplays the degree to which the social context of the depression reflects the dysthymic temperamental liabilities of those depressed women. Recent research indicates that even social support is determined to a considerable degree by the genetic mechanisms that underlie mood disorders. Indeed, the short alleles of the serotonin transporter gene may mediate between adverse events and clinical depression.

Biologic Stressors. Many physical diseases and pharmacologic agents are known to precede the onset of both depressive and manic episodes. Like psychosocial stressors, however, other diseases and drugs do not generally seem to cause de novo episodes, but mobilize them in persons with a personal and family history of mood disorders. Thyroid disturbances have a role in practice because they are associated with rapid cycling in bipolar patients, especially women; lithium is often contributory to such disturbances occurring in the depressions in which bipolar women are not uncommonly “stuck.”

Neuroplasticity Hypotheses. Neuroplasticity hypotheses propose that the atrophy of already-developed neurons causes depression. In this version, rather than a deficit of nerve growth, atrophy occurs in already mature neurons. As noted, chronic stress can increase glucocorticoid levels, which can cause atrophy. It can also decrease BDNF expression, which is essential for the survival, growth, and differentiation of neurons in the brain; the result is atrophy. As this preferentially happens in the hippocampus, this can account for the finding of decreased hippocampal volume in depressed patients.

Sex. Clinical and epidemiologic studies agree that women are at higher risk for mood disorders, with the highest risk for depression. Despite many changes in the overall prevalence of depression, the female:male ratio of global disability from the disorder remains unchanged at 1.7:1. This ratio is consistent for developing and developed countries. The global consistency suggests an essential role for biologic sex differences instead of sociocultural and economic factors—the difference in rate starts at puberty and declines after age 65.

This observation appears to be, in part, a function of anxious-depressive traits represented by neuroticism. These traits have strong genetic determinants. Women have higher concentrations of MOA (the enzyme that breaks down monoamine transmitters) in the brain and more precarious thyroid status. In addition, low-estrogen and high-progesterone concentrations are possible mediating factors in postpartum depressions, premenstrual accentuation of affective instability, and women's vulnerability to the depressant effect of steroidal contraceptives. Finally, data point to the role of estradiol in depressions occurring during the transition to menopause.

Personality factors might also be relevant to the sex differences in depression. In collaborative work with University of Pisa psychiatrist Giulio Perugi, Akiskal proposed that female sex might favor the greater expression of dysthymic attributes, whereas hyperthymic traits appear to favor male sex. Those considerations tend to parallel the *ruminative* and *active* cognitive response styles reported by Susan Nolen-Hoeksema, originally at Stanford University, to distinguish the sexes. What specific sex-related biographical factors might interact with sex-related biologic factors to produce such trait differences is mainly unknown. An intriguing possibility is that women, because of temperamental inclination to depressive cognitions, might react more intensely to childhood adversities and be more specifically vulnerable to adult stressors related to bonding with men and child-rearing. Research by Mark George and colleagues has raised the provocative possibility that women over-respond to sad circumstances over a lifetime, thereby permanently altering anterior limbic and prefrontal brain function in a "depressive" direction. The high prevalence of anxious-depressive conditions in women—most pronounced at the clinical level—might be linked, hypothetically, to an evolutionary adaptive advantage conferred by traits of fear, inhibition, and avoidance to women who bear the responsibility of pregnancy and child-

rearing. The higher prevalence of minor depressions in women, rediscovered in a recent Danish study, is in line with the previous hypothesis.

Integrative Approaches

It remains difficult, if not impossible, to incorporate all the various observations and research findings on depression into one grand unified theory. However, the various attempts by investigators and theoreticians to incorporate these findings have certain common features.

It seems clear that there exists some genetic vulnerability that puts persons at risk for depression. Such persons who then encounter stress, either external or internal, have epigenetic changes that differ from normal responses to stress; for example, they may be less able to transcribe certain growth factors in response to stress. This deficit results in subtle neuronal loss, and this loss is particularly apparent in some vulnerable areas (e.g., the hippocampus). The result is a disruption of the usual regulatory systems in the brain, causing changes in the expressions of transmitters, hormones, and other regulatory systems. This combination of effects causes the physical changes that we associate with depression and our behavioral response to this is the subjective feeling of depression.

Therapeutic Perspectives

The previous integrative model mandates the joint use of somatic-pharmacologic and psychosocial interventions. Although the milder forms of mood disorders are manageable with psychotherapy, somatic treatments are usually required to reverse the biologic disturbances in melancholia before the patient can respond to interpersonal feedback. Depressive disorders with psychotic features often necessitate more definitive somatic interventions, such as electroconvulsive therapy (ECT). Continued psychopharmacologic treatment is also effective in decreasing rates of relapse and future recurrence in most. Bipolar disorder and most forms of depression are considered lifelong illnesses that need indefinite maintenance pharmacotherapy.

Psychosocial therapy by skilled clinicians can provide support, combat demoralization, change maladaptive self-attributions, and improve conjugal and vocational functioning. Recent fascinating data support the notion that psychosocial interventions such as cognitive-behavioral therapy modulate cortical-limbic function described earlier as the final

common pathway of depressive illness. Whether such therapy can also modify personality traits to fortify the patient against new episodes is a future research challenge. It might prove more profitable to attempt to help patients to explore professional and object choices that match their temperamental proclivities and assets, which, in turn, might provide them greater harmony and adaptation in life. Although we need to learn much about the indications for medication and psychotherapy in different subtypes of mood disorders, research not only does not support a negative interaction between the two forms of treatment but, on selected parameters, suggests additive and even synergistic interaction. There is a great need for patients, their families, and clinicians to understand how we can approach a biologically driven illness like depression from a pragmatic psychotherapeutic perspective.

The challenge for psychiatric research in the decade ahead is to elucidate the basic mechanisms by which the predisposing, precipitating, and mediating variables reviewed here and others yet to be identified interact to produce the final common path of decompensation in melancholia. Because of the heterogeneity of depressive conditions presenting as a psychobiologic final common clinical syndrome and because antidepressant agents, irrespective of specificity to one or another biogenic amine, are approximately equally effective in two-thirds of those with depressive disorders, the antidepressant agents may be acting not on the primary lesions of these disorders but a neurochemical substrate distal to the underlying biologic faults. Choice of antidepressants is still highly determined by the side effect profile least objectionable to a given patient's physical status, temperament, and lifestyle. That so many different classes of antidepressants—with different mechanisms of action—have been marketed since the 1990s represent indirect evidence for heterogeneity of putative biochemical lesions. The investigation of central neurotransmitter receptor function continues to occupy much current effort to delineate the mechanism of antidepressant action and side effects of classic agents, as well as the new compounds that have made the treatment of depression "clinician and patient friendly." Whether the study of specific receptors will unravel the molecular mystery of depression remains to be seen. Since the 1990s, studies have begun on antidepressant and mood-stabilizing effects on molecular mechanisms believed to be closer to the "genetic underpinnings" of mood disorders. Herein is the promise of the future—a new generation of psychiatrists

conversant with both clinical phenomenology and molecular biology. Data suggest that the biologic specificity of genetic factors in mood disorders might translate into distinct temperamental dysregulations, which, in turn, might predispose to different affective subtypes.

Returning to the therapeutic arena, mounting clinical evidence indicates that, in a particular subgroup of depressed patients with bipolar disorder, antidepressants might provoke mixed episodes, hypomanic episodes, or both and possibly increase later cycling. The kindling-sensitization model suggests the utility of anticonvulsant medication on episode escalation and might represent yet another example of pathophysiologic intervention. Whatever the merit of this model, the 1990s witnessed intense clinical and research interest and U.S. Food and Drug Administration (FDA) approval of the clinical introduction of sodium valproate and lamotrigine for bipolar disorder, and many other promising anticonvulsants are being developed for that disorder. Anticonvulsant mood stabilizers appear to possess a broad spectrum of activity on bipolar disorders, including mixed dysphoric and rapid-cycling forms. Lithium, by contrast, seems more specific to euphoric, or “classic,” mania.

On the other hand, the introduction of atypical antipsychotics—such as olanzapine, risperidone, quetiapine, and aripiprazole—for mania raises intriguing questions about a common neural substrate for schizophrenic and manic disorders. Psychoeducational interventions geared to disturbed rhythms of the disorder represent another example of rational therapeutics. Mood clinics should help patients and their significant others dampen stimulation to keep it at an optimal level for depressed patients with cyclothymic traits. We should also aim to gradually eliminate all offending drugs (e.g., cocaine, caffeine, and sedative-hypnotic agents) and minimize circadian disruptions and sleep loss. The more significant challenge is to learn how to curb the ill-advised actions of patients with cyclical depressions. Unfortunately, current data indicate neurocognitive deficits, particularly in executive function, that underlie or complicate these disorders. Psychoeducation and psychotherapy have the task of ameliorating the resulting social problems, and despite much progress in this realm, these deficits remain stable over time. Compliance with mood-stabilizer regimens that, for many, would attenuate episodes and prevent such sequelae is challenging to achieve. We need further research on treatment or medication adherence techniques for promoting the more efficient use of mood stabilizers.

It is tempting to suggest that biogenic amines, the “humors” of modern psychobiology, play the same heuristic role as the ancient humors did for many centuries. The black humor, appropriately evoked in the construct of melancholia in DSM-5, may not have the same claim for etiologic relevance to depressive disorders as norepinephrine and serotonin, but at least it has a classic heritage. Dopamine, by contrast, may represent the sanguine humor that drives hypomanic temperaments and manic behavior. When we discover the genetic factors contributing to clinical depression and mania, in all likelihood, they will link to temperamental dispositions rather than full-blown affective disease phenotypes. The clinician will still need to interpret the myriad influences that affect such inclinations to produce disease in an individual patient—that is, fundamental scientific advances in mood disorders, rather than diminishing the role of practitioners, will increase it. Regrettably, despite destigmatization efforts and a rich armamentarium of therapeutic developments, the clinical care of affectively ill patients at the severe end of the spectrum continues to be grossly inadequate. More research will not improve this dismal situation unless we address severe mood disorders’ human and social dimensions with the requisite clinical and public health policies. Caring for patients with mental illness is a dimension distinct from evidence-based treatments along psychopharmacologic and psychotherapeutic lines: it requires allocating human resources and integrated mental health structures geared to the total patient.

In any discipline, scientific truth is a function of its technology, but understanding the phenomena under consideration is a philosophical temperament that seeks integration and the hope for a unified vision. Research into the causes and treatment of mood disorders has generated considerable recent data suitable for integrating theory and practice. Conceptualizing the origin and treatment of mood disorders can no longer be justified on the grounds of ideologic preference alone.

ACKNOWLEDGMENT

This chapter is a revision of a previous chapter written by Hagop S. Akiskal, M.D. Sadly, Dr. Asiskal passed away before the writing of this book.

13.2 Mood Disorders: Epidemiology

Kathleen Ries Merikangas, Ph.D., and Zoltán Rihmer, M.D., Ph.D., D.Sc.

Application of the tools of epidemiology to psychiatry over the past several decades has led to numerous advances in our understanding of the magnitude, correlates, patterns of comorbidity, course, impact, and service patterns of mood disorders. Recent contributions of epidemiology continue to be both methodologic developments and substantive knowledge derived from shifting the focus of research from clinical to population-based samples. Methodologic aspects still focus on defining clinical phenomenology including the overlap between mood disorder subtypes, the core features such activation as a core feature of mania, and the spectrum of manifestations of mood disorders. Substantive developments have emerged from the expansion of epidemiologic research from North America, Europe, and developed pan-Pacific countries to less economically advantaged countries across the world that provide global estimates of the tremendous burden of mental disorders and the glaring gap in access to treatment. There also have been advances in documenting medical mental comorbidity that has been facilitated by the increased use and availability of data from electronic health records. Integration of genetic and environmental risk factors is being accomplished with more sophisticated methods that may inform our ability to intervene by preventing these conditions. Increased awareness of diversity of gender, age, ethnicity, and class is leading to increased efforts to address differences in risk profiles in population strata.

This section will provide (1) an update prevalence rates of mood disorder subtypes from international studies, (2) a summary of the demographic and social correlates of mood disorder subtypes, (3) changes in service patterns for mood disorders in general community

samples, and (4) update evidence on the individual and global impact of mood disorders.

DESCRIPTIVE EPIDEMIOLOGY

Bipolar Disorder

The largest series of international studies that provide prevalence rates of mood disorders is the World Health Organization (WHO) World Mental Health (WMH) surveys. Data on BPD was collected in a subset of 11 population-based surveys carried out in the Americas (São Paulo metropolitan area, Brazil; Colombia; Mexico; and the United States), Europe (Bulgaria and Romania), Asia (Shenzhen, People's Republic of China; Pondicherry region, India; and nine metropolitan areas in Japan), Lebanon, and New Zealand. Apart from Japan (unclustered 2-stage probability sample), all surveys were based on stratified multistage clustered area probability samples. In the past few decades, the lifetime prevalence of bipolar I disorder (BPI) has generally been estimated at about 1.0%. The most recent estimates from the largest population-based survey, the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) have reported substantially greater lifetime prevalence estimates of BPI of 3.3, bipolar II (BPII) of 1.1 with corresponding 12-month rates of 2.0 and 0.8, respectively. Recent studies have begun to include estimates for BPII and bipolar spectrum (BPS) disorders as well as BPI. As would be expected, prevalence tends to increase with successively more inclusive disorder definitions. For example, in the WMH Surveys, the cross-national lifetime prevalence of BPS disorders was 2.4%; of which 0.6% met criteria for BPI, 0.4% for BPII, and 1.4% for subthreshold bipolar disorder (sub-BPD) In many (but not all) studies assessing BPII, its prevalence is actually lower than that of BPI; this may indicate that the majority of people who experience hypomanic episodes also experience manic episodes, or may be explained by the major depressive episode (MDE) requirement for diagnosis of BPII.

An increasing number of studies have estimated the occurrence of BPD disorder in youth. Lifetime prevalence rates of BPD in youth range from <1% to 2.9% for BPI/II. A few studies have also estimated 12-month prevalence rates of bipolar disorder, ranging from 1.3% to 2.5%., suggesting that bipolar disorder tends to be enduring. Prevalence rates of

mania range from 0.4% (12 months) to 2.0% (12 months; and rates of hypomania range from 0.1% (Lifetime) to 0.9% (6-month). The results of longitudinal studies converge in estimating the prevalence of bipolar disorder at between 1.4% and 2.1%, which approximates cross-sectional prevalence rates in adult samples. Meta-analysis of epidemiologic studies of BPD in children and adolescents yielded a mean prevalence of 1.8%.

Major Depression

The WMH surveys also provided the largest aggregate data on the prevalence of major depressive disorder (MDD). As shown in Figure 13.2–1, lifetime and 12-month prevalence rates were estimated in 18 countries, divided according to high- and low-middle income. The lifetime prevalence estimates average 11.1 (range 8.0 to 18.4) in low and 14.6 (range 6.6 to 21.0) in high-income countries, whereas the 12-month prevalence rates average 5.5 in high (range 2.2 to 8.3) and 5.9 (range 3.8 to 10.4) in low-income countries. More recent prevalence estimates from the NESARC study were 13.2 for lifetime and 5.3 for 12-month MDD. Although there is a wide range of estimates, the average rates of both lifetime and 12-month depression are consistent across studies that employ comparable methodology.

Several cross-sectional and prospective studies have also reported rates of MDD in youth. A recent meta of 41 studies conducted in 27 countries from every world region yielded a 12-month estimate of any depressive disorder of 2.6% (CI 95% 1.7–3.9). The prevalence of MDD increases significantly across adolescence, more marked among females than males. Most cases of MDD are associated with psychiatric comorbidity and severe role impairment, and a substantial minority reported suicidality. Treatment in any form was received by most adolescents with 12-month DSM-IV MDD (60.4%), but only a minority received treatment that was disorder-specific or from the mental health sector.

Numerous studies have begun to expand the diagnostic criteria for mental disorders to collect information on the spectra of expression of conditions. With respect to mood disorders, the spectrum concept of bipolar disorder long advocated by clinicians has now been validated in community samples of adults and children. Application of the spectrum concept of BPD has yielded rates of bipolarity of up to 5% and depression of up to 20%. Likewise, many individuals in the community may show

some (a few or more) depressive symptoms that do not reach the severity or duration threshold for specific mood disorders in the DSM-5 system but nevertheless, also have substantial morbidity and dysfunction. Although these subthreshold disorders may be less severe forms of major depressive or bipolar disorders, they may also cause substantial suffering as well as disability. Subtypes of subthreshold depression identified in the Zurich Cohort Study and replicated in numerous subsequent studies include recurrent brief depressive disorder and minor depressive disorder (as well as recurrent brief hypomania).

CORRELATES OF MOOD DISORDERS

Sex/Gender

The most consistent finding across all the studies on the prevalence and incidence of unipolar major depression is that it is approximately twofold more common among women than men. This gender difference begins in early adulthood, is most pronounced in people between the ages of 30 and 45, and persists in the older adults. Because there are no data (aside from biologic–hormonal differences) that show that female gender per se means increased vulnerability for depression, increased stress sensitivity, maladaptive coping strategies, and multiple social roles (all of which are frequently seen in women), and substance use disorders that can mask depressive symptoms (more frequently seen in men) have been suggested for the explanation of the gender difference. In addition to these psychosocial theories, recent studies showed that because prior anxiety disorders are more common in women, preceding anxiety disorder may also be a significant factor contributing to the higher depressive morbidity in women. Thus, gender difference in unipolar major depression seems to result from the complex interaction of the mentioned biologic and psychosocial variables. Minor depressive disorder and recurrent brief depressive disorder are also more common among women, but the difference is not so marked as that in major depression.

In contrast to MDD, the gender ratio in BPD (all subtypes combined) is approximately 1:1. However, among bipolar II patients and in special subpopulations (mixed/dysphoric mania, mixed depressive episode, winter depression, bipolar depression with atypical clinical features, rapid cycling BPD), women are overrepresented. Looking at the depression–mania continuum as a whole spectrum, there is a clear trend: the higher

the depressive component, the higher the proportion of women. Consequently, in the rare cases of unipolar mania (manic episode without any major or minor depression), men are markedly overrepresented. The gender differences in lifetime prevalence rates are more marked than in 1-year and current prevalence rates, which may be attributable—at least in part—to the stronger male tendency to forget previous episodes and deny emotionally negative events. Recent population-based epidemiologic surveys showed that the lifetime prevalence and 1-year prevalence of MDD, dysthymia, and bipolar (I + II) disorders were much higher among people with same-sex sexual behavior, (including bisexuality), particularly in the case of men.

FIGURE 13.2–1. Lifetime prevalence of major depression in the world mental health surveys. (Data from Merikangas KR, Jin R, He JP, et al. Prevalence and correlates of bipolar spectrum disorder in the world mental health survey initiative. *Arch Gen Psychiatry*. 2011;68(3):241–251.)

Sexual orientation (lesbians, gay people, bisexual, and transgender [LGBT]) as a potential risk factor for mood disorders has also been increasingly recognized. People from the LGBT community are frequently not just victims of stigmatization, aggression, and physical/sexual abuse, but they are vulnerable to many major mental disorders, including BPD and MDD, anxiety as well as substance-use disorders. LGBT people have also been thought to be at elevated risk of mood disorders as well as suicide attempts and to lesser extent completed suicide. The elevated risk of suicidal behavior of transgender persons does not further increase after sex reassignment (hormonal and/or surgical) therapy. In addition to major suicide risk factors (including elevated rate of mood and anxiety disorders), commonly present in these subgroups, stigmatization, resulting in psychological discomfort is a central contributory factor.

Age

The higher lifetime prevalence of depression is much greater among people younger than 45 years, but the age of onset differs between unipolar and bipolar and familial and nonfamilial cases. The average age of onset of recurrent MDE falls between the ages of 30 and 35 years, whereas single-episode major depression that often lacks family history of mood disorders usually begins some years later. The genetic predisposition for depression decreases with age. However, social stressors appear to place younger individuals at a greater risk for depression than older adults. On the other hand, isolation, loss of interpersonal contacts, medical disorders, and disability play a more important role in the development of depression in later life. Early-onset depression is associated with a higher female-to-male ratio than late-onset depression. Because MDD is a frequent and highly recurrent illness, the probability of recurrence does not decrease with age. The incidence of MDD in old age is lower in both sexes, but first incidence and prevalence of minor depressive disorder show the opposite trend. The incidence of unipolar MDD in the postpartum period is just slightly increased, but this is not the case in the postmenopausal years. Pure (primary) dysthymic disorder typically starts in late adolescence or early adulthood, but, in the absence of appropriate treatment, almost all cases develop later into major depression. The first incidence of dysthymia is also common in old age, but this is typically the consequence of the adverse psychosocial and biologic conditions frequently seen among the older adults.

The age of onset of BPD, most commonly around 20 years of age, is substantially (about 10 years) lower than that of unipolar depression. Men with BPD appear to have a 4 to 5 years earlier onset than bipolar women. In more than half of the cases, onset is before the age of 20, frequently in late adolescence. In contrast to this, first-onset mania is very rare among older adults. The ages of onset of BPI and BPII disorders are similar, but there is a slight tendency for higher age of onset in BPII patients. The incidence of the depressive phase of BPD after childbirth is relatively high, and most patients with “postpartum depression” have bipolar disorder. Like MDD, people with BPD with positive family history of mood disorders are significantly younger at the beginning of the illness and need less stressors to precipitate the illness than those lacking such history.

Race and Ethnicity

It is well-known that cultural differences may influence the clinical presentation of depression and mania, leading to unreliable figures in prevalence studies performed by standard methodology. However, there is now consistent evidence that rates of mood disorders are lower in blacks and Hispanic than in whites. Because of their increased exposure to psychosocial stress and other risk factors for mood disorders, the lower rate in these ethnic subgroups is paradoxical.

Differences in mood disorders in immigrants have been of growing interest because of their implications for both treatment and prevention. European research suggests that immigrants are at greater risk of mental illness, and suicide than are nonimmigrants. Whereas immigrants into the United States are significantly *less* likely than U.S.-born individuals to meet criteria for a range of mental disorders, their offspring often have elevated rates of these conditions. With the increases in worldwide immigration, studies of differential risk to native-born will be a powerful way to identify cultural and environmental exposures related to mood disorders.

SOCIAL CORRELATES

Marital Status

The relationship between marital status and mood disorders is quite complex. For example, being single, divorced, or separated can be either a risk factor for depression or the result of the adverse life events generated by depressive or manic psychopathology, or both. MDD and BPD are most frequent among divorced, separated, or widowed individuals. Single women have lower rates of depression than married women do, but the opposite is true for men. However, being single because of having never married, because of the dissolution of a difficult marriage, and because of widowhood represent three very different conditions. The risk of a MDE is very high among recently widowed individuals of all ages but is particularly high in the older adults. Patients with mood disorder are over-represented among the divorced, and the rate of family breakdown (separation, divorce) is elevated slightly in dysthymic patients, substantially in major depressive patients, and markedly in bipolar I and bipolar II patients. The presence of mania, hypomania, or major depression is a strong predictor for future separation or divorce, which can cause serious distress for the patients and for their

spouses and may generate negative life events for their children. These early negative life events (e.g., parental loss before adolescence) are well-known predisposing factors for adult mood disorders, particularly in the case of family loading (case of subjects with positive family history of mood disorders).

Socioeconomic Factors

Although the relationship between depressive symptoms and low social class is well-documented, most studies found only a weak (but consistent) correlation between MDD and BPI with lower socioeconomic status. Individuals with lower socioeconomic status have a lower level of educational, lower income, and poorer living conditions, as well as a higher rate of unemployment and, ultimately, homelessness. The proportion of MDE was approximately three times higher among individuals without a workplace than among those with one. However, as in the case of marital status and mood disorder, cause and effect may be reversed here, too. Mood disorder can easily lead to unemployment, divorce, or low income, resulting in regression on the social hierarchy scale. Because hypomania is not as disruptive as mania, in terms of academic and social carrier, the educational level of BPII patients is above the average and, in contrast to those with MDD, people with BPI and BPII tend to belong to higher social classes and are relatively overrepresented among socially active, creative people.

Residence

As urban communities are more stressful than rural ones, it is not surprising that most studies performed in Western societies concluded that major depression was more frequent in urban residents than in their rural counterparts. The urban–rural distinction tells us little about the real living and social conditions in general, but it can be a good marker for the density of the population and for other important sociologic variables.

Seasonal Factors

Even though more than two-thirds of patients with recurrent major mood disorders show irregular seasonal patterns individually, statistically, spring and fall are the peak times for depression, just as summer is for mania. Because seasonal affective disorders (fall–winter depression and spring–

summer depression) occur in approximately 20% to 25% of the patients with recurrent major mood disorders, it is possible that the seasonal pattern observed in MDD and BPD, in general, is the consequence—at least in part—of the characteristic annual rhythms of these specific seasonal subtypes. The seasonal profiles of committed and attempted suicides, the prescription of antidepressants and ECT, and the availability of L-tryptophan (the main precursor of serotonin) are very similar to the seasonal onset of MDD. However, acute, and long-term pharmacotherapy of mood disorders (more precisely, its cessation) can change the seasonal pattern of depression and mania, which should be considered either in planning studies or in the interpretation of the results. On the other hand, the decreasing seasonal variation in suicides that has been observed in many countries in the last two decades may reflect, among others, the reduced rate of depression-related suicides in the given population.

There has been growing interest in circadian rhythms that underlie the temporal dynamics of suicide in terms of seasonality as well as shorter-term fluctuations. There has been an increasing focus on motor activity, now a core criterion for mania, as well as it's inter-relationships with sleep and mood regulation, particularly with the increasing availability of mobile tools to track these systems in real-time.

Geographic Trends

There is a general, but weak, trend for lower prevalence of depression and higher rate of mania in regions located closer to the equator. Consistently, at least in the Northern Hemisphere, winter depression (which affects between 1% and 6% of the community) seems to be more frequent in countries situated farther from it. A significant positive correlation was found between prevalence of winter depression and latitude in North America (where its prevalence is twice as high as in Europe), whereas a similar, but only slight, tendency was observed in Europe. On the other hand, the distribution of summer depression across the latitudes shows the opposite tendency. However, the relationship between these two forms of seasonal affective disorder and latitude (e.g., the length of daily photoperiod) is weak. Other climatic and genetic influences, as well as social and cultural factors—which can also be interrelated with the daily photoperiod—may play a role, too. Regarding the West–East dimension, the lower prevalence rates of MDD and BPD reported from Far Eastern countries may be related primarily to cultural

differences and methodologic shortcomings, but there is some recent evidence indicating that the prevalence of major mood disorders in these countries may, in fact, be lower.

PSYCHOSOCIAL FACTORS

Social Stressors

Social stressors, in general, have been well-recognized as risk factors for mood disorders. However, different kinds of social stressors (i.e., childhood vs. adulthood events, acute vs. chronic stressors, positive vs. negative life events) can play different roles in the predisposition and precipitation of depressive or manic disorders. In the case of major depression and bipolar disorder, the association of acute stressors and the onset of illness become progressively weaker with the increasing number of previous episodes, and patients at high-genetic risk for mood disorders commonly experience depressive or manic episodes without any negative life event. In the development of major mood disorders, chronic stressors (e.g., unemployment, difficult marriage) play a more important role than specific, acute stressors. However, accumulation of stressful negative life events is the strongest predisposing factor. The higher level and, probably, the different nature of social stressors in individuals living in urban communities may be among the main sources accounting for their higher psychiatric morbidity. The fact that subjective perception of life events is more important than the event itself makes the estimation of the causative role of life events more difficult. On the other hand, it has also been demonstrated that acute, positive life events (that are quite rare in Western communities) can also precipitate either major depression or mania in vulnerable individuals. Negative life events should not be considered as only predisposing or precipitating factors, as they are frequently the result of the behavior of patients with MDD and, particularly, patients with bipolar disorder.

Social Support

Social support can improve coping and modify (e.g., reduce or eliminate) the occurrence of psychosocial stressors or the adverse consequences of them. The consistent finding in the literature is that living alone, having low socioeconomic status, and being unemployed are significant risk

factors for mood disorders. In other words, it means that weak or lacking social support (including social network, social interaction, and instrumental support) can also be considered a major risk factor. However, regarding social interactions, the frequency of the interactions is more important than the amount. Poor social support is related to onset, relapse, and recurrence of depression, but there is no evidence for the excess of depression among women is caused by reduced social support.

COMORBIDITY

Individuals with major mood disorders are at an increased risk of having one or more additional comorbid Axis I disorders. The most frequent disorders are alcohol abuse or dependence, panic disorder, obsessive-compulsive disorder (OCD), and social anxiety disorder. Conversely, individuals with substance use disorders and anxiety disorders also have an elevated risk of lifetime or current comorbid mood disorder. In both unipolar and bipolar disorder, men more frequently present with substance use disorders, whereas women more frequently present with comorbid anxiety and eating disorders. In general, bipolar patients more frequently show comorbidity of substance use and anxiety disorders than do patients with unipolar major depression. Both clinical and epidemiologic studies show that, if BPII disorder is also considered, comorbidity of substance use disorders and anxiety disorders is the highest in the BPII subgroup. Because comorbid substance use disorders and anxiety disorders worsen the prognosis of the illness and markedly increase the risk of suicide among those with MDD and BPD, the data presented above are consistent with previous findings showing that those with BPD (particularly BPII) are at the highest risk of suicide. These findings also indicate that Axis I comorbidity might be among the most important contributing factor to that risk. However, there is a substantial overlap between mood and substance use disorders. Data from the NESARC study revealed that 41% of those with alcohol use disorders met criteria for primary depression, 17% for concurrent depression, and 42% for secondary depression. This finding supports and extends the results of previous studies conducted among alcoholics in treatment and has strong diagnostic and treatment implications.

Untreated major mood disorders (and particularly BPD) carry extremely high risk of both completed and attempted suicide. This is partly because

they use more violent/more lethal methods. If patients with major mood disorders attempt or commit suicide, they do it mostly during their severe MDE and less frequently in mixed affective episodes or dysphoric mania but very rarely during euphoric mania and euthymia suggesting that suicidal behavior in patients with major mood disorder is a “state-dependent” and severity-dependent. Consequently, the early recognition and appropriate acute and long-term treatment of mood disorders is crucial for suicide prevention. The careful and systematic exploration of clinically detectable suicide risk factors helps clinicians to identify suicidal patients but unfortunately, at the stage of our present knowledge we cannot predict and prevent all suicides.

There is growing interest in studies of comorbidity of mood disorders with medical conditions. Systematic collection of data on chronic conditions in the WMH Surveys provided systematic evaluation of patterns of comorbidity of mental disorder subtypes with the full range of common medical disorders, their impact on severity and course. Prospective studies have continued BPD. There is growing effort to identify biomarkers, particularly inflammatory/immunologic factors-related to the stress system, as potential explanations for comorbidity of mood disorders with cardiovascular disease, diabetes, and cancer. However, it has not been possible to distinguish whether there may underlying common pathophysiologic factors, or the comorbidity was attributable common risk factors, such as smoking, sedentary behavior, alcohol and drug use, and other unhealthy behaviors that are elevated among people with mood disorders.

SERVICE PATTERNS

Adults

Despite the great progress in the diagnosis and treatment of depressions in the last two decades, they remain underdiagnosed and undertreated. North American and European surveys show that approximately half of those who develop mood disorders seek treatment for them, but only a small fraction (about one-third) of recognized depressives receive appropriate treatment. The results of the NESARC study revealed that only 36.8% of those with a current mood disorder had sought disorder-specific treatment for a mood disorder. Interestingly, people with manic episodes were less likely than those with MDE to seek disorder-specific

treatment. An increasing rate of health service utilization is related to increasing severity of depression and to comorbid psychiatric and medical disorders.

Even though many patients with depressive disorders seek help in primary care, general practitioners still have difficulties recognizing and treating depression. The current prevalence of MDD in primary care is approximately 10% to 15% and that of dysthymic disorder is approximately 6% to 8%. Paradoxically, because severe major depression is much more common among those with comorbid chronic medical disorders, depressions with significant somatic comorbidity remain unrecognized in primary care. Population-based studies also show that in individuals with two or more chronic physical illnesses, the 1-year prevalence of severe major depression is fourfold higher than that of individuals without such conditions. Women more often seek treatment for their depression and are more compliant with the treatment than are men, but, unfortunately, “male depression” is less frequently recognized. Because there is no gender difference in the response to antidepressant pharmacotherapy, these facts can help to explain the so-called suicide paradox—that is, even though major depression is much more common in women, it is men who are markedly over-represented among suicide victims. Besides general practitioners, other professionals (i.e., internists, cardiologists, neurologists) also frequently see depressed patients. The point prevalence of MDD in acute (medical–surgical hospital) care is also higher than 10%, a figure well more than the point prevalence rate for the general population. Concomitant depression increases the morbidity and mortality from concurrent medical illness, and patients with simultaneous medical disorder and depression are less compliant with treatment and take longer to recover than nondepressed medical patients.

People with MDD, particularly those who go unrecognized, frequently seek general health care, but depression, if correctly identified, can be effectively treated even in primary care. On the other hand, even though more than half of suicide victims contact different levels of health care 4 weeks before committing suicide, the rate of adequate (antidepressive) pharmacotherapy among depressed suicide victims is disturbingly low. However, epidemiologic and clinical studies, as well as the steadily increasing use of antidepressants (the latter is accompanied by a constant decline in suicide rates in North America, and in Europe, particularly in those countries with traditionally high-suicide rates), indicate that, in the

last 20 to 25 years, the referral, recognition, and successful treatment of depression increased, suggesting that the prognosis for depressive illness, in general, is improving.

Youth

Despite the magnitude and serious consequences of depression in youth, only about one-quarter to less than half of those with mental disorders receive mental health services. Factors associated with service utilization include ethnicity, high-global impairment, comorbidity, prior history of depression, suicide attempt, and impact of the child's problem on the family. School services are the most common point of entry for children seeking services, although those who enter through the education sector are least likely to transition to specialty mental health services. The actual diagnostic process and services provided differ dramatically by the context of entry to service.

There has been accumulating controlled research on the effects of antidepressants in youth, but few studies of either the comparative efficacy of various agents that are commonly used in clinical practice or of individual and family therapies either in conjunction with or independent from drug treatments. There is now growing evidence for a stepped-care approach with increasingly intensive interventions moving from psychosocial to pharmacologic interventions, as well as their combinations.

IMPACT OF MOOD DISORDERS

The importance of role disability has become increasingly recognized as a major source of indirect costs of illness because of its high economic impact on ill workers, their employers, and society. The introduction of the concept of Disability Adjusted Life Years, which estimate the disease-specific reduction in life expectancy attributable to disability and increased mortality has highlighted the dramatic public health impact of mental disorders. By the year 2020, it is estimated that psychiatric and neurologic disorders will account for 15% of the total burden of all diseases. MDD is the leading cause of disability among those age 5 and over, and the second leading source of disease burden surpassing cardiovascular diseases, dementia, lung cancer, and diabetes.

In the most recent estimates of the impact of chronic diseases by the WHO, 2.5% of the total proportion of DALYs was attributable to MDD, and 0.5% to BPD. In terms of DALYs for Mental, Neurologic, and Substance Use Disorders, 24.5% was attributable to MDD and 5% to BPD. Comparative studies of role disability reveal that the effects of mood disorders outweigh those of most other mental and neurologic disorders with a few exceptions. The dramatic impact of mood disorders on lifetime disability highlights the importance of epidemiology in surveillance, understanding, and control of the major mental disorders.

The global burden of mental disorders in children and adolescents up to 24 years of age has also been examined. Like studies within the United States., there is a broad range of estimates of the rates of mental disorders. A recent review reported estimates that ranged from 8% (in the Netherlands) to 57% (for young people receiving services in five sectors of care in San Diego, California, USA). Results from The Australian National Survey of Mental Health and Well-being showed that at least 14% of adolescents younger than 18 years had a diagnosable mental or substance use disorder within the previous 12 months, and this figure rose to 27% in the 18- to 24-year age group. Meta-analysis of the childhood and adolescent data has shown that at least one out of every 4 to 5 young people in the general population will suffer from at least one mental disorder in any given year. However, there is much less information on the burden of mental disorders in developing countries and substantial cross-cultural variations are likely.

Mortality and Mood Disorders

There are now several prospective studies have investigated mortality among those with a range of mental disorders. Data from large population registries in Sweden and Denmark have shown that BPD is associated with substantial elevation in risk of both mortality in general, particularly death by suicide (see Chapter Pompili and Rihmer: Mood Disorders: Suicidal Behavior). The mortality risk associated with mood disorders tends to decrease with age; that is, the high-risk of death by suicide associated with affective disorders in the Danish Registry was much greater during the first 12 months following the initial admission compared to later years. No differences in excess mortality have been shown for different subgroups of mood disorders in either of these registries. A more recent prospective population-based study with direct examinations of

both psychiatric and medical conditions, the CoLaus|PsyCoLaus study found that current Major Depression was associated with a nearly threefold increase in mortality after adjustment for socio-demographic and lifestyle characteristics, comorbid anxiety disorders, antidepressant use, and cardiovascular risk factors and diseases.

HISTORICAL TRENDS

Whereas early community surveys suggested a strong cohort effect for mood disorders, both retrospective and prospective studies show that there has been no direct evidence for a marked increase in the incidence and prevalence of depression over the past decades. The observed changes are mainly due to artifacts of memory and, to a lesser degree, to higher subjective awareness, better definitions, and methods of case identification, redistribution by age and sex (with higher rates among younger women being of recent origin), and increase in childhood-onset mood disorders. Similar findings have emerged for depression in youth with comprehensive meta-analyses showing that there has been no increase in rates of depression across the last three decades.

13.3 Mood Disorders: Clinical Features

ROBERT J. BOLAND, M.D.

TERMINOLOGY

Mood disorders are a pervasive dysregulation of mood and psychomotor activity and related biorhythmic and cognitive disturbances. The rubric of *affective disorder,* which, in some European classifications, also subsumes morbid anxiety states, is increasingly being replaced by the nosologically more delimited concept of *mood disorder.* Thus, *mood disorder* is now the preferred term in the WHO's 10th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) and the American Psychiatric Association's (APA's) fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5). Official mood disorder categories in current use include bipolar disorders (with manic or hypomanic, depressive, or mixed episodes) and major depressive disorders and their respective attenuated variants known as *cyclothymic* and *dysthymic disorders* (called persistent depressive disorder in DSM-5). The term *unipolar* is avoided in DSM-5 because major depressive disorder, especially when early in age at onset, is an unstable diagnosis and can switch to bipolar. Earlier editions had various types of depression, such as *endogenous depression, involutional melancholia,* and *psychotic depressive reaction;* however, starting with DSM-III, they were all incorporated in major depressive disorder. This change meant the end of the neurotic–endogenous distinction, but we now use the term *melancholic features* to qualify major depressive disorders in which biologic concomitants predominate. The United States and international classifications recognize the common occurrence of mixed anxiety–depressions, which underscores the value of the broader affective disorder rubric. It is uncertain whether classic neurasthenic conditions, which have recently reemerged and overlap to some extent with the so-called chronic fatigue syndrome, should be classified under this broad rubric.

RECENT DIAGNOSTIC TRENDS

The reshuffling and reclassification of various affective conditions into the mood disorders chapter of the APA classification in DSM-5 have, on balance, considerably broadened their boundaries. This change reflects, in part, developments in pharmacotherapy that have resulted in considerable alleviation of suffering for persons whose illnesses fall short of and sometimes beyond the boundaries of classic mood disorders. As a result, many individuals with recurrent mood disorders who would have been disabled can now expect to live relatively free of significant episodes and personal or occupational disruptions. Such gratifying results have, in turn, helped to destigmatize this group of disorders. Published self-revelations of famous persons with depressive and bipolar disorders have also helped to destigmatize the disorder. Unfortunately, access to competent mental health care is not available to large segments of the population.

Moreover, destigmatization, which has led to global efforts to detect and treat mood disorders—particularly depression—in public and private sectors, may have had unintended sequelae. Despite the apparent public health advantages of such destigmatization, some authorities nonetheless now contend that a global *depression-centric* perspective has emerged in psychiatric and general medical sectors at the expense of bipolar disorders and may have led to overtreatment with antidepressants and unmasking of latent bipolar disorders. Others believe that the opposite to be true—that is, that we overdiagnose bipolar disorders and overprescribe mood stabilizers. The data, however, indicate that, on balance, it is the continuing underdiagnosis of bipolar disorder that presents the greatest threat to public health. Indeed, recent epidemiologic data suggest considerable disability in untreated or inadequately treated bipolar disorder.

SPECTRUM OF MOOD DISORDERS

The preceding considerations notwithstanding, the increasing clinical diagnosis of major depressive and bipolar disorders should not be dismissed as a mere therapeutic fad. External validating strategies, such as familial-genetic studies and prospective follow-up, can now be used to buttress the broadened concept of mood disorders, including that of bipolar disorder. New research comparing monozygotic and dizygotic twins has demonstrated that the genetic propensity to mood disorders embraces entities that extend beyond endogenous depression (melancholia) to subsume a wider variety of depressions, including some encountered in persons in the community who have never received psychiatric treatment. Although such data might seem counterintuitive to those who would restrict depression to a core primary “biologic” disease, they suggest that the constitutional predisposition for affective dysregulation occurs in as many as one of every three persons. That ratio is similar to the proportion of those who progress to a complete depressive syndrome after bereavement, rhesus monkeys developing depressive-like behavior after a separation paradigm, and dogs that develop learned helplessness after inescapable shock. The fact that these rates are considerably higher than those observed in clinical populations suggests that many people have protective factors against major depressive episodes; alternatively, the data suggest that other factors determine which person with emotional distress becomes a clinical case. Therefore, the study of self-limiting affective conditions on the border of mood disorders can reveal a great deal about the nature of pathologic affective processes.

Evidence from long-term prospective studies indicates that mood disorders consist of various gradations of affective oscillations from the subsyndromal level to the syndromic level. Major episodes represent an operational convention to define a clinical threshold. Subchronic course, dominated by subthreshold symptoms, occurs in 50% to 60%. This is equally true for major depressive disorder and bipolar disorders. Detecting the illness in its subthreshold stage and treating interepisodic subthreshold phases are important clinical considerations.

The suffering and dysfunction resulting from mood disorders are among the most common reasons for consulting psychiatrists and other physicians. In fully developed cases of depression, all activity stops—including creative powers—and life is grim and in total disarray. Although a few talented individuals with milder forms of hypomania may have periods of great creativity, this is not the norm, and most individuals with bipolar

disorder have poor judgment and insight, refuse treatment, and suffer a deteriorative course.

All great physicians of the past, beginning with Hippocrates, have devoted considerable space in their general medical texts to the clinical characterization of melancholic and manic states and their alternations in the same patient. The relationship between anxious and melancholic states was also known. A broad spectrum of affective disturbances—ranging from the relatively mild temperamental variants (represented in the official U.S. nosology by dysthymic and cyclothymic disorders) to their severest forms (including what today is considered mood disorder with mood-congruent and mood-incongruent psychotic features)—has been described in classical medical and psychiatric treatises. Finally, classical authors noted that melancholia and certain physical diseases shared seasonal exacerbation, and they described the common occurrence of alcohol indulgence, especially in individuals prone to mania. These boundary problems continue to pose challenges today, with the addition of substance use disorders.

AFFECTS, MOODS, TEMPERAMENTS, AND THE MORBID MOOD STATES

Ethologic Considerations

Affects and *moods* refer to different aspects of emotion. We communicate affect through facial expression, vocal inflection, gestures, and posture, and (according to current ethologic research) affect is intended to move human beings and other primates to appraise whether an individual is satisfied, distressed, disgusted, or in danger. Thus, joy, sadness, anger, and fear are basic affects that serve a communicative function in primates and many other mammalian species.

Affects tend to be short-lived expressions reflecting momentary emotional contingencies. Moods convey sustained emotions; they are more sustained than mere fleeting emotion, and we experience them inwardly as our current feeling state. We manifest our moods in subtle ways, and assessment requires an empathic interviewer. The words that persons use to describe their inner emotions may coincide with the technical terms used by researchers or clinicians and often vary from one culture to another. Furthermore, the inward emotion and the prevailing affective tone may be discordant. This conflict could be due to deliberate simulation (i.e., the person does not wish to reveal their inner emotion), or it could result from a pathologic lesion or process that has altered the emotions and their neural substrates. Thus, evaluating moods and affective expression requires considerable clinical experience. Such evaluation is obviously of great importance in the differential diagnosis. Finally, it is of great usefulness in the therapeutic process; the admonition to “go after the affect” in psychotherapy helps find where it hurts, thereby making treatment possible.

Sadness and Joy

The usual emotions of sadness and joy are part of everyday life, and we must differentiate them from major depressive disorder and mania. Sadness or routine depressive feelings are a universal human response to defeat, disappointment, or other adversities. The response may be adaptive, in an evolutionary sense, by permitting withdrawal to conserve

inner resources, or it might signal the need for support from significant others. Transient depressive periods also occur as reactions to particular holidays or anniversaries. They can also occur during the premenstrual and postpartum periods. Called various names—*holiday blues, anniversary reactions, premenstrual tension*, and *maternity blues*—this emotional state is not psychopathologic per se, but individuals predisposed to mood disorder may develop clinical depression during such times.

Grief

Normal bereavement or grief, considered the prototype of reactive depression, occurs in response to significant separations and losses. Such losses might include death, divorce, romantic disappointment, leaving familiar environments, forced emigration, or civilian catastrophes. DSM-5 tends to limit the concept of normal grief to loss due to the death of a loved one. However, the work of Elie Karam and colleagues showed that bereavement and other losses associated with the civil war in Lebanon served as potent forces in depression formation. The same was true for the losses due to the earthquake in Armenia. The boundary between normal reactions and clinical depression is blurry in the face of such complex losses. In addition to depressed affect appropriate to the loss, we characterize bereavement reactions by the prominence of sympathetic arousal and restlessness. From an evolutionary perspective, these symptoms may represent physiologic and behavioral mechanisms to facilitate the search for the lost object. Like other adversities, bereavement and loss do not generally seem to cause depressive disorder, except in individuals predisposed to mood disorder. Reactions to significant catastrophes might represent a partial exception.

Elation

Colloquially, we associate the positive emotion of elation with success and achievement. In many cases, it is as simple as that. However, paradoxical depressions may also follow such positive events, possibly because of the increased responsibilities often faced alone. Elation is conceptualized psychodynamically as a defense against depression or as a denial of the pain of loss, as exemplified by *maniacal grief,* a rare form of bereavement reaction in which elated hyperactivity may replace the expected grief. The character of the "merry widow" in opera seems to be of similar derivation.

Other pseudomanic states include the brief energetic and unusually lucid periods encountered in dying patients or those who need to take superhuman action in the face of unusual duress, both of which some experts think of as a *flight into health.* In predisposed persons, such reactions might be the prelude to a genuine manic episode. Sleep deprivation, which commonly accompanies major stressors, might represent one of the intermediary mechanisms between a stressor and adverse clinical outcomes.

Affective Temperaments

Another mediating factor between normal and pathologic moods is temperament. Most persons have a characteristic pattern of basal affective oscillations that defines their temperament. For instance, some are easily moved to tears by sad or happy circumstances, whereas others tend to remain placid. Usually, oscillations in affective tone are relatively minor, resonate with day-to-day events, and do not interfere with functioning.

Some persons exhibit more significant variability of emotional responses whereby, with no apparent provocation, the person alternates between normal mood and sadness or elation. Temperament traits tend to cluster into basic types. Depressive episodes often complicate a worrying temperament associated with generalized anxiety disorder. The episode overlaps considerably with the depressive temperament; such inclination to melancholy makes the person more easily sink into weary and sad moods and occurs in 3% to 6% of the general population.

The hyperthymic temperament, in which the person is ordinarily cheerful, occurs in perhaps 2% to 5% of young adults. Similarly, the cyclothymic temperament, swinging between cheerful and sad moods, characterizes 4% to 6% of young adults. All four types have an early insidious onset and tend to persist throughout adult life. Of interest, these temperaments may be the prelude to episodes of depressive or hypomanic and manic polarity, which underscores the inherent instability of temperamental inclinations. Marked irritable–explosive traits occur in 2% to 3% of young persons and tend to attenuate by middle age. Current data suggest that such traits often coexist with the mood–labile cyclothymic type, representing this temperament's dark "borderline" side.

Examining the traits associated with these temperaments can help support the hypothesis that these traits subserve social and evolutionary functions (Table 13.3–1). Thus, the person with a depressive temperament is hard working, dependable, sensitive to the suffering and needs of others, and suitable for jobs that require sustained devotion to meticulous details; we think of such persons as shouldering the burdens of existence without experiencing its pleasures. A person with the hyperthymic temperament, endowed with high levels of energy, extroversion, and humor, assumes leadership positions in society or excels as a performer in media or entertainment; such persons are also successful from a Darwinian perspective in that they are adept in amorous advances and engender a large number of offspring. In talented persons, the cyclothymic temperament, which alternates between sadness and elation, could inspire love and the emotional intensity needed for composing music, writing poetry, and painting. A person with an irritable temperament might be best suited for a military career or even revolutionary action. The danger with extreme temperaments is that they could swing too far in one direction or both directions (i.e., major depressive, manic, or mixed episodes). The use of such substances as alcohol, caffeine, and other stimulants might destabilize affective regulation in persons with those attributes. Some adolescent girls with irritable cyclothymia might develop the extreme emotional disequilibrium that, in contemporary psychiatry, is considered a borderline personality disorder. Temperament concepts can enrich understanding of the boundary between normal moods and emotional disorders and supplement the DSM-5 descriptors of personality disorders with valuable information about individual vulnerability and assets. A new instrument—the Temperament Evaluation of Memphis, Pisa, Paris, and San Diego—has been developed in an auto questionnaire version (TEMPS-A) and validated in at least 12 languages.

Table 13.3–1.
Attributes, Assets, and Liabilities of Depressive and Hyperthymic Types Derived from Classic Concepts of Temperaments

Depressive	Hyperthymic
Gloomy, incapable of fun, complaining	Cheerful and exuberant
Humorless	Articulate and jocular
Pessimistic and given to brooding	Overoptimistic and carefree
Guilt-prone, low self-esteem, and preoccupied with inadequacy or failure	Overconfident, self-assured, boastful, and megalomaniac
Introverted, with restricted social life	Extroverted and people seeking
Sluggish, living a life out of action	High energy level, full of plans
Few but constant interests	Versatile and broad interests
Passive and “sensitive”	Overinvolved and meddlesome
Reliable, dependable, and devoted	Uninhibited and stimulus seeking

Morbid Mood States

Mood disorders represent abnormal or extreme variations in mood and associated manifestations and have the following features: pathologic mood change, endoreactive moods, recurrence, and impairment.

Pathologic Mood Change. Pathologic moods differ from their normal counterparts by being out of proportion to any concurrent stressor or situation; being unresponsive to reassurance; being sustained for weeks, months, and, sometimes, years; and having a pervasive effect on the person that the mood seriously compromises judgment.

Endoreactive Moods. We diagnose depression and mania, respectively, when sadness or elation is overly intense and continues beyond the expected impact of a stressful life event. Indeed, the morbid mood might arise without apparent or significant life stress. We define the pathologic process in mood disorders, in part by the ease with which an intensely emotional state is released and, especially, by its tendency to persist autonomously even when the offending stressor is no longer operative. Rather than being endogenous (i.e., occurring in the absence of precipitants), mood disorders are best conceptualized as endoreactive (i.e., once released, they tend to persist autonomously). The homeostatic dyscontrol of mood, which is part of more pervasive mood dysregulation, resists the habitual baseline affective tone.

Recurrence. In a more descriptive vein, what sets mood disorders apart from their normal emotional counterparts is the clustering of signs and symptoms into discrete syndromes that typically recur on an episodic basis or pursue an intermittent, subthreshold course over many years, if not a lifetime. Cyclic course and, in some cases, regular periodic recurrence are other signs of mood dysregulation that are particularly relevant to bipolar disorder.

Impairment. Normative reactions to adversity and stress, including biologic stress, typically consist of transient admixtures of anxiety and dysphoria, which DSM-5 includes under the rubric of adjustment disorder with mixed anxiety and depressed mood. That is, self-limiting reactions are best qualified broadly as normal affective states that often produce minor or transient impairments in our core functions.

Although anxiety, irritability, and anger occur in various mood disorders, pathologically sustained mood states of depression and elation characterize those disorders. Morbid mood states (mood disorders) then consist of protracted emotional reactions that deepen or escalate, respectively, into clinical depression or mania, with a tendency to recur or to evolve into unremitting chronicity in 15% to 20% of cases. The contribution of temperamental peculiarities to such outcomes should be apparent. We base the impaired functioning characteristic of mood disorders on a combination of factors, including severity, autonomy, recurrence, and chronicity of the clinical features.

To recapitulate, dysregulation in mood disorders can take different forms. It may occur as a single severe episode that persists autonomously for many months and sometimes years, or it might recur with episodes of varying severity, years apart or in rapid succession, with or without interepisodic remission. In general, the earlier the age at onset, the more likely are recurrences, especially those of bipolar nature. Thus, depending on the course of the illness, impairment could be state dependent and could occur during an episode, or it could extend into the interepisodic period. According to the National Institute of Mental Health (NIMH) estimates, on average, a woman with bipolar disorder spends 12 years in florid episodes (often hospitalized), loses 14 years from a productive career and motherhood, and has her life curtailed by 9 years. The NIMH Collaborative Depression Study, which used weekly prospective observations for up to two decades, showed that patients with bipolar I disorder are symptomatic 47% of the time, and bipolar II disorder patients are symptomatic 53% of the time, much of it spent in subthreshold depression. In this study, the unipolar major depressive disorder was even more pervasive, with subacute chronicity 59% of the time.

Recent observations have also revealed another pattern of impairment. In dysthymic and cyclothymic disorders, which represent an intensification of temperamental instability, impairment is not due to the severity of the mood disturbance per se but to the cumulative impact of the dysregulation beginning in the juvenile or early adult years and continuing unabated or intermittently over long periods; hence, the frequent confusion with character pathology. Here, the impairment is more subtle but is pervasive. Persons with the cyclothymic disorder tend to be dilettantes, whereas those with the dysthymic disorder often lead morose and colorless lives. We should seek the fundamental causes of mood disorders in the preclinical expressions found in the offspring of adults with these disorders.

PSYCHOPATHOLOGY

Depressive Syndrome

Like other illnesses, depressive disorder clusters into signs and symptoms. These criteria attempt to set an operational threshold for the depressive disorder based on a specified number of items and their temporal patterns. A checklist cannot accomplish the diagnosis of clinical depression, but the DSM-5 diagnostic criteria for major depressive disorder

provide a general guide. Only after an in-depth phenomenologic approach can a clinician ascertain the diagnosis of a depressive disorder. Disturbances in all four spheres (mood, psychomotor activity, cognitive, and vegetative) should be ordinarily present for a definitive diagnosis of major depressive disorder.

Mood Disturbances. Mood change, usually considered the sine qua non of morbid depression, manifests in a variety of disturbances, including (1) painful arousal, (2) hypersensitivity to unpleasant events, (3) insensitivity to pleasant events, (4) insensitivity to unpleasant events, (5) reduced anticipatory pleasure, (6) anhedonia or reduced consummatory pleasure, (7) affective blunting, and (8) apathy. The phenomenology and psychometric properties of this broad range of mood disturbances are under investigation at the Salpêtrière Hospital in Paris. The focus in the description that follows is primarily on painfully aroused mood (depression) and diminished capacity for pleasure (anhedonia), two mood disturbances given selective weight in DSM-5 and ICD-10 and 11.

DEPRESSED MOOD. The term *depressed mood* refers to negative affective arousal, variously described as *depressed, anguished, mournful, irritable,* or *anxious.* These descriptions tend to trivialize a morbidly painful emotion, typically experienced as worse than the severest physical pain. Thus, a depressed mood has a somatic quality that, in the extreme, is indescribably painful. Even when not so severe, depressive suffering is qualitatively distinct from its “neurotic” counterparts, taking the form of groundless apprehensions with severe inner turmoil and torment. This description is particularly apt for middle-aged persons and older adults, historically diagnosed as having *involutional melancholia.* The sustained nature of the mood permits no respite, although it tends to lift somewhat in the evening. Suicide may represent an attempt to find deliverance from such unrelenting psychic torment; a depressed person may consider death as comforting.

Patients with a milder form of the malady typically seen in primary care settings might deny experiencing mournful moods and instead complain of physical agony, such as headache, epigastric pain, or precordial distress, in the absence of any evidence of diagnosable physical illness. Past psychiatrists described such conditions as *depressio sine depressione* or *masked depression.* In such cases, often in older patients, the physician should examine the patient’s facial expression, vocal inflection, and overall appearance to help decide whether there is a mood disturbance behind the complaints.

ANHEDONIA AND LOSS OF INTEREST. Paradoxically, patients with a heightened perception of pain may also feel unable to experience normal emotions. Patients exhibiting the disturbance may lose the capacity to cry, a deficit that reverses as the depression lifts.

In evaluating anhedonia, inquiring whether the patient has lost the sense of pleasure is not enough; the clinician must document that the patient has given up previously enjoyed pastimes. When mild, patients with anhedonia have a decreased interest in life. Later, patients complain that they have lost all interest in things. These phenomena are reminiscent of Hamlet’s lament: “How weary, stale, flat, and unprofitable seem to me all the uses of the world” (William Shakespeare, *Hamlet,* Act I, Scene II). In the extreme, patients lose their feelings for their children or spouses, who once were a source of joy. Thus, the hedonic deficit in clinical depression might represent a particular instance of a more pervasive inability to experience emotions.

Patients with severe depression may complain of being emotionally cut off from others and experience depersonalization and a world that seems strange to them (derealization). The impact of the loss of emotional resonance can be so pervasive that patients may denounce values and beliefs that had previously given meaning to their lives. For instance, members of the clergy might present with the complaint that they no longer believe in the Church and have lost faith in God. The inability of the person with a depressive disorder to experience normal emotions (commonly observed among young depressed patients) differs from the flat affect of patients with schizophrenia in that the loss of emotions is itself experienced as painful; that is, the patient suffers immensely from the inability to experience emotions.

Psychomotor Disturbances. In depression, psychomotor changes consist of abnormalities in the motor expression of mental and emotional activity. In severe cases, these changes manifest in specific facial features (Fig. 13.3–1).

PSYCHOMOTOR AGITATION. Although agitation (pressured speech, restlessness, hand wringing, and hairpulling) is the more readily observed abnormality, it appears less specific to the illness than retardation (slowing of psychomotor activity). Psychophysiological studies have documented that such slowing often coexists with agitation.

FIGURE 13.3–1. The Swiss neuropsychiatrist Otto Veraguth described a peculiar triangle-shaped fold in the nasal corner of the upper eyelid. The fold, often associated with depression, is referred to as Veraguth's fold. The photograph illustrates this physiognomic feature in a 50-year-old man during a major depressive episode. Veraguth's fold may also occur in persons who are not clinically depressed, usually while harboring a mild depressive affect. Distinct changes in the tone of the corrugator and zygomatic facial muscles accompany depression, as shown in electromyograms. (Courtesy of Heinz E. Lehmann, M.D.)

PSYCHOMOTOR RETARDATION. Underlying many of the deficits seen in clinical depression, some authorities believe psychomotor retardation to be the core, or primary, pathology in mood disorders. Morbid depression—what patients describe as being "down"—can be understood in terms of moderate-to-extreme psychomotor slowing. The patient experiences inertia, being unable to act physically and mentally. Brain imaging research revealing subcortical (extrapyramidal system) disturbances in mood disorders tend to support the centrality of psychomotor dysfunction in these disorders.

Long neglected in psychopathologic research, psychomotor retardation is one of the few symptoms of depression that is reasonably simple to measure objectively. The Salpêtrière Retardation Scale developed by Daniel Widlocher and colleagues places particular emphasis on the following disturbances: (1) paucity of spontaneous movements; (2) slumped posture with downcast gaze (Fig. 13.3–2); (3) overwhelming fatigue (patients complain that everything is an effort); (4) reduced flow and amplitude of speech and increased latency of responses, often giving rise to monosyllabic speech; (5) a subjective feeling that time is passing slowly or has stopped; (6) poor concentration and forgetfulness; (7) painful rumination or thinking that dwells on a few (usually unpleasant) topics; and (8) indecisiveness or an inability to make simple decisions.

DSM-5 places greater emphasis on the more easily observable objective or physical aspects of retardation. For the patient, however, the subjective sense of slowing is as pervasive and disabling. It is easier to measure this more psychological dimension of retardation in depressed persons with good verbal skills.

Ms. A, a 34-year-old literature professor, presented to a mood clinic with the following complaint: "I am in a daze, confused, disoriented, staring. My thoughts do not flow, my mind is arrested . . . I seem to lack any sense of direction, purpose. . . I have such an inertia, I cannot assert myself. I cannot fight; I have no will."

FIGURE 13.3–2. A 38-year-old woman during a state of deep retarded depression **(A)** and 2 months later, after recovery **(B)**. Note the turned-down corners of her mouth, stooped posture, drab clothing, and hairdo during the depressed episode. (Courtesy of Heinz E. Lehmann, M.D.)

Less linguistically sophisticated patients would simply complain of an inability to perform household chores or difficulty in concentrating on their studies. Such psychomotor deficits, in turn, underlie depressed patients' diminished efficiency or their inability to work.

STUPOR. Psychomotor slowing in young persons is sometimes so extreme that patients might slide into a stupor, unable to participate even in essential biologic functions, such as feeding themselves. Such an episode is often the precursor of bipolar disorder, which later declares itself in a manic episode. Today, we usually diagnose depressive disorders earlier and are more likely to encounter more subtle stupor.

A 20-year-old male college student seen in the emergency room spoke of "being stuck—as if I have fallen into a black hole and cannot get out." Further evaluation revealed that the patient was metaphorically describing his total loss of initiative and drive and felt engulfed by the disease process. A clinician without the requisite phenomenologic training might consider such a patient bizarre and perhaps even psychotic. Nevertheless, the patient responded dramatically to fluoxetine and, in 2 weeks, was back in school.

Cognitive Disturbances. The cognitive view of depression considers negative evaluations of the self, the world, and the future (the negative triad) central to understanding depressed mood and behavior. However, it is equally likely that the depressed mood colors perceptions of the self and others or that disturbed psychomotor activity leads to negative self-evaluations. Therefore, instead of being considered causal,

the cognitive triad in depression is best approached empirically as a psychopathologic manifestation of depression. Depressed persons express faulty thinking patterns as (1) ideas of deprivation and loss; (2) low self-esteem and self-confidence; (3) self-reproach and pathologic guilt; (4) helplessness, hopelessness, and pessimism; and (5) recurrent thoughts of death and suicide.

The essential characteristic of depressive thinking is that the patient views everything in a highly negative light. The self-accusations are typically unjustified or are blown out of proportion. An example might be the case of a middle-aged woman who was tormented by guilt because, as a child, she had not repaid a nickel that she had borrowed from a classmate. Some of the thoughts may verge on the delusional. For instance, an internationally renowned scientist complained that he was "nothing." Self-evaluations that indicate a shallow image of one's self might, nonetheless, reflect an accurate perception of one's impairment from psychomotor retardation.

In addition to content, the cognitive symptoms include various cognitive difficulties, the most pronounced being mental slowing. Patients may also have general difficulties with attention, concentration, and memory. This deterioration of cognitive functions can be so pronounced in older adult that they experience disorientation and confusion. At times the term "pseudodementia" has been used to describe this. However, that may be ill-advised as it implies that the cognitive symptoms are not genuine, which is not the case. Of most concern is the data suggesting that such cognitive symptoms persist beyond antidepressant response and impact the likelihood of recurrence. Because of these findings, there is a growing interest in recognizing and treating the cognitive symptoms of depression.

MOOD-CONGRUENT PSYCHOTIC FEATURES. In depressive disorders with psychotic features, negative thinking acquires grossly delusional proportions and is maintained with such conviction that the thoughts are not amenable to change by evidence to the contrary. According to Kurt Schneider, delusional thinking in depression derives from humankind's four basic insecurities—those regarding health, financial status, moral worth, and relationship to others. Thus, severely depressed patients may have delusions of worthlessness and sinfulness, reference, and persecution: They believe that others single them out for their past mistakes and that everyone is aware of their incompetence. Persecutory ideation in depression is often *prosecutory* in that it derives from the belief that one deserves punishment for such transgressions. A severely depressed man may feel so incompetent in all areas of functioning, including the sexual sphere, that he may suspect his wife of having an affair (delusion of infidelity).

Other depressed persons believe that they have mismanaged their finances in such a way that their children will starve (delusions of poverty); that they are harboring an occult illness, such as cancer or the acquired immune deficiency syndrome (AIDS) (delusions of ill health); or that parts of their bodies are missing (nihilistic delusions). In more severe illness, the patient might feel that the world has changed and that calamity and destruction await everyone. In rare tragic instances, a parent with such delusions might kill their young children to save them from moral or physical decay and commit suicide. In women with psychotic depression, infanticide is most likely to occur in the postpartum period, often leading to all types of inappropriate interpretations in the media. Finally, a minority of depressed persons have fleeting auditory or visual hallucinations with

extremely unpleasant content along the lines of their delusions (e.g., hearing accusatory voices or seeing themselves in coffins or graveyards). All of these psychotic experiences are genuine affective delusions or hallucinations. They are mood congruent in the sense that they are phenomenologically understandable in light of the prevailing pathologic mood.

MOOD-INCONGRUENT PSYCHOTIC FEATURES. Sometimes so-called first-rank or Schneiderian-type symptoms can arise in the setting of a major depressive episode.

> A 42-year-old civil servant said that her depression was so paralyzing that she felt no personal initiative or volition; she believed that some malignant force had taken over her actions and commented on every action she was undertaking. The patient recovered fully with thymoleptic medication. There is no reason to believe that, in this patient, the feelings of somatic passivity and running commentary indicated a schizophrenic process.

Thus, with proper phenomenologic probing, certain classes of apparently mood-incongruent psychotic experiences can be understood as arising from the pathologic mood and the profound changes in psychomotor activity that accompany them. (In other instances, the clinician must seek a history of alcohol or substance use disorder or withdrawal as a putative explanation for mood incongruence in psychotic depression.) In brief, incidental Schneiderian first-rank symptoms should not distract from the diagnosis of an affective psychosis if otherwise typical signs and symptoms of mood disorder are present.

HOPELESSNESS AND SUICIDE. Given that most, if not all, clinically depressed patients find themselves locked in the private hell of their negative thoughts, it is not surprising that many untreated or inadequately treated patients give up hope of ever recovering and kill themselves. The suicide attempt is not, however, undertaken in the depth of melancholia. For example, when asked if she had any suicide plans, a severely depressed patient replied, “Doctor, I don’t exist—I am already dead.”

Thus, the risk of suicide is less pronounced during acute severe depression. Emil Kraepelin observed that when psychomotor activity is improving, yet mood and thinking are still dark, the patient is most likely to muster the requisite energy to commit the suicidal act. Aaron Beck’s work has shown that hopelessness on mental status evaluation in a patient recovering from depression should alert the clinician to the possibility of such an outcome. The discovery of a therapeutic modality that could improve psychomotor, mood, and cognitive components in tandem will constitute a significant clinical advance.

Despite a common belief otherwise, inquiring about suicide does not provoke it. On the contrary, patients are often relieved that the physician appreciates the magnitude of their suffering. Patients commonly express suicidal ideation indirectly (e.g., wish not to wake up or die from a malignant disease). Some depressed persons are tormented with suicidal obsessions and constantly resist unwanted urges or impulses to destroy themselves. Others might yield to such urges passively (e.g., careless driving or walking into high-speed traffic). A third group harbors elaborate plans, carefully preparing a will and taking

out insurance. Deliberate planning indicates a high suicidal risk. The preceding examples are not exhaustive; they are simply reminders to clinicians with depressed patients to be alert always to the possibility of suicide.

Vegetative Disturbances. The Greeks considered depression a somatic illness and ascribed it to black bile; hence, *melancholia.* The mood change in depressive disorder includes measurable alterations of biorhythms that implicate midbrain dysfunction. Once the changes occur, they tend to be independent of the environment throughout much of the episode, and, as a consequence, they do not respond to interpersonal feedback of a pleasant or upbeat nature. The biologic concomitants of melancholia include profound reductions in appetite, sleep, and sexual functioning and alterations in other circadian rhythms, especially matinal worsening of mood and psychomotor performance. These disturbances are central to the concept of melancholia, a form of depression in which such biologic concomitants predominate. An equally important subgroup of depressed persons exhibits a reversal of the vegetative and circadian functions, increasing appetite and sleep—and sometimes in sexual functioning—and an evening worsening of mood; in this atypical pattern, patients characteristically exhibit mood reactivity and sensitivity to rejection. Marked retardation might herald a manic switch, whereas atypicality should raise the suspicion of bipolar II disorder. Table 13.3–2 summarizes the vegetative symptoms of depression.

ANOREXIA AND WEIGHT LOSS. The most reliable somatic indicators of the depressive disorder include anorexia and weight loss. In addition to being a hypothalamic-based disturbance in depression, anorexia might be secondary to blunted olfactory or taste sensations or a decreased enjoyment of food, or (rarely) it might result from a delusional belief that someone has poisoned one's food.

Inanition, especially in older adults, can lead to malnutrition and electrolyte disturbances that represent medical emergencies in their own right. If weight loss is severe, especially after 40 years of age, the psychiatrist should first use appropriate medical consultation to rule out the likelihood of an occult malignancy.

WEIGHT GAIN. Overeating, decreased activity, or both may result in weight gain. In middle-aged patients, it may aggravate pre-existing diabetes mellitus, hypertension, or coronary artery disease. In younger patients, especially women, weight problems may conform to a bulimic pattern that often expresses the depressive phase of a bipolar disorder with infrequent hypomanic periods (bipolar II disorder).

INSOMNIA. Sleep disturbance, a cardinal sign of depression, often is characterized by multiple awakenings, especially in the early hours of the morning, rather than by difficulty falling asleep. The light sleep of a depressed person, in part a reflection of the painful arousal of the disorder, tends to prolong the depressive agony over 24 hours. Thus, deep stages of sleep (III and IV) are decreased or deficient. The attempt to overcome the problem by drinking alcohol may initially succeed but ultimately aggravates the sleep patterns and insomnia. This paradox is also true for sedative–hypnotic agents, which a busy general practitioner might prescribe, having not recognized the underlying depressive condition. Although sedatives (including alcohol) effectively reduce the number of awakenings in the short term, they are not effective in the long run because

they further diminish stage III and stage IV sleep. They are not antidepressants, and they tend to prolong the depression.

Table 13.3–2.
Neurovegetative Symptoms of Depression

Common:
Fatigue, low energy
Inattention
Insomnia, early morning awakening
Poor appetite, associated weight loss
Sometimes included:
Decreased libido and sexual performance
Menstrual irregularities
Worse depression in the AM

HYPERSOMNIA. Young depressed patients, especially those with bipolar tendencies, often exhibit excessive sleep and have difficulty getting up in the morning.

Kevin, a 15-year-old boy, was referred to a sleep center to rule out narcolepsy. His main complaints were fatigue, boredom, and a need to sleep all the time. Although he had always started the day somewhat slowly, he now could not get out of bed to go to school. That alarmed his mother, prompting sleep consultation. Formerly a B student, he failed most of his courses in the 6 months before referral. Psychological counseling, predicated on the premise that his family's recent move from another city had led to Kevin's isolation, had not been beneficial. Extensive neurologic and general medical workup had also proven unremarkable. He slept 12 to 15 hours per day but denied cataplexy, sleep paralysis, and hypnagogic hallucinations. During the psychiatric interview, he denied being depressed but admitted that he had lost interest in everything except his dog. He had no drive, participated in no activities, and had gained 30 pounds in 6 months. He believed that he was "brain damaged" and wondered whether it was worth living like that. The question of suicide disturbed him, as it was contrary to his religious beliefs. These findings led to the prescription of an antidepressant. Not only did the antidepressant reverse the presenting complaints, but it also pushed him to the brink of a manic episode.

The affective nature of the disorder in such patients is often unrecognized, and observers attribute their behavior to "laziness." The vignette also illustrates the emergence of manic behavior during antidepressant treatment. Such shifts in polarity are typical in major depressive disorder and necessitate revising the diagnosis to a bipolar disorder. Hypersomnia associated with lethargy should raise a strong suspicion of bipolar disorder in young depressive patients. In older adults, organic or brain pathology should be suspected.

CIRCADIAN DYSREGULATION. Many circadian functions, such as temperature regulation and cortisol rhythms, are disrupted in major depressive disorder. Disturbances of sleep rhythms, however, have received the most significant research focus. These include deficits in stage IV or delta sleep and more intense REM activity in the first one-third of the night. More specific to depressive disorders—whether suffering from insomnia or hypersomnia—nearly two-thirds of patients exhibit a marked shortening of REM latency, the period from the onset of sleep to the first REM period. This abnormality is observed throughout the depressive episode and may also occur during relatively euthymic periods in persons with recurrent depression. The occurrence of short REM latency in the younger, clinically healthy relatives of the affectively ill may be an early presymptomatic warning sign of the disease. However, on closer scrutiny, these "well" relatives are often found to meet the criteria for subthreshold mood conditions.

Few data exist on the consistency of sleep electroencephalographic (EEG) abnormalities in patients from episode to episode. However, clinical experience suggests that a patient observed over time (even during the same episode) may exhibit insomnia and morning worsening of mood and activity during one period of the disorder and hypersomnia extending to late morning hours during another period. In either case, persons with a depressive disorder are characteristically tired in the morning, which means that even prolonged sleep is not refreshing. Most often, we see this propensity to exhibit such divergent patterns of sleep disturbance in bipolar disorders. Patients with major depressive disorder tend to exhibit insomnia more stereotypically episode after episode; despite extreme fatigue, they rarely oversleep. Such fatigue coexisting with negative affective arousal is even more exhausting.

SEASONALITY. Another classic biorhythmic disturbance in mood disorders is seasonal (especially autumn–winter) accentuation or precipitation of depression. Most of those patients experience increased energy and activation, if not frank hypomania, in the spring. In the fall and winter, they complain of fatigue, tend to crave sugars, and overeat and oversleep. The hypersomnia in some of these patients is associated with delayed (rather than short) REM latencies. These data suggest dysregulation of circadian rhythms in depressive disorders rather than mere phase advance. Given the biphasic nature of the clinical phenomenology, some autumn–winter depressions belong to the bipolar spectrum (type II). Although autumn–winter depression has received the most significant attention, there also exist summer depressions; the former appears to be related to a reduction in daylight (photoperiods), and the latter appears to be related to increased temperature.

SEXUAL DYSFUNCTION. Decreased sexual desire occurs in depressed men and women. In addition, some women experience a temporary interruption of their menses. Depressed women are often unresponsive to lovemaking or are disinclined to participate in it, a situation that could lead to marital conflict. Psychotherapists might mistakenly ascribe the depression to the marital conflict and devote unnecessarily zealous psychotherapeutic attention to those issues. Decreased or lost libido in men often results in erectile failure, which may prompt endocrinologic or urologic consultation. Again, clinicians may mistake depression for sexual dysfunction rather than the reverse, and the focus on the sexual complaint may delay definitive treatment. In the past, some men with depressive disorder received permanent penile implants before any depression treatment. This mistreatment

is less likely to occur in the sildenafil era, but even treatment with such agents would not necessarily resolve erectile disorder in clinically depressed patients without competent treatment of the mood disorder. SSRIs typically aggravate sexual dysfunction, whereas bupropion may improve it.

A small subgroup of patients with depressive disorders may exhibit increased sexual drive or activity of a compulsive nature. These patients tend to have other atypical features as well; hence, the increased sexual drive can be considered the *fifth reverse vegetative sign* (after evening worsening of mood, initial insomnia, hypersomnia, and weight gain). Several patients have derived temporary reversal of their depression after intense sexual encounters. In these depressed persons, increased sexual drive, intensity, or both may indicate a mixed episode of bipolar disorder (type II). Further scrutiny in such cases often reveals a premorbid cyclothymic or hyperthymic temperament. Current data suggest that, depending on the breadth of the criteria used, 30% to 70% of depressions with atypical features belong to the bipolar spectrum.

Manic Syndrome

As with clinical depression, we can organize the psychopathology of mania in terms of mood, psychomotor, circadian, and cognitive disturbances. The clinical features of mania are generally the opposite of those of depression. Thus, instead of lowered mood, thinking, activity, and self-esteem, the patient has an elevated mood, rush of ideas, psychomotor acceleration, and grandiosity. Despite those contrasts, the two disorders share such symptoms as irritability, anger, insomnia, and agitation. An excess of the last symptoms of escalating intensity suggests a mixed phase or mixed episode of mania and depression co-occurring. Manic and mixed episodes represent the hallmark of what psychiatrists used to call *manic-depressive psychosis;* today, we call it *bipolar I disorder.*

Although milder or hypomanic features can contribute to success in business, leadership roles, and the arts, even mild manic symptomatology recurrences are typically disruptive. The elated mood tends to produce overoptimism concerning one's abilities, which, coupled with the impulsivity characteristic of mania, often leads to disaster. Thus, accurate and early diagnosis is paramount.

Classic mania, as formulated in the DSM-5, is relatively easy to recognize. Misdiagnosis was once rampant in North American practice as clinicians confused severe mania with schizophrenia and confused its milder variants with normality or narcissistic and sociopathic personality disorders. As with misdiagnosed depression, these errors of clinical judgment represent a lack of familiarity with the phenomenology of the classic illness. Again, DSM-5 criteria provide only a guideline. The actual diagnosis requires a careful history and phenomenologic understanding by an empathic observer. The manic patient lifts the observer's mood and makes the examiner smile and even laugh, but it can also be irritating. The patient's speech is fast and may even appear to the novice psychiatry student as "loose," but it can often be witty. Finally, the behavior is typically dramatic, expansive, and jesting. Current research indicates that social disinhibition and pathologic overfamiliarity with strangers represent cardinal features of mania which we can contrast with the withdrawal of most schizophrenic patients. For the experienced clinician, the overall gestalt experienced in the presence of manic patients is emotionally and qualitatively distinct from that of persons with schizophrenia or frontal lobe diseases; the latter conditions tend to leave the examiner cold. These considerations become

apparent when the clinical observer systematically examines the psychopathology of mania in the areas of mood, behavior, and thinking.

Mood Disturbance. Mood disturbance in mania represents a contrast to that observed in depression, but not entirely.

MOOD ELEVATION. The mood in mania is classically one of elation, euphoria, and jubilation, typically associated with laughing, punning, and gesturing.

LABILITY AND IRRITABILITY. The prevailing positive mood in mania is not stable, and momentary crying or bursting into tears is common. In addition, the high is so excessive that many patients experience it as intense nervousness. When crossed, patients can become highly irritable and hostile. Thus, lability and irritable hostility are as much features of the manic mood as is elation. In mixed manic states, they dominate the clinical picture, giving rise to what is now termed *dysphoric mania* (and what Kraepelin characterized as *anxious-depressive mania*).

Psychomotor Acceleration. Accelerated psychomotor activity, the hallmark of mania, is characterized by overabundant energy and activity and rapid, pressured speech. Subjectively, the patient experiences an unusual sense of physical well-being (eutonia).

FLIGHT OF IDEAS. Thinking processes are accelerated, subjectively experienced as a flight of ideas, and thinking and perception are unusually sharp. The patient may speak with such pressure that associations are difficult to follow; such “clang” associations are often based on rhyming or chance perceptions and can be lightning fast. The pressure to speak may continue despite the development of hoarseness.

IMPULSIVE BEHAVIOR. Manic patients are typically impulsive, disinhibited, and meddlesome. Pathologic familiarity with total strangers is also a feature not explicitly listed in the DSM-5 schema for mania, yet it is one of its cardinal signs. They are intrusive in their increased involvement with others, leading to friction with family members, friends, and colleagues. They are distractible and move quickly, not only from one thought to another but also from one person to another, showing heightened interest in every new activity that strikes their fancy. They are indefatigable and engage in various activities in which they usually display poor social judgment. Examples include preaching or dancing in the street; abusing the use of long-distance calling; buying new cars, hundreds of records, expensive jewelry, or other unnecessary items; paying the bills of total strangers in bars; giving away furniture; marrying impulsively; engaging in risky business ventures; gambling; and taking sudden trips. Such pursuits can lead to personal and financial ruin.

DELIRIOUS MANIA. Although not listed in DSM-5, a highly severe expression of mania (once known as *Bell mania*), called delirious mania, involves frenzied physical activity that continues unabated and leads to delirium and disorientation—a life-threatening medical emergency. This complication, the manic counterpart of stupor, is rare today.

WITH CATATONIC FEATURES. As a symptom, catatonia can be present in several mental disorders. The presence of catatonic features in patients with mood disorders may have

prognostic and treatment significance. The hallmark of symptoms of catatonia—stuporousness, blunted affect, extreme withdrawal, negativism, and marked psychomotor retardation—can be seen in both catatonic and noncatatonic schizophrenia, major depressive disorder (often with psychotic features), and medical and neurologic disorders. Clinicians often do not associate catatonic symptoms with bipolar I disorder because of the marked contrast between these symptoms of stuporous catatonia and the classic symptoms of mania.

VEGETATIVE DISTURBANCES. Vegetative disturbances are more challenging to evaluate in mania than in depression.

Hyposomnia. Hyposomnia is the cardinal sign of a decreased need for sleep—the patient sleeps only a few hours but feels energetic on awakening. Some patients may go sleepless for several days. This sleep deprivation could lead to a dangerous escalation of manic activity, which might continue despite signs of physical exhaustion.

Inattention to Nutrition. There does not seem to be a clinically significant level of appetite disturbance, but weight loss may occur because of increased activity and neglect of nutritional needs.

Sexual Excesses. Hypersexuality is a cardinal sign of mania. The sexual appetite is typically increased and may lead to sexual indiscretion. Married women with previously stable sexual lives may become promiscuous and involve themselves with strange and even potentially dangerous men. Men typically overindulge in alcohol, frequent bars, and may squander their savings on prostitutes. The sexual misadventures of manic patients result in marital disasters—hence the multiple separations or divorces that are almost pathognomonic of the disorder. The sexual excesses of bipolar patients can also put them at risk of sexually transmitted diseases, including AIDS.

Cognitive Distortions. Manic thinking is overly positive, optimistic, and expansive.

GRANDIOSITY, LACK OF INSIGHT, AND POOR JUDGMENT. The patient exhibits inflated self-esteem and a grandiose sense of confidence and achievements. Behind that facade, however, may be a vague and painful recognition that the positive self-concepts do not represent reality. However, such insight (if present at all) is transient, and manic patients are notoriously refractory to self-examination and insight. Denial and lack of insight are cardinal psychological derangements of mania. This lack of insight—coupled with poor judgment—leads manic patients to engage in activities that harm themselves and their loved ones. It also explains, in part, their nonadherence to medication regimens during the manic phase.

DELUSION FORMATION. Manic patients often harbor delusional beliefs. They may include delusions of exceptional mental and physical fitness and talent, wealth, aristocratic ancestry or another grandiose identity, or assistance (i.e., from powerful or supernatural people). They may also have delusions of reference or persecution, based on the belief that enemies observe or follow them out of jealousy at their unique abilities. At the height of the mania, patients may even see visions or hear voices congruent with their euphoric

mood and grandiose self-image (e.g., they might see images of heaven or hear cherubs chanting songs to praise them). The denial characteristic of mania—and the frequently psychotic nature of episodes—means that clinicians must routinely obtain diagnostic information about past episodes from significant others. Lack of insight also, unfortunately, means that physicians may have to resort to involuntary hospitalization.

MOOD-INCONGRUENT PSYCHOSIS. Psychosis in the setting of mania and mixed manic episodes is typically mood congruent. The sense of physical well-being and mental alacrity is so extraordinary that it is understandable why manic patients believe that they possess superior powers or perhaps are great scientists or famous reformers. Moreover, their senses are so vivid that reality appears more luxurious or exotic. They may interpret their misperceptions as being visions.

Likewise, their thoughts are so rapid and vibrant that they feel that they can hear them. Thus, specific first-rank Schneiderian-type symptoms that have been traditionally considered mood incongruent can be understood phenomenologically to arise from the powerful mental experiences of mania.

A 37-year-old engineer had experienced three manic episodes for which he was hospitalized; before each episode, he had several weeks of moderate psychomotor retardation. Although he had responded to lithium each time, he had been reluctant to take it once outside the hospital and eventually refused to do so. Now that he was euthymic, after his third and most disruptive episode during which he had severely beaten his wife, he could more accurately explain how he felt when manic. He experienced mania as “God implanted in him,” so he could serve as “testimony to man’s communication with God.” He elaborated as follows: “Ordinary mortals will never, never understand the supreme manic state which I am privileged to experience every few years. It is so vivid, so intense, so compelling. When I feel that way, there can be no other explanation: To be manic is, ultimately, to be God. God himself must be supermanic: I can feel it when mania enters through my left brain like laser beams, transforming my sluggish thoughts, recharging them, galvanizing them. My thoughts acquire such momentum. They rush out of my head to disseminate knowledge about the true nature of mania to psychiatrists and all other ordinary mortals. That’s why I will never accept lithium again—to do so is to obstruct the divinity in me.” Although he was on the brink of divorce, he would not yield to his wife’s plea to go back on lithium.

The vignette illustrates the possibility that even some of the most psychotic manifestations of mania represent explanatory delusions, the patient’s attempt to make sense of the experience of mania. Many manic patients abuse alcohol and stimulants to enhance their mental state; we can sometimes explain mood incongruence on that basis.

HYPOMANIA VERSUS MANIA. Nonpsychotic and nondisruptive variants of mania are much more common, and DSM-5 recognizes them as hypomanic episodes. They are the historical clinical marker for bipolar II. Diagnostically, significant others can provide a history of hypomania, as the subject may be unaware of it or may tend to deny it. Others experience irritable or dysphoric hypomanic episodes, which may be difficult to recognize

clinically because of a stereotype that emphasizes the positive aspects of hypomania. Some patients feel that they benefit from the energy and confidence of hypomania. This potential benefit is true if hypomania is mild and "sunny." But, many patients, especially those with "darker" irritable activation, experience impairment in occupational and interpersonal functioning over time. DSM-5 stipulates a minimum duration of 4 days for hypomania; however, current evidence indicates that bipolar II disorders with long (4 or more days) and short (2 to 3 days) hypomania are indistinguishable based on bipolar family history. It is, therefore, recommended that the threshold for detecting the duration of hypomania be set at 2 days. Ultimately, the duration of hypomanic experiences might be less important than the fact that they recur. In other words, the occurrence of brief recurrent hypomanias, even if their duration is 1 day, interspaced with major depressive episodes, can be taken as presumptive evidence for bipolar II. Finally, although DSM-5 states that treatment-emergent hypomania in a depressed patient does not count toward a diagnosis of bipolarity, prospective observations show that nearly all such episodes are followed eventually by spontaneous hypomania (or mania); moreover, family history for bipolar disorder is comparable in patients with spontaneous and antidepressant-associated hypomania. In brief, antidepressant-associated hypomanias are likely a genetically less penetrant variant of bipolarity (which, in the literature, are often referred to as *bipolar III disorders*).

DIAGNOSTIC CLASSIFICATION

Tables 13.3–3 through 13.3–7 list the most significant mood disorder diagnoses and compare the DSM-5 and ICD-11 approaches to diagnosing these disorders.

The classification of mood disorders in DSM-5 subsumes many patients seen in private, public, ambulatory, and inpatient settings. The main demarcation in that large clinical terrain is between bipolar and depressive disorders. Thus, bipolar disorders range from the classic manic and depressive episodes, often of psychotic intensity (bipolar I disorder), to recurrent major depressive episodes alternating with hypomanic episodes (bipolar II disorder) and cyclothymic mood swings. Likewise, depressive disorders include those with psychotic severity, melancholia, atypical features, and dysthymic variants.

We can distinguish the major and specific attenuated subtypes by their severity and duration. In dysthymic and cyclothymic disorders, a partial mood syndrome consisting of subthreshold features as subdepressive and hypomanic periods is maintained, intermittently or continuously, for at least 2 years. Subdepressive periods dominate in dysthymia; in cyclothymia, they alternate with brief hypomania. The onset is typically in adolescence or childhood, and most persons with these diagnoses first seen clinically in young adulthood have had low-grade mood symptoms for 5 to 10 years. Major mood disorders, which generally begin much later in life, require the presence of a full manic episode or a full depressive episode—sustained for at least 1 and 2 weeks, respectively—and an episodic course, typically permitting recovery or remission from episodes. As many as one-third of persons with major depressive disorders fail to achieve full symptomatic recovery and should thus be qualified as chronic or partial remission.

Dichotomy or Continuum?

Although we can discriminate between bipolar and depressive disorders clinically and therapeutically (Table 13.3–8), clinical observations testify to a vast overlap between those extremes. Thus, the distinctions among the various affective subtypes are not as hard and fast as DSM-5 attempts to portray. For instance, full-blown bipolar disorder can superimpose on a cyclothymic disorder that tends to persist after the resolution of manic or major depressive episodes. Even more common is major depressive disorder complicating cyclothymic disorder, which should be a significant course variant of bipolar II disorder. Likewise, recent evidence indicates that dysthymic disorder may precede major depressive disorder in as many as one-third of cases. DSM-5 recognizes this overlap by including "mixed" subtypes for both major depressive disorder and bipolar disorder. However, it does not entirely resolve the question of where the boundaries lie.

Moreover, as much as 50% of persons with a major depressive disorder during long-term prospective follow-up develop hypomanic or manic episodes and have bipolar disorder. In some, if not many instances, apparent switching of polarity might be due to earlier misclassification of bipolar disorder as major depressive disorder. Finally, there may be an unexpected crossing from dysthymic disorder to hypomanic or manic episodes, suggesting that some forms of dysthymic disorder are subaffective precursors of bipolar disorder. The concept of *subbipolar dysthymia* (not a formal category in DSM-5) can bring clinical attention to this subgroup of patients. Such observations are in line with Kraepelin's historic attempt to bring all mood disorders under one rubric. Epidemiologic studies in the community have also shown much fluidity among various subthreshold and major mood disorders.

Heterogeneity undoubtedly exists among mood disorders. However, the classic unipolar–bipolar distinction might not be the best way to capture it. The preceding observations suggest that much of the recurrent depressive terrain might be *pseudounipolar* (i.e., soft bipolar). The clinical significance of these considerations lies in the fact that many DSM-5 subtypes of mood disorders are not pure entities, and considerable overlap and switches in polarity take place. They also provide some rationale, for instance, for why lithium or other mood stabilizer augmentation may be effective in some unipolar depressions; such patients do not necessarily experience brief spontaneous hypomanic episodes but often exhibit high baseline level hyperthymic traits. Finally, several studies have shown that bipolar patients with cyclothymic premorbid adjustment and interepisodic adjustment are at considerable risk of *antidepressant-induced rapid cycling,* defined as a rapid succession of major episodes with few or no intervals of freedom.

As Kraepelin illustrated in his monograph, we can best capture the course graphically (Fig. 13.3–3). After diagramming 18 illustrative patterns for the entire spectrum of manic-depressive illness, Kraepelin declared that the illness pursued an indefinite number of courses. Although not represented in the official U.S. and international classifications, some of these course patterns are of considerable interest today. For instance, a biphasic course (a sequence in which episodes of opposite polarity succeed each other, followed by a free interval) is relevant to treatment response. Thus, depression followed by mania or hypomania—compared to mania or hypomania followed by depression—appears less responsive to lithium based on replicated studies.

DEPRESSIVE DISORDERS

The broad category of depressive disorders includes major depressive disorder, dysthymic disorder, and depressive disorder not otherwise specified.

Major Depressive Disorder

Episodes usually begin over a prodromal period of weeks to months. The DSM-5 and text revision, or DSM-5-TR diagnosis of major depressive disorder requires one of the following: (1) dysphoric mood or (2) decreased interest in usual activities. Table 13.3–3 lists the full range of signs and symptoms. Such symptoms continue for at least 2 weeks, and there is no alternative process that can otherwise explain the depressive symptoms (such as normal bereavement or other physical or mental disorders known to cause depressive symptoms). It can be a single episode or, commonly, recurrent, or both.

Comorbid Physical Disease. The preceding considerations raise the question of whether major depressive disorder should be limited to depressions of unknown etiology (i.e., those without documented physical causes). The DSM-5 approach has been that, when the cause is known, we should diagnose the condition as a mood disorder due to a general medical condition (that must be specified) or substance-induced mood disorder. The problem with this approach is that many common medical factors historically associated with depression do not seem to be causative in the etiologic sense but rather are triggering agents in otherwise predisposed persons. This problem is analogous to the role of life events, which we no longer use to distinguish between reactive and endogenous subtypes of depression. A more troubling implication is that major depressive disorders without demonstrable physical disease are not medical or otherwise biologic. More importantly, there appears to be no reliable or valid way for a clinician to decide that a depressive condition is due to a specified medical condition. In brief, the designation *due to a general medical condition* is cumbersome and redundant. We would be better off thinking of major depressive disorder as a final common pathway of multifactorial interacting factors—physical and psychological—a syndrome that we should diagnose irrespective of the presumed cause.

Table 13.3–3.
Major Depressive Disorder

	DSM-5-TR	ICD-10	ICD-11
Diagnostic Name	Major Depressive Disorder	Major Depressive Episode	Major Depressive Disorder
Duration	2-week period	N/A	
Symptoms	Dysphoria/Depressed mood Anhedonia Change in weight or appetite Change in sleep pattern Psychomotor disturbance: agitation or retardation Fatigue/decreased energy Depressive ruminations: worthlessness, guilt Poor concentration Recurrent thoughts of death, suicidal ideation, or a plan	Lowered mood Reduced energy Decreased activity Reduced capacity for enjoyment Reduced interest Reduced concentration Fatigue after even minimal effort Disturbed sleep/early morning awakening Disturbed appetite/weight loss Poor self-esteem Poor self-confidence Guilt or worthlessness Mood unreactive to circumstances Anhedonia Worse symptoms in the AM Psychomotor disturbance: agitation or retardation Loss of libido	**Affective cluster** ▸ Depressed mood ▸ Anhedonia **Cognitive-behavioral cluster** ▸ Poor concentration ▸ Low self-worth or inappropriate guilt ▸ Hopelessness ▸ Recurrent thoughts of death, suicidal ideation, or a plan **Neurovegetative cluster** ▸ Disrupted sleep ▸ Change in appetite ▸ Psychomotor agitation/retardation ▸ Fatigue/decreased energy
Required number of symptoms	5 (1 of these has to be symptom 1 or 2 listed above)	N/A	5 (≥1 from the affective cluster)
Psychosocial	Distress or impaired	Depends on	Significant impairment

consequences	functioning (social, occupational, or other significant areas)	severity	in ≥1 domain
Exclusions	Other medical condition Substance or medication, including withdrawal Other mental illness History of: ▶ manic episode ▶ hypomanic episode	Adjustment disorder Conduct disorder Recurrent depressive disorder (which is considered a separate diagnosis)	Bereavement Mixed episode bipolar disorder Other medical consideration Effects of substance or medication
Symptoms specifiers	**With anxious distress** ▶ 2+ symptoms of anxiety **With mixed features** ▶ 3+ manic/hypomanic symptoms occurring during the depressive episode (if occur independently, diagnose bipolar disorder) **With melancholic features** ▶ Loss of pleasure or reactivity to pleasure ▶ 3+ of the following: ▶ Severe depression/despair ▶ Mood worse in AM ▶ Early morning awakening ▶ Psychomotor disturbance ▶ Anorexia/weight loss ▶ Guilt **With atypical features** ▶ Mood reactivity ▶ ≥2: ▶ Increased appetite/weight ▶ Hyposomnia ▶ Leaden paralysis ▶ Rejection sensitivity ▶ With mood-congruent psychotic features	Depressive reaction Psychogenic depression Reactive depression	Mild Moderate Severe Unspecified With/without psychotic symptoms With prominent anxiety symptoms With panic attacks Current depressive episode persistent Current depressive episode with melancholia With seasonal pattern Associated with pregnancy, childbirth, or puerperium

	▶ With mood-incongruent psychotic features **With psychotic features:** symptoms occur only during a depressive episode. Also specify if delusions are mood congruent or incongruent. **With catatonia** ▶ Must be present during most depressive episodes **With peripartum onset** **With seasonal pattern** ▶ Usually occurs during a specific season		
Course specifiers	**In partial remission:** full criteria no longer met **In full remission**: no symptoms of an episode for the past 2 months	**Recurrent depressive disorder** (coded as a separate disorder). Repeated episodes of the above symptoms. No mania.	**In partial remission** **In full remission**
Severity specifiers	**Mild:** Minimum # symptoms **Moderate:** between mild and severe **Severe:** # of symptoms, the severity of symptoms, or dysfunction is much more than required for a diagnosis	**Mild** ▶ 2–3 symptoms. ▶ Functions normally despite the distress **Moderate** ▶ 4+ symptoms ▶ Difficulty with functioning **Severe** ▶ Several symptoms marked and distressing	

- Loss of self-esteem/feels worthless and guilty
- Suicidal ideation/acts
- Somatic symptoms of depression

Severe with psychotic symptoms

- As above but with psychosis

Other

- Atypical depression
- Single episodes of “masked depression”

Unspecified

Table 13.3–4.
Persistent Depressive Disorder/Dythymia/Dysthymic Disorder

	DSM-5-TR	ICD-10	ICD-11
Diagnostic Name	Persistent Depressive Disorder	Dysthymia	Dysthymic Disorder
Duration	Symptoms continuously present for ≥2 years No time during the affected period of no symptoms for >2 months		≥2 years
Symptoms	Depressed mood most of the time on a majority of days over a period of ≥2 years (NOTE: in children, irritability may be present, and duration must be for a period of ≥1 year) During the depressed period: ▶ Abnormal appetite (↑ or ↓) ▶ Abnormal sleep (↑ or ↓) ▶ ↓ energy ▶ ↓ self-esteem ▶ ↓ concentration or ↑ indecisiveness ▶ Hopelessness	Chronically depressed mood that does not meet criteria for a depressive episode, though criteria may have been met in the past.	Persistent depressed mood Additional symptoms of depression. May include: ▶ Anhedonia or decreased interest ▶ Poor concentration ▶ Low self-worth or inappropriate guilt ▶ Hopelessness ▶ Disturbed sleep ▶ Change in appetite ▶ Fatigue or low energy
Required number of symptoms	≥2 bulleted symptoms		
Psychosocial consequences	Marked distress and/or functional impairment		Marked distress and/or functional impairment
Exclusions	This cannot occur if a history of bipolar disorder Other medical condition Substance or medication, including withdrawal Other mental illness	Result of: ▶ Anxiety ▶ Depression ▶ Bereavement ▶ schizophrenia	A depressive episode in the first 2 years of the disorder History of manic, mixed, or

		hypomanic episodes Other medical condition Substance or medication, including withdrawal
Symptoms specifiers	**With pure dysthymic syndrome:** criteria for the depressive episode not met in the last 2 years **With persistent major depressive episode:** has met diagnostic criteria for a depressive episode for an entire 2-year period **With intermittent major depressive episode, with current episode:** though may currently meet criteria for major depressive disorder, has had a period of ≥8 weeks during the prior 2-year period during which symptoms were below the diagnostic threshold for a depressive episode **With intermittent major depressive episode, without current episode:** Does not currently meet criteria for a depressive episode, though has experienced ≥1 depressive episode over the course of the prior 2 years. **With anxious distress:** including ≥2 symptoms among feeling tense, restlessness, difficulty with concentration due to worrying, excessive fear without an identifiable cause, fear of loss of control **With mixed features—**full criteria met for either depressive or manic/hypomanic episode, with	

	additional symptoms of depressive or manic/hypomanic period without also meeting full criteria **With melancholic features—** involving loss of pleasure, reduced reactivity with ≥3 of the following: ▶ Depressed mood/despair ▶ Depressive symptoms worse in the morning ▶ Early morning awakening ▶ Psychomotor changes ▶ Loss of appetite/weight loss ▶ Excessive guilt **With atypical features:** during most days, an individual is experiencing mood reactivity with ≥2 symptoms: ▶ Weight gain or increased appetite ▶ Excessive sleeping ▶ Leaden paralysis ▶ A pattern of heightened interpersonal rejection sensitivity **With mood-congruent psychotic features—**mood-congruent delusions or hallucinations **With mood-incongruent psychotic features—**mood-incongruent delusions or hallucinations
Course specifiers	**With peripartum onset—**full criteria for a mood episode are met during pregnancy or within 4 weeks of delivery
Severity specifiers	**Mild—**few symptoms in excess of minimum diagnostic criteria, with no to minimal impairment and/or distress **Moderate—**moderate symptomatology and impairment

Severe—symptoms in marked excess of minimum diagnostic requirement, with marked distress and impairment in functioning

Table 13.3–5.
Bipolar 1 Disorder

	DSM-5-TR	ICD-10	ICD-11
Diagnostic Name	Bipolar 1 Disorder	Bipolar Affective Disorder ***NOTE**:* ICD-10 does not distinguish between Bipolar 1 and 2, requiring only a history of discrete episodes of mania, hypomania, and/or depression, with episodes demarcated by switches in mood/affect.	Bipolar 1 Disorder
Duration	Manic episode: 1 week+ Hypomanic episode: 4 days+ Major depressive episode: 2 weeks+	Manic episode: 1 week+ Hypomanic episode: 4 days+ Major depressive episode: 2 weeks+	1 week+
Symptoms	**Manic or hypomanic episodes** ▶ Abnormally ↑ or irritable mood (required) ▶ Grandiose thoughts ▶ ↓ need for sleep ▶ Pressured speech ▶ Racing and expansive thoughts ▶ Distractibility ▶ Hyperactivity ▶ Impulsivity/high-risk activities **Depressive episodes** Similar to that for major depressive disorder	History of episodes of mania, hypomania, and/or depression Switches in mood/affect **Mania** ▶ Abnormally ↑ or irritable mood (required) ▶ Abnormally elevated or irritable mood ▶ ↑ activity ▶ ↑ talkativeness ▶ Flight of ideas/racing thoughts ▶ Social disinhibition ▶ ↓ need for sleep ▶ Grandiose thoughts ▶ Distractibility ▶ Impulsivity/recklessness ▶ Hypersexuality **Hypomania** ▶ Abnormally ↑ mood (required) ▶ Psychomotor agitation ▶ ↑ talkativeness ▶ Poor concentration/distractibility ▶ ↓ need for sleep ▶ Hypersexuality	**Manic episode** ▶ Extreme mood state (euphoria, irritability of expansiveness) ▶ Increased activity ▶ Talkativeness ▶ Flight of ideas ▶ Increased self-esteem ▶ Decreased need for sleep ▶ Distractibility ▶ Impulsivity ▶ Increased libido, sociability, or goal-directed activity **Mixed episode** Several prominent manic and several prominent depressive symptoms

		▶ Impulsivity/ or ↑ spending ▶ Over-familiarity **Depressive episode** ▶ Depressed mood ▶ Loss of interest or pleasure ▶ Decreased energy *Additional symptoms:* ▶ Low self-esteem ▶ Excessive guilt or shame ▶ Recurrent thoughts of death or suicide ▶ Poor concentration ▶ Psychomotor changes ▶ Sleep disturbance ▶ Change in appetite and/or weight	
Required number of symptoms	≥1 manic episode Abnormally ↑ or irritable mood required 3 of the other symptoms (4 if irritable mood)	**Bipolar affective disorder, current episode hypomanic** Hypomania (elevated mood and ≥3 symptoms History of a prior affective episode (manic, hypomanic, depressed, mixed) **Bipolar affective disorder, current episode manic** Mania (elevated or irritable mood and ≥3 symptoms (4 if irritable mood) History of prior affective episodes (manic, hypomanic, depressed, mixed) **Bipolar disorder, current episode mild/moderate/severe depression** depressive episode (2/3 of the first 2 symptoms and 2 more of the additional symptoms) History of prior affective episodes (manic,	≥1 manic or mixed episode consisting of first 2 symptoms listed above, plus several of the other symptoms listed.

		hypomanic, depressed, mixed) **Bipolar disorder, current episode mixed** A mixture or rapid alternation of hypomanic, manic, and/or depressive symptoms (defined above) History of prior affective episodes (manic, hypomanic, depressed, mixed)	
Exclusions	Other medical condition Substance or medication, including withdrawal Other mental illness	Psychoactive substance use Another mental disorder	Other medical condition Substance or medication, including withdrawal
Psychosocial Consequences	***Manic Episode:*** impaired functioning or needing hospitalization Hypomanic episode: No impairment or need for hospitalization Depressive episode: marked distress and/or psychosocial impairment		Impairment in ≥1 functional domain, or requiring intensive treatment (hospitalization), or includes hallucinations or delusion.
Symptom specifiers	**Mild—**2 symptoms **Moderate—**3 symptoms **Moderate-severe—4–5** symptoms **Severe—**4–5 symptoms + motor agitation **With mixed features**	**Current episode hypomanic** **Current episode manic without psychotic symptoms** **Current episode manic with psychotic symptoms** **Mood congruent** **Mood incongruent** **Current episode of depression** **Current episode mixed**	**Current/most recent episode:** Manic Hypomanic Depressive Mixed **With/without psychotic symptoms** **With prominent anxiety**

	Either a depressive or manic/hypomanic episode Additional symptoms of depressive or manic/hypomanic period (not full criteria) **With rapid cycling** ≥4 mood episodes in 1 year ≥2-month period of partial/full remission between episodes **With melancholic features** Similar to that for major depressive disorder **With atypical features** Similar to that for major depressive disorder **With anxious distress:** ≥2 symptoms among the following: Feeling tense Restlessness Difficulty with concentration due to worrying XS fear without cause Fear of loss of control	**Currently in remission**–no symptoms. History of previous episodes. ***With somatic syndrome*** *≥4 of the following:* ▶ *Loss of interest or pleasure* ▶ *Lack of emotional reactivity* ▶ *Early morning awakening* ▶ *Depression gets worse in the mornings* ▶ *Psychomotor changes* ▶ *Loss of appetite* ▶ *Weight loss* ▶ *Loss of sexual drive*	**symptoms** **With panic attacks** **With Seasonal pattern** **With rapid cycling** **Associated with pregnancy, childbirth or the puerperium**
Course specifiers	**With peripartum onset:** episode occurs during pregnancy or within 4 weeks after delivery		

	With seasonal pattern: pattern present for ≥2 years		
Severity specifiers		**For the current episode of depression** **Mild:** 4 symptoms **Moderate:** 6 symptoms, including ≥2 among loss of pleasure, depressed mood, and low energy **Severe depression** ≥8 symptoms, including all loss of pleasure, depressed mood, and low energy **without psychotic symptoms** **with psychotic symptoms** **mood congruent** **mood incongruent**	**Mild** **Moderate** **Severe** **Unspecified severity**

Diagnostic Threshold. Another question concerning the definition of major depressive disorder relates to the threshold at which a constellation of depressive features becomes a condition distinct from the ordinary blues. Within the current definition, if a person responds to a setback with lowered spirits and self-doubt, difficulty in sleeping and concentration, and decreased sexual interest for 14 days, they would qualify for the diagnosis of a major depressive disorder of mild intensity. Many clinicians would consider such a condition a relatively minor departure from normality, probably no more than an adjustment disorder. Criteria other than signs, symptoms, and duration are necessary to differentiate a major depressive disorder from adjustment reactions to life situations. The presence of the following characteristics might assist in such a differentiation:

Table 13.3–6.
Bipolar 2 Disorder

	DSM-5-TR	ICD-10	ICD-11
Diagnostic Name	Bipolar 2 Disorder	Bipolar Affective Disorder ***NOTE**:* ICD-10 does not distinguish between Bipolar 1 and 2, requiring only a history of discrete episodes of mania, hypomania, and/or depression, with episodes demarcated by switches in mood/affect.	Bipolar Type II Disorder
Duration	**Hypomanic episode:** lasting ≥4 days, with symptoms, present most of the day for most days **Major depressive episode**: symptoms lasting ≥2 weeks	Manic episode: lasting ≥1 week Hypomanic Episode: lasting ≥4 days, Major depressive episode: symptoms lasting ≥2 weeks	Several days
Symptoms	Hypomanic episodes involve abnormally elevated or irritable mood with: ▶ Grandiosity ▶ Decreased need for sleep ▶ Pressured speech ▶ Racing thoughts with expansiveness of thought ▶ Distractibility ▶ Goal-directed or non-goal-directed hyperactivity ▶ Engagement in high-risk activity or increased impulsivity Depressive episode involving depressed mood and/or decreased	History of discrete episodes of mania, hypomania, and/or depression, with episodes demarcated by switches in mood/affect. Episodes are defined as follows: **Mania:** abnormally elevated or irritable mood with ≥3 of the following (≥4 if mood irritable) ▶ Increased activity ▶ Increased talkativeness ▶ Flight of ideas/racing thoughts ▶ Social disinhibition ▶ Decreased need for sleep ▶ Grandiosity ▶ Distractibility ▶ Increased recklessness and impulsivity ▶ Hypersexuality **Hypomania:** abnormally elevated mood with ≥3 of the following: ▶ Psychomotor agitation ▶ Increased talkativeness	**Hypomanic episode** Elevation of mood or irritability outside of the usual mood range Increased activity Talkativeness Flight of ideas Increased self-esteem Decreased need for sleep Distractibility Impulsivity Increased libido, sociability, or goal-directed activity **Depressive episode**

	interest/pleasure with: ▶ Unintentional weight loss or change in appetite ▶ Disruption of sleep ▶ Psychomotor changes ▶ Loss of energy ▶ Difficulty with concentration and/or attention ▶ Excessive feelings of worthlessness and/or guilt ▶ Recurrent thoughts of death, including passive and/or active suicidal ideation	▶ Poor concentration or increased distractibility ▶ Decreased need for sleep ▶ Hypersexuality ▶ Impulsivity or increased spending ▶ Over-familiarity Depressive episode: 4 total symptoms from among the following ≥2: ▶ Depressed mood ▶ Loss of interest or pleasure ▶ Decreased energy Additional symptoms: ▶ Low self-esteem ▶ Excessive guilt or shame ▶ Recurrent thoughts of death or suicide ▶ Poor concentration ▶ Psychomotor changes ▶ Sleep disturbance ▶ Change in appetite and/or weight	*See depressive disorders*
Required number of symptoms	Lifetime history of a hypomanic episode involving elevated/irritable mood with ≥3 of the above symptoms (4 if mood irritable) Lifetime history of a depressive episode with ≥5 of the above symptoms, which must include ≥1 depressed mood or loss of pleasure	**Bipolar affective disorder, current episode hypomanic—**meets the above criteria for hypomania (elevated mood with ≥3 listed symptoms) and has a history of prior affective episodes (manic, hypomanic, depressed, mixed) **Bipolar affective disorder, current episode manic—**meets above criteria for mania (elevated or irritable mood with ≥3–4 listed symptoms) and has a history of prior affective episodes (manic, hypomanic, depressed, mixed)	≥1 hypomanic episode ≥1 depressive episode

		Bipolar disorder, current episode mixed—mixture or rapid alteration in hypomanic, manic, and/or depressive symptoms, with symptoms, present most of the time for ≥2 weeks, in addition to having a history of prior affective episodes (manic, hypomanic, depressed, mixed) **Bipolar disorder, current episode mild/moderate/severe depression—**current symptoms meet criteria for a depressive episode, in addition to having a history of prior affective episodes (manic, hypomanic, depressed, mixed)	
Exclusions	Other medical condition Substance or medication, including withdrawal Other mental illness	Psychoactive substance use Another mental disorder	H/o manic episodes Other medical condition Effect of substance or medication
Psychosocial consequences	Hypomanic episode: NO marked impairment in functioning and NO hospitalization necessitated Depressive episode: marked distress and/or impairment in psychosocial functioning		Does not cause marked functional impairment
Symptom specifiers	**Current episode:** ***Depressed*** ***Hypomanic*** **Additional specifiers to be added to the above:**	**Current episode hypomanic** **Current episode manic without psychotic symptoms** **Current episode manic with psychotic symptoms**	**Current/most recent episode** Hypomanic Depressive

With anxious distress: including ≥2 symptoms among feeling tense, restlessness, difficulty with concentration due to worrying, excessive fear without an identifiable cause, fear of loss of control

With mixed features—full criteria met for either depressive or manic/hypomanic episode, with additional symptoms of depressive or manic/hypomanic period without also meeting full criteria

With rapid cycling—the presence of ≥4 mood episodes over the course of a 12-month period, with ≥2-month period of partial/full remission between mood episodes

With melancholic features—involving loss of pleasure, reduced reactivity with ≥3 of the following:

- Depressed mood/despair
- Depressive symptoms worse in the morning
- Early morning awakening
- Psychomotor changes

- *With mood-congruent psychotic symptoms*
- *With mood-incongruent psychotic symptoms*

Current episode moderate or mild depression— ≥4 (mild) or 6 (moderate) symptoms present, including ≥2 among loss of pleasure, depressed mood, and low energy

With somatic syndrome*—≥4 of the following:*

- *Loss of interest or pleasure*
- *Lack of emotional reactivity*
- *Early morning awakening*
- *Depression gets worse in the mornings*
- *Psychomotor changes*
- *Loss of appetite*
- *Weight loss*
- *Loss of sexual drive*

Without somatic syndrome

Current episode severe depression without psychotic symptoms—≥8 symptoms present, including all 3 of loss of pleasure, depressed mood, and low energy

Current episode severe depression with psychotic symptoms—≥8 symptoms present, including all 3 of loss of pleasure, depressed mood, and low energy, occurring either

- *With mood-congruent psychotic symptoms*
- *With mood-incongruent psychotic symptoms*

Current episode mixed

Currently in remission—does not currently meet

With/without psychotic symptoms

With prominent anxiety symptoms

With panic attacks

With seasonal pattern

With rapid cycling

Associated with pregnancy, childbirth, or the puerperium

	▶ Loss of appetite/weight loss ▶ Excessive guilt **With atypical features:** during most days, an individual is experiencing mood reactivity with ≥2 symptoms of: ▶ Weight gain or increased appetite ▶ Excessive sleeping ▶ Leaden paralysis ▶ A pattern of heightened interpersonal rejection sensitivity **With mood-congruent psychotic features—**mood-congruent delusions or hallucinations **With mood-incongruent psychotic features—**mood-incongruent delusions or hallucinations **With catatonia**—catatonic features present during most of the mood episode	criteria for an affective episode despite a prior history of a manic or hypomanic episode
Course specifiers	**With peripartum onset—**full criteria for a mood episode are met during pregnancy or within 4 weeks of delivery **With seasonal pattern** (for ≥1 type of episode)—pattern present for ≥2 years	

	In partial remission **In full remission**		
Severity specifiers	**Mild—**few symptoms in excess of minimum diagnostic criteria, with no to minimal impairment and/or distress **Moderate—**moderate symptomatology and impairment **Severe—**symptoms in marked excess of minimum diagnostic requirement, with marked distress and impairment in functioning	See the above criteria for mild, moderate, and severe depression	Mild Moderate Severe
Comments	**Note**: A diagnosis of Bipolar 2 cannot be made if there is a history of a manic episode, in which case a diagnosis of Bipolar 1 disorder would be made.		

Table 13.3–7.
Cyclothymic Disorder

	DSM-5-TR	ICD-10	ICD-11
Diagnostic Name	Cyclothymic Disorder	Cyclothymia	Cyclothymic Disorder
Duration	Symptoms lasting ≥2 years (≥1 year in children), with depressive and hypomanic symptoms present for ≥half the time.	2-year period involving periods of depression and elevated mood, without ever meeting criteria for a depressive episode or manic episode.	≥2 years
Symptoms	Hypomanic episodes involve abnormally elevated or irritable mood with: ▶ Grandiosity ▶ Decreased need for sleep ▶ Pressured speech ▶ Racing thoughts with expansiveness of thought ▶ Distractibility ▶ Goal-directed or non-goal-directed hyperactivity ▶ Engagement in high-risk activity or increased impulsivity Depressive Episode involving depressed mood and/or decreased interest/pleasure with: ▶ Unintentional weight loss or change in appetite ▶ Disruption of sleep ▶ Psychomotor changes ▶ Loss of energy ▶ Difficulty with concentration and/or attention ▶ Excessive feelings of worthlessness and/or guilt	Periods of depressed mood involving: ▶ Low energy ▶ Insomnia ▶ Low self-esteem ▶ Poor concentration ▶ Social withdrawal ▶ Loss of pleasure/enjoyment ▶ Reduced talkativeness ▶ Excessive pessimism Period of elevated mood involving: ▶ Increased energy ▶ Decreased need for sleep ▶ Inflated self-esteem ▶ Increased creativity ▶ More talkative ▶ More socially outgoing ▶ Hypersexuality and increased participation in pleasurable activities ▶ Grandiosity	Mood instability, with numerous hypomanic (see Bipolar type II disorder) and depressive periods (see depressive disorders). Children instead may show irritability. Hypomanic periods may or may not have been severe or long enough to meet criteria for hypomanic episode.

	▶ Recurrent thoughts of death, including passive and/or active suicidal ideation		
Required number of symptoms	Symptoms of hypomania and depression present without ever meeting the full criteria for a depressive episode or manic episode	≥3 symptoms during periods of mood elevation without meeting the full criteria for a. manic episode ≥3 symptoms during periods of low mood without meeting the full criteria for a depressive episode	–
Exclusions	Other medical condition Substance or medication, including withdrawal Other mental illnesses (Bipolar I or II)	Bipolar affective disorder (though a history of bipolar affective disorder may be present)	Other medical condition Substance or medication, including withdrawal Other mental illness
Psychosocial consequences	Marked distress or impairment in areas of functioning		Marked distress or impairment in areas of functioning
Symptom specifiers	**With anxious distress:** including ≥2 symptoms among feeling tense, restlessness, difficulty with concentration due to worrying, excessive fear without an identifiable cause, fear of loss of control		
Course specifiers		**Early onset:** before the ’20s **Late onset:** onset between ages 30 and 50	
Severity specifiers	**Mild—**2 symptoms **Moderate—**3 symptoms		

Moderate-Severe—4 or 5 symptoms
Severe—4–5 symptoms with motor agitation

Table 13.3–8.
Differentiating Characteristics of Bipolar and Unipolar Depressions

	Bipolar	Unipolar
History of maina or hypomania (definitional)	Yes	No
Temperament and personality	Cyclothymic and extroverted	Dysthymic and introverted
Sex ratio	Equal	More women than men
Age of onset	Teens, 20s, and 30s	30s, 40s, and 50s
Postpartum episodes	More common	Less common
Onset of episode	Often abrupt	More insidious
Number of episodes	Numerous	Fewer
Duration of episode	3–6 months	3–12 months
Psychomotor activity	Retardation > agitation	Agitation > retardation
Sleep	Hypersomnia > insomnia	Insomnia > hypersomnia
Family history		
Bipolar disorder	Yes	±
Unipolar disorder	Yes	Yes
Alcoholism	Yes	Yes
Pharmacologic response		
Most antidepressants	Induce hypomania–mania	±
Lithium carbonate	Prophylaxis	±

FIGURE 13.3–3. Typical courses of depression represented graphically. The *dotted line* indicates euthymia. **A:** Major depressive disorder, recurrent, with complete remission between episodes. **B:** Major depressive disorder, recurrent, with partial remission between episodes. **C:** Major depressive disorder, recurrent, with an overlapping dysthymic disorder, hence antecedent dysthymia and a return to that dysthymia between episodes, often referred to as double depression. (Data from Keller MB, Boland RJ, Leon A, Solomon D, Endicott J, Li C. Clinical course and outcome of unipolar major depression. In: Keller MB, Coryell WH, Maser JD, eds. *Clinical Guide to Depression and Bipolar Disorder: Findings from the Collaborative Depression Study*. American Psychiatric Press; 2013.)

- By definition, a major depressive disorder should be incapacitating. Previously, we paid much attention to the interpersonal consequences of depression. Recent evidence indicates that measurable deficits in work performance are often early manifestations. Afflicted persons also do not benefit from taking leisure time, and, hence, prescribing vacations is futile.
- We perceive major depressive disorder as a break from a person's usual or premorbid self, which can be so striking that patients may feel they are losing their minds. The critical point is that the patient and significant others can usually relate the onset of the illness to a given month or quarter of a year, which is not valid, for instance, for dysthymic disorder.
- The patient often experiences major depressive disorder as qualitatively distinct from grief or other understandable reactions to loss or adversity. William James described it as follows:

> *There is a pitch of unhappiness so great that the goods of nature may be entirely forgotten, and all sentiment of their existence vanish from the mental field. For this extremity of passion to be reached, something more is needed than adversity; the individual must in his own person become the prey of pathological melancholy. Such sensitiveness and susceptibility of mental pain is a rare occurrence where the nervous constitution is entirely normal: one seldom finds it in a healthy subject even where he is the victim of the most atrocious cruelties of outward fortune; it is an active anguish, a sort of psychical neuralgia wholly unknown to healthy life.*

Two additional features, when present, would further validate the diagnosis of major depressive disorder.

- History of past episodes.
- Consecutive-generation family history of mood disorder—especially when many family members are afflicted with depression or mood disorder—is characteristic of clinical

depression. For instance, one study that prospectively followed persons with minor or neurotic depression found that such pedigrees predicted the development of future major episodes. In clinical practice, these factors would strongly weigh whether to take the depression seriously.

Single-Episode and Recurrent Subtypes. A significant minority—perhaps one-third—of all major depressive episodes do not recur. Such patients tend to be older and less likely to have a positive family history of mood disorders and have a more protracted (1 to 2 years) course of the disorder. We should distinguish patients with a single-episode major depressive disorder from those experiencing their first episodes of recurrent major depressive disorder. The latter group tends to be younger, and the disorder is more likely to have been preceded by a depressive temperament or dysthymic disorder. Those who switch to bipolar disorder are more likely to have experienced recurrent depressions (as many as five or more episodes).

Research has established that recurrent major depressive disorders are more familial than their single-episode counterparts. The average length of episodes is 6 months, whereas the mean interval between episodes tends to vary (typically years). According to retrospective and prospective studies, the mean number of major episodes over a lifetime is five to six, in contrast to an average of eight to nine major episodes in bipolar disorder. These figures are likely an underestimate as they rely on such data as clinical referrals or hospitalization, or both.

Melancholic Features. *Melancholic features* is a qualifying phrase for major depressive disorders in which anhedonia, guilt, and psychomotor–vegetative disturbances dominate the clinical picture. In addition, severe suicidal ideation may be present.

Atypical Features. Reverse vegetative signs with rejection sensitivity, often contrasted to melancholia on phenomenologic and pharmacologic grounds, represent a major depressive disorder qualifier occurring in as many as one-third of all major depressive disorders. Atypical features are so common in bipolar disorder, especially bipolar II disorder, that some consider them to be clinical markers for soft bipolar disorders. Although there is no consensus on this question, before diagnosing major depressive disorder in such cases, it is clinically wise to exclude bipolar II disorder, especially where hostile–labile features predominate.

Mixed Features. DSM-5 added a category of “mixed features” to its major depressive subtypes. This subtype describes a category of patients with major depressive disorder or who display subsyndromal symptoms of mania or hypomania but do not meet the criteria for either syndrome. This subtype reflects the reality that many patients diagnosed with major depressive disorder have occasional mania-type symptoms. However, the new subtype blurs an already blurry boundary between depressive disorders and bipolar disorders. Some experts have questioned whether antidepressants are the preferred treatment for patients in this category or whether mood stabilizers are preferable. Existing studies have focused on atypical antipsychotics. We currently lack sufficient evidence to make a definitive statement about the implications of this category and await further longitudinal studies.

Psychotic Features. The separation of depressed patients with psychotic symptoms—*psychotic depression*—as a distinct subtype of depression was spurred by observations that patients whose depressive disorder included psychotic features had a differential treatment response than other depressive patients. Early subtyping treated psychotic depression as a severe type of major depression. However, newer data suggest that the subtype includes a range of severity. However, in most cases, patients with psychotic depression have more severe depression, including melancholic features. Perhaps 10% to 20% of depressed adults have psychotic symptoms, although clinicians often miss these symptoms in their depressed patients, so this may be an underestimate.

Typically, the symptoms are hallucinations or delusions. The delusions are classically considered to be mood congruent, often self-deprecatory or imagined poverty or illness. There are cases of mood-incongruent delusions, which seem to have a worse outcome, although this is not a consistent finding. The trait of psychosis is likely transdiagnostic, and relatives of patients with psychotic depression may have relatives with other psychotic illnesses. Patients with this subtype are more likely than other depressed patients to progress to a bipolar illness.

Chronic Depression. The symptom profile in chronic depressions usually displays low-grade intensity rather than severe syndromic chronicity. Severe depressive disorder, in its psychotic forms, is so agonizing that the patient is at risk of committing suicide before the disorder has a chance to become chronic. The psychotic symptoms often respond to medication or ECT, but residual depressive symptoms may linger for a long time. In other persons with chronic depressions, the chronicity arises from more mundane (nonpsychotic) major depressive episodes, representing depressive residua following one or several clinical episodes that fail to remit fully. Instead of the customary remission within 1 year, the patients are ill for years. The level of depression varies, fluctuating between syndromic illness and milder symptoms. A landmark analysis from the NIMH Collaborative Depression Study by Lewis Judd and colleagues showed that as many as 60% of patients with major depressive disorder have a subthreshold fluctuating chronic course.

Rather than exhibiting a frankly depressive mood, many persons with chronic depression experience deficits in their ability to enjoy leisure and display an attitude of irritable moroseness. They also show a sense of resignation, generalized fear of an inability to cope, adherence to rigid routines, and inhibited communication. Such deficits, along with irritable humor, tend to poison their conjugal lives: Their marriages are typically in a state of chronic deadlock, leading to neither divorce nor reconciliation. Somatic features dominate the residual phase in other patients, such as sleep and other vegetative or autonomic irregularities. The persistent sleep EEG (especially REM and delta phase) abnormalities that are indistinguishable from their acute depressed counterparts demonstrate that the interpersonal, conjugal, and autonomic manifestations represent unresolved depression. Unfortunately, self-treatment with alcohol or iatrogenic benzodiazepine dependence rather than definitive treatment of the ongoing low-grade depression is common.

Failure to recover from major depressive disorder is associated with increased familial loading for depression, disabled spouses, deaths of immediate family members, concurrent disabling medical disease, relying on depressant pharmacologic agents, or

excessive alcohol and sedative–hypnotic agents. Persons with residual depression through the death or illness of significant others may then lack social support. Therefore, a thorough medical evaluation and socially supportive interventions should be essential ingredients of the overall approach to these patients.

Interpersonal disturbances in such patients are usually secondary to the distortions produced by longstanding depression. Therefore, observed pathologic characterologic changes—clinging or hostile dependence, demanding tendencies, touchiness, pessimism, and low self-esteem—are best considered as *postdepressive personality* changes. Dangerous stereotypical thinking holds that the disorder must have a characterologic substrate because a patient has not responded adequately to standard treatments (the illness has become chronic). The long duration of the disorder often leads the patient to identify with the failing functions of depression, producing the self-image of being a depressed person. This self-image represents a malignant cognitive manifestation of the depressive disorder and dictates vigorous treatment targeted at the mood disorder.

Dysthymic Disorder (Persistent Depressive Disorder in DSM-5)

Dysthymia, called persistent depressive disorder in DSM-5 (see Table 13.3–4), is distinguished from chronic depressive disorder because it is not a sequel to well-defined major depressive episodes. Instead, in the most typical cases, patients complain that they have always been depressed. Thus, most cases are of early onset, beginning in childhood or adolescence and certainly by the time patients reach their 20s. A late-onset subtype, much less prevalent and not well characterized clinically, has been identified among middle-aged and geriatric populations, mainly through epidemiologic studies in the community.

Although the dysthymic disorder category in DSM-5 can occur as a secondary complication of other psychiatric disorders, the core concept of dysthymic disorder refers to a subaffective disorder with (1) low-grade chronicity for at least 2 years, (2) insidious onset with origin often in childhood or adolescence, and (3) persistent or intermittent course. Although not part of the formal definition of dysthymic disorder, the family history is typically replete with depressive and bipolar disorders, which is one of the more robust findings supporting its link to primary mood disorder.

Social Adjustment. Dysthymic disorder is typically an ambulatory disorder compatible with relatively stable social functioning. However, the stability is precarious; recent data document that many patients invest whatever energy they have in work, leaving none for leisure and family or social activities, which results in marital friction. These empirical findings on persons with dysthymic disorder echo earlier formulations in German and Japanese literature. For instance, Kraepelin described such persons as follows: “Life with its activity is a burden which they habitually bear with dutiful self-denial without being compensated by the pleasures of existence.”

The dedication of persons with a dysthymic disorder to work may be an overcompensation and a defense against their battle with depressive disorganization and inertia. Nevertheless, Ernst Kretschmer suggested that such persons are the “backbone of society,” dedicating their lives to jobs that require dependability and great attention to detail. Epidemiologic studies have demonstrated that some persons with protracted dysthymic complaints, extending over many years, have never experienced clear-cut

depressive episodes. Some may seek outpatient counseling and psychotherapy for what some clinicians might consider *existential depression,* with feelings of being empty and lacking any joy in life outside of their work. Some have described them as leading "monocategorical existences." Others present clinically because their low-grade dysphoria has intensified into a major depressive disorder.

Course. An insidious onset of depression dating back to late childhood or the teens, preceding any superimposed major depressive episodes by years or even decades, represents the most typical developmental background of dysthymic disorder. A return to the low-grade depressive pattern is the rule after recovery from superimposed major depressive episodes, if any; hence, the designation *double depression* as a prominent course pattern. This pattern, commonly seen in clinical practice, consists of the baseline dysthymic disorder fluctuating in and out of depressive episodes. The more prototypical patients with dysthymic disorder often complain of having been depressed since birth or of feeling depressed all the time. In the apt words of Kurt Schneider, they seem to view themselves as belonging to an "aristocracy of suffering." Such descriptions of chronic gloominess in the absence of more objective signs of depression earn these patients the label of *characterologic depression.* Further reinforcing the description is the fluctuating depressive picture that merges imperceptibly with the patient's habitual personality makeup. This conceptual uncertainty notwithstanding, given the confluence of data on the efficacy of many classes of antidepressants, patients with dysthymia should not be denied the potential benefit of antidepressants.

Clinical Picture. The profile of dysthymic disorder overlaps with that of major depressive disorder but differs from it in that symptoms tend to outnumber signs (more subjective than objective depression). This means that marked disturbances in appetite and libido are uncharacteristic, and we do not see any psychomotor agitation or retardation. The result is depression with attenuated symptomatology. However, it is not uncommon to see subtle endogenous features: inertia and anhedonia that are characteristically worse in the morning.

Although dysthymic disorder represents a more restricted concept than its parent, neurotic depression, it is still quite heterogeneous. Anxiety is not a necessary part of its clinical picture, yet we often diagnose dysthymic disorder in patients with anxiety and neurotic disorders. That clinical situation is perhaps a secondary or *anxious dysthymia* or, in the framework of Peter Tyrer, as part of a *general neurotic syndrome.*

It is best to restrict dysthymic disorder to a primary disorder for greater operational clarity, which a nonmood disorder cannot explain. The essential features of such primary dysthymic disorder include habitual gloom, brooding, lack of joy in life, and preoccupation with inadequacy. Dysthymic disorder is a longstanding, fluctuating, low-grade depression experienced as part of the habitual self and representing an accentuation of traits observed in the depressive temperament. Sleep EEG data indicate that many persons with dysthymic disorder at baseline exhibit the sleep patterns of those with acute major depressive disorder, providing support for the constitutional nature of the disorder. Further evidence for that position comes from studies demonstrating high rates of familial affective disorder in dysthymic disorder or depressive temperament, or both.

The clinical picture of dysthymic disorder that emerges from the preceding description is quite varied, with some patients proceeding to major depression, whereas others

manifest the pathology primarily at the personality level. The previous considerations suggest that a clinically satisfactory operationalism of dysthymia must include symptomatic, cognitive, and trait characteristics.

A 27-year-old male grade-school teacher presented with the chief complaint that life was a painful duty that had always lacked luster for him. He said that he felt "enveloped by a sense of gloom" that was nearly always with him. Although his peers respected him, he felt "like a grotesque failure, a self-concept I have had since childhood." He stated that he merely performed his responsibilities as a teacher and never derived any pleasure from anything he had done in life. He said he had never had any romantic feelings; sexual activity, in which he had engaged with two different women, had involved pleasureless orgasm. He said that he felt empty, going through life without any sense of direction, ambition, or passion, a realization that itself was tormenting. He had bought a pistol to end his "useless existence" but did not carry out suicide, believing that it would hurt his students and the small community where he lived.

Dysthymic Variants. Dysthymia is not uncommon in patients with chronically disabling physical disorders, particularly among older adults. Dysthymia-like clinically significant subthreshold depression lasting 6 or more months occurs in some neurologic conditions, including stroke. According to a WHO conference dedicated to the subject, depression worsens the prognosis for the underlying neurologic disease and deserves pharmacotherapy. Ongoing studies should provide more explicit clinical recommendations on this topic.

Prospective studies on children have revealed an *episodic course* of dysthymia with remissions, exacerbations, and eventual complications by major depressive episodes, 15% to 20% of which might even progress to hypomanic, manic, or mixed episodes postpuberty. Persons with dysthymic disorder presenting clinically as adults tend to pursue a chronic unipolar course complicated by major depression. They rarely develop spontaneous hypomania or mania. However, when treated with antidepressants, some may develop brief hypomanic switches that typically disappear when decreasing the antidepressant dose. In this particular subgroup of persons with dysthymic disorder, the family histories are often positive for bipolar disorder. These patients represent a clinical bridge between major depressive disorder and bipolar II disorder.

Premenstrual Dysphoric Disorder. Given the higher prevalence of depressive disorders in women, premenstrual affective changes—dysphoria, tension, irritability, hostility, and labile mood—have received clinical and, more recently, research attention. DSM-5 includes the diagnosis of premenstrual dysphoric disorder, focusing on these symptoms. As with most psychiatric disorders, it should be sufficient to affect social or work functioning or other mental and physical functions, such as concentration, energy, appetite, and sleep. It may also include gynecologic symptoms such as breast tenderness or swelling or bloating, or weight-gain sensations.

Although women with severe premenstrual complaints appear to have higher rates of lifetime major mood disorders, some data find that genetic and environmental factors

contributing to premenstrual depression and major depressive disorders are primarily distinct. Furthermore, events such as migraine, epileptic attacks, and panic states may, in some instances, associate with the premenstrual phase. The preceding considerations suggest the hypothesis that premenstrual psychobiologic changes exacerbate different neuropsychiatric disorders to which women are otherwise predisposed. In DSM-5-TR Premenstrual Dysphoric Disorder is classified as a separate mood disorder, in which symptoms should be present in the week leading up to menses and then improving with the onset of menses and resolving the week afterward. This disorder is discussed in more detail in Chapter 31.1 Psychiatry and Reproductive Medicine.

Other Specified Depressive Disorder and Unspecified Depressive Disorder

Minor Depressive Disorder. In so-called minor depression, observed in primary care settings, the depression is subthreshold, milder than major depressive disorder, yet not protracted enough to be considered dysthymic. These varied manifestations of depression argue for a continuum model (Fig. 13.3–4) as initially envisaged by Kraepelin. Lewis Judd and collaborators at the University of California at San Diego have suggested that subthreshold depressive symptoms—without necessarily meeting the criterion for mood change—might represent the most common expressions of a depressive diathesis. From such a subsyndromal symptomatic depressive base, individuals predisposed to depressive illness fluctuate in and out of the various DSM-5 and subthreshold subtypes of depressive disorders. This viewpoint is presently most cogent for subsyndromal symptomatic depression that follows major depressive disorder, a strong predictor of subsequent frequent relapse or chronic course. There is a vital message for the clinician: Treat subsyndromal symptomatic depression residual to major depressive disorder.

FIGURE 13.3–4. Relation of various depressive conditions supporting a spectrum concept. (From Akiskal HS. Dysthymia: clinical and external validity. *Acta Psychiatr Scand*. 1994;89(S383):19–23, with permission. doi:10.1111/j.1600-0447.1994.tb05879.x.)

Recurrent Brief Depressive Disorder. Recurrent brief depressive disorder derives from British work on young adults with frequent suicide attempts and epidemiologic

studies conducted in a young adult cohort in Zurich. It is short-lived depressions that usually recur monthly but are *not* menstrually related. They could coexist with major depressive disorder or dysthymic disorder and with hypomania. Again, the existence of hypomanic-prone recurrent brief depressive disorder argues for a bridge between depressive and bipolar II disorders. Such patients are more prevalent in primary care than in psychiatric settings. Those seen in psychiatric settings are likely to be given personality disorder diagnoses, such as borderline personality disorder. The current nosologic status of recurrent brief depressive disorder is uncertain, but it testifies to Kraepelin's observation that many transitional forms link the depressive temperament to affective episodes:

> *A permanent gloomy stress in all the experiences of life usually perceptible already in youth, and may persist without essential change throughout the whole of life (or) there is actually an uninterrupted series of transitions to periodic melancholia in which the course is quite indefinite with irregular fluctuations and remissions.*

Reactive Depression. Classically, *reactive depression* results from a specific life event. In an ideal case, the depression would not have occurred without the event (e.g., love loss) to which it is a reaction. It continues as long as the event is present, and it terminates with the reversal of the event (e.g., return of the lover). We rarely see depressions exhibiting all of those features in clinical practice. With interpersonal support, most people can face life's reverses, which explains why reactive depression tends to be self-limiting. Hence, adjustment disorder is the more appropriate diagnosis for many cases of reactive depression.

Chronic Demoralization. Conceptually, however, one can envision chronically unsatisfactory life situations that might lead to chronic helplessness. However, such a condition, which could warrant chronic reactive depression, is a contradiction in terms. The question often raised is why a person would continue to stay in the situation. Sometimes psychodynamic authors invoke the concept of masochism to explain why certain persons cannot rid themselves of painful life situations, implying that they somehow contribute to their maintenance. Current thinking is that some presumed self-defeating traits are more situation specific than previously believed and might resolve with eliminating the situation. So-called self-defeating features are best considered psychodynamic mechanisms rather than indicators of a specific personality. This concept is not well understood and does not currently deserve to be considered a nosologic entity (it is not in DSM-5). Chronic adjustment disorder might describe the chronic demoralization observed among some individuals stuck in chronically unsatisfactory life situations. Others might fulfill the criteria for dysthymia. Finally, if the chronically unsatisfactory life conditions involve conjugal violence and trauma, PTSD may be the appropriate diagnosis.

Neurasthenia. A century-old term developed by the American neuropsychiatrist George Beard, *neurasthenia* refers to a more chronic stage of anxious–depressive symptomatology. The anxiety generated by overstimulation is so excessive that a chronic disposition to irritability, fatigue (especially mental fatigue), lethargy, and exhaustion replaces it. It is as if the patient's mind refuses to take on new stresses. The clinical picture described by Beard suggests that anxious manifestations were pre-eminent in his

time. They included headache, scalp tenderness, backache, heavy limbs, vague neuralgias, yawning, dyspepsia, palpitations, sweating hands and feet, chills, flushing, sensitivity to weather changes, insomnia, nightmares, pantophobia, asthenopia, and tinnitus.

Although the diagnosis of neurasthenia is now used more in China than in the rest of the world, the recent worldwide popularity of the concept of chronic fatigue syndrome attests to the clinical acumen of classic physicians. Despite much energy invested in finding a viral or immunologic cause, current descriptions tend to suggest an anxiety or mood disorder basis for many, but certainly not all, those with the syndrome. Some patients with neurasthenia would meet the criteria for major depressive disorder with atypical features and a history of panic and phobic disorders. What circumstances would lead anxiety or depression to manifest primarily in fatigue is as elusive as it was 100 years ago. Like many other patients presenting to primary care settings with somatic complaints, those with chronic fatigue tend to denounce psychiatric diagnoses as inadequate explanations for their ills.

Postpsychotic Depressive Disorder of Schizophrenia. Postpsychotic depression can occur during the residual phase of schizophrenia. It includes the persistence of negative or positive symptoms in an attenuated form (e.g., odd beliefs, unusual perceptual experiences). The depressive symptoms include loss of interest or pleasure and a sad or depressed mood. The major depressive episode typically follows the active phase of the psychotic episode. Sometimes it may follow after a short or extended interval during which there are no psychotic symptoms. Mood symptoms due to the direct physiologic effects of a drug of abuse, a medication, or a general medical condition would suggest a different cause for the depressive symptoms.

In all postpsychotic depressions, one must first exclude a missed bipolar diagnosis. Negative symptoms due to classic antipsychotics—especially depot phenothiazines and those due to the residuum of schizophrenia once positive symptoms are under control—should be distinguished from the depressive episodes that complicate the course of schizophrenia in young, intelligent patients. This phenomenon is so common (at least 30% of patients with schizophrenia) that we consider it a part of the natural course of schizophrenia rather than a separate nosologic entity.

BIPOLAR DISORDERS

There are several types of bipolar disorder categories included in DSM-5. We categorize some on a descriptive level, such as bipolar I disorder, bipolar II disorder, cyclothymic disorder, and unspecified bipolar disorder. We classify others according to etiology, such as substance- or medication-induced bipolar disorder and bipolar disorder due to another medical condition. The clinical picture for each is similar regardless of etiology.

Tables 13.3–5 and 13.3–6 compare the DSM-5 and ICD-11 approaches to diagnosing bipolar disorders.

Bipolar I Disorder

Typically beginning in the teenage years, the 20s, or the 30s, the first episode of bipolar I disorder could be manic, depressive, or mixed. One typical onset is mild retarded

depression or hypersomnia for a few weeks or months, switching into a manic episode. Others begin with a severely psychotic manic episode with schizophreniform features; only when a more classic manic episode occurs is the affective nature of the disorder clarified. In a third group, several depressive episodes occur before the first manic episode. A careful history from significant others often reveals hyperthymic or cyclothymic traits that antedated the frank onset of manic episodes by several years, if not longer.

A single manic episode describes patients having a first episode of mania. Most such patients eventually develop depressive episodes. We use the remaining subcategorization to specify the nature of the current or most recent episode in patients who have had recurrent mood episodes. For clinicians and researchers alike, it is more meaningful to chart a patient's course in color over time—for example, using red for manic, blue for depressive, and violet for mixed episodes, with hypomanic, dysthymic, and cyclothymic periods drawn in the appropriate colors on a smaller scale between the major episodes. Arrows can indicate life events, biologic stressors, and treatment on the time axis. Initially championed by Kraepelin, this approach is routinely used in mood or bipolar clinics to chart retrospectively the past course of illness in mood disorders, especially bipolar disorders. Robert Post at the NIMH has developed this approach into systematic clinical science. An international conference in Barcelona recommended adopting this approach for clinical use. Data from the NIMH Collaborative Depression Study—using a prospective method of life charting—of bipolar I disorder clinical cohorts followed in five major U.S. medical centers show more depression, especially its subthreshold variants, during an average of 12 years of follow-up. These patients were symptomatic nearly 50% of the weeks through the entire follow-up, suggesting a more pervasive course of illness than previously appreciated. Although such data indicate some degree of tertiary care bias in favor of patients willing to be retained in a long-term study, they underscore a clinical reality faced by many clinicians in their daily practice (see Fig. 13.3–5).

On average, manic episodes predominate in youth, and depressive episodes predominate in later years. Although the overall sex ratio is approximately 1:1, men, on average, undergo more manic episodes, and women experience more mixed and depressive episodes. Bipolar I disorder in children is not as rare as previously thought; however, most reported cases are in boys, and mixed manic (dysphoric–explosive) and rapid-cycling presentations are typical. Childhood-onset depression must also be considered a significant risk for ultimate bipolar transformation. This is based on the following characteristics: (1) early age at onset; (2) even sex ratio; (3) prominence of irritability, labile moods, and explosive anger, suggesting mixed episodes; (4) questionable response to antidepressants, hypomanic switches, or both; (5) high recurrence rate after depression; and (6) familial affective loading. Mania can also first appear after 65 years of age, although a diligent search often reveals a past mild, forgotten, or untreated depressive or excited episode in earlier years.

Acute Mania. Mania typically escalates over 1 to 2 weeks; more sudden onsets can also occur. The DSM-5 criteria stipulate (1) a distinct period that represents a break from premorbid functioning, (2) at least 1 week in length, (3) an elevated or irritable mood, (4) at least three or more classic manic signs and symptoms, and (5) the absence of any physical factors that could account for the clinical picture. The irritable mood in mania can

deteriorate to cantankerous behavior, especially when rebuffing the person. Such patients are among the most aggressive seen in the emergency room. Florid grandiose psychosis with paranoid features, a typical presentation of mania, further contributes to the aggression. Alcohol use, observed in at least 50% of bipolar I patients (often during the manic phase), further disinhibits the patient and might lead to a dangerous frenzy. Such patients may attack loved ones and hurt them physically. So-called crimes of passion have been committed by patients harboring delusions of infidelity on the part of spouses or lovers, usually when the patient is under the influence of alcohol.

FIGURE 13.3–5. Graphing the course of a mood disorder. Prototype of a life chart. (Courtesy of Robert M. Post, M.D.)

Delusional, hallucinatory, even first-rank, psychotic experiences in mania can also occur. Recent research has documented that most formal thought disorders are common to schizophrenic and mood psychoses; only poverty of speech content (vagueness) emerges as significantly more common in schizophrenia. In addition, posturing and negativism may occur during manic periods. Finally, even cognitive deficits resembling dementia can occur. Mania is a phase of bipolar I disorder, which has strong genetic determinants. The evidence does not permit separating recurrent mania without depressive episodes from that type as a distinct nosologic entity.

Secondary Mania. Although there is some suggestion that postpartum mania without depression is distinct from familial bipolar I disorder (in which depressive, manic, and especially mixed manic episodes occur in the postpartum period), the evidence for a distinct puerperal mania is not compelling. Mania without prior bipolarity can arise in the setting of such somatic illnesses as thyrotoxicosis, systemic lupus erythematosus or its treatment with steroids, rheumatic chorea, multiple sclerosis (MS), Huntington disease, cerebrovascular disorder, diencephalic and third ventricular tumors, head trauma, complex partial seizures, syphilis, and (most recently) AIDS. The family history is reportedly low in such cases, suggesting a relatively low genetic predisposition and, thus,

a lower risk of recurrence. These patients do not easily fit into the DSM-5 category of mood disorder due to a general medical condition because most of the conditions appear to be cerebral. Such factors may be more typical in manias of late life.

Less well-defined forms of mania are the so-called reactive manias. Personal loss and bereavement may be triggering factors, and the reaction is conceptualized psychodynamically as a denial of loss. Although such explanations may be plausible in individual cases, no systematic data suggest that these patients differ in family history from persons with other manias. The same is generally valid for depressed patients who switch to hypomania or mania after abusing stimulant drugs, taking antidepressants, or sleep deprivation. A bipolar diathesis usually manifests in a family history of mania or spontaneous excited episodes during prospective observation. First-onset manic episodes can also occur in persons who abruptly abstain from alcohol after one or more decades of chronic use and then develop classic bipolar I disorder.

Chronic Mania. About 5% of bipolar I disorder patients have a chronic manic course. These cases commonly represent a deteriorating course dominated by recurrent manic episodes grafted onto a hyperthymic baseline. Noncompliance with pharmacologic treatment is the rule. Recurrent excitement is personally reinforcing, subjective distress is minimal, and insight is seriously impaired. Thus, the patient sees no reason to adhere to treatment. Episodic or chronic alcohol abuse, prevalent in such patients, may contribute to the chronicity. Some authorities further consider comorbid cerebral pathology responsible for nonrecovery (and increased mortality) from manic excitements occurring in late life.

Grandiose delusions (e.g., delusions of inventive genius or aristocratic birth) are not uncommon in chronic mania and may lead to the mistaken diagnosis of paranoid schizophrenia. Because of their social deterioration, Kraepelin subsumed such patients under the category *manic dementia.* Organic factors, such as head trauma and chronic alcohol abuse, may contribute to the deterioration. Nonschizoid premorbid adjustment, a family history of bipolar I disorder, and the absence of flagrant formal thought disorder may help establish the affective basis of these poor-prognosis manic states.

Bipolar Mixed Phase. Momentary tearfulness and even depressed mood are commonly observed at the height of mania or during the transition from mania to retarded depression. These transient labile periods, which occur in most bipolar I disorder patients, must be contrasted with mixed episodes.

The latter, variously referred to as *mixed mania* or *dysphoric mania,* are characterized by dysphorically excited moods. These moods may include symptoms of irritability, anger, panic attacks, pressured speech, agitation, suicidal ideation, severe insomnia, grandiosity, hypersexuality, or persecutory delusions and confusion. It is challenging to distinguish severely psychotic mixed states that involve hallucinations and Schneiderian symptoms from schizoaffective disorder. A correct diagnosis helps avoid conventional antipsychotic drugs known to exacerbate the depressive component; in such patients, failure to use mood stabilizers can prolong the patient's misery.

Research data from mood centers worldwide on mixed mania suggest that dysphoric mania—mania and full-blown depression co-occurring—is relatively uncommon. Two to four depressive symptoms from the list of depressed mood, helplessness, hopelessness, fatigue, anhedonia, guilt, and suicidal ideation, impulses, or both in the setting of a manic syndrome appear to suffice for the diagnosis of mixed manic states, which occur in 50%

of patients with bipolar disorder sometime during their lives. Mixed states occur predominantly in women with mania superimposed on a depressive temperament or a dysthymic baseline. The emerging conceptualization of mixed mania is a manic state intruding on long-term depressive traits. Other mixed manic states, especially in men, often arise from the interaction of substance or alcohol use in bipolar I disorder.

Depressive Phase. Psychomotor retardation, with or without hypersomnia, marks the uncomplicated depressive phase of bipolar I disorder. Onset and offset are often abrupt, although onset can also occur gradually over several weeks. Patients may recover into a free interval or may switch directly into mania. Switching into an excited phase is particularly likely when using antidepressants. However, not all patients develop mania after antidepressant treatment of bipolar depression. Some develop a mixed agitated depression; indeed, patients may linger for many months in a severe depressive phase with some manic admixtures, such as racing thoughts and sexual arousal. Delusional and hallucinatory experiences are less common in the depressive phase of bipolar I disorder than in the manic and mixed manic phases. Stupor is the more common psychotic presentation of bipolar depression, particularly in adolescents and young adults. Pseudodemented organic presentations appear to be the counterpart of stupor in older adults.

Cyclothymic Disorder

An attenuated bipolar disorder that typically begins insidiously before 21 years of age, cyclothymic disorder is characterized by frequent short cycles of subsyndromal depression and hypomania. Table 13.3–7 compares the diagnostic approaches to cyclothymic disorder in DSM-5 and ICD-11. The course of cyclothymia is continuous or intermittent, with infrequent periods of euthymia. Shifts in mood often lack adequate precipitants (e.g., sudden profound dejection with social withdrawal for a few days switching into cheerful, gregarious behavior). Circadian factors may account for some of the extremes of emotional lability, such as the person's going to sleep in good spirits and waking up early with suicidal urges. The mood changes of cyclothymia are best described as *endoreactive* in the sense that endogenous overreactivity seems to determine the sudden shifts in mood and behavior (e.g., falling in love with a person one has just met and as quickly falling out of love).

Mood swings in these ambulatory patients are overshadowed by the chaos the swings wreak in their personal lives. Repeated romantic breakups or marital failures are common because of interpersonal friction and episodic promiscuous behavior. Uneven performance at school and work are also typical. Persons with cyclothymic disorder are dilettantes; they show great promise in many areas but rarely bring their efforts to fruition. As a result, their lives are often a string of improvident activities. Geographical instability is a characteristic feature; easily attracted to a new locale, job, or love partner, they soon lose interest and leave in dissatisfaction. Polysubstance abuse, which occurs in as many as 50% of such persons, is often an attempt at self-treatment. Suicidality has emerged as a public health hazard in adolescents. Clinicians may mistake this for borderline personality disorder, especially in young people, when they may suffer from an undiagnosed temperamental expression of bipolar disorder.

Bipolar II Disorder

Research conducted during the last three decades has shown that, between the extremes of manic-depressive illness and major depressive disorder, there exists an overlapping group of intermediary forms characterized by recurrent major depressive episodes and hypomania. Current data worldwide indicate that bipolar II disorder is more prevalent than bipolar I disorder. This prevalence certainly appears to be true in the outpatient setting, in which an average of 50% (and in one French national study up to 65%) of persons with major depressive disorder conform to the bipolar II disorder pattern. The depressive phase of bipolar disorder, particularly bipolar II, is a significant public health problem.

The following self-description provided by a 34-year-old poet illustrates the pattern:

> *I have known melancholy periods, lasting months at a time when I would be literally paralyzed: All mental activity comes to a screeching halt, and I cannot even utter one word. I become so dysfunctional that I was once hospitalized. Although the paralysis creeps into me insidiously—often lasting months—it typically reverses within hours. I am suddenly alive and vibrant. I cannot turn off my brain neither during the day nor at night; I usually go on celebrating like this for many days, needing no more than few hours of slumber each day.*

This vignette is nearly identical to the autobiographical description provided by the British poet William Cowper three centuries earlier:

> *I have known many a lifeless and unhallowed hour . . . long intervals of darkness interrupted by short returns of peace and joy . . . for many succeeding weeks to rejoice day and night was all my employment. Too happy to sleep much, I thought it was lost time that was spent on slumber.*

Although some hypomanias last for weeks, the hypomania at the end of depressive episodes in most bipolar II disorder patients does not last long; usually, a few days. As discussed earlier, hypomanias with short duration (less than 4 days) are familially similar to those with longer duration (more than 4 days). Another common form of bipolar II disorder is major depressive disorder superimposed on cyclothymic disorder, in which hypomania precedes and follows major depressive disorder, with the entire interepisodic period characterized by cyclothymic mood instability. Such patients tend to have an unstable course, stormy interpersonal relationships, and more irritable and hostile hypomanic episodes—hence the confusion with borderline personality disorder. Current data indicate that cyclothymic and noncyclothymic bipolar II disorder have similar rates of familial bipolarity, which suggests that the borderline characterologic features represent a complication of the unstable course that cyclothymia imparts to bipolar II disorder. Such individuals with unstable course have a high risk of suicide—indeed, based on research in Budapest; it appears that the high burden of suicide in mood disorders appears to be due to bipolar II disorder. Descriptively, *hypomania in bipolar II disorder* includes mini manic episodes occurring spontaneously. Bipolar II disorder—especially with superimposed major depressions and cyclothymia—is best characterized as cyclical or *cyclothymic depression.*

The depressive episodes of patients with bipolar disorder often have admixtures (e.g., flight of ideas and increased drives and impulsivity in sexual and other domains). These are likely depressive mixed states. DSM-5 is the first to describe such states. Depressive mixed states are not as severe as dysphoric mixed states but are refractory to antidepressants nonetheless and, according to current data, are overrepresented in suicide. Research conducted by Franco Benazzi and Hagop Akiskal indicates that such

depressive mixed states occur in as much as 60% of cases of bipolar II disorder and as much as 30% of cases of “unipolar” major depressive disorder. Both groups have similar rates of familial bipolarity, suggesting that one of three patients with “unipolar” depression belongs to the bipolar II spectrum.

Hypomania. The common denominator of the soft spectrum of bipolar disorders is hypomania. *Hypomania* refers to a distinct period of at least a few days of mild elevation of mood, sharpened and positive thinking, and increased energy and activity levels, typically without the impairment characteristic of manic episodes. It is not merely a milder form of mania. Hypomania occurring as part of bipolar II disorder rarely progresses to manic psychosis, and insight is relatively preserved. Hypomania is distinguished from mere happiness in that it tends to recur (happiness does not!), and antidepressants can sometimes mobilize hypomania. In cyclothymic disorder, it alternates with mini depressions; in hyperthymic temperament, it constitutes the person’s habitual baseline. These definitions, developed by empirical research, recognize three patterns of hypomania: *episodes* heralding the termination of a retarded depressive state (bipolar II disorder), cyclic alternation with mini depressions (cyclothymic disorder), and an elevated baseline of high mood, activity, and cognition (hyperthymic or chronic hypomanic *traits*).

Because people experience hypomania as a rebound relief from depression or as a pleasant, relatively short-lived, ego-syntonic mood state, persons with bipolar II disorder rarely spontaneously report it or even see it as a problem. Skillful questioning is required to diagnose soft bipolar conditions; as in mania, collateral information from family members is crucial. During a patient interview, we typically ask questions like, “Have you had a distinct sustained high period when your mood was so intense that you felt nervous?” Alternatively, we might ask, “Have you had such energy that others could not keep up with you, or your thinking and perceptions were unusually vivid or rapid?” Many bipolar patients react to inquiries about “high moods” or “high periods” with a negative: “I am not a manic-depressive!” Benazzi and Akiskal suggested that it is better to inquire about signs and symptoms referring to behavioral activation initially. Once remembering energized periods, the patient is more likely to recall the mood change associated with these periods.

Clinical and epidemiologic studies in the United States and Europe have revealed a rich range of hypomanic manifestations, including increased cheerfulness and jocularity; gregariousness and people seeking; more interest in sex; talkativeness, self-confidence, and optimism; and decreased inhibitions and sleep need. The clinician must ascertain that those experiences are not due to stimulant use or alcohol withdrawal. Depressive and hypomanic periods are often not easily discerned because chronic caffeine use, stimulant abuse, or both may complicate the depression. In such instances, we should defer a diagnosis for 1 month after detoxification. Cocaine and stimulant use is also not uncommon in hypomania, especially in patients with hyperthymic traits, and constitutes an attempt to augment the baseline energy and mood rather than self-treatment of low moods. When in doubt, direct clinical observation of hypomania—sometimes elicited by antidepressant pharmacotherapy—provides definitive evidence for the bipolar nature of the disorder.

Seasonal Patterns. Seasonality occurs in many cyclic depressions, often with autumn or winter anergic depression and energetic periods in the spring. This natural propensity

explains why phototherapy may provoke mild hypomanic switches. Seasonal depressions conform, in considerable measure, to the bipolar II disorder or bipolar III disorder pattern. Furthermore, preliminary evidence suggests that treatment with classic antidepressants disrupts the baseline seasonality, with the depressive phase appearing in the spring and summer. The changes that antidepressants induce in seasonal depressions probably represent a particular variant of the rapid-cycling phenomenon.

Temperament and Polarity of Episodes. Systematic clinical observations suggest that bipolar II disorder (characterized predominantly by depressive attacks) arises more often from a hyperthymic or cyclothymic baseline. Bipolar I disorder (defined by manic attacks) not uncommonly arises from the substrate of a depressive temperament. In line with these observations, a prospective 11-year NIMH study of major depressive disorder patients who switched to bipolar II disorder showed that *mood–labile* (cyclothymic) and *energetic–active* (hyperthymic) temperament traits were highly specific (86%) and reasonably sensitive (42%) predictors of such an outcome.

We usually think of *bipolarity* as alternating manic (or hypomanic) and depressive episodes. The previous data on temperaments suggest that a more fundamental characteristic of bipolarity is the reversal of temperament into its “opposite” episode (in the bipolar II disorder spectrum, from cyclothymia and hyperthymia to major depression). Such findings suggest that the intrusion of cyclothymic and hyperthymic traits into a depressive episode may underlie the instability of the bipolar II disorder subtype and could partly explain why bipolar II depression often has mixed features. These considerations may have important implications for preventing recurrence. For instance, a prospective study of the onset of bipolar disorder in the offspring or siblings of adults with the disorder found that children with depressive onsets as their first episode (typically treated with antidepressants) had significantly higher rates of recurrence than those with manic or mixed onsets (treated with lithium) during a 3-year prospective observation. It appears that temperamental instability in the depressive group might have predisposed them to the cycling effect of antidepressants.

Alcohol and Substance Abuse. New evidence supports the high prevalence of alcohol and substance abuse in mood disorder subtypes, especially those with interepisodic cyclothymia and hyperthymia. The relation appears to be particularly strong in the teenage and early adult years when taking such substances may represent self-medication for mood instability. It is not just self-treatment of selected symptoms associated with the down or up phases (e.g., alcohol to alleviate insomnia and nervousness characteristic of both phases); it also augments certain desired ends (e.g., stimulants to enhance performance or sexual behavior associated with hypomania). Alcohol may be sought both for its disinhibiting effects and sedation to calm the nervousness of the high periods. How many patients display alcohol and substance abuse secondary to an underlying bipolar diathesis remains to be determined. However, given findings suggesting a link between polysubstance abuse and suicide in adolescents with bipolar familial backgrounds, we should strongly consider using mood stabilizers in these adolescents. Although alcohol and stimulant use continues into adult years in many bipolar disorder patients, such use is often unrelated to familial alcoholism and frequently tends to dwindle during long-term follow-up. This finding supports the self-medication hypothesis.

Rapid-Cycling Bipolar Disorder. *Rapid cycling* is the occurrence of at least four episodes of depression and hypomania (or mania) per year. Thus, rapid cyclers are rarely free of affective symptoms and experience severe vocational and interpersonal incapacitation. Lithium is only modestly helpful to those patients, as are traditional antipsychotic agents; most antidepressants readily induce excited episodes and aggravate the rapid-cycling pattern. Balancing mood stabilizers, atypical antipsychotic drugs, and antidepressants is challenging. We should avoid antidepressants because depression follows every provoked hypomania, and the roller coaster is further prolonged. Many such patients require frequent hospitalization because they develop explosive excitement and precipitous descent into severe psychomotor inhibition. The disorder is a roller coaster nightmare for the patient, significant others, and the treating physician. Treating these patients is an art. Lamotrigine, a mood stabilizer that stabilizes "from below," has been reported to be efficacious in this group of patients.

As expected, rapid cycling commonly arises from a cyclothymic substrate, which means that most rapid cyclers have bipolar II disorder. Factors favoring its occurrence include (1) female gender, (2) borderline hypothyroidism, (3) menopause, (4) temporal lobe dysrhythmias, (5) alcohol, minor tranquilizer, stimulant, or caffeine abuse, and (6) long-term, aggressive use of antidepressant medications. Most clinically identified patients are bipolar II women in middle age or upper socioeconomic status. Rapid cycling is uncommon from a bipolar I disorder base.

Leadership and Creativity. Persons with hyperthymic temperament and soft bipolar conditions, in general, possess assets that permit them to assume leadership roles in business, the professions, civic life, and politics. Increased energy, sharp thinking, self-confidence, and eloquence represent the virtues of an otherwise stormy life.

Creative achievement is relatively uncommon among those with the manic forms of the disorder, which are too severe and disorganizing to permit the necessary concentration and application. We do see some notable artistic achievements among those with soft bipolar disorders, especially cyclothymic disorders. Psychosis, including severe bipolar swings, is generally incompatible with creativity. That conclusion tends to refute the romantic tendency to idolize insanity as central to the creative process. Because talent is the necessary ingredient of creativity, how might soft bipolarity contribute? The simplest hypothesis is that depression might provide insights into the human condition, and the activation associated with hypomania helps produce the artistic work. A more profound interpretation suggests that the repeated self-doubt accompanying recurrent depression might be a significant ingredient of creativity, because an original artistic or scientific expression is often initially rejected. The self-confidence that accompanies repeated bouts of hypomania can help rehearse such ideas or expressions. Finally, the tempestuous object relations associated with bipolarity in the parent's or the patient's life often create unique biographical landmarks that the artist might then immortalize in their art.

Ultrarapid Cycling. In these patients, hypomanic or manic and depressive episodes alternate rapidly over a few days. In many, the alternation occurs regularly. The episodes in such cycling patients have greater amplitudes than in cyclothymia, leading to marked impairment. We might consider them as an intermediary between cyclothymia and full-blown rapid cycling. Of considerable theoretical and methodologic interest, they are

challenging to manage clinically. Some individuals with this condition learn to change their work days to coincide with the hypomanic periods.

Recurrent Brief Hypomania. This hypomanic counterpart of recurrent brief depressive disorder is a variant of soft bipolarity, as described previously. It tends to coincide with cyclothymic depression, in which hypomanias are short (less than 4 days).

Hysteroid Dysphoria. Hysteroid dysphoria combines reverse vegetative signs with the following characteristics: (1) giddy responses to romantic opportunities and an avalanche of dysphoria (angry-depressive, even suicidal, responses) to romantic disappointment; (2) impaired anticipatory pleasure, yet the capability to respond with pleasure when others provide it (i.e., preservation of consummatory reward); and (3) craving for chocolate and sweets, which contain phenylethylamine compounds and sugars believed to facilitate cellular and neuronal intake of the amino acid L-tryptophan, hypothetically leading to the synthesis of endogenous antidepressants in the brain. Historically, clinicians used the term *hysteroid* to convey that the apparent character pathology was secondary to a biologic disturbance in the substrates governing affect, drives, and reward. The intense, unstable life of the patient with hysteroid dysphoria suggests links to cyclothymic disorder or bipolar II disorder. Researchers such as those at Columbia tend to subsume those patients under atypical depressions (some of which, as indicated, have bipolar affinities). Like patients with bipolar depression, they may respond preferentially to monoamine oxidase inhibitors (MAOIs). In brief, hysteroid dysphoria appears to be a variant of bipolar II disorder with cyclothymic-irritable traits. Clinicians often relegate such patients to the realm of borderline personality. The Pisa–San Diego collaboration (for which Dr. Akiskal was a member) suggested that cyclothymic traits represent the underlying diathesis of atypical depression, borderline personality, and bipolar II disorders.

UNSPECIFIED MOOD DISORDERS

After obtaining all diagnostic information, a clinician may find that some patients with affective symptoms do not meet the specific criteria for the mood conditions described thus far, nor do they fit the examples listed in the not otherwise specified categories for depressive and bipolar disorders. One example is individuals with acute suicidal ideation of an ego-dystonic nature, not accompanied by other affective symptoms. Family or close follow-up, or both, often suggests a more discrete mental condition. In general, we should consider such cases as undiagnosed mood disorders. However, there are two hybrid conditions that we have not addressed elsewhere in this chapter and can conveniently discuss here.

Mixed Anxiety–Depressive Disorder

Both anxiety and depression can occur together when confronted with a significant aversive life situation. The admixture implies that the psychopathology progresses from anxiety to depression, that the patient's mental state is still in flux, and that the ongoing dynamics partly explain the disorder's subacute or chronic nature. Anxious depression points to the common presence of anxiety in depressive states, especially its greater visibility when the depression is less prominent. Patients with the latter presentation are

reportedly most prevalent in general medical settings. This prevalence should not come as a surprise, because depressive symptoms that motivate medical consultation tend to complicate generalized anxiety states with a subthreshold level of symptomatology. Some authorities argue that neurotic depressions arise as maladaptive responses to anxiety and, on that basis, suggest retaining the *neurotic depression* rubric. Some genetic data indirectly support the contention that certain (unipolar) depressive and (generalized) anxiety states are related. As currently defined, anxious depressions are heterogeneous. In patients refractory to anxiolytic or antidepressant treatment, practitioners must entertain the diagnosis of a complex bipolar II disorder with mixed features. Indeed, recent familial-genetic investigations suggest that bipolar II disorder with panic attacks might represent a particular form of bipolar disorder.

Atypical Depression

Initially developed in England and under investigation at Columbia University in New York City, *atypical depression* refers to fatigue superimposed on a history of somatic anxiety and phobias, together with reverse vegetative signs (mood worse in the evening, insomnia, tendency to oversleep and to overeat). Experience suggests that increased sexual interest or desire is another reverse vegetative sign, although it remains undescribed in this literature. Sleep is disturbed in the first half of the night in many persons with atypical depressive disorder, and so irritability, hypersomnolence, and daytime fatigue would be expected. Sensitive traits characterize the temperaments of these patients. The MAOIs and serotonergic antidepressants seem to show some specificity for such patients, which is why we take atypical depression seriously.

Other research reveals several classifications of reverse vegetative signs: (1) the anxious type just described or (2) a subtle bipolar subtype with protracted hyperphagic–hypersomnic–retarded dysthymic disorder with occasional brief, extroverted, hypomanic-type behavior, often elicited by antidepressants. Increasing evidence indicates considerable affinity between atypical depression and bipolar II and III disorders. Furthermore, many patients with dysthymic disorder exhibit atypical features at various times. Some research suggests that many patients with atypical depression meet the criteria for brief hypomania or cyclothymic disorder. Such patients also resemble those with hysteroid dysphoria, the precursor of the construct of atypical depression.

DIFFERENTIAL DIAGNOSIS

A missed mood disorder diagnosis means that the disorder does not receive specific treatment, which has serious consequences. Many such persons drop out of school or college, lose their jobs, or get divorced, and some commit suicide. Those with unexplained somatic symptoms are frequent users of the general health system. Others are unwell, despite interminable psychotherapy. Some, treated with conventional neuroleptics, develop tardive dyskinesia unnecessarily. As with other medical disorders for which specific treatments are available, accurate diagnosis and early treatment are within the purview of all physicians and mental health professionals. Psychiatrists, in particular, should develop the competence to detect the entire spectrum of mood disorders. Despite massive educational efforts, underdiagnosis and undertreatment of mood disorders remain serious problems worldwide. The most pernicious of these is

downplaying the mood component because a clinician gives a personality disorder undue prominence.

Although much enthusiasm was generated three decades ago about the potential use of specific biologic markers (e.g., REM latency, DST, and thyrotropin-releasing hormone [TRH] test) to corroborate the differentiation of mood disorder from adjacent disorders, no definitive progress justifies their routine use in clinical practice. The same is true, at least for now, for brain imaging, neuropsychologic testing, and genetic screening. Given that the presentations can be unusual or confusing, we are best off applying a systematic clinical approach. Such an approach helps (1) to detail all clinical features of the current episode, (2) to elicit a history of more typical major mood episodes in the past, (3) to assess whether the presenting complaints recur periodically or cyclically, (4) to substantiate adequate social functioning between periods of illness, (5) to obtain a positive family history for a classic mood disorder and to construct a family pedigree, and (6) to document a history of unequivocal therapeutic response to thymoleptic medication or ECT in the patient or the family.

Normal Bereavement

Bereaved persons exhibit many depressive symptoms during the first 1 to 2 years after their loss, so how can we identify the 5% of bereaved persons who have progressed to a depressive disorder? Table 13.3–9 outlines some features that suggest that bereavement has become a “full-blown” depressive disorder.

In another form of bereavement depression, the patient simply pines away, unable to live without the departed person, usually a spouse. Although not necessarily pathologic by the preceding criteria, such persons do have a severe medical condition. Their immune function is often depressed, and their cardiovascular status is precarious. Death can ensue within a few months of that of a spouse, especially among older men. Such considerations (highlighted in the work of Sidney Zisook and his colleagues at the University of California at San Diego) suggest that it would be clinically unwise to withhold antidepressants from many persons experiencing an intensely mournful form of grief. A case vignette illustrates this point:

Table 13.3–9.
Signs that a Bereaved Person Has Progressed to a Depressive Disorder

Beliefs. Grieving persons and their relatives perceive bereavement as a normal reaction whereas those with depressive disorder often view themselves as sick and may actually believe they are losing their minds.

Emotional reactivity. Unlike the melancholic person, the grieving person reacts to the environment and tends to show a range of positive effects.

Psychomotor activity. Marked psychomotor retardation is not observed in normal grief.

Guilt. Although bereaved persons often feel guilty about not having done certain things that they believe might have saved the life of the deceased loved one (guilt of omission), they typically do not experience guilt of commission.

Delusions. Delusions of worthlessness or sin and psychotic experiences in general point toward mood disorder.

Suicidal ideation. Active suicidal ideation is rare in grief but common in major depressive disorder.

Behaviors. "Mummification" (i.e., keeping the belongings of the deceased person exactly as they were before their death) indicates serious psychopathology.

Anniversaries. Severe anniversary reactions should alert the clinician to the possibility of psychopathology.

From Akiskal. Mood disorders. In: Sadock BJ, Sadock VA, Ruiz P, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 10th ed. Wolters Kluwer; 2017.

A 75-year-old widow was brought to the treatment by her daughter because of severe insomnia and total loss of interest in daily routines after her husband's death 1 year before. She had been agitated for the first 2 to 3 months and, after that, "sank into total inactivity—not wanting to get out of bed, not wanting to do anything, not wanting to go out." According to her daughter, she was married at 21 years of age, had four children, and had been a homemaker until her husband's death from a heart attack. Past psychiatric history was unrevealing; compulsive traits had characterized premorbid adjustment. She was dressed in black during the interview, appeared moderately slowed, and sobbed intermittently, saying, "I search everywhere for him … I don't find him." When asked about life, she said, "Everything I see is black." Although she expressed no interest in food, she did not seem to have lost an appreciable amount of weight. The patient declined psychiatric care, stating that she "preferred to join her husband rather than get well." She was too religious to commit suicide, but by refusing treatment, she felt that she would "pine away … find relief in death and reunion."

Anxiety Disorders

Anxiety symptoms, including panic attacks, morbid fears, and obsessions, are common during depressive disorders, and depression is a common complication of anxiety states. Systematic British studies have shown that early-morning awakening, psychomotor retardation, self-reproach, hopelessness, and suicidal ideation are the most robust clinical

markers of depression in that differential diagnosis. On follow-up of depressed patients, the manifestations tend to remit, whereas those with anxiety states continue to exhibit marked tension, phobias, panic attacks, vasomotor instability, feelings of unreality, and perceptual distortions, as well as hypochondriacal ideas. A predominance of such anxiety features antedating the present illness suggests the diagnosis of an anxiety disorder. Because anxiety disorders rarely first appear after 40 years of age, a late appearance of marked anxiety features strongly favors the diagnosis of melancholia. The clinical picture is often one of morbid groundless anxiety with somatization, hypochondriasis, and agitation. Superior response to ECT further supports the depressive nature of the illness. Periodic monosymptomatic phobic and obsessional states exist which we can regard as affective equivalents based on a family history of mood disorders and their response to thymoleptic agents. Recent data from a large clinical series suggest that 15% of cases have hypomanic symptoms; these patients likely have bipolar II disorder. Social phobias often usher in adolescent depression, even a bipolar II disorder; the latter is particularly likely when pairing the phobia with alcohol abuse.

We have not resolved the psychopathologic differentiation of anxiety and depressive states. Cognitive factors may differentiate them best (Table 13.3–10). Although recurrent (particularly retarded) major depressive disorder is a distinct disorder from anxiety states, some forms of depression may share a common diathesis with anxiety disorders, particularly generalized anxiety disorders. Before assigning patients to such putative mixed anxiety–depressive group (not yet an official nosologic entity), the clinician must note that it is best to consider anxiety arising primarily during depressive episodes as epiphenomenal to depressive disorder. The same is generally true for anxiety symptoms in a patient with a depressive disorder who uses alcohol, sedative–hypnotics, or stimulant drugs. Finally, anxiety symptoms could be prominent features of mixed bipolar states and complex partial seizures.

Table 13.3–10.
Unique Cross-Sectional Profiles of Clinical Anxiety and Depression

Anxiety	Depression
Hypervigilance	Psychomotor retardation
Severe tension and panic	Severe sadness
Perceived danger	Perceived loss
Phobic avoidance	Loss of interest—anhedonia
Doubt and uncertainty	Hopelessness—suicidal
Insecurity	Self-deprecation
Performance anxiety	Loss of libido
	Early-morning awakening
	Weight loss

Major Depressive Disorder versus Bipolar Disorder

This "internal" boundary question of whether a patient has major depressive disorder versus bipolar disorder has been discussed extensively throughout this work. With the increasing availability of mood-stabilizing agents, it has emerged as a significant challenge in clinical practice. Numerous studies have shown that bipolar disorder is confused not only with personality, substance use, and schizophrenic disorders but also with depressive and anxiety disorders. Table 13.3–11 summarizes the features predictive of bipolar disorder based on results of prospective and other systematic studies.

Table 13.3–11.
Features of a Depressive Episode that Are More Predictive of Bipolar Disorder

Early age at onset
Psychotic depression before 25 years of age
Postpartum depression, especially one with psychotic features
Rapid onset and offset of depressive episodes of short duration (less than 3 months)
Recurrent depression (more than five episodes)
Depression with marked psychomotor retardation
Atypical features (reverse vegetative signs)
Seasonality
Bipolar family history
High-density three-generation pedigrees
Trait mood lability (cyclothymia)
Hyperthymic temperament
Hypomania associated with antidepressants
Repeated (at least three times) loss of efficacy of antidepressants after initial response
Depressive mixed state (with psychomotor excitement, irritable hostility, racing thoughts, and sexual arousal during major depression)

From Akiskal. Mood disorders. In: Sadock BJ, Sadock VA, Ruiz P, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 10th ed. Wolters Kluwer; 2017.

More broad indicators of bipolarity include the following conditions, none of which, by itself, clinches a bipolar diagnosis but should raise clinical suspicion in that direction: agitated depression, cyclical depression, episodic sleep dysregulation, or a combination of these; refractory depression (failed antidepressants from three different classes); depression in someone with an extroverted profession; periodic impulsivity, such as gambling, sexual misconduct, and wanderlust, or periodic irritability, suicidal crises, or both; and depression with erratic personality disorders.

Personality Disorders

Most personality measures are state dependent. In general, clinicians should refrain from using personality disorder labels to describe patients with active affective illness and focus instead on the competent treatment of the mood disorder. Unfortunately, many clinicians ignore this advice. Even in patients with chronic or subthreshold mood disorders, we should consider personality maladjustment as postaffective, arising from the distortions and conflicts that affective disturbances produce in the patient's life. The most problematic of the personality labels used in patients with mood disorders is borderline personality disorder, usually applied to teenage and young adult women. Table 13.3–12 shows that the overlap between borderline personality and mood disorders is extensive so that giving a *borderline* diagnosis to a person with a mood disorder may be redundant. The use of personality disorder diagnoses may lead to a neglect of the mood disorder or, perhaps, half-hearted treatment of the mood disorder; we then blame the patient's nonresponse on their "self-defeating character" or "resistance to getting well," thus exculpating ourselves.

Although we need more systematic research on the complex interface of personality and mood disorders, clinically, they are often inseparable. As with alcohol and substance use disorders, it is generally preferable to diagnose mood disorders at the expense of personality disorders, which should not be difficult to justify in most cases that satisfy the validating strategies outlined previously. When personality and mood disorders coexist, it is good practice to defer personality disorder diagnoses and treat the mood disorder. Although not all personality disturbances recede with the competent treatment of mood disorders, so many experienced clinicians have seen such disturbances melt away with the successful resolution of the mood disorder that erring in favor of mood disorders is justified.

Table 13.3–12.
Overlap of Borderline Personality Disorder and Mood Disorders

Familial
High rates of mood disorder
Phenomenology
Dythymic disorder
Cyclothymic disorder
Bipolar II disorder
Mixed state
Pharmacologic response
Worsening on most antidepressants
Stabilization on anticonvulsants
Prospective course
Major mood episodes
Suicide

Data from Akiskal HS, Chen SE, Davis GC, Puzantian VR, Kashgarian M. Borderline: an adjective in search of a noun. *Clin Psychiatry.* 1985;46(2):41.

A 19-year-old single woman presented with the chief complaint that “all men are bastards.” Since her early teens, with the onset of her menses, she had complained of extreme variability in her moods on a nearly daily basis; irritability with hostile outbursts was her primary affect, although more-protracted hypersomnic depressions with multiple overdoses and wrist slashings had led to at least three hospitalizations. She also had migrainous headaches that, according to her mother, had motivated at least one of those overdoses. Despite her tempestuous and suicidal moods that led to these hospitalizations, she complained of “inner emptiness and a bottomless void.” She had used heroin, alcohol, and stimulants to overcome this troubling symptom. She also gave a history of ice cream craving and frequent purging. She was talented in English and wrote much-acclaimed papers on the American confessional poet Anne Sexton. She said she was mentally disturbed by a series of stepfathers who had forced “oral rape” on her between 11 and 15. She subsequently gave herself sexually to any man she met in bars, no longer knowing whether she was a “prostitute” or a “nice little girl.” On two occasions, she had inflicted cigarette burns inside her vagina “to feel something.” She had also engaged in a “brief lesbian relationship” that ultimately left her “emptier” and guilt ridden; nonetheless, she now believed that she should burn in hell because she could not get rid of “obsessing” about the excitement of mutual cunnilingus with her much older female partner. The patient’s mother, who owned an art gallery, had been married five times and gave a history of unmistakable hypomanic episodes; a maternal uncle had died from alcohol-induced cirrhosis. The patient’s father, a prominent lawyer, known for his “temper and wit,” had committed suicide. Her psychiatrist gave the patient phenelzine, at which point, the mother described her as “the sweet daughter she was before age 13.” At her next premenstrual phase, the patient developed insomnia, ran away from home at night, started “dancing like a go-go girl, met an incredibly handsome man” of 45 years of age (a pornography shop owner), and had a clandestine marriage to him. After many dose adjustments, she currently takes a combination of lithium and valproic acid. The patient now attends college and has completed four semesters in art history. In addition to control of her irritable and suicidal moods, bulimic and migraine attacks have abated considerably. She was able to annul her marriage, contending that she was not mentally competent at the time of the wedding. She is no longer promiscuous and now expresses fear of intimacy with men to whom she is attracted. She is receiving individual psychotherapy for this problem.

This case illustrates the intimate relationship among atypical depression, borderline personality, and bipolar II disorder. These three conditions may share an underlying psychobiologic or genetic diathesis. Clinicians often complain that even when diagnosing a mood disorder in a “borderline” patient, the antidepressant response is disappointing. The problem is that affective disorders in these patients usually conform to bipolar II disorder—often complicated by ultrarapid cycling—and many clinicians trained in an earlier era, including some with biologic orientation, may lack sufficient experience in the art of pharmacologically managing patients who markedly deviate from classic bipolar I disorder.

Alcohol and Substance Use Disorders

We cannot explain the high comorbidity of alcohol and substance use disorders with mood disorders as merely the chance occurrence of two prevalent disorders. Psychiatrists and other clinicians dealing with addiction do not sufficiently appreciate self-medication for mood disorders. Given the clinical dangers of missing an otherwise treatable disorder, we should seriously consider a mood disorder as the primary diagnosis if marked affective manifestations persist or escalate after detoxification (e.g., 1 month). This consideration also pertains to cyclothymic disorder and dysthymic disorder, which appear particularly likely to invite self-medication. The clinical validating strategies listed previously can further buttress a mood disorder diagnosis.

The DSM category of substance-induced mood disorder is challenging to validate clinically because, in the absence of an affective diathesis, detoxification should, in principle, rapidly repair affective disturbances in persons whose primary problem is that of substance abuse. A dual diagnosis of a mood disorder and a substance use disorder is a more realistic clinical approach to this group of patients. Bipolarity, particularly bipolar II disorder, should be sought in the interface of mood and substance use disorders.

A 27-year-old married businessman employed in an international family venture owned by his father presented with a court-ordered request for psychiatric treatment. He had been found “bringing” cocaine across the United States–Mexican border and was briefly jailed. He had used stimulants since his late teens to enhance his already high level of energy. His family was wealthy, and he had no difficulty affording cocaine. During the previous year, he had needed more cocaine because of more remarkable moodiness and fleeting suicidal ideation, which he linked to increasing tensions between him and his father: “My father was never satisfied with me and demanded greater and greater performance from me.” His arrest by police was a major embarrassment for him and his family and motivated his compliance with psychiatric hospitalization to detoxify him. He had not had cocaine for 10 days, exhibited marked lability of mood, and gradually sank into a severe hypersomnic-retarded depression of stuporous proportions. He was hospitalized on an inpatient psychiatric unit and treated with tranylcypromine 20 mg twice a day, and, within 10 days, he switched into hypomania, his mind “exploding with creativity and confidence,” marked jocularity and witticisms that entertained other patients, and marked seductiveness toward the nurses. His wife recalled that the patient previously had several such periods naturally (i.e., “off cocaine”), which had strained their marriage due to “brief sexual liaisons.” Reducing the tranylcypromine dose by 50% did not eliminate the hypomanic behavior, and lithium, 900 mg per day, was added. He has since been maintained on a combination of tranylcypromine and lithium for 4 years; he has not relapsed into cocaine use, and, following a few psychoeducational sessions involving father and spouse, relationships with family and spouse have been less tempestuous. (Since then, consultation was sought by the patient’s 60-year-old mother, an attractive, sophisticated woman who confessed that for years she had been engaged in “love relationships” with young artists, with, apparently, her husband’s “tacit consent;” since at least her mid-20s, she, by history, would meet the criteria for bipolar II disorder, only was treated “on the couch,” and her sister and brother had received treatment of “alcohol excesses.”) The patient stated that pharmacotherapy, which did require adjustment now and then, helped in balancing the “rough edges” of his “high-nervous temperament” and his “periodic lapse into paralyzing fatigue states that occurred at stressful times.”

If his doctors had assumed his mood states were merely due to cocaine withdrawal, they would never have treated his bipolar II disorder. There is emerging interest in treating dually diagnosed patients with anticonvulsant mood stabilizers and their judicious combination. Among the antidepressants, bupropion is a suitable agent to “replace” stimulant craving; serotonin reuptake inhibitors help concurrent social phobia and anxious components. The intention is to treat any substance-related withdrawal while also treating any underlying or emerging bipolar diathesis.

Physical Disease

Somatic complaints are common in depressive disorders. Some, such as vegetative disturbances, represent the hypothalamic pathology believed to underlie a depressive disorder. Autonomic arousal, commonly associated with depression, could explain such

symptoms as palpitations, sweating, and headache. In some instances, the physical symptoms might reflect delusional experiences. The clinician must be vigilant about the likelihood that somatic complaints in depression can also reflect an underlying physical illness. Table 13.3–13 lists the most common medical conditions associated with depression. When depressive symptoms occur in the setting of physical illness, it is not always easy to determine whether they constitute a genuine depressive disorder. Before diagnosing depression, psychiatrists must ensure that they are not dealing with *pseudodepression*. By "pseudodepression," we mean (1) functional loss due to physical illness; (2) vegetative signs, such as anorexia and weight loss, as manifestations of such an illness; (3) stress and demoralization secondary to the hospitalization; (4) pain and discomfort associated with the physical illness; and (5) medication adverse effects. However, nonpsychiatric physicians who manage such patients must consider the diagnosis of depression in the presence of persistent anhedonia; observed depressed mood with frequent crying; observed psychomotor retardation or agitation; indecisiveness; convictions of failure, worthlessness, or guilt; and suicidal ideation. The physician should also suspect clinical depression in all patients who refuse to participate in medical care.

Table 13.3–13.
Pharmacologic Factors and Physical Diseases Associated with Onset of Depression

Pharmacologic
Steroidal contraceptives
Reserpine (Serpalan), á-methyldopa
Anticholinesterase insecticides
Amphetamine or cocaine withdrawal
Alcohol or sedative–hypnotic withdrawal
Cimetidine (Tagamet), indomethacin (Indocin)
Phenothiazine antipsychotic drugs
Thallium, mercury
Cycloserine (Seromycin)
Vincristine (Oncovin), vinblastine (Velban)
Interferon
Endocrine–metabolic[a]
Hypothyroidism and hyperthyroidism
Hyperparathyroidism
Hypopituitarism
Addison disease
Cushing syndrome
Diabetes mellitus
Infectious
General paresis (tertiary syphilis)
Toxoplasmosis
Influenza, viral pneumonia
Viral hepatitis
Infectious mononucleosis
Acquired immune deficiency syndrome
Collagen
Rheumatoid arthritis
Lupus erythematosus
Nutritional
Pellagra
Pernicious anemia
Neurologic
Multiple sclerosis
Parkinson disease
Head trauma
Complex partial seizures
Sleep apnea
Cerebral tumors
Cerebrovascular infarction (and disease)
Neoplastic
Abdominal malignancies
Disseminated carcinomatosis

[a]Cholesterol is not mentioned because low levels as a factor in depression have been inconsistently reported.

Diagnosing depression in medically ill older adult patients can be particularly difficult. We should diligently undertake this task, given the data showing that depression can accelerate mortality in the medically ill (especially in those with cardiovascular disease). Depressed older adults often deny being depressed but complain of anxiety, fatigue, and worsening memory. Hypochondriacal symptoms and pain are common. Patients may exhibit extreme negativism and querulousness when invited to participate in medical procedures; others develop inadequate fluid and food intake out of proportion to their physical conditions.

Another critical diagnostic problem at the interface of mood disorder and physical disease is the rare development of malignancy in patients with an established mood disorder. Patients who had responded well to a given antidepressant during previous episodes now have an unsatisfactory response to the same medication. Even a small dose may cause such alarming symptoms as agitation, dizziness, depersonalization, and illusions, which might indicate an occult malignancy, perhaps in the abdomen or the brain. The psychiatrist should always be vigilant for possible life-threatening physical diseases developing in patients with pre-established depressive disorder.

A 55-year-old woman had four previous episodes of severe depression that had responded to ECT, amitriptyline, or a combination in her native city in the Middle East. She immigrated to the United States at 43 years of age and encountered several significant stresses, including an unfamiliarity with English, her daughter dating a man of Chinese extraction, and a complicated series of operations for uterine prolapse. Then, her husband confessed that he had had an affair with a much younger woman. For months, the patient had complained of intermittent fatigue and expressed hostility toward her husband. He had slapped her on her face on two occasions. Her ensuing fifth depressive episode (with pain localized to her face) appeared entirely "understandable," but her physician's prescription of 25 mg of amitriptyline resulted in dizzy spells that culminated in syncope. Citalopram, 10 mg, did not fare any better. An extensive medical workup revealed a retroperitoneal lymphoma. She died 6 months later.

Stupor. Although less common today, stupor still raises a diagnostic problem differentiating between a mood disorder and somatic disease, and other psychiatric disorders. Depressive stupor is relatively easy to distinguish from so-called hysterical mutism; in the latter, the patient directs the behavior to significant others in the patient's environment. It is best to reserve the rubric of catatonic stupor for a phase of schizophrenia; in such patients, the schizophrenic origin of the catatonia might be apparent from the patient's history. Otherwise, most acute-onset stupors are probably of affective origin. The primary differential diagnosis here is from organic stupor (due to drugs or acute intracranial events); the physical and neurologic examination is not always decisive in such cases. Diagnosis depends on a high index of suspicion of possible somatic factors.

Dementia. We can usually distinguish the cognitive symptoms caused by depression (sometimes called "pseudodementia," although this can be a misleading term) by their

acute onset without prior cognitive disturbance. Also, a personal or family history of past affective episodes, psychomotor retardation with reduced social interaction, self-reproach, and diurnal cognitive dysfunction (worse in the morning), can help with the differential. Often described are the subjective complaints of memory dysfunction, which appear much worse than what we find on objective testing. In some cases, we can reverse circumscribed memory deficits with proper encouragement or coaching. Sometimes the deficits seem to improve with sleep deprivation. The deficits do not improve with depression treatment for some patients, which may signal the early stages of a dementing disease. Such patients may be labile, aggressive, and disinhibited and may become easily confused. A family history of bipolar disorder or a history of mild manic-like expressions helps distinguish these patients from those whose cognitive deficits are due to depression. The distinction is essential because antidepressants and anti-Alzheimer agents often worsen patients with an underlying bipolar disorder, who would instead benefit from a mood stabilizer. Prospective follow-up reveals the definitive diagnosis. The main clinical message here is not to miss treatable or potentially reversible depressive and bipolar states in older adult patients with dementia-like illnesses or early- and even mid-stage dementia.

Chronic Fatigue Syndrome. Chronic fatigue syndrome is a complex differential diagnostic problem, given the subtle immunologic disturbances presumably associated with it. The following self-report by such a patient illustrates many uncertainties marking the present knowledge of the interface between the syndrome and mood disorders.

I am a 39-year-old, never-married woman, trained as a social worker but currently on disability. I have experienced extreme lethargy and fatigue for many years. I have always felt foggy headed and had trouble thinking and concentrating. My complaint is of fatigue, not of depression. My body feels like lead and aches all over. My brain feels achy and sore. I feel much worse in the morning, and I cannot get out of bed; I feel better at night. I feel bad every day. I ache all over as though someone had beaten me up. Exercise has been prescribed to me, but it makes me worse. Also, I am very sensitive to hot and cold. My sexual drive is low. I have a general feeling of anhedonia. As far back as I remember—in junior high school—I was always exhausted. I always complained about fatigue, not depression, because that has been the overwhelming problem. I feel the depression is secondary to the fatigue. In high school, I was a compulsive overeater, and I was bulimic for a few years, but it was never severe, and I was only about 10 pounds overweight. In those days, I would sleep 10 or 12 hours a night on the weekend and still feel exhausted; I could not get up for school on Monday. As an adolescent, I felt inferior. I could not make decisions. I did not want to go to camp or leave home for long periods of time—I felt so insecure. Recently, I had a sleep study done, which showed a short latency to stage REM sleep (49 minutes). I was diagnosed as having dysthymic disorder and began taking antidepressants. When I took tranylcypromine, it was the first time in my life that I felt like a normal person. I could play sports, had a sex drive, had energy, and was able to think clearly, but the benefits lasted for barely 2 months. My response was equally short lived to phenelzine, imipramine, selegiline, and bupropion. I have not responded to SSRIs at all. I also wish to point out that I had never experienced high periods before I took antidepressants. My main problem has always been one of exhaustion. When I responded to medications, they worked very quickly (within a few days), and I felt great, but they all stopped working after a short time. The dose would be raised, and, again, I would feel better. Eventually, when I got to high doses, I either could not tolerate the high dose, or the drug would no longer help. I have taken different combinations of drugs for 10 years, and I have not been able to feel well for more than 6 weeks at a time. Recently, I went to an immunologist. He said I have an abnormality in regulating antibody production and recommended gamma-globulin shots. They did not help. When I first started working, I always felt tired and foggy headed, so it was difficult to be sharp while at work. At times, I would close the door to my office and put my head down. Working has become increasingly difficult for me. I had two great jobs, which I blew. As of last year, I had to go on disability. I am desperate for relief, as my condition has drastically affected my life. Disability has been hard for me. I am single and have no other financial resources. I am very despondent, as I feel that my life is passing by without the hope of my ever really improving.

This clinical picture is compatible with a pseudounipolar or bipolar III disorder as described previously. If so, mood stabilizer augmentation of the tranylcypromine would have been a therapeutic choice to pursue. Some biologists and immunologists, and some psychiatrists, believe that abnormal substances circulate in the bloodstream, supplying the patients' brains. Some have suggested industrial toxins as a factor. Although awaiting more definitive research on the etiology of chronic fatigue syndrome, the psychiatrist can

cautiously consider certain patients for thymoleptic trials. The following supports such a trial: The patient wakes up with fatigue and dread of facing the day; fatigue is part of a more generalized psychomotor inertia or lack of initiative; fatigue is associated with anhedonia, including sexual anhedonia; and fatigue coexists with anxious and pessimistic ruminations. Although none of the previous considerations alone is pathognomonic for depression, they point in that direction in aggregate. The occurrence of hypomanic-like periods (as in the previous vignette) further supports the link between some cases of chronic fatigue and mood disorder. Several recent neuroendocrine challenge studies suggest that some chronic fatigue patients might have a strong anxiety substrate. These observations do not suggest that chronic fatigue is mostly a matter of missed affective diagnoses with bipolar II and panic disorder features; yet, it would be a pity to miss potentially treatable diagnoses. A family or past personal history of classic affective illness or episodes should strongly weigh in this direction. Definitive data are lacking on the essential nature of chronic fatigue, and practitioners should be guided by their clinical experience with therapeutic trials of nonsedating thymoleptic agents while they await new research developments.

Schizophrenia

Despite some genetic overlap between schizophrenic and bipolar disorders, clinically, the two groups of disorders are in the main separate. Young patients with bipolar disorder might seem psychotic and disorganized and, thus, schizophrenic. Their thought processes are so rapid that they may seem loose, but, unlike patients with schizophrenia, they display an expansive and elated affect, which is often contagious. By contrast, the severely retarded bipolar depressive person, whose affect may superficially seem flat, rarely exhibits significant fragmentation of thought. The clinician, therefore, should place greater emphasis on the pattern of symptoms than on individual symptoms in the differential diagnosis of mood and schizophrenic psychoses. No pathognomonic differentiating signs and symptoms exist. Differential diagnosis should consider the overall clinical picture, phenomenology, family history, course, and associated features. Because the two groups of disorders entail different combinations of pharmacologic treatments on a long-term basis (such as mood stabilizers for bipolar disorder), the differential diagnosis is of paramount clinical importance. In the past, many bipolar patients, especially those with prominent manic features at onset, were labeled as having *acute schizophrenia* or *schizoaffective schizophrenia.* In the past, such misdiagnoses (which typically led to long-term treatment with conventional neuroleptic agents) were costly in terms of tardive dyskinesia, vocational and social decline, and even suicide. For instance, some patients with postpsychotic depressive disorder of schizophrenia have postmanic depressions but are treated with classic neuroleptic monotherapy without the benefit of more definitive thymoleptic agents.

Modern antipsychotics tend to keep many persons with schizophrenia out of the hospital. However, they do not always seem to prevent an overall downhill course. By contrast, the intermorbid periods in bipolar illness are relatively normal or even supernormal, and yet, over time, some social impairment may result from the accumulation of divorces, financial catastrophes, and ruined careers. (Although rapid-cycling disorders, which have sharply risen during the past two decades, cause considerable social impairment, mood symptoms are so prominent that differentiation

from schizophrenia is generally not complicated; in addition, such patients usually display more classic bipolar phases before the rapid cycling.)

Postpsychotic depressions in persons with established schizophrenia are sometimes due to inadequate control of schizophrenic symptomology. In other patients, particularly more intelligent young patients with schizophrenia, they reflect the experience of losing one's ego and sanity. It would be more meaningful to give such patients a diagnosis of schizophrenia and a superimposed major depressive diagnosis and treat the patient accordingly.

Schizoaffective Disorder

As the previously mentioned considerations suggest, depression in the setting of a schizophrenic disorder does not necessarily constitute a distinct nosologic entity. We should restrict the concept of schizoaffective (or cycloid) psychosis to recurrent psychoses, with full affective and schizophrenic symptoms occurring nearly simultaneously during each episode. We should not consider this diagnosis for mood psychosis in which mood-incongruent psychotic features (e.g., Schneiderian and Bleulerian symptoms) are better explained by one of the following: (1) affective psychosis superimposed on mental retardation, giving rise to extraordinarily hyperactive and bizarre manic behavior; (2) affective psychosis complicated by concurrent brain disease, substance abuse, or substance withdrawal, known to give rise to numerous Schneiderian symptoms; or (3) mixed episodes of bipolar disorder (which are notorious for signs and symptoms of psychotic disorganization). Official diagnostic systems, such as DSM-5, use the category of schizoaffective disorder broadly. Thus, patients with clear-cut manic episodes receive a schizoaffective diagnosis if delusions or hallucinations occur in the interepisodic period in the absence of prominent affective symptoms. Many psychotic symptoms in mood disorders are often explanatory (albeit delusional), whereby the patient tries to make sense of the core experiences of the affective illness. In patients with recurrent episodes, delusional thinking can carry over into the interepisodic period. Such patients are thus delusional in the absence of prominent mood symptoms and technically might be considered schizoaffective.

However, affective illness is typically a lifelong process, and limiting its features to discrete episodes is artificial. In the past, neuroleptic agents were prescribed on an as-needed basis to reduce the affective charge of those interepisodic delusions, but they did not effectively eliminate the affect-laden experiences. Atypical antipsychotic agents introduced during the 1990s are more likely to be beneficial in this regard. Augmenting with continued thymoleptic treatment (resorting to ECT, if necessary) and an empathic psychotherapeutic approach may prove more rewarding in the long run.

A 29-year-old female college graduate, a mother of two children, and wife of a bank president had experienced several manic and retarded depressive episodes that had responded to lithium carbonate. She was referred to me because she had developed the delusion that she was involved in an international plot. Careful probing revealed that the delusion represented further elaboration, in a rather fantastic fashion, of a grandiose delusion that she had experienced during her last postpartum manic episode. She believed that she had played an essential role in uncovering the plot, thereby becoming a national hero. Nobody knew about it, she contended, as the circumstances of the plot were top secret. She further believed that she had saved her country from the international scheme and suspected that she was singled out for persecution by the perpetrators of the plot. At one point, she had even entertained the idea that the plotters sent unusual radio communications to intercept and interrupt her thoughts. As is typical in such cases, she was on a heavy dose of a lithium–antipsychotic combination. The consultation was requested because the primary mood symptoms were under control, and yet she had not given up her grandiose delusion. She flippantly remarked that "I must be crazy to believe in my involvement in an international plot," but she could not help but believe in it. Over several months, seen typically in 60-minute sessions weekly, the patient had developed sufficient trust that her psychiatrist could gently challenge her beliefs.

She was, in effect, told that her self-professed role in the international scheme was highly implausible and that someone with her superior education and high social standing could not entertain a belief, to use her own words, "as crazy as that." She eventually broke into tears. She said that everyone in her family was so accomplished that she had to be involved in something grand to keep up with them. In effect, the international scheme was her only claim to fame. She said, "Nobody ever gives me credit for raising two kids and throwing parties for my husband's business colleagues: My mother is a dean, my older brother holds high political office; my sister is a medical researcher with five discoveries to her credit [all true] and who am I? Nothing. Now, do you understand why I need to be a national hero?" As she alternated, over subsequent months, between such momentary flashes of insight and delusional denial, she was able to discontinue her antipsychotic medication gradually. Maintained on lithium, she now only makes passing reference to the grand scheme. She was encouraged to pursue her career goal toward a master's degree in library science.

The vignette illustrates how we can fruitfully combine phenomenologic understanding, rational pharmacotherapy, and practical psychotherapeutic or vocational guidance in our approach to patients with psychotic mood disorders. It also indicates that problems with insight are not necessarily state dependent in mood disorders. Cognitive disturbances have recently been described in all mood disorders, even when they are nonpsychotic. At a more fundamental level, the vignette suggests that clinical diagnoses cannot be based entirely on operational criteria; the treatment response does not always change one's opinion of a patient's illness.

ACKNOWLEDGMENT

This chapter is a revision of a previous chapter written by Hagop S. Akiskal, M.D. Dr. Akiskal, a giant in this field, passed away in January of 2021.

13.4 Mood Disorders: Intrapsychic and Interpersonal Aspects

John C. Markowitz, M.D., and Barbara L. Milrod, M.D.

The symptom criteria listed in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) reliably define mood disorders, but they do not completely describe these syndromes or explain how patients experience them. Depressed patients suffer emotionally, cognitively, and physically. Three key theoretical psychotherapeutic approaches have been applied to mood disorders: psychoanalytic/psychodynamic, cognitive, and interpersonal. They vary in their frequency of use in clinical practice and in the amount of research that they have received.

Theory has uses and limitations. Theory can help to organize clinical and research thinking about depression and can pinpoint aspects of the syndrome. A theory can provide a narrative thread or focus on anchoring a clinical formulation and giving coherence to a therapy. Indeed, some theoretical approach is necessary for clinicians to impose order on the overwhelming amount of clinical data with which patients present for treatment. Theories may also allow us to make predictions about treatment mechanisms and outcomes. We submit that an organizing theoretical framework is as essential to structure psychotherapy as grammar is to speech. Hence understanding the theoretical backgrounds of psychotherapies is crucial for the psychotherapeutic clinician.

Theories should be considered approximations of truth, needful of testing, and subject to disconfirmation. Thomas Huxley, in 1870 famously described “The great tragedy of Science—the slaying of a beautiful hypothesis by an ugly fact.” Dogma and ideology have done psychiatrists and other mental health professionals more harm than good, for example, in separating psychotherapy and pharmacotherapy into opposing camps—a rift from the 1950s that is only now healing. Inasmuch as the etiology of mood disorders is complex and no single theory comprehensively explains it, rigid adherence to any theory is unwarranted and potentially

problematic. Clinicians should understand and use multiple theories, flexibly choosing the optimal theoretical perspective to apply to a given patient's illness and then persevering in using that model for an appropriate course of treatment. They should then proceed following that single, coherent theoretical approach rather than devolving into eclecticism. (The authors of this chapter recommend formal training in any treatment modality the clinician plans to undertake. Theoretical understanding does not suffice.) On the other hand, to develop clinical expertise in any therapy, it is essential to be able to understand patients' problems through the lens of its underlying theory.

Psychodynamic theory has the longest historical tradition. Both cognitive theory and psychodynamic theory largely focus on intrapsychic phenomena, whereas interpersonal theory, the newest and least formally developed, focuses more on interpersonal, extrapsychic reality. It is widely accepted that aspects of both cognitive and interpersonal theories derive from psychoanalysis. Each approach provides a potentially useful explanation of the plight of the depressed patient. Although the utility of therapies derived from cognitive theory (cognitive behavioral therapy [CBT]) and interpersonal theory (interpersonal psychotherapy [IPT]) has been better tested for depression than psychodynamic therapy to date (albeit psychodynamic therapies have been found efficacious for depression), no theories of depression have been formally tested in all of their assumptions. They are best considered working clinical models.

PSYCHODYNAMIC ASPECTS OF MOOD DISORDERS

A contemporary psychoanalytic understanding of mood disorders includes a comprehensive focus on biologic underpinnings, cognitive function, and interpersonal situation and style. What is unique to psychoanalysis is its attention to intrapsychic, unconscious pressures in its consideration of psychological symptoms, including mood disorders. In order to describe intrapsychic aspects of mood disorders, several basic psychoanalytic ideas about mental life first must be defined:

1. From a psychodynamic view, mental life exists on two levels: Both within the realm of consciousness and also within a less accessible realm described as "*the unconscious*." Psychic or emotional symptoms arise from aspects of mental life that are at least in part unconscious. This is true of mood disorders.

2. Psychoanalysts have found it useful to conceptualize the mind as comprising three basic theoretical psychic structures, *the id*, *the ego*, and *the superego*. In brief, *the id* is considered the aspect of the mind that subsumes the drive derivatives and desires. *The ego* serves as an intermediary between the id and the external world. It contains many intrapsychic functions, including motor action, perception, self-esteem, relationship to reality, and the ability to modulate the drives, and to modulate anxiety. Defense mechanisms, which are unconscious intrapsychic mechanisms employed to modulate both the drives and anxiety, are ego functions. *The superego* is conceptualized to comprise the person's value system. The superego can both punish and reward the person, depending upon whether or not their actions are consonant with their moral values.
3. Moods are pervasive ego states that color the entire ego with the same affect state. Unlike simple affective responses to events, they are not focused but general, either because the affect is too strong or because the ego is too weak to contain a focused response. Because moods tend to be generalized states, they typically involve some degree of denial of the opposite feelings. From a psychoanalytic vantage, moods carry an unconscious significance, notwithstanding their presumed biologic and neurotransmitter underpinnings.
4. Since Sigmund Freud's discovery of the importance of the unconscious in everyday mental life and of individuals' capacity to shut off unwanted, painful, emotionally laden experiences using defense mechanisms, our understanding of moods and symptoms has been enhanced by the recognition that these psychic phenomena represent a breakthrough of *unconscious fantasy* into consciousness. Persistent unconscious fantasies often underlie people's psychological symptoms, dreams, personalities, and important life choices. They can underlie depression as well.
5. Freud initially described another central principle in the organization of mental life: That people unconsciously avoid "unpleasure" and that ideas that produce unpleasure are screened from consciousness by "repression," or processes that we now call *defenses*. Clinically, the degree to which unpleasure is avoided varies from person to person, and Freud later modified his original theory about people avoiding unpleasure. In *Beyond the Pleasure Principle*, he attempted to describe intrapsychic mechanisms that could account for phenomena in which the pursuit of pleasure is given up for the more fundamental need to discharge intense emotional tensions to protect the individual.

Thus, major depression is a condition in which the person is living beyond the pleasure principle.

PSYCHOANALYTIC DESCRIPTIONS OF MAJOR DEPRESSION

Psychoanalytic formulations highlight the phenomenology of aspects of major depression, helping to make the emotional backdrop of the illness more understandable. Although these theories provide a clinically rich set of ideas that can be useful in treating such patients, it should be emphasized that no theoretical positions in any analytic school are supported by systematic research. The field of psychoanalysis has been fairly resistant to research. Nor are various psychoanalytic formulations, despite their differences, mutually exclusive. The following sections outline some of these formulations and provide illustrative clinical examples.

Response to Loss/Anger Turned Inward

The classic psychoanalytic understandings of depression were stated by Karl Abraham, Freud, and Sandor Rado and emphasized depressed patients' reactions to object loss, in reality or in fantasy. In these formulations, the profound response to loss is believed to occur in part because the current loss invokes an earlier childhood loss, also either of a fantasy or a reality nature. These authors noted depressed patients' ambivalent or hostile object relations, along with object attachments characterized by excessive dependency, laced with an emphasis on need for gratification in emotionally charged relationships. Major depression only occurs after the tie to the object is shattered. In *Mourning and Melancholia*, Freud highlighted the way in which depressed patients irrationally attack themselves. In his formulation, this occurs because aspects of an ambivalent object become internalized or incorporated into the patient's sense of self, and hostility directed toward the object is instead directed at the self. This state of affairs serves to preserve the relationship with the other person (the object) in reality.

Stuart Asch described a variation on these dynamics in which some patients become depressed not because of object loss but due to maintaining a submissive tie to the object. This tie is maintained because the patient perceives separation to be an aggressive act with destructive

consequences. Rage at having to play this part is directed toward the self, as the patient feels devalued because of the submission.

Joseph Sandler and Walter Joffe, also focusing on the phenomenon of loss leading to depression, called the Hampstead Index, a comprehensive clinical registry of childhood responses to abandonment and loss, for cases of childhood depression. They inferred that depression is a basic affective response to loss. They emphasized that more than just the other person is lost and that the child feels that they have also lost a sense of self in relationship to the lost object or a previous set of feelings about the self. Thus, as Freud and Abraham also noted, Sandler and Joffe emphasize a symbiotic or narcissistic tie to the object. They saw individuals predisposed to depression as struggling against feelings of helplessness and injured self-esteem in childhood.

Ms. A, a 26-year-old woman, presented with severe major depression in the context of her boyfriend B's expressing increasing anger at her and his saying that he wanted to move out of their home. An anxious person at baseline, Ms. A took to her bed for several weeks, closing the blinds so that no light could enter her room. She stopped eating, lost weight, and slept most of the time. She dropped out of school and took a leave of absence from work. She thought almost constantly of suicide, although she had not picked a method and her deep religious commitment made this an unacceptable choice. In her first session, she spoke about how worthless she felt and how she blamed herself for her boyfriend wanting to break up with her. She said she thought that she was too "pointless," "anxious," and "boring" for him and that her presence stifled him. She expressed no anger toward B at the time of her presentation, saying that she "understood" why he was like this. She also said she hoped that this was just a "bad phase" that he would get over, although he told her repeatedly that he was dating another woman. In psychotherapy, it gradually emerged, however, that over the past month, B had been breaking dishes and furniture in their home. He yelled at Ms. A almost constantly. This patient's depression remitted with psychodynamic psychotherapy only as she became aware of her own murderous rage toward B, at which time she began to view herself in a less negative and denigrated manner.

Guilt

Melanie Klein postulated that depressed patients fear that they cannot protect an idealized or good, internalized “other” from destructive, rageful impulses. Although emphasizing a different facet of major depression, this view coincides with Freud’s focus on the destruction of the object tie to major depression. As a result, the depressed patient’s characteristic guilt, inhibitions, and punitive superego develop. However, not all depressions are characterized by excessive guilt, and Klein’s description applies only to this subset of patients. Klein also highlighted the danger that depressed patients foresee in “triumphing” over parents or siblings via any life success: success is experienced as aggressively humiliating to loved ones or as damaging to others. Klein theorized that idealization and devaluation are “manic defenses” against the guilt and sense of loss experienced in the resulting depression.

Ms. C, a 23-year-old, became acutely depressed when she was accepted to a prestigious graduate school. Ms. C had been working diligently toward this acceptance for the past 4 years. She reported being “briefly happy, for about 20 minutes” when she learned the good news but rapidly slipped into a hopeless state in which she recurrently pondered the pointlessness of her aspirations, cried constantly, and had to physically stop herself from taking a lethal overdose of her roommate’s insulin. In treatment, she focused on her older brother, who had regularly insulted her throughout the course of her life, and how “he’s not doing well.” She found herself very worried about him. She mentioned that she was not used to being the “successful” one of the two of them. In connection with her depression, it emerged that Ms. C’s brother had had a severe, life-threatening, and disfiguring pediatric illness that had required much family time and attention throughout their childhood. Ms. C had become “used to” his insulting manner toward her. In fact, it seemed that she required her brother’s abuse of her in order not to feel overwhelmed by survivor guilt about being the “healthy, normal” child. “He might insult me, but I look up to him. I adore him. Any attention he pays to me is like a drug,” she said. Ms. C’s acceptance to graduate school had challenged her defensive and essential compensatory image of herself as being less successful or damaged, in comparison with her brother, thereby overwhelming her with guilt. Her depression remitted in psychodynamic psychotherapy as she better understood her identification with and fantasy submission to her brother.

Impairment in Self-Esteem Regulation

A general trait of patients with major depression is the loss of self-regard. Yet, the loss of self-regard can occur in the absence of depression. Edward Bibring disagreed with Klein’s formulation that emphasized the importance of a punitive superego and argued that conflicts about aggression and object loss were secondary determinants of depression. He viewed depression instead as resulting from a sense of helplessness, impaired self-esteem, and self-directed anger triggered by failures to live up to the narcissistic aspirations of any developmental phase.

Charles Brenner also deemphasized the classic psychoanalytic focus on object loss, seeing a depressive propensity as equally likely to connect

with organizing fantasies of narcissistic injury, and particularly of castration. Brenner states that these fantasies are accompanied by reactive aggression against those blamed for the painful affects, with consequent guilt.

Mr. D, a 39-year-old successful and aggressive lawyer, had “never been depressed a day in my life” before developing a kidney stone that required a 5-day hospital stay full of medical interventions. He was well on discharge but developed major depression, with lethargy, decreased energy, hopelessness, and weight loss. He cried all the time. “I feel like a big, fat failure,” he announced. Handsome but insecure, Mr. D prided himself on his physical prowess and appearance and on his ability to attract the amorous attentions of “beautiful women.” “I’m not supposed to be sick,” he said, “Especially down there. It makes me feel old, ugly, and unattractive. Disgusting, in fact.” In describing his experiences in the hospital, he reported that the humiliation, or narcissistic blow to his self-esteem resulting from the illness and hospitalization, had so overwhelmed him (“I was hooked up to these disgusting tubes—even in my penis!” he wailed) that he had uncharacteristically not even complained about being placed into a four-bed hospital room with three homeless people who hadn’t showered. “I figured they were in control, so I didn’t even think about it,” he said. His symptoms remitted in psychoanalysis with a therapeutic exploration of the way in which the hospitalization had in fantasy felt like a castration.

Many contemporary psychoanalysts amplify upon these models in their understanding of depression while acknowledging the prominence of impaired self-esteem regulation. Edith Jacobson emphasized the development of self and object representations in depressed patients. She noted depressed patients’ disappointment with parental figures, resulting in devaluation and degradation of their images and self-representation, especially when a mature separation had not been achieved.

Inadequacy of Early Caregivers

Psychoanalysts have given a personal, intrapsychic face to the much later articulated and researched, well-known epidemiologic observation of the

connection between parental (particularly maternal) depression and subsequent depression in children. Hans Kohut described depression as connected to experiences of profound emptiness in patients whose parents were unable to empathize with their early affective experiences. Such is the case, as many parents of depressed patients are themselves depressed. These patients crave compensatory relationships ("self-object" relationships, mirroring experiences, and idealizing relationships), leaving them vulnerable to disappointment, as real relationships cannot live up to these compensatory fantasies.

Leo Stone highlighted depressed patients' refusal to accept the separateness and autonomy of the object. Again, this view emphasizes the symbiotic tie to the object to compensate for an incomplete sense of self. Stone suggested that depressed patients unconsciously coerce objects; they are disappointed in them and prone to envy and rage because of an early history of "oral frustration." (The "oral frustration" aspect of this formulation is somewhat outdated in its drive-derivative focus and might be better understood from a relational perspective, of parental relationships being experienced as being disengaged or depriving.) Aggressive fantasies about disappointing and hurting loved ones give rise to the severe guilt with which these patients struggle.

Ms. E, a 21-year-old college student, presented with major depression and panic disorder since early adolescence. She reported hating herself, crying constantly, and feeling profoundly hopeless in part because of the chronicity of her illness. Even at the time of presentation, she noted her sensitivity to her mother's moods. "My mother's just always depressed, and it makes me so miserable, I just don't know what to do," she said. "I always want something from her, I don't even know what, but I never get it. She always says the wrong thing, talks about how disturbed I am, stuff like that, makes me feel bad about myself." In one session, E poignantly described her childhood: "I spent a lot of time with my mother, but she was always too tired; she never wanted to do anything or play with me. I remember building a house with blankets over the coffee table and peeking out, spying on her. She was always depressed and negative, like a negative sink in the room, making it empty and sad. I could never get her to do anything." This patient experienced extreme guilt in her psychotherapy when she began to talk about her mother's depression. "I feel so bad," she sobbed. "It's like I'm saying bad things about her. And I love her so much, and I know she loves me. I feel it's so disloyal of me." Her depression remitted in psychodynamic psychotherapy as she became more aware of and better able to tolerate her feelings of rage and disappointment with her mother.

Sidney Blatt, a psychoanalytic researcher, contrasted *anaclitic* depressed patients, anxiously attached individuals who struggle with excessive dependence on others, with *introjective* depressed patients, who are compulsively self-reliant. Blatt contended that anaclitic patients suffer more from feelings of loneliness, helplessness, and weakness, introjective patients from a sense of worthlessness, self-criticism, and guilt.

PSYCHOANALYTIC FORMULATIONS OF DYSTHYMIA

Psychoanalysts have largely written about major depression, but some have also addressed dysthymia, or what DSM-5 now calls persistent depression. Asch noted underlying masochistic pathology in dysthymic patients, a view that has been deemphasized by contemporary dysthymia

researchers, who have underlined that chronic depression can appear phenomenologically like masochistic character structure simply because of its chronicity. (In other words, masochism is a redundant concept in chronic depression.) Milton Horowitz emphasizes the “pleasure of revenge” in the patient’s defeating all around them through failure, hopelessness, and negativity, and he regards this as more important than the experience of personal suffering for many such patients. David Milrod describes both the rewarding and the punitive aspects of superego function in response to narcissistic injury in patients with chronic dysthymia and self-pity.

Ms. F, a 20-year-old college student, came to psychotherapy complaining of chronic depression. She described herself as “dull, but difficult too.” While she enjoyed school, she had trouble finding things outside of school that she enjoyed doing. She was bored, lethargic, and unhappy most of the time. Although she had friends and a boyfriend—albeit a man much less desirable than she might otherwise have been expected to find—she resented their demands on her time, often because she found herself upset when she was with them. Her relationships with her boyfriend, some of her closer friends, and her mother were characterized by intermittent “crises,” events when Ms. F felt ignored, criticized, and abused by them, and she wound up locking herself in her room to cry, sometimes for days. As psychotherapy unfolded, it became clear that her boyfriend was very demanding of her time yet rarely actually spoke to her. For example, he preferred to have her “around” while he worked on his computer for hours on end, but when he went out “to hang out,” he preferred to spend time with his friends without her. Ms. F handled this situation with a combination of resignation and resentment: She stayed with him while he worked, then often ignored him at parties that they both attended in order to “get back at him.” In psychodynamic psychotherapy, her dysthymia and passive masochism resolved simultaneously, enabling her to stop feeling worthless in social situations and with her boyfriend and to become more assertive in all of her relationships.

SYNTHESIS: DYNAMICS OF DEPRESSION

Features common to many psychoanalytic theories of depression include feelings of exquisite narcissistic vulnerability stemming from a variety of sources, including early loss or experiences with parents perceived as traumatically unempathic, frustrating, or rejecting. A sense of helplessness or inadequacy in relation to these experiences, with accompanying fantasies of damage or castration, can contribute to this vulnerability. The resulting impairment in self-esteem regulation is common to all depressed patients, who are prone to a self-image of being unlovable, damaged, or inadequate.

Depressed patients perceive that they have either failed to live up to their ambitions or to their moral values in the ego ideal, the intrapsychic mechanism that triggers guilt in depression. Many psychoanalysts hypothesize that the resulting aggression toward a frustrating parent or toward the self as damaged contributes decisively to the propensity toward depression. In depressed patients, aggression is largely self-directed. Guilt (conscious or unconscious) or shame theoretically results from the patient's perceived sense of failure, with a diminished sense of self. Difficulties in self-esteem regulation contribute to a self-representation of being "bad" or shamefully out of control, aggravating the original problem in a vicious cycle.

The sine qua non of depression in this conceptualization is aggression directed toward the self-representation, aggression that proves uncontainable and spreads to a mood state. This may arise from a withdrawal of positive, or "libidinal," supplies to the self-representation and replacement with aggression in the following ways:

1. By not living up to personal aspirations (giving rise to shame, rather than guilt);
2. By not living up to the ego ideal (precipitating guilt);
3. In an interpersonal depression, as described by Freud, in which a symbiotic bond to an ambivalent object is shattered. From a psychoanalytic perspective, this type of depression is associated with more primitive pathology, and these patients are more likely to be in a borderline or psychotic spectrum because of the nature of the primitive, symbiotic interpersonal bond.

These different pathways trigger a common self-assessment of being worthless, bad, inadequate, or unlovable. The resulting hostility directed toward the self is a core feature of depression.

Retroflected hostility has been pinpointed in the historical psychoanalytic literature as also contributing to borderline and obsessional pathology. Indeed, many patients with these underlying character structures also experience major depression. From a psychoanalytic perspective, the essential feature of all depressions is self-directed aggression, which becomes a mood state. Difficulty with self-esteem regulation, which is not an essential component of other syndromes, is always prominent in depression, coupled with aggression turned inward that exacerbates guilt and shame.

PSYCHOANALYTIC FORMULATIONS OF MANIA

From a psychoanalytic perspective, the clinical presentation of mania arises as a result of a global, massive regression that affects all three psychic structures: The id, the ego, and the superego. The regression leads to a primitive mental state in which the pleasure principle is reinstated. In *Group Psychology and Analysis of the Ego*, Freud described mania as a fusion of the ego with its superego. Less cryptically, psychoanalysts have highlighted a common organizing fantasy in manic patients of a fantasy incorporation, or mystical union, of the patient with someone of great power, often an aristocrat, or God, as in the story of St. Theresa's mystical union with God. Such organizing fantasies, couched in both sexual and "oral" terms, magically impart a sense of omnipotence and specialness to the patient, highlighting one aspect of the common phenomenology of mania. Bertram Lewin noted that in mania, early relationships with both parents that had become desexualized during the process of superego formation during latency become resexualized during the manic episode and that in fantasy, the manic patient is identified with both partners (male and female) during the sexual act. The states of mania and hypomania involve massive utilization of the defense mechanism of denial, in which sad and negative aspects of reality are entirely ignored. One author hypothesized that the manic episode was precipitated by the need to control the memory and experience of intolerable pain. In this way, mania could be considered a defensive reaction, different from depression, in response to pain and distress. True mania is not amenable to psychotherapy treatment alone, requiring pharmacologic interventions.

Ms. G, a 42-year-old housewife and mother of a 4-year-old boy, developed symptoms of hypomania and later of frank mania without psychosis when her only son was diagnosed with acute lymphocytic leukemia. A profoundly religious woman who had experienced 10 years of difficulty with conception, Ms. G was a devoted mother. She reported that she was usually rather "down." Prior to her son's illness, she used to joke that she had become pregnant with him by divine intervention. When her son was diagnosed and subsequently hospitalized, he required painful medical tests and emergency chemotherapy, which made him very ill. The doctors regularly barraged Ms. G with bad news about his prognosis during the first few weeks of his illness.

Ms. G was ever-present with her son at the hospital, never sleeping, always caring for him, yet the pediatricians noted that as the child became more debilitated and the prognosis more grim, she seemed to bubble over with renewed cheerfulness, good humor, and high spirits. She could not seem to stop herself from cracking jokes to the hospital staff during her son's painful procedures, and as the jokes became louder and more inappropriate, the staff grew more concerned. During her subsequent psychiatric consultation (requested by the pediatric staff), Ms. G reported that her current "happiness and optimism" were justified by her sense of "oneness" with Mary, the Mother of God. "We are together now, she and I, and she has become a part of me. We have a special relationship," she winked. Despite these statements, Ms. G was not psychotic and said that she was "speaking metaphorically, of course, only as a good Catholic would." Her mania resolved when her son achieved remission and was discharged from the hospital.

COGNITIVE THEORY OF DEPRESSION

Learning theory has long been a branch of behavioral psychology. Aaron Beck, finding that psychoanalytic theory did not sufficiently explain dreams of depressed patients, developed a theory of depression based on educating the patient about their negative thinking or cognitions ("automatic thoughts"), then conducting behavioral tests to disconfirm depressively distorted cognitions. Beck and colleagues then successfully

tested CBT, a treatment built on this theory, in clinical trials. The cognitive model is based on the recognition that people are not objective; rather, an individual's idiosyncratic perception of events affects their emotions and behaviors. Depressed individuals perceive reality in subjectively depressed ways. Elaborate discussions of cognitive theory exist, and cognitive explanations have been extended from their original depressive origins to a range of psychopathology. Brad Alford and Beck argue that cognitive theory provides a comprehensive and coherent paradigm for psychopathology.

Beck's initial observations about major depression have salience and simplicity worth repeating. He noted that depressed patients tend to have characteristically skewed and negative thoughts about (1) themselves, (2) their environment, and (3) the future, a cluster he termed the *cognitive triad*. Indeed, depressed individuals frequently report negative thinking about themselves: "I'm a loser," "Everything I do goes wrong," "I'm weak and defective." The environment appears hostile and overwhelming: "Even if I felt capable—which I don't—there's no way I could cope with what I have to do"; "My friends will react badly if I try to speak up"; "She will reject me." Finally, not only do things look grim in the present but there is no prospect of relief in the future: "It's never going to get any better." These three aspects of negative perspective converge to provide a convincingly, despairingly bleak, and mood-congruent view of the world. This outlook helps to explain why depressed patients see no way out of their misery and contemplate suicide.

Cognitive theory has explored the form as well as the content of thinking characteristic of depressed patients. Not only are cognitions skewed to the negative and pessimistic, but particular types of distortions occur. Depressed individuals tend to engage in "all or nothing" dichotomous thinking: If things aren't entirely one way, then they must be the opposite. Depressed individuals make arbitrary (negative) inferences about events, selectively abstract negative details out of context, overgeneralize (concluding negative rules from single instances), magnify (the negative) and minimize (the positive), and take personally events that may not be directly about them. Depressed patients "catastrophize," leaping from one imagined worst-case scenario to the next in disastrous cascade:

> He will take what I said as an insult, and will never speak to me again, and will tell all our friends. Then no one will like me, I'll be all alone, and my social life will be ruined

forever.

Depressed individuals selectively focus on negative evidence, failures, and setbacks that confirm their theories of defectiveness while ignoring or discounting the successes they have achieved as “flukes.”

> J, a 19-year-old college sophomore, made two mistakes on a test. Although his overall grade was high and the mistakes themselves appeared minor to the therapist, J took them as proof that he was defective and deficient. His perfect score on the next test, by contrast, he discounted as “luck…the teacher was easy on me,” not as any evidence of his personal competence. If, while depressed, you consider yourself a loser, then you pay most attention to outcomes that fit that schema.

Beck made the important point that the depressed outlook is not objective but irrational. “Automatic thoughts” of characteristically self-deprecatory and hopeless nature pop involuntarily into the patient’s head. Because these thoughts are mood-congruent, depressed individuals find them believable and tend not to question them. The negative thinking characteristic of depressed patients is damaging in two respects. First, it is painful and depressing: Many patients are barraged with negative ideas about themselves and their situation, in effect a stream of insults. Second, these thoughts tend to inhibit action: If you know you are incompetent and going to fail, feelings of hopelessness and thoughts like, “Why bother?” follow. Depressive thinking patterns not only hurt, but they also paralyze individuals into inaction, which then leaves them more time to ruminate on their inactivity (“I’m not doing anything with my life”), and to suffer self-criticism. The deterioration of productive behavior due to negative thinking will then lead to more things going wrong in the patient’s life, providing further examples of the patient’s incompetence and reinforcing the negative thinking.

The case examples above provide good examples of self-critical thinking, which in cognitive theory would be understood as the irrational, automatic thoughts of a depressed patient: Ms. A felt “pointless” and “boring”; Mr. D “like a big, fat failure,” “old, ugly, and unattractive… disgusting”; Ms. F as “dull, but difficult too.”

Immediate and specific negative cognitions (“He doesn’t like me”) fit into larger, more basic, and stable patterns of self-conception called “schemas” or core beliefs. For depressed patients, these tend to be global, negative, all-or-nothing assumptions based on early childhood experience: “If I do something imperfectly, it’s (and I’m) worthless”; “If I’m not in total control, I’m completely helpless.” Early cognitive theory presented such negative thinking as a cause rather than an effect of depression. Although cognitions are clearly an important aspect of depression, it seems naive at this point to expect that this is the single etiology of a complex and multidetermined syndrome that has both genetic and environmental components. Hence over time, cognitive theory has tended to back away from that etiologic stance.

A general cognitive explanation of a major depressive episode is that a vulnerable individual, perhaps predisposed both by biology and by negative schemas based on early childhood, experiences a current life situation that evokes “automatic” thoughts. For example, a relatively minor setback at work might activate underlying schemas by eliciting the thoughts, “I’ve done a bad job,” and thereby “I’m a terrible worker,” “I’ve let the company and my coworkers down,” “My boss hates me,” and therefore “I’ll never succeed,” “I’m a failure.” Or a disagreement in a relationship might rouse ideas such as, “K doesn’t like me,” evoking and seemingly confirming the more general core beliefs: “I’m a terrible person,” “I’m a lousy parent,” and furthermore “No one could possibly love me.” The onset of these thoughts and accompanying depressive symptoms further compromises functioning, reinforcing the negative outlook. As the mood darkens and the negative thoughts become ever more credible and pervasive, the patient gives up activities (“Why bother?”) and feels still more helpless and hopeless.

Cognitive therapy, the treatment that follows from this approach, includes a Socratic discussion and evaluation of the patient’s thoughts, weighing the evidence supporting and contradicting such thoughts. The patient actively tests hypotheses based on automatic thoughts (“I’ll fail at whatever I do”) by attempting various selected behaviors as homework. As the patient learns to recognize the irrational nature of depressive thinking, they can challenge rather than simply believe it and can begin to extinguish such thinking, replacing automatic irrational thoughts with rational responses. Outcome research repeatedly has shown that this

approach is efficacious in treating mood disorders and other psychiatric syndromes.

The decades since Beck developed this original approach to depression have yielded various CBT adaptations. More recent “third wave” cognitive approaches have emphasized mindfulness: learning to recognize that you have negative thoughts and feelings but letting them pass nonjudgmentally, learning to ignore them. Thus although CBT has diffused in various directions and adapted to the treatment of various disorders, the basic principles of Beck’s 1960s theory persists.

Dysthymic and Bipolar Disorders

Cognitive theory has not been particularly altered for dysthymic disorder. Rather, the chronicity of depression would simply seem to ingrain negative core beliefs more deeply. Cognitive behavioral analysis system of psychotherapy (CBASP), an eclectic treatment that James McCullough developed specifically to treat chronic depression, postulates that chronically depressed patients fail to behave appropriately in interpersonal encounters. CBASP combines elements of cognitive, behavioral, psychodynamic, and interpersonal therapies in focusing on the patient’s behaviors and thinking in interpersonal encounters, including those with the therapist.

Cognitive-behavioral treatments have been developed not only for unipolar depression but also as an adjunct to medication for bipolar disorder. Mania may be viewed as the mirror of depression, wherein overvalued positive ideas (“I’m special” or “I’m the greatest”) automatically arise, again distorting reality, but this time in the opposing direction. Thinking itself accelerates in mania. By and large, cognitive theory has had less to say about manic than depressed states, and adaptations of cognitive therapies for mania are more practical than theoretical. They focus on psychoeducation about the illness, behavioral stabilization, such as maintaining a regular sleep schedule and emphasize the importance of adherence to pharmacotherapy. Following these principles, Francisco Colom and Eduard Vieta have developed an empirically tested psychoeducational treatment for bipolar patients.

Aspects of cognitive theory have been tested for unipolar depression, with sometimes contradictory results. CBT, which directly addresses depressive, negative cognitions, and helps patients to weigh their evidence rather than simply believe them, has repeatedly demonstrated

efficacy as a treatment for major depression and does improve negative cognitions. Yet other antidepressant treatments relieve depression and improve cognition without specifically addressing cognitions, and behavioral activation—a behavioral approach without the cognitive component—has been shown to be at least as efficacious as CBT. Efficacious treatments for depression may spread from a particular theorized target to have generalized benefits.

Comparison to Psychodynamic Theory

It will be seen that cognitive theory does not contradict and, to some degree, overlaps with psychoanalytic theory. The treatments emerging from these theories differ greatly, however, in large part due to their differing definitions of the role of the therapist, handling of the therapeutic relationship, and approach to the meaning of that relationship: In psychoanalytic terms, the transference. Both theories focus on intrapsychic processes and on self-critical thinking, but cognitive theory emphasizes the distinction between rational and irrational thinking and their connection to mood rather than to unconscious fantasy. In practice, psychodynamic and cognitive therapies also differ dramatically in their structure, application of homework, and therapist stance.

INTERPERSONAL THEORY OF DEPRESSION

Interpersonal theory dates back to the era after World War II when it arose as a heretical response to the more intrapsychic emphasis of psychoanalysis. Psychoanalytic theory emphasized the importance of early life experience, and many therapists at that time saw the patient's psychic structure as essentially formed by the end of adolescence. Psychiatrists such as Adolf Meyer, Harry Stack Sullivan, Erich Fromm, and Frieda Fromm-Reichmann challenged then-current theory by emphasizing the influence of the real impact of current life events on their patients' psychopathology, focusing on environmental and interpersonal encounters rather than underlying intrapsychic drives and structures.

Sullivan coined the term "interpersonal" as a rubric for considering current life experience. He scrutinized communications in the social field, a more external outlook than traditional psychoanalysis. The interpersonal theorists worked mainly with inpatients diagnosed with schizophrenia in a prepharmacologic era. Although their work stirred great controversy at the

time and a Sullivanian school distinct from the psychoanalysis of drives and ego psychology still exists, Sullivan was trained in psychoanalysis and did not entirely disagree with his forebears. Over time, the rift between Sullivanians and other psychoanalysts has narrowed.

The consideration of current interpersonal factors gained currency over succeeding decades, and it is now mainstream clinical thinking that current life events and interpersonal functioning affect and are affected by psychopathology. A school of interpersonal psychoanalysis—not particularly focused on mood disorders—arose. Psychoanalytically trained therapists like Silvano Arieti and Jules Bemporad emphasized interpersonal factors in the treatment of depressed patients. Jack Anchin and Donald Kiesler have reviewed other interpersonally based psychotherapies. None of these theories has received empirical testing.

Researchers did develop a host of related data about interpersonal issues associated with depression. For example, research showed that interpersonal support protects an individual against depression: Having a confidant to talk to reduces the risk of developing a depressive episode. Major life stressors, including the death of a significant other, struggles in important relationships, and upheavals such as a change in marital status, housing, job status, or physical health, have been shown to increase the risk of depressive episodes in vulnerable individuals. Moreover, the onset of depressive episodes leads to deterioration in relationships and social functioning and generates negative life events.

John Bowlby postulated that people have an evolutionarily determined, instinctual drive to form emotional attachments. Animal evidence now supports this theory. This basic component of human nature ensures infant survival: Children need to have parents nearby or available for feeding and protection. As children develop, they begin to explore their environment, gradually moving out from the “secure base” of their attachment figure. Disruptions in this early caregiving connection may lead to vulnerability of attachment style. For example, the loss of one’s mother in the first decade of life has been shown to be a risk factor for subsequent depression. Children with insecure childhood attachments may not learn to ask for help from others. Individuals with insecure attachment styles may have difficulty developing comfortable relationships on which they can rely for support in times of need. When such vulnerable individuals face stressors or feel an absence or inadequacy of

interpersonal support during times of stress, they may be helpless to respond effectively and prone to developing symptoms.

In the 1970s, when Gerald L. Klerman, Myrna M. Weissman, and their colleagues were designing a randomized controlled pharmacotherapy trial of outpatients with major depression, they recognized that many such patients received psychotherapy in community treatment. They sought accordingly to add psychotherapy to their trial but realized that it was unclear then (as now) what such community psychotherapy consisted of. They then developed IPT as a manualized, time-limited treatment for outpatients with major depressive disorder based on interpersonal and attachment theories as well as empirical evidence of the psychosocial nature of depression. IPT is thus one specific therapeutic application of more general interpersonal theory. IPT demonstrated efficacy for major depression in this and in numerous subsequent outcome trials.

In simplest terms, interpersonal theory as applied to IPT can be understood as a link between mood and events. For all people, upsetting external events evoke a sad or demoralized mood: In lay terms, they are "depressing." For biologically or environmentally predisposed individuals, however, a sufficiently disturbing life event can trigger an episode of major depression. Examples of such life events are the death of a significant other (complicated bereavement), a problematic relationship (role dispute), or other major life changes (role transition). Once a depressive episode starts, its symptoms compromise functioning, producing more negative life events that further worsen mood in a vicious downward cycle. This formulation seems straightforward, even commonsensical, but depressed patients have a peculiar amnesia for external events and tend to blame themselves for how they feel or to see the depressed state as who they are. IPT helpfully employs a medical model to remind patients that they are ill, not defective, and that outside events may have contributed to their distress.

IPT therapists do not propose this as an etiologic theory of depression but as a pragmatic one: The depressive mood episode can be linked either to a precipitating life event or to consequent life events that become the focus for treatment. The IPT therapist defines major depression as a medical illness—a treatable medical problem that is not the patient's fault—and links it to an interpersonal focus such as a role dispute. The therapeutic contract for the patient is to solve the interpersonal focus within a time-limited period. Solving the interpersonal problem is at once a

realistic relief (e.g., improving a marriage), relieves depressive symptoms, conveys a sense of mastery over the environment, and builds interpersonal skills that may hopefully protect against future interpersonal triggers and depressive episodes. Typical areas of interpersonal skill-building are issues such as self-assertion, confrontation, effective expression of anger, and the taking of social risks.

Clinicians armed with differing theories approach the same material in different ways. IPT seeks a life event or interpersonal situation as a plausible and pragmatic framework on which to focus a time-limited treatment in which the patient can work on interpersonal skills. For example, the case of Ms. A might be conceptualized as major depression arising in the context of a role dispute with her boyfriend, B. Had she been treated in IPT, the focus might have been on recognition and appropriate expression of her own anger as part of learning to renegotiate that relationship to ensure her own needs were met. Alternatively, or additionally, clinical judgment might have defined the breakup of that relationship as a role transition that Ms. A needed to mourn and accept in order to move on to better relationships or activities. Ms. C's difficulty in tolerating her acceptance to graduate school might similarly be considered a role transition, as might Mr. D's bout with renal stones. Medical illnesses, even if transient, frequently provoke role transitions by shifting a patient's perception of his life trajectory; Mr. D may have interpreted his hospitalization as evidence of his fading potency, aging, and mortality. Ms. E's situation might conceivably be defined either as a role transition—adjusting to college life away from her mother—or as a role dispute with her mother.

Preliminary evidence supports the theory underlying IPT as a treatment. Patients in two IPT treatment trials were asked to report the degree to which they had resolved the interpersonal crisis (e.g., role transition) on which their treatment had focused. Subjects' report of making changes in this interpersonal focal area correlated with symptomatic improvement during the trial. We recently found that time-limited IPT improves separation anxiety in patients with PTSD and might work in part by repairing insecure attachment.

Dysthymic Disorder

An adaptation of IPT has been developed for dysthymic disorder, but differences in the treatment are largely those of technique. Patients with

chronic depression tend to be socially isolated (Ms. F above is slightly unusual in having a boyfriend, although her choice of boyfriend was in keeping with the disorder) and invariably have interpersonal difficulties. If the syndrome began early in life, as is often the case, patients might never have developed important communication skills. Even more than people with acute depression, they tend to be passive and unassertive, to experience self-assertion as “selfish” rather than a healthy and sometimes necessary negotiation of one’s own goals in life, and to view anger as a “bad” feeling rather than a useful interpersonal signal that someone is bothering them. Even if they have had such capabilities in the past, their interpersonal functioning will have eroded under the pounding discouragement of chronic depression. Chronicity breeds resignation and entrenches maladaptive interpersonal patterns. The adaptation of IPT for chronic depression focuses on the patient’s inevitable confusion of chronic mood with who they truly are beneath it and seeks to disentangle the two by helping the patient to trust their feelings by handling events in a more assertive fashion.

Bipolar Disorder

In all of the theoretical approaches under discussion, mania has received less attention than unipolar depression. There is no real adaptation of interpersonal theory for mania. Clinically, it is apparent that manic patients lose social judgment and become overinvolved and labile in relationships with others. Ellen Frank and colleagues have adapted IPT for bipolar patients as an adjunctive treatment to pharmacotherapy by combining it with a behavioral strategy. Interpersonal social rhythms therapy (IPSRT) is a hybrid of IPT and social zeitgeber theory, which stresses the importance of maintaining diurnal structure through regular patterning of circadian events or social rhythms. In particular, this involves ensuring a regular bedtime to prevent the loss of sleep that often triggers a manic episode. As with CBT for bipolar disorder, this represents more of a clinically reasonable, pragmatic extension of an already established treatment than a theoretical evolution. This approach, described in a manual, has shown benefits as an adjunct to pharmacotherapy in randomized controlled trials for bipolar patients.

Future Directions

Psychoanalytic, cognitive, and interpersonal theories all provide insights into mood disorders. None is received truth, none can be considered fully tested in empirical studies, and all are surely incomplete. Nor has this section covered all theories of mood disorder: Biologic, behavioral, feminist, and many other theories have been proposed for depression. Psychoanalytic, cognitive, and interpersonal theories each capture important aspects of complex syndromes. In the hands of skilled clinicians, therapists, and patients may find each approach useful in conceptualizing the patient's status and organizing their treatment.

Future research may elaborate more comprehensive applications of these theories to bipolar disorder. And theory alone does not suffice to train a clinician: clinical experience and supervision, as well as personal therapy, help to expand clinical understanding and ability.

13.5 Mood Disorders: Suicidal Behavior

Suicidal behavior is a major public health concern worldwide, with approximately 800,000 people dying annually from completed suicide. Suicide attempts are at least 10 times higher than the number of suicides. Furthermore, suicidal ideation and planning, although difficult to ascertain, are much more frequent phenomena than suicidal behavior. Mood disorders have been unanimously associated with suicidal behavior due to the nature of the patient's symptoms, and mood-disorder patients die from suicide, on average, 10 years earlier than from other causes. Depression, both unipolar or bipolar, seems insidious in precipitating suicide risk. However, suicide is a multifactorial phenomenon, with an array of variables influencing such risk. Mood disorders are, therefore, major contributory but not exclusively factors for suicidal behavior. For instance, feelings of hopelessness (e.g., not having future expectations, etc.) are found to be more predictive of suicide risk than a diagnosis of depression *per se*. Therefore, it seems reasonable to acknowledge the interplay of mood disorders with other critical factors, such as familial–genetic disorders, personality, and psychosocial and demographic risk factors, which also play a significant role.

The exploration of these factors' role helps to better understand what makes the minority of patients with mood disorders suicidal. Furthermore, nowadays, clinicians are considering suicide risk from the neurodevelopmental perspective, comparing distal risk factors (family history of suicide, epigenetic factors, early life adversity, personality traits, and early substance abuse) with proximal risk factors (psychopathology, suicidal ideation, hopelessness, recent life events). History of untreated major mood disorders (particularly in previous suicide attempts) constitutes an important risk factor for many illness-related health and economic problems, such as loss of productivity, secondary substance-use disorders, family breakdown, and increased somatic morbidity and mortality. Given the high lifetime prevalence of unipolar major depressive, and bipolar disorders, they are among the most frequent and potentially life-threatening psychiatric illnesses. Despite the great clinical and public health significance of major mood disorders, people with these disorders are still under-referred, underdiagnosed, and undertreated. This is particularly true for those who die by suicide and for those who attempt suicide and receive medical attention. As killing oneself is considered a

major cause of years of life lost, its prevention is receiving more and more attention.

FROM SUICIDE RISK ASSESSMENT TO SUICIDE RISK FORMULATION

Suicide risk assessment should be part of health professionals' skills, although it is often taken for granted that only mental health professionals should deal with such tasks. Recently, experts on suicide realized that collecting risk factors and assessing the risk yielded an incomplete process, lacking proper judgment on the risk level and proper interventions for that specific risk.

Experts on suicide introduced the suicide risk formulation (SRF) as a data-dependent process in the suicide risk assessment. SRF assigns a suicide risk level intended to inform decisions about triage, treatment, management, and preventive interventions. Considering that the traditional model points to a low, medium, and high risk of suicide, the risk formulations summarize the data into four different judgments to directly inform intervention plans (Fig. 13.5–1): (1) risk status (the patient's risk compared to a specified subpopulation), (2) status risk (the patient's risk concerning baseline or other specified time points), (3) available resources that the patient can draw on in the crisis, and (4) foreseeable changes that may exacerbate the risk. This approach aims to consider the risk factors coming from the literature and consider specific factors that surround a specific individual who may be threatened by specific and unitary sources of distress for which the risk of suicide is increased.

FIGURE 13.5–1. Prevention-oriented risk formulation. The model flows from left to right. The left side of the model shows eight domains of "clinical data" that a clinician gathers and synthesizes in collaboration with the patient and other individuals central to the patient's life and care. (Adapted from Pisani AR, Murrie DC, Silverman MM. Reformulating suicide risk formulation: from prediction to prevention. *Acad Psychiatry.* 2016;40:632–629. doi:10.1007/s40596-015-0434-6. Recent analyses of the study of suicide provided broader perspectives with new explanatory models. A paradigm change seems to be emerging, and the analyses of personality and a mentalistic process have substituted the classic medical model for explaining suicide risk. As suicide risk has been traditionally viewed as a symptom of psychiatric disorders, a paradigm shift is now necessary to address a much broader entity, pointing to the peculiarity of the suicidal dimension, partly overlapping with the dimension that includes psychiatric disorders. A more phenomenologic approach, uncovering the features of the suicidal mind, seems imperative. Integration between psychiatry and suicidology seems the new emerging paradigm, providing an understanding of unique individuals' suffering. Both data are emerging from empirical research and

neuroimaging studies focused on the role of mental pain in shedding light on the extreme suffering of the mind. Such experience seems to share neuroanatomical circuits of somatic pain and appears a strategic point to investigate suicide risk.

According to this model, the suicidal individual experiences unbearable mental pain (also known as psychache) or suffering, and suicide might be, at least in part, an attempt to escape from this suffering. Among the constructs used to describe the wish to die, a simple but extraordinary model has proved, at least for its straightforwardness, to be useful in describing the suicidal mind. According to this model, suicide is an escape from intolerable suffering, emphasizing that suicide is not a movement toward death but rather an escape from intolerable emotion and unendurable or unacceptable anguish. Experiencing negative emotions, with an internal dialogue making the flow of consciousness painful and leading the individual to the ultimate conclusion, may be related to the fact that, if tormented individuals could somehow stop consciousness and still live, they would opt for that solution. Suicide occurs when that individual deems the psychache to be unbearable. Therefore, understanding the suicidal mind allows the clinician to familiarize with dynamic risk factors and address them through a personalized, empathic approach and critical appraisal of the suicide risk in mood disorders.

Clinicians who consider suicidal ideation to merely be a symptom of depression may miss the rare opportunity to get to know a very private aspect of patients and reduce their suffering. They may even uncover that they are treating not necessarily major depression with suicidal ideation but rather severe human sadness emerging with suicidal wishes. Mental health professionals should provide differential diagnoses for the various conditions for which they are requested to intervene and, regardless of what is assessed, deal with the need for treatment. In line with this, the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) states, “Diagnosis of a mental disorder should have clinical utility,” but “the diagnosis of a mental disorder is not equivalent to a need for treatment. Need for treatment is a complex clinical decision that takes into consideration symptom severity, symptom salience (e.g., the presence of suicidal ideation), the patient’s distress (mental pain).” Furthermore, “Clinicians may thus encounter individuals whose symptoms do not meet full criteria for a mental disorder but who demonstrate a clear need for treatment or care. The fact that some individuals do not show all

symptoms indicative of a diagnosis should not be used to justify limiting their access to appropriate care" (18, p. 20).

EXPLORATION OF SUICIDE RISK IN MOOD DISORDERS: DATA FROM PSYCHOLOGICAL AUTOPSIES

Most of the data shedding light on suicide come from psychological autopsies. These procedures collect information from crucial persons—spouse, lover, parent, grown child, friend, colleague, physician, supervisor, or coworker—who knew the decedent to reconstruct their mental status before death. The literature has reported some of the limits of such procedures, pointing to a lack of standardized instruments for assessing psychopathology, life events, and the procedure for interviewing informants. Studies investigated concordance among different informants (caregivers, spouses, clinicians, etc.) on diagnoses of living cases and showed that agreement ranges from poor to moderately good. The authors concluded that the informant's profile might significantly influence the information obtained on cases, with an overlap in data from different sources that are far from perfect.

Despite the limitations of psychological autopsy studies, we learn from such studies in several countries that up to 90% of those who die of suicide have a mental disorder, possibly a mood disorder. The retrospective reconstruction considers how much it can belong, for example, to a depressive disorder and how much it is a humanly understandable sadness reaction instead. Although the ratio of completed suicide attempts in the general population is approximately 15 to 40: 1, it is much lower (5 to 10: 1) among patients with major mood disorders, suggesting that these patients use more lethal (or more violent) methods of suicide. Patients with mood disorders, particularly bipolar patients, often have a low ratio of suicide attempts to completed suicides, indicating the relatively high mortality of suicide attempts in bipolar disorder. These results indicate that bipolar patients have an unusually high level of intention to die and high lethality of the methods used. Suicide and suicide attempts are two different but highly overlapping phenomena: about half of those who complete suicide have attempted suicide at least once previously. The first attempt (even if the method used is nonviolent or non-lethal) significantly increases the risk of suicide in the future. Such a fact is

in part because those who repeatedly attempt suicide often change their method from nonviolent to violent or from nonlethal to lethal. Suicidal ideation, suicide attempt, and suicide are three different but highly overlapping phenomena. Previous suicide attempts and current major depression are the two strongest predictors of future suicides. The vast majority of suicide attempts or those who have completed suicide come from a population of people with current suicidal ideation, often in association with an untreated major depressive episode.

It has been reported that the standardized death rate from suicide in patients (unipolar and bipolar) with mood disorders greater than that of the general population is 10 to 30 times. While suicide is about the 10th most common cause of mortality in the general population in well-developed countries, it is among the most common leading causes of death among unipolar major depression and bipolar disorder. The life expectancy of these patients is decreased by about 10 to 12 years. Consolidated studies in the literature estimate that 15% to 19% of severe (mostly hospitalized) patients with unipolar and bipolar major depressive episodes would have died from suicide. However, the most recent studies, perhaps reflecting the most popular and effective treatments, have found that this figure is less than 10%, especially diversified for subpopulations, such as patients hospitalized for suicide risk, patients hospitalized for a mood disorder, and outpatient patients.

Other long-term follow-up studies also show that the suicide rate is higher in bipolar disorder (types I and II combined) than in unipolar depression. Similarly, population-based epidemiologic studies have also found a substantially higher rate of suicide attempts in bipolar I and II disorders than in patients with unipolar major depressive disorder: More than half of bipolar patients and about a third of unipolar depression patients report a life history of one or more suicide attempts, and suicidal ideation, a major precursor of suicidal behavior in patients with mood disorders, is even more common. Most studies show that of the three different clinical manifestations of major mood disorders (unipolar depression, bipolar I disorder, and bipolar II disorder), bipolar patients in general and bipolar II people, in particular, carry the highest risk of both attempted and committed suicide. Although the literature has indicated that patients with bipolar II disorder (BP-II) are at increased risk of suicide, such evidence does not appear to emerge from recent meta-analysis studies. However, BP-II accounts for 30% to 58% of all major depressions

in psychiatric practice, and mixed states are very common in the BP-II spectrum. Furthermore, the cyclothymic temperament is the most prevalent in BP-II and has been shown to be a predictor of suicide, and rapid mood shifts are the hallmark of BP-II. Apparently, BP-II suicides are the most likely to be lethal, as they use the most aggressive methods.

The risk of complete and attempted suicide in bipolar disorder is most pronounced at a younger age, especially in the first few years after onset. However, bipolar patients with previous suicide attempts have an earlier age of onset than those with no prior suicidal tendency. Because the correct diagnosis of bipolar disorders usually occurs on average 8 to 10 years after the onset of the disease and delays an accurate diagnosis, as well as delays in the onset of mood stabilizers at the onset of the disease, increase the risk of suicidal behavior, these findings strongly suggest that early recognition of the bipolar nature of depressive disorders and adequate short- and long-term treatment are crucial to preventing suicide.

The first suicide attempt significantly increases the risk of future suicide attempts or completed suicide, and about 20% of those who attempt suicide will eventually die at their own hands. However, up to half of the suicide victims have made at least one previous suicide attempt, indicating that about 50% of suicide victims die from their first suicide act. Therefore, detecting the risk of suicide in patients with mood disorders and planning prevention strategies as early as possible, even before the first suicide act, are crucial in suicide prevention. This chapter summarizes the risk of suicide and the most clinically detectable protective factors in mood disorders and briefly highlights the most effective preventive strategies. It will focus on complete suicide (an act of deliberately taking one's own life) and attempted suicide (an act of self-harm with the intent to end one's life), both commonly referred to as "suicidal behavior," but it will not cover deliberate self-harm (defined as an intentional injury to one's body with no apparent suicidal intent).

CLINICALLY DETECTABLE SUICIDE RISK AND PROTECTIVE FACTORS IN PATIENTS WITH MOOD DISORDERS

Risk factors often yield too many false positives because they are static elements referred to other populations and do not necessarily convey suicide risk in a specific individual. Therefore, clinicians are requested to

investigate classic risk factors and other, more dynamic conditions belonging to a given individual.

Because suicide is a rare event in the community, its precise prediction in individual cases is challenging but not impossible. However, suicidal behavior (completed suicide and suicide attempt) is quite frequent among patients with mood disorders who contact different health care levels some weeks or months before their death or attempt, which emphasizes the potentially key role of health care workers in suicide prevention. The scientific literature identifies several clinical, biologic, psychosocial, and demographic risk and protective factors that are statistically significant with suicidal behavior. A meta-analysis found that a family history of suicide was also reported, especially in cases of a family history of psychiatric disorder. Few clinical characteristics of depression were indicators of risk, just more severe psychopathology and hopelessness, with only a trend for suicidal ideation. Suicide risk factors are classified as short-term versus long-term, proximal versus distal, changeable versus unchangeable, psychiatric–medical versus sociodemographic, and clinical versus biologic.

In addition, considering the competence, the field of responsibility, and the changeable/unchangeable nature of these suicide risk factors, they can also be classified hierarchically. Although the statistical relationship between the different *tertiary (*demographic) risk factors like male gender, old age, etc., and *secondary* (psychosocial) risk factors like unemployment, living alone, etc., and suicidal behavior is well-demonstrated, their predictive utility is very limited in individual cases. *Primary* (psychiatric-medical) suicide risk factors, for example, untreated depression, suicide attempt, etc., are the most powerful and clinically useful predictors of suicidal behavior, especially if secondary and tertiary risk factors are also present.

As for biologic risk factors, a decreased (dysregulated) central serotonergic system in suicide victims and suicide attempters (particularly in those with the violent method), regardless of the psychiatric diagnosis, is a very strong correlate of suicidal behavior and is one of the most consistent neurobiologic findings in the field of psychiatry. Some studies, however, suggest that alterations in other neurotransmitter systems (norepinephrine, dopamine, GABA, and *N*-methyl-D-aspartate [NMDA]) and cholesterol, as well as omega-6 and omega-3 metabolism, might also be important in this respect. Studies consistently show that hyperactivity

of the hypothalamic–pituitary–adrenal (HPA) axis (as reflected in the abnormal dexamethasone suppression test) is a robust predictor of future completed suicide, primarily in patients with major depressive episodes. As decreased central serotonin metabolism is more strongly related to impulsive–aggressive personality characteristics than to any specific psychiatric disorder, these trait-related features increase the likelihood of suicidal behavior, particularly in the simultaneous presence of an acute episode of major psychiatric disorder and adverse psychosocial situations, including lack of social support. Even though current studies on the biology of suicidal behavior are promising in everyday clinical practice (particularly in urgent need of action), they have limited practical value. Therefore, as discussed below, clinically explorable risk and protective factors are the most important aids in this complicated and highly responsible task.

Specific Clinical Characteristics of the Current Mood Episode

The interplay among factors associated with the history of the individual, proximal adverse life events, and psychopathology is often traceable in patients who attempt or complete suicide. In the majority of cases, mood-disorder patients are at higher risk of suicide during major depressive or mixed episodes and very rarely during euphoric mania or euthymia (clinical recovery). Patients suffering from mixed states, experiencing depression which escalates into mania with volatile and erratic moods associated with dysphoria and agitation, are more vulnerable to the precipitation of suicide risk.

Severe major depressive episodes and the simultaneous presence of major depressive and manic syndrome (DSM-IV mixed affective episode and DSM-5 major depressive episode or manic episode “with mixed features”) are the most important time-related risk periods of suicidal behavior in patients with mood disorders. Both the DSM-IV mixed affective episode and DSM-5 mania or major depressive episode “with mixed features” are characterized not only by increased suicide risk but also by an earlier age of onset, higher frequency of manic and depressive episodes, higher rate of rapid cycling course, as well as substance use and anxiety disorder comorbidity, all of which increase the risk of suicidal behavior.

According to both clinical and research observations, depression of suicide victims differs qualitatively from living depressed controls. Suicidal

depressives often experience more severe forms of depression, with features highly related to suicide risks, such as insomnia, hopelessness, anxiety, agitation, weight or appetite loss, feelings of worthlessness or inappropriate guilt, and thoughts of death or suicidal ideation. Comorbidity with substance (including alcohol) use disorder(s) is also often observed in depressed suicide victims. Patients with mood disorders who exhibit volatile and erratic moods associated with dysphoria and agitation or present the classic mixed states have a notably higher risk of suicide. Predisposing factors interact with precipitating stressors, but deaths, separations, and other major losses, scandals, or imprisonment rarely precipitate suicide in the absence of a psychiatric disorder. Current mood states are critical determinants of suicidal risk in patients with mood disorders, particularly depressive and dysphoric-irritable mixed states (DSM-5 major depressive or manic episode with mixed features) that together are present in at least 75% of suicides in bipolar patients. In contrast, suicide is extremely rare in pure mania, hypomania, and after clinical recovery.

Subthreshold lifetime or current (hypo)manic symptoms during DSM-IV unipolar major depressive disorder (subthreshold bipolar depression and mixed depression that shows great overlap with the clinical category of agitated depression) or the DSM-5 category of the major depressive or manic episode with mixed features also increases the risk of suicidal behavior. Studies also show that the psychotic nature of major mood episodes also increases the risk of suicide, particularly in patients with bipolar depression. In contrast to a major depressive episode, minor depression and pure dysthymic disorder (dysthymia without “comorbid” major depression) do not markedly increase the risk of suicide. Still, many patients with these milder forms of mood disorders develop major depressive episodes and, consequently, an increased risk of suicide during the long-term course.

Comorbid Psychiatric, Personality, and Medical Disorders

Patients with mood disorders with comorbid anxiety disorders, substance use disorders, cigarette smoking, personality disorders (mainly borderline-type), and serious, disabling, painful, and fatal medical illness are also at increased risk of attempted and committed suicide. Young persons with bipolar disorder and ADHD have an increased likelihood of suicidal behavior than young patients who have only bipolar disorder. Besides the

well-known role of chronic alcoholism, acute alcohol intake is also a significant risk factor for attempted and completed suicide, even in nonalcoholic depressives. It could trigger the actual suicidal behavior and increases the lethality of suicidal acts. Strong evidence suggests that in addition to alcohol and substance use disorders, cigarette smoking is also positively related to suicidal behavior in the general population and—according to most studies—also in samples of patients with major mood disorders. Major depression, bipolar disorder, and schizophrenia are associated with higher cigarette smoking rates than that of the general population, but smoking remains a significant suicide risk factor even after controlling for psychiatric morbidity. Smokers, in general, are more impulsive, and current smokers with major depressive disorder show a greater number of depressive symptoms and higher levels of suicidality (suicide attempts, suicidal ideations) during their depressive episode than those with major depressive disorder who have never smoked. Patients suffering from disabling, painful, and/or life-threatening medical disorders, including cancer, are also at elevated risk of suicide, mainly when depression is also present. The actual risk of suicide in patients with cancer varies with the anatomical location, stage of cancer, and the result of cancer therapy. Despite recent cancer treatments, this diagnosis is still a major stressor for many patients, especially those with other psychiatric or psychosocial suicide risk factors.

Prior Course of the Mood Disorder

Suicide risk appears to be particularly high, primarily early in the course of bipolar illness. This underlines the importance of precise diagnosis and effective treatment of specific mood disorders as early as possible. Clinically detectable suicide risk factors related to the prior course of the illness in patients with mood disorders are early onset of the unipolar or bipolar disorder, relatively early stage of the illness, first episode depression, predominantly depressed polarity during the prior course of the illness (which is typical for bipolar II disorder), rapid cycling bipolar disorder, and, of course, suicidal ideation or suicide attempt in the past; all of these have been repeatedly demonstrated to increase the risk of attempted or completed suicide in patients with mood disorders.

Affective Temperaments and Specific Personality Features

Affective temperaments have been studied in connection with suicide risk. The literature has indicated that hyperthymic temperament is protective against suicide risk, whereas cyclothymic, irritable, depressive, and anxious temperaments were associated with suicide risk. Some temperaments may present features that are more related to suicide. For instance, the role of cyclothymic temperament in suicidal behavior is supported by the finding that anger and hostility are most common in remitted bipolar and major depressive patients with a cyclothymic affective temperament. The role of unstable affective temperament in suicidal behavior is also demonstrated by findings showing that cyclothymic temperament significantly predicts future bipolar transformation and suicide attempts in adult and juvenile depressives, and bipolar I, bipolar II, and unipolar major depressive disorder patients with cyclothymic temperament have a significantly higher rate of prior suicide attempts and lifetime or current suicidal ideation than noncyclothymic depressives. The persistent, frequent, and marked instability of mood, thinking, and behavior is the most characteristic feature of cyclothymia, the attenuated manifestation of major bipolar mood disorders. However, marked affective temperament, which can be detected in about 15% to 20% of the general population, become suicide risk factor only during major depressive episodes. People with marked affective temperaments have a much higher chance of developing major mood disorders. Patients with cyclothymic and irritable affective temperaments who attempt suicide significantly more frequently report childhood physical and/or sexual abuse, suggesting that besides impulsivity, cyclothymic or irritable temperaments are further mediating variables between these early negative life events and adult suicidal behavior.

Impulsivity, aggressivity, pessimism, and a few reasons for living, like personality traits, markedly increase the risk of all forms of suicidal behavior when combined with depression. There is a strong association between impulsiveness and bipolar disorder, and impulsivity becomes more pronounced during depressive or (hypo)manic episodes. Even modest manic symptoms during bipolar depressive episodes are associated with greater impulsivity and higher suicide attempts. Pessimistic personality features, cognitive rigidity, ruminative thinking, maladaptive coping strategies, and disturbed neurocognitive functions like impaired decision-making, as could also be detected by specific neurocognitive tests, are also characteristics of most suicidal depressives.

The interaction between personality features and illness characteristics in the suicidal process is best formulated in the “stress-diathesis model,” which proposes that suicidal behavior is determined not only by the stressor (acute major psychiatric illness or acute major personal crisis) but also by a diathesis or predisposition (impulsive, aggressive, pessimistic personality traits).

Previous Suicide Attempt

The literature consistently reports that previous suicide attempts, particularly in violent or more lethal methods, are the most powerful single predictor of future attempts and fatal suicide in patients with major mood disorders or other psychiatric diagnoses. A recent study, analyzing 101 articles in the international literature, found that one-third of unipolar and about 30% to 50% of bipolar depressives attempt suicide at least once during their lifetime, and suicidal behavior shows high consistency across major depressive episodes. Suicide attempters are, on average, 35% more frequent among women than men. And despite some consolidated observations, recent studies found no difference in suicide attempter risk between types I and II bipolar disorder.

Bipolar patients use more violent and more lethal suicide methods than unipolar depressives, which are more common in males. Nonviolent or low-lethality suicide attempts do not mean low suicide risk, as those who repeatedly attempt suicide commonly change their method from nonviolent to violent, but the opposite pattern is rare. Bipolar depressives with a history of suicide attempts have more severe symptomatology in general. They report more hopelessness, self-blame, guilt, and current suicidal ideation, and they more frequently show aggressive–impulsive personality traits than nonsuicidal bipolar depressives do. Therefore, higher rates of suicidal behavior (mainly completed suicide) in patients with bipolar disorder than in unipolar major depression may be partly due to a specific effect of bipolar disorder, resulting in more dangerous or more lethal suicidal behaviors.

Family History of Suicidal Behavior

Suicide risk is notably associated with the heritability of endophenotypes, and no real genetic pattern seems satisfactory for explaining the role of a family history of suicide. It appears that cultural and coping styles are transferred across generations more than specific genetic transmission.

However, family, twin, and adoption studies show that a family history of suicidal behavior and major mood disorders in first- and second-degree relatives are among the strongest risk factors for both attempted and completed suicide in psychiatric patients in general and in patients with a major mood disorder in particular. The heritability index of completed suicide is approximately 40%, and it is even higher among depression-related suicides. However, the familial component of suicidal behavior seems to be partly independent of specific psychiatric disorders, as relatives of suicidal persons are 10 times more likely than relatives of comparison subjects to attempt or complete suicide after controlling for psychopathology. Similarly, it emerged from the literature that the children of parents with mood disorders who attempted suicide were five times more likely to attempt suicide, even after controlling other offspring risk factors for suicidal behavior, such as previous suicide attempt and history of mood disorder (both assessed at baseline) or mood disorder at the time point before the suicide attempt. Bipolar and unipolar major depressive patients who have a family history of suicidal behavior and who were exposed to childhood physical and/or sexual abuse are at greater risk of suicidal behavior. Impulsivity and irritable temperament seem to link childhood abuse and suicidal behavior, particularly in pure or mixed major depressive episodes. Research data, including twin and adoption studies, show that the familial aggregation of suicidal behavior has several components: genetic background of major psychiatric disorders, genetic–familial nature of impulsive–aggressive personality traits irrespective of a psychiatric disorder, and, in some cases, copycat mechanisms. However, it should be noted that the “suggestive” effect of a suicidal family member becomes active mainly when a major depressive or other severe mental disorder develops.

Negative Life Events and Adverse Life Situations

As a multifactorial phenomenon encompassing both distal and proximal risk factors, recent negative life events may trigger suicidal behavior in vulnerable persons, particularly in high-risk groups, such as those with major depression. Adverse, unwanted, or stressful life events play an important role in the suicidal process as predisposing (childhood events, including physical and sexual abuse) and precipitating (adulthood events) factors. Although negative life events do not inevitably lead to suicidal behavior in healthy persons or even in high-risk groups such as

psychiatric (particularly mood disorder) patients, they may actually trigger the suicidal process, particularly if other risk factors or adverse situations are also present. One-third of patients with unipolar major depression or bipolar disorder report a history of childhood physical and sexual abuse or neglect, and depressed patients with such a history have an earlier age of onset of bipolar illness, greater psychiatric comorbidity, and increased rates of suicide attempts. These adverse childhood events may lead to developmental and neuroendocrinologic scars that render the subject vulnerable to suicidal behavior in a crisis situation during adulthood, including severe major depression or bipolar disorder.

Affect mastery, or the capacity to regulate affect, is gradually acquired after birth–it is not present early on. Only with time and reasonable parenting do children attain the capacity to regulate themselves and keep themselves in reasonable emotional composure. The various developmental stages bring different emotional stresses to children. They must learn to deal with separations, frustrations, or other emotionally challenging circumstances. Thus, the importance of good early attachment experiences is unambiguous. The parent who is frightened, insecure, or vindictive prevents the child from making a “secure attachment.” Insecure attachment with affective dysregulation, which is now identified in various central nervous system activities and HPA-axis activity, is considered a suicide risk.

About half of all completed suicides in bipolar and unipolar mood disorders are associated with recent severe, acute negative life events or adverse life situations, such as the death of a relative or close friend, isolation, living alone, separation, or divorce, and being unmarried. However, the stressors are commonly dependent on the victims’ own behavior, particularly in bipolar I or bipolar II disorder. Hypomanic episodes, but mainly manic episodes, can easily lead to financial extravagance, aggressive–impulsive behavior, or episodic promiscuity, thus generating several interpersonal conflicts, marital breakdown, and new negative life events, all of which have a negative impact on the further course of the illness and on the family atmosphere of the patients as well, which may ultimately trigger a new depressive episode and suicidal behavior. Other relevant stressful events identified as suicide risk factors include interpersonal or occupational difficulties; personal or economic losses; retirement; bereavement; social isolation; feeling stigmatized, as also commonly seen in patients with mood disorders; and

limited access to support or health care or social services. Permanent adverse life situations (e.g., unemployment and social isolation), as well as acute psychosocial stressors (e.g., loss events and financial breakdowns) in adult patients with unipolar or bipolar disorders, are useful indicators of suicidality in clinical practice, primarily if other risk factors are also present. It should be noted that unemployment is frequently the consequence of a major mood disorder, particularly in comorbid substance-use disorder cases. The risk of suicide is very high in the first few days of hospitalization and a few days and weeks after discharge from an inpatient psychiatric department, particularly in the case of unplanned discharge, in patients with a short hospital stay, in patients with a high number of previous hospitalizations, and, of course, in the case of lack of follow-up care. Doctors should be alert when a patient discharged from an inpatient or outpatient psychiatric department seeks help for any psychological or even medical problem.

Critical Appraisal of Suicide Risk in Mood Disorders and Clinical Utility of Suicide Risk Factors

A mental state examination is an integral part of the assessment. The suicide risk factors in mood disorders are shown in Table 13.5–1. This table organizes the risk factors from the clinical examination point of view when clinicians collect information about the present clinical manifestations and patients' history with mood disorders. However, these risk factors have different clinical relevance and diverse predictive utility; illness-related factors are more alarming and more powerful than personality-related risk factors. Suicide risk factors have an additive effect; the more risk factors present, the higher the suicide risk.

Understanding the suicidal mind requires knowledge of the individual's perturbed state in crisis since this provides the motivation for the individual to contemplate suicide. Therefore, asking where the suffering comes from and how it has changed and becoming more acute is a method of intervention that, although intuitive and straightforward, is often forgotten by those responsible for managing the person in crisis. Clinicians should interpret the internal debate of the individual in crisis. Patients experience ambivalence about dying, and if clinicians can empathize with the suffering of patients, they can invigorate the wish to live. Patients often have an internal dialogue with ruminations that need to be interrupted with pharmacologic agents, reducing anguish and despair,

and other nonpharmacologic treatments. In a phenomenologic view of the suicidal mind, perturbation supplies the motivation for suicide, whereas lethality is the fatal trigger. Suicidologists believe that suicidal individuals feel driven to suicide as an escape from intolerable mental pain and feel that suicide is the only option left. To explain some features of the suicidal mind, the concept of “constriction” is often defined as a type of tunnel vision with which the suicidal individual cannot consider a valid option to reduce the source of suffering. In such a condition, suicidal individuals experience a particular way of thinking, often described as dichotomous. The options considered by the suicidal subject as valid to reduce his suffering are either a magical immediate resolution of his state or a concrete option, which is suicide. It seems that, although there may be effective supports from family and friends, the individual is unable to benefit from them. The pleasant memories and their history concerning others are not helpful, and the individual focuses on intolerable emotions and how to escape from them.

Table 13.5–1.
Clinically Explorable Suicide Risk Factors in Mood Disorders

I. Illness-related risk-factors
    1. Risk factors related to current mood episodes
        a. Severe major depressive episode
            Current suicide attempt, plan, ideation
            Hopelessness, guilt, pessimism, few reasons for living, unusual behavior (i.e., making a will = testament, etc.)
            Major depressive episode with mixed features (mixed depression), agitated depression
            Past mania or hypomania (bipolar I or II diagnosis)
            Insomnia, anxiety
            Appetite and/or weight loss
            Comorbid anxiety/anxiety disorder disorders, substance use disorder, acute alcohol intake, cigarette smoking
            Comorbid personality disorder(s)
            Comorbid disable medical disorder(s)
            Lacking medical care and lacking family/social support
            Noncompliance, treatment-resistance
            First few days/weeks of the treatment (particularly if appropriate care and comedication are lacking) and first few weeks after hospital discharge
        b. Major depressive or manic episode with mixed features
    2. Risk factors related to the prior course of the mood disorder
        Previous suicide attempt/ideation (particularly in the case of violent/highly lethal methods)
        Early-onset/early stage of the illness
        Predominantly depressive course/high proportion spent in major depressive or mixed mood episode, first episode depression
        Rapid cycling course of bipolar I or II disorder
II. Personality-related and historical risk factors
    1. Risk factors related to personality features
        Aggressive/impulsive/pessimistic personality traits
        Cyclothymic, irritable, depressive, anxious affective temperament
    2. Risk factors related to personal history and/or family history
        Early childhood adverse events (parental loss, separation, emotional, physical, and sexual abuse)

Permanent adverse life situations (unemployment, financial problems, isolation, living alone, chronic/disabling medical disorders)

Acute psychosocial stressors (loss events, acute financial catastrophe)

Family history of depressive or bipolar disorders (first- and second-degree relatives)

Family history of suicide and/or suicide attempt (first- and second-degree relatives)

In this perspective, the authors referred to the cessation concept in which the suicidal individual concludes that death will relieve his suffering. During this internal debate, helpers can deliver prevention action as long as they pay attention to both clinical signs and warning signs. It is essential to monitor suicide risk at all times by taking into consideration warning signs for suicide, such as any change in habits, especially if insomnia is presented, and any reference to the wish to die. People may feel trapped and may engage in maladaptive behavior, such as drinking alcohol and using psychoactive substances. Suicidal individuals also often put their affairs in order and give away symbolic items, as if they wish another person would take care of a prized possession, regardless of its economic value.

Table 13.5–2.
Suicidal Risks

- I Ideation—threatened or communicated
- S Substance abuse—excessive or increased
- P Purposeless—no reasons for living, anhedonia
- A Anxiety, agitation, and insomnia
- T Trapped—feeling no way out, perceived burdensomeness
- H Hopelessness
- W Withdrawal—from friends, family, society
- A Anger (uncontrolled)—rage, seeking revenge
- R Recklessness—risky acts, unthinking
- M Mood changes (dramatic)

Source: American Association of Suicidology.

The American Association of Suicidology proposed the acronym “Is Path Warm” (Table 13.5–2) to remind clinicians of potential risks factors.

Clinicians should be aware of communications about suicide; very often, patients talk about suicide, death, and/or having no reason to live. Most suicidal individuals give definite warnings of their suicidal intentions. Still, significant others are either unaware of the significance of these warnings or do not know how to respond to them. However, suicidal intent is sometimes denied or minimized. Clinicians should never forget to ask about suicide; questioning patients about suicidal thoughts and plans are always indicated and crucial for proper prevention. Talking about suicide does not increase the risk. During a suicidal crisis, patients may withdraw from friends and/or social activities, and they may also lose interest in hobbies, work, school, and so on. Suicidal individuals may also prepare for death by writing out a will (unexpectedly) and making final arrangements, giving away prized possessions, clearing up business matters about survivors, accumulating drugs or poisons for taking their life, and so on. Because these warning signs, which are highly indicative of current suicidal danger, are reported mostly by patients’ relatives, keeping contact with family members or with significant others is also important. Several suicidal intent scales have been developed that could be useful in special circumstances, but they are routinely used mostly in clinical research. Table 13.5–3 lists some tips for managing a suicide crisis.

Suicide Protective Factors in Patients with Mood Disorders

In contrast to the numerous suicide risk factors, only a few circumstances are known to have a protective effect against suicidality, and suicidal behavior is always the result of the complex interplay between risk and protective factors. Good family and social support, pregnancy and the postpartum period, having a large number of children, holding strong religious beliefs (regardless of the nature of religion), regular physical activity, restricting lethal suicide methods whenever possible (e.g., to reduce domestic and car exhaust gas toxicity, barriers at train stations and bridges), and introducing stricter laws on drug and gun control seem to have some protective effect. Recent studies have found that optimistic personality features and hyperthymic temperament may also be a protective factor and that there is a strong relationship between psychological resilience and hyperthymic temperament in both depressive

and healthy individuals. However, one of the most extensively studied and changeable suicide protective factors in major mood disorders is acute and long-term treatment, both pharmacologic and nonpharmacologic.

Table 13.5–3.
Tips for Managing the Suicide Crisis

How to Communicate

- Listen carefully, calmly
- Understand the feelings of the other with empathy
- Emit nonverbal signals of acceptance and respect
- Express respect for the opinions and values of the person in crisis
- Speak honestly and simply
- Express concern, care, and solidarity
- Focus on the feelings of the person in crisis

How not to Communicate

- Interrupt too often
- Express discomfort
- Give the impression of being busy and hasty
- Give orders
- Make intrusive or unclear statements
- Ask too many questions

Useful Questions

- Are you feeling sad?
- Do you feel that no one is taking care of you?
- Do you think it is not worth living?
- Do you think you would like to die by suicide?

Suicide Planning Investigation

- Have you ever made plans to end your life?
- Do you have an idea how to do this?

Investigation of Possible Methods of Suicide

- Do you have drugs, firearms, or other means to commit suicide?
- Are they easily accessible and available?

Investigation Over a Specific Time Frame

- Have you decided when you want to end your life?
- When are you going to do this?

Suicidal behavior, as a final act, is always the result of a dynamic interplay between risk and protective factors. However, in individual

cases, suicide risk factors have more practical relevance, and the presence of one or more suicide risk factors is more important than the lack of protective ones. In most cases, more than one suicide risk factor is present simultaneously, and the effect is cumulative: The higher the number of risk factors, the higher the suicide risk. They are usually closely related to each other. For example, older adult major depressives frequently have multiple medical disorders, and they commonly experience loss events and isolation; major depression easily leads to secondary alcoholism, loss of job, family breakdown, financial problems, and so on. When a clinician considers the clinically relevant suicide risk factors in patients with mood disorders, suicidal behavior is predictable but, of course, not guaranteed in the majority of cases. Severe major depression with agitation, anxiety, insomnia, or hopelessness, particularly in combination with a prior suicide attempt and, of course, with current suicidal ideation, are the most important signs for identifying acute or hyperacute suicide risk that requires prompt action.

SUICIDAL RISK EMERGING DURING ANTIDEPRESSANT TREATMENT: THE ROLE OF UNDERLYING BIPOLARITY

Given that suicidality is the most visible outcome of *untreated or inadequately treated* depressive illness, the U.S. Food and Drug Administration (FDA) warning of emergent suicidality in children and adolescents based on the antidepressant arm of placebo-controlled randomized trials has created understandable concern in clinical practice. The issues involved are of broader public health importance for all patients, not just for youngster patients. In 2004, the FDA advised that antidepressants could sometimes be related to suicidal behavior, which mainly pertains to children and adolescents in their database. Newer meta-analyses have confirmed the FDA's position for a slightly increased risk of suicidality (suicidal ideation and attempts but not completed suicide) in juvenile patients in randomized controlled antidepressant trials on unipolar major depression. As in other branches of medicine, psychiatrists must always be vigilant of iatrogenesis's rare risk when prescribing potent agents like antidepressants to patients with depressive disorders where the risk of suicidality is inherent and quite common. They could increase the risk only in a small, vulnerable subpopulation (mostly in

young depressives who are predominantly prebipolar); therefore, in everyday clinical practice, the suicide preventive effect of antidepressants highly overshadows this unwanted iatrogenic.

There is no doubt that suicide mortality is much higher among untreated depressives than among antidepressant-treated depressives. The rarely occurring suicidal behavior in patients taking antidepressants is mostly the consequence of the lack of antidepressant effect (antidepressant-associated suicidality) and is rarely the result of the suicide-inducing potential of antidepressants (antidepressant-induced suicidality), as antidepressants can sometimes worsen depression as they can mobilize intradepressive hypomanic symptoms resulting in mixed/agitated clinical picture, frequently called also as “activation syndrome.” It would appear that in highly suicidal individuals, the administration may pose risks, especially when such individuals experience agitation, akathisia, anxiety, irritable dysphoria, insomnia, anger, aggression, or threats of aggression. Patients may also be at higher risk of suicide during antidepressant therapy when experiencing worsening depression, hopelessness, anguish, helplessness, social isolation, or current stressors (loss, separation, scandal, financial crisis). This is probably because these agents do not calm down the anguish and despair, and the effects mentioned above may add consistent sufferance to already fragile subjects. It is also important to emphasize that removing the antidepressant or adding a centrally active agent with mood-stabilizing, sedative, anxiolytic, antimanic, antipsychotic, or antiaggressive activity led to a favorable outcome in most cases. Furthermore, because antidepressants may not be appropriate in some mood disorders, the precise and early diagnosis of bipolar disorder, even in first-episode depressives, and the formal recognition of bipolar depressive mixed states are crucial.

PREVENTION OF SUICIDE IN PATIENTS WITH MOOD DISORDERS

Prevention of suicide in patients with depressive disorders is not only a great challenge for everyone who cares for or has contact with them but could also be among the most reliable indicators of the efficacy as well. As much of the putative psychosocial and demographic suicide risk factors are not modifiable in the frame of individual health care, suicide

preventive efforts of psychiatrists and other medical professionals should focus on the treatable and amendable contributory psychiatric disorders involved in such behavior. The health care system's role in suicide prevention varies as a function of the setting (e.g., psychiatric settings vs. primary care practice), with specialized suicide prevention centers (where they exist) playing the most important role. Because suicidal behavior is a complex phenomenon, even in patients with mood disorders, its prevention should also be complex. The majority of suicide attempts and completed suicides in patients with mood disorders are preventable. As suicidal behavior in patients with mood disorders is very rare in the absence of a major depressive or mixed affective episode, reducing the time spent in these high-risk states is essential for their suicide prevention. While successful acute treatment can only prevent suicide connected with the given mood episode, given the highly recurrent nature of major mood disorders, adequate long-term therapy can provide effective protection for a longer period.

In acute suicide danger, the patient needs close observation and urgent hospitalization, even against their own wish. Crisis intervention, whenever needed, is also helpful. After an open discussion with the patient and relatives, involuntary admission is rarely needed. It should be explained that hospitalization will be as short as possible and that it is best for the patient. In cases when acute hospitalization is not indicated, close observation by family members and removing possible means of suicide (i.e., guns, drugs, pesticides, and car keys) is advised, as is consultation with a local outpatient psychiatrist in the GP and other nonpsychiatric practice. As anxiety, psychomotor agitation, and insomnia markedly increase acute suicide risk, prompt pharmacologic treatment of these symptoms is always needed, and these treatments provide immediate results. In the most severe suicidal (sometimes stuporous or catatonic) depressives, electroconvulsive therapy (ECT) is the most useful treatment strategy.

Pharmacologic and Nonpharmacologic Approaches

Large-scale, retrospective, and prospective open-naturalistic and controlled long-term clinical studies, including severely ill, comorbid, frequently suicidal depressives (most often inpatients), have shown that appropriate acute and long-term pharmacotherapy (antidepressants in unipolar depression and mood stabilizers in bipolar disorder) markedly

reduces suicide morbidity and mortality—and probable other forms of aggressive, violent behaviors—even in this high-risk population. Bipolar patients on mood stabilizers with or without antidepressants or antipsychotics, and unipolar depressives on antidepressants, show a 70% to 80% (range 56% to 93%) risk reduction of completed and attempted suicide compared to those without pharmacologic treatment. Although long-term treatment with lithium and antiepileptic mood stabilizers results in a similar reduction in suicide mortality, lithium may have some superiority in preventing suicide. Register-based observational cohort studies also show that former inpatients with unipolar major depression who continued treatment with antidepressants, and former inpatients with bipolar disorder who continuously took mood stabilizers (lithium or antiepileptic mood stabilizers), had a markedly decreased rate of completed suicide compared with those who stopped taking antidepressants or mood stabilizers.

This marked antisuicidal potential of lithium seems to be more than the simple result of its **episode-prophylactic effect**, as it has been shown that during the long-term lithium prophylaxis of recurrent bipolar or unipolar affective disorder patients with at least one prior suicide attempt, a significant reduction in the number of suicide attempts was found not only in the excellent responders but also in moderate responders and nonresponders. This finding's clinical importance is that in the case of lithium nonresponse, when the patient has one or more suicide risk factors, instead of switching from lithium to another mood stabilizer, the clinician should retain lithium (even on a lower dose) and combine it with another mood stabilizer. The well-documented strong antisuicidal effect of lithium in patients with bipolar and unipolar major mood disorder has also been supported by results derived from the general population: Investigating the lithium levels in tap water and drinking water in Texas, Japan, Austria, and Greece, lithium levels were significantly and negatively associated with suicide rates. The evidence that suicide rates among depressed patients have progressively and significantly lowered through the first half of the "pretreatment era" (1900 to 1939), "ECT era" (1940 to 1959), and "antidepressant era" (1960 to 1992) also supports the suicide-preventive effect of antidepressants in depressed patients. As comorbid anxiety, agitation, and insomnia increase the short-term suicide risk for depressed patients, anxiolytics, atypical antipsychotics, and sleep-

promoting drugs—mostly for short-term use—are also part of the therapeutic arsenal.

Recent pharmacotherapy innovations pointed to the role of glutamate, the most abundant excitatory neurotransmitter in the brain. Esketamine, a glutamatergic NMDAR antagonist, proved to reduce depressive symptoms faster than typical antidepressants. Esketamine blocks NMDA receptor-mediated activation of specific GABA interneurons. GABA interneurons are nerve cells that are inhibitory in function; they dampen the release of glutamate. Esketamine-mediated inhibition of these GABA interneurons could enhance the release of glutamate and, hence, greater glutamate action on AMPA receptors.

Such enantiomer of ketamine was then approved in combination with oral antidepressants to treat the major depressive disorder with suicidal ideation or behavior or in some geographical regions to treat major depressive disorder with psychiatric emergencies. Studies demonstrated efficacy for improvement of depression after 24 hours from first administration but not for suicide risk *per se*, probably due to extra clinical care also delivered to the placebo plus oral antidepressant arm.

Pharmacotherapy, however, is a necessary but insufficient method of reducing suicidal behavior in depressed patients, and psychosocial interventions are always needed. Psychoeducation and supportive psychotherapy are also always needed. There is some evidence that concurrent depression-focused psychotherapies, combined with pharmacotherapy, improve patients' adherence, increase pharmacotherapy effectiveness, and contribute to suicide prevention for severe unipolar or bipolar disorders. The interaction between pharmacotherapy and psychosocial interventions is quite complex. It has been reported, for example, that successful episode-preventive medication with mood stabilizers in bipolar patients counteracted dysfunctional cognitions (including lowered self-esteem), and adjunctive cognitive therapy could help to optimize the long-term course of bipolar illness.

However, psychotherapy for depression *alone* is not enough for preventing depression-related suicide. A systematic review and meta-analysis show that there is little evidence for the assumption that suicidality in depressed patients can be reduced with psychotherapy for depression despite decreasing depressive symptomatology, indicating that in suicidal depressives, psychotherapy and psychosocial

interventions should always be combined with appropriate acute (and, if necessary, long-term) pharmacotherapy. Concurrent depression-focused psychotherapies, combined with pharmacotherapy, improve patients' adherence, increase pharmacotherapy effectiveness, and contribute to suicide prevention for severe recurrent unipolar or bipolar disorders. Both hopelessness–pessimism and aggressiveness–impulsiveness may be amenable to cognitive-behavioral therapy and pharmacotherapy (e.g., selective serotonin reuptake inhibitor [SSRI] antidepressants, lithium, and other mood stabilizers).

Suicide Prevention in Primary Care

Although more than two-thirds of suicide victims contact different levels of health care (mostly in General Practice (GP) and psychiatrists) during the last few weeks or months before their death, the rate of recognition of depression and adequate pharmacotherapy among depressed suicide victims is around 20% to 25%, which is disturbingly low. While the current prevalence of major mood disorders in the primary care practice is around 8% to 12%, many depressed patients are not recognized by their GPs. However, more recent studies reported much higher recognition and treatment of depression in primary care practice (62% to 85%), and 33% to 50% of them were treated with antidepressants. Physician factors related to poor recognition of depression include lack of experience, insufficient or suboptimal knowledge about symptoms, treatment and good prognosis in treated depression, prejudices about mental illness, lack of postgraduate psychiatric training, insufficient interview skills, lack of cooperation with psychiatrists, and a low level of empathy.

Although suicidal behavior is a relatively rare event in primary care, given that depression is quite frequent in GP and is very common among completed suicides, major depression, particularly in combination with past or current suicidal behavior, should be taken very seriously in primary care. Compared to nonsuicidal patients, suicide victims visit their GPs much more frequently in the last four weeks of their life. Many physicians and even mental health care professionals avoid discussing suicide directly and frankly with patients for fear of provoking suicidal behavior or, more likely, because of personal discomfort. However, asking questions about suicidal ideation and past suicide attempts does not trigger suicide. This is particularly true if such a discussion is accompanied by some sentences explaining that depressive disorders can be successfully

treated and that suicidal intent will vanish after (or even before) the recovery from depression. Asking simple questions (e.g., “What do you think about the future”? “Do you feel that life is not worth living”?) can easily facilitate further, deeper, and honest discussion on the topic of suicide. This is beneficial, as many patients think they are alone or unique in their suicidal ideas. Leaflets, posters, and fliers left in the waiting room and providing appropriate websites indicating the symptoms, dangers, and treatable nature of depression and preventable nature of suicide are also beneficial.

Postgraduate training on better recognition and management of depressive disorders among psychiatrists and primary care appears to prevent suicide. The first example of the significant role of GPs in suicide prevention comes from the Swedish Gotland Study. The study demonstrated that after a short intensive postgraduate training for GPs on Gotland’s Island on the diagnosis and treatment of depression, suicide rates and the number of depression-related hospital admissions declined significantly, and antidepressant prescription increased markedly a few years after the training. The rate of depressive suicides among all suicides decreased substantially after the training, indicating that the decline in suicide mortality after the education resulted directly from a robust decrease in depressive suicides and suggesting that this result might not be caused by random fluctuation of other unknown factors. However, the decline in depressive suicides after the GP training mainly resulted from a reduction in female depressive suicides. Few suicidal males were known to the local medical services, although many were known to the police and social welfare services.

However, primary care education in isolation does not have any significant long-term effect on suicide mortality, and primarily complex, permanent, and multilevel educational and organizational interventions are useful. The multilevel community program should be based on the involvement and the strong collaboration with psychiatrists, GPs, gatekeepers, and media. The effect of these multilevel community suicide prevention programs has been demonstrated recently by the German Nuremberg Alliance Against Depression Study and the International European Alliance Against Depression Project, a multifaceted community-based action program against depression and suicide. Better management of depression requires improved recognition and treatment skills from the doctors and good compliance. Nonadherence to

antidepressant therapy is one of the most common causes of treatment failure. GPs should work in close and permanent collaboration with the local mental health services. Outpatient psychiatric consultation is also helpful in differential diagnostic problems, treatment resistance, and comorbid substance-use disorder, regardless of whether the patient is suicidal. If long-term prophylactic pharmacotherapy is needed (bipolar disorder, recurrent unipolar major depression), the GP may direct the patient to a psychiatrist to optimize the therapy. Although depressive disorders represent an important target for suicide prevention in old age, there should be increased attention also for psychosocial and somatic–medical risk factors in this age range.

Regular aftercare with fixed appointments is highly recommended, particularly for patients with previous suicide attempts. Psychological support should be available for each suicidally depressed patient. This is important because the actual clinical picture immediately after a suicide attempt is often misleading due to the cathartic effect of self-aggression, resulting in a short-lived but sometimes marked improvement in depression. This can also serve as one of the explanations for why some health care workers misinterpret suicide attempts as manipulative acts.

Health care professionals, of course, are unable to prevent all suicides, including those occurring in the context of patients with mood disorders. Nevertheless, the current theoretical knowledge and the available treatment and preventive strategies are sufficient to prevent many, probably most, of them. The most important methods of suicide prevention in patients with mood disorders are shown in Table 13.5–4. However, as health and social care workers can only help those who contact them, public education media campaigns on symptoms, dangers, treatability, and referral pathways are vitally important.

Table 13.5–4.
Suicide Prevention Strategies in Patients with Mood Disorders

I. Elimination of acute suicide danger (physical inhibition, emergency hospitalization, sedation, anxiolysis, crisis-intervention)
II. Improving the early diagnosis and treatment of mood disorders with particular regard to the soft (subthreshold) clinical manifestations of bipolar disorder
    1. Education of health care workers, patients, relatives, and gatekeepers (clergymen, policemen, teachers, social workers, peer-helpers, etc.)
    2. Adequate acute and long-term treatment/aftercare (pharmacotherapy, nonpharmacologic interventions such as psychoeducation, psychotherapy, cognitive therapy, family counseling/family therapy, regular long-term care/contact, etc.)
III. Improving the patients' compliance (psychoeducation, psychotherapy, cognitive therapy, etc.)
IV. Education of the public via printed and electronic media, including the internet
    1. Education on the symptoms, dangers, and treatable nature of mood disorders and the preventable nature of suicidal behavior
    2. Reducing the stigma against mood disorders and suicide
    3. Providing information on how and where to get help in the case of mood disorder and suicide crisis

13.6 Mood Disorders: Pharmacologic Treatment of Depression and Bipolar Disorders

Lakshmi N. Yatham, M.B.B.S., F.R.C.P.C.S., M.R.C.Psych(UK), M.B.A. (Exec), Sidney H. Kennedy, M.D., F.R.C.P.C., F.R.C.Psych., Ayal Schaffer, M.D., F.R.C.P.C., and Wegdan Rashad, M.D.

Mood disorders comprise two separate chapters in the DSM-5: "Depressive Disorders" and "Bipolar and Related Disorders." Among the major changes, mixed episode as a diagnostic entity was eliminated and a course specifier "with mixed features" has been added for both major depressive episodes (MDEs) and manic/hypomanic episodes. This allows an individual in an MDE with three or more (hypo)manic symptoms and no prior manic/hypomanic episodes to remain within the MDD domain, rather than be classified as a forme fruste of bipolar disorder.

Other changes within the Depressive disorders chapter are the inclusion of disruptive mood dysregulation disorder (DMDD) and premenstrual dysphoric disorder as new diagnoses, and the replacement of chronic depression and dysthymia with a single diagnostic entity—persistent depressive disorder (PDD). The essential feature of PDD is depressed mood and at least two depression symptoms present for 2 years or more (1 year for children or adolescents). There is still the possibility that MDEs may occur intermittently with PDD (i.e., PDD with intermittent MDE) or persistent MDEs may occur with PDD (i.e., PDD with persistent MDE). Abnormally and persistently increased goal-directed activity or energy has been added to the stem criterion for a manic/hypomanic episode. Further, manic/hypomanic episodes emerging during antidepressant treatment are indicative of bipolar disorder provided the symptoms persist beyond the physiologic effects of treatment. The not otherwise specified (NOS) category has been replaced with "other specified depressive disorder," "other specified bipolar and related disorder," and "unspecified bipolar and related disorder." Unfortunately,

there is a limited evidence base from clinical studies to inform treatment recommendations for these additional diagnostic categories. Therefore, the focus of this chapter will be on the treatment of MDD and bipolar I and II disorder.

TREATMENT OF MAJOR DEPRESSIVE DISORDER—FOCUS ON PSYCHOPHARMACOLOGY

MDD is typically a disorder of recurrent depressive episodes rather than a single episode. Several treatment options are available for managing patients with MDD and the list of treatment options continues to expand, although progress in identifying novel strategies has been slow. This section will outline the foundations of management for MDD from a psychopharmacologic perspective.

Since MDD is not a homogeneous entity, even in the absence of co-occurring psychiatric disorders, there is major symptom heterogeneity among persons presenting with an MDE: hence, diverse treatment modalities have a place in the management of MDE. The reader is referred to other chapters in this book for the management of MDD at different phases across the lifespan: pregnancy and postpartum, and the management of MDD in children and adolescents as well as older individuals.

Foundations of Management

Core Concepts. A thorough biopsychosocial assessment, including attention to safety, is the nucleus to quality care. In the psychiatric assessment, it is important to consider other diagnostic possibilities such as bipolar disorder, and complete a full characterization of clinical aspects that may include anxiety disorders, substance use, suicidality, psychotic features, and other psychiatric comorbidities. Reports on psychiatric comorbidity indicate that anxiety disorders (60%), substance use disorders (25%), and impulse control disorders (30%) are highly prevalent among patients with lifetime MDD diagnosis. Information on previous psychiatric treatments and sensitivity to psychopharmacology is also required.

An assessment of physical health, functionality, sociodemographic, and family history as well as concurrent prescription medications can guide the

treatment plan. Collecting collateral information is valuable at this stage.

A medical workup should focus on patient symptoms and evidence of change. There is also a bidirectional relationship between MDD and physical health. Individuals with prior depressive episodes have high risk of medical disorders including heart disease and diabetes, while patients with medical disorders, including cardiovascular disease and stroke, chronic pain, obesity, diabetes, epilepsy, and other central nervous system (CNS) disorders, and cancer have two- to fourfold increases in risk of MDD.

The next step includes formulating a diagnosis and differential diagnosis followed by a dialogue on treatment options and recommendations. It is important to establish a therapeutic alliance and to engage in a dialogue on perceptions about psychiatric treatments and antidepressants, in particular. The psychiatrist often plays the role of an educator and "myth buster." Many patients will also have searched the Internet for information and will welcome a chance to discuss the materials they have collected online: it is important to explore these perceptions and often misperceptions. These discussions are likely to recur during ongoing supportive care and it is important to establish good rapport at the initial visit.

Effective management of MDD requires a focus on both acute and maintenance aspects of the disorder from the outset (see Table 13.6–1). It is imperative to recognize the patient as a partner in determining goals of treatment. The primary goal in the acute phase is to achieve remission—a state that comes close to being symptom-free (typically remission represents a score of ≤7 on the Hamilton Rating Scale for Depression [HAM-D] or ≤10 on the Montgomery-Asberg Depression Rating Scale [MADRS]). Since failure to achieve remission is associated with a higher risk of recurrence, this has replaced the previously accepted treatment aim of response, defined as a reduction of ≥50% on one of the above scales as a goal of treatment.

Although symptomatic response or remission are the traditional goals of treatment, it is increasingly recognized that improvement in function (e.g., return to work or other meaningful activities) and overall quality of life are the priority goals of most patients: it is, therefore, important to listen to their apprehensions and expectations and provide education about depression and treatment options.

Evaluate Adherence. The first step in exploring minimal or no response is evaluating adherence, which is a pivotal component of any therapy. Unfortunately, many patients neglect to take their medication on a frequent basis, missing doses for days or weeks, or discontinuing altogether. This increases the risk of relapse or recurrence. “Forgetting” to take medication as prescribed is more likely to occur as patients begin to feel better and about 50% admit to decreased adherence by 3 months. On the positive side, there is evidence that adherence improves in the weeks leading up to and just after a follow-up appointment. Although not currently a routine practice, plasma monitoring of antidepressant blood levels provides an additional method to assess adherence. There is also evidence that a brief telephone contact to monitor symptoms and side effects early in the course of treatment improves adherence and ultimately outcome. Strategies for improving adherence include fostering a stronger therapeutic alliance, patient education, teaching self-management, and harnessing digital tools.

Table 13.6–1.
Phases of Antidepressant Treatment

Treatment Phase	Duration	Goals	Activities
Acute and continuation	8–12 weeks	▶ Achieve symptomatic remission ▶ Monitor side effects ▶ Restore function	▶ Establish therapeutic alliance ▶ Provide psychoeducation ▶ Select optimal antidepressant treatment(s) ▶ Apply supportive and measurement-based care ▶ Monitor progress
Maintenance	6–24 months or longer	▶ Return to full function and quality of life ▶ Prevention of recurrence	▶ Continue psychoeducation ▶ Rehabilitate ▶ Manage comorbidities ▶ Monitor for recurrence

Modified from Lam RW, McIntosh D, Wang J, et al. Canadian Network for Mood and Anxiety Treatments (CANMAT) 2016 clinical guidelines for the management of adults with major depressive disorder: section 1. Disease burden and principles of care. *Can J Psychiatry*. 2016;61(9):510–523.

Self-management techniques may help patients to understand and manage their symptoms and psychosocial sequelae. Behavioral activation techniques, communication skills, coping with difficult emotion, engaging in healthy lifestyle habits (integrating nutrient-dense foods and exercise), relapse prevention planning, skill development, and self-monitoring. Through these skills, individuals are less reliant on health care providers and in turn are more empowered and self-efficacious. Patients may be helpful in attending peer support services.

Monitor Outcomes with Measurement-Based Care. Implementing measurement-based care requires routine use of standard rating scales to identify and track changes in symptoms and function during an MDE. The

advantages of administering a rating scale include longitudinal monitoring and promoting a therapeutic alliance to achieve better outcomes.

Several clinical instruments are readily available and completion times range from 5 to 20 minutes depending on the scale length. Abbreviated versions such as the HAMD-7 item scale are also available. The Patient Health Questionnaire (PHQ-9), a self-report scale containing the nine items listed in DSM-5, rated according to their frequency of occurrence and the Quick Inventory for Depression Symptomatology (QIDS), available in both observer-rated and self-report forms are among the most frequently used scales. Early reduction of at least 20%–in severity on a rating scale predicts greater likelihood of response at 6 to 8 weeks and failure to achieve a 20% reduction should trigger dose increase or other options (switching or augmentation). The GAD-7 compliments these depression scales in assessing anxiety. Two easy-to-administer scales that evaluate functional outcomes are the Sheehan Disability Scale (SDS) and the Lam Employment Absence and Productivity Scale (LEAPS). In this era of remote care, these scales can be completed on electronic personal devices and may be combined with objective data such as sleep–wake patterns, body temperature, or physical activity.

Digital Tools. There is burgeoning evidence that internet and digital applications on computers and mobile devices can improve access to care, care quality, and clinical outcomes. E-mental health applications are widely available for screening, assessment, and monitoring as well as platforms for self-management and psychotherapy. However, clinicians should be aware of the potential harms of using and recommending e-mental health applications and become familiar with attention to validity, privacy, and practical aspects. Websites that rate and rank digital applications are increasingly available including appraisal frameworks such as the American Psychiatric Association App evaluation model.

After addressing goals of treatment, a comprehensive management plan should be outlined including safety, social supports, adherence, and clinical follow-up. Regular follow-up appointments are important, particularly in the first 2 to 3 months. The first follow-up visit should generally be 2 weeks after initiating treatment, although high-risk patients with suicidal intent or psychotic features should be seen sooner and more frequently. At each visit, the psychiatrist should review adherence,

symptom severity and change, side effects, and function, as well as evaluate psychosocial stressors and supports.

Most patients who achieve remission will do so by 6 to 8 weeks, although a minority may achieve early response (within the first 4 weeks). Typical rates of remission are between 30% to 40% with most antidepressants and response rates are generally in the 50% to 65% range, for patients who are not considered treatment resistant.

Sequencing and Staging of Treatment. Approximately half of individuals with MDD do not respond to their first prescribed antidepressant treatment, and 20% to 30% have not responded after at least two treatment trials. This introduces the possibility of treatment-resistant depression (TRD) defined as failure to respond to at least two antidepressant trials, adequate in dose and duration. To better define and manage TRD, several staging models have been proposed.

Antidepressant Treatment Strategies

Recognize First-, Second-, and Third-Line Approaches. Selecting an antidepressant requires a balance between physician expertise and patient preference, considering symptom profile, past history of treatment response and tolerability, potential for drug–drug interactions, and in many instances, cost. First-line antidepressants include selective serotonin reuptake inhibitors (SSRIs), SNRIs, other second-generation, and novel antidepressants (see Table 13.6–2). These agents have comparable efficacy but superior tolerability to the first-generation MAOI and tricyclic antidepressant (TCA) agents, which are considered third-line treatments for MDD. Second-line options include novel antidepressants and adjunctive treatments. The sequenced treatment alternatives to relieve depression (STAR*D) remains the largest effectiveness trial to directly evaluate remission rates among sequential monotherapies and adjunctive antidepressant treatment strategies in MDD. These findings are complemented by two network analyses by Cipriani and colleagues in 2009 and 2018. Combining knowledge from these trials with course specifiers for individual patient episodes of depression can help to refine treatment selection.

Table 13.6–2.
Recommendation Level and Drug Class with Dose Range for Treatment of Major Depressive Disorder

Recommendation Level	Drug Class	Recommended Dose Range (mg) per day
1	SSRI	Varies
1	SNRI	Varies
1	Agomelatine[a]	25–50
1	Bupropion	150–450
1	Mianserin[a]	60–120
1	Mirtazapine	15–60
1	Vortioxetine	10–20
2	Tricyclic Antidepressants	Varies
2	Moclobemide[b]	300–600
2	Quetiapine	150–400
2	Selegiline transdermal	6–12
2	Trazodone	150–300
2	Vilazodone	20–40
3	Phenelzine	45–90
3	Reboxetine[a]	8–10
3	Tranylcypromine	20–60

Adapted from Vaccarino SR, Kennedy SH. Treatment-resistant depression. In: Vazquez GH, Zarate CA, Brietzke E, eds. *Ketamine for Treatment-Resistant Depression: Neurobiology and Applications*. 1st ed. Academic Press; 2021, 33–84.

COMPARATIVE ANTIDEPRESSANT STUDIES. In STAR*D, medications from each of the above drug classes were administered over four stages, starting with approximately 3,000 participants who received citalopram in

Phase I. Based on the QIDS Self Report scale, 33% of those in Phase I achieved remission, and 47% achieved response. Those who did not achieve remission in Phase I were allocated to Phase II, a comparison of switching and adjunctive treatments: to another SSRI (sertraline); an SNRI (venlafaxine); bupropion, or CBT in which remission rates ranged from 18% (sertraline switch) to 30% (buspirone augmentation). Despite the large initial sample size, the number of subjects evaluated in the third and fourth phases was substantially smaller, and it is difficult to draw conclusions about the relative effectiveness of TCA, MAOI, and other adjunctive strategies.

Overall, STAR*D highlighted the relatively low rate of remission (approximately 30%) following an adequate trial of citalopram. In addition, the study did not support conventional thinking that switching to a different drug class (e.g., from SSRI to SNRI) following failure with an SSRI was superior to switching within the same class. There was also no difference in outcomes between switching and adjunctive treatment strategies. While the time to achieve remission was longer in those who received CBT, the overall rates of remission did not differ significantly from pharmacotherapy strategies. STAR*D also highlighted the marked reduction in remission rates after two consecutive trials and the high rates of dropout after each phase.

The first network meta-analysis examined 12 second-generation antidepressants from 117 published trials that collectively included almost 26,000 participants. To incorporate all trials, the authors accepted different severity rating measures (HAM-D, MADRS, and Clinical Global Impression) with “response” as the primary efficacy outcome. The percentage of patients dropping out was a proxy for intolerability. Escitalopram, mirtazapine, sertraline, and venlafaxine were ranked as the top four antidepressants for efficacy, although escitalopram and sertraline were preferred when tolerability and efficacy rankings were combined. While sample size was a major strength in this study, methodologic differences across trials may have influenced conclusions. Other studies suggest comparable efficacy between bupropion and SSRIs, as well as superiority for escitalopram compared to other SSRIs. However, many have argued that differences among first-line antidepressants are minimal. A limitation of this trial was the absence of a placebo comparison.

The subsequent meta-analysis by the same investigators involved nearly 116,500 participants. They compared the efficacy and acceptability

of 21 antidepressants with both placebo-controlled and head-to-head studies. All antidepressants were more effective than placebo. Regarding acceptability, only agomelatine and fluoxetine were associated with fewer dropouts than placebo. In head-to-head studies, agomelatine, amitriptyline, escitalopram, mirtazapine, paroxetine, venlafaxine, and vortioxetine were more effective than other antidepressants, whereas fluoxetine, fluvoxamine, reboxetine, and trazodone were the least efficacious drugs.

COURSE SPECIFIERS FOR DEPRESSIVE EPISODES. Course specifiers for depressive episodes also provide some guidance when selecting a medication. In the case of anxious distress (tense, restless, fearful, etc.), it would be preferable to select an antidepressant with established efficacy in the treatment of generalized anxiety disorder (GAD). There is also evidence that patients who display melancholic features (specifically anhedonia and lack of reactivity) may have a different response to current first-line antidepressants (e.g., SNRI and SSRI) compared to those with nonmelancholic features. Historically, patients with atypical features (preservation of mood reactivity, hypersomnia, hyperphagia, weight gain, and a heightened sensitivity to interpersonal rejection) were thought to respond better to MAOIs, but it appears that current first-line antidepressants are equally effective in patients with atypical features. Two specifiers that are most likely to influence treatment selection are "with seasonal pattern," where light therapy is recommended, at least as an adjunctive treatment, and with "mood congruent or mood incongruent delusions," where either an antidepressant/antipsychotic combination therapy or ECT is recommended.

An additional specifier in DSM-5 is MDD with mixed features. Currently, it is unclear whether patients within this subtype will continue to meet criteria for MDD or switch to bipolar disorder. Lurasidone is an appropriate first-line therapy currently and has produced improvement in both depressive and hypomanic symptoms in patients with MDD with mixed features.

SELECTING A FIRST-LINE ANTIDEPRESSANT. Generally, clinicians should select a first-line agent from the SSRI or SNRI classes. While overall efficacy is likely similar among these agents, differences in their receptor pharmacology and the adverse event profile may influence treatment

selection. For instance, the SSRI antidepressants share blockade of the serotonin (5HT) transporter as their common mechanism of action, but they differ in their actions on additional receptors. Differences among SNRI antidepressants are even more distinct. Venlafaxine, duloxetine, and desvenlafaxine preferentially block the 5HT transporter, while levomilnacipran predominantly blocks the norepinephrine (NE) transporter. Among other first-line antidepressants, differences in transporter and receptor affinities are also important, for example, activating effect of bupropion and sedating effect of mirtazapine. These differences allow clinicians to tailor the selection of antidepressants for individual patients and increase acceptability.

Some second-generation antidepressants with unique mechanisms of action also have noradrenergic effects. Bupropion is both an antidepressant and a medication for smoking cessation with predominantly noradrenergic and dopaminergic effects. It is an activating antidepressant; hence, it is frequently prescribed in combination with a more sedating 5HT-enhancing antidepressant. Mirtazapine promotes release of both 5HT and NE through blockade of α2-noradrenergic receptors. Its sedating profile is often beneficial for patients with depression and severe insomnia. Mirtazapine is also associated with weight gain. Trazodone is another antidepressant with dual effects on 5HT and NE receptors. Because of its highly sedating properties, it is more often prescribed at subtherapeutic antidepressant doses (50 to 100 mg) as a hypnotic. Nefazodone has a similar mode of action to trazodone with additional NE transporter-blocking effects. Despite a favorable efficacy profile, reports of life-threatening hepatotoxicity have resulted in the virtual discontinuation of its use. Moclobemide is a reversible inhibitor of MAO-A that may be prescribed to treat MDD without dietary precautions, although it is not available in the United States. For a list of additional side effects of antidepressants discussed above, see Table 13.6–3.

Another major consideration when choosing an antidepressant is the side effect profile of the drug and patient sensitivity to side effects. Gastrointestinal, CNS, and sexual side effects are particularly common with SSRIs, while patients with pre-existing hypertension may be more prone to further elevation in blood pressure with an SNRI such as venlafaxine. Prolongation of QTc interval has also been noted at higher doses with various antidepressants, including citalopram. The relative frequencies of side effects associated with SSRIs and SNRIs are listed in

Table 13.6–3. Clinicians need to be vigilant about the emergence of hypo(manic) symptoms during treatment with antidepressants, particularly in patients with a family history of bipolar disorder and in those who display reverse vegetative symptoms as a part of an MDE. It is important to highlight these risk factors in such patients. The risk of antidepressant-induced mood elevations in patients who meet criteria for an MDE with mixed features in the context of MDD is likely higher, and hence such patients also need to be educated and monitored closely.

While emergent suicidal ideation is of greatest concern in adolescents and young adults during antidepressant clinical trials resulting in "black box warnings" about prescribing SSRIs and other antidepressants to this age group, suicidal ideation should also be a consideration in ongoing assessment of MDD in adults. However, the relationship between increased suicidal ideation and completed suicide remains controversial. Other rare but serious adverse effects of antidepressants include the serotonin syndrome, increased upper gastrointestinal bleeding (particularly when antidepressants and nonsteroidal anti-inflammatory agents are coprescribed); hyponatremia has also been of concern, especially in older adult patients with depression, and most antidepressants, particularly bupropion reduce the seizure threshold.

NOVEL ANTIDEPRESSANTS. Several newer antidepressants exhibit serotonin multimodal actions. Vilazodone is an SSRI with additional 5HT-1A partial agonist effects, providing the effect of combining a 5HT-1A partial agonist, such as buspirone, with an SSRI. Favorable aspects of the drug include low rates of sexual side effects, lack of cardiac arrhythmias, and minimal weight gain. Vortioxetine is also a 5HT transporter blocker, with additional receptor effects including 5HT3 and 5HT7 antagonism, as well as 5HT1A and 5HT1B agonism. During clinical trial development, measures of cognition including executive function, verbal learning, memory, and processing speed were evaluated and found to be significantly improved.

Table 13.6–3.
Prevalence of Side Effects among Selective Serotonin-Reuptake Inhibitors and Serotonin- and Norepinephrine-Reuptake Inhibitors

Drug Class	Recommended Dose Range (mg)	Side Effect Frequency	
		10–30%	>30%
SSRI			
Citalopram	20–40	Nausea, dry mouth, sweating	None
Escitalopram	10–20	Male sexual dysfunction and nausea	None
Fluoxetine	20–60	Nausea, dry mouth, somnolence, nervousness, anxiety, insomnia, tremor, anorexia	None
Fluvoxamine	100–300	Dry mouth, headaches, somnolence, agitation, insomnia, sweating, tremor, anorexia, dizziness, constipation	Nausea
Paroxetine	20–60	Nausea, diarrhea, dry mouth, headaches, somnolence, insomnia, sweating, asthenia, male sexual dysfunction, dizziness	None
Sertraline	50–200	Nausea, diarrhea, dry mouth, headaches, somnolence, insomnia, fatigue, tremor, male sexual dysfunction, dizziness	None
SNRI			
Venlafaxine	75–375	Headaches, somnolence, dry mouth, dizziness, nervousness, insomnia, sweating,	Nausea

		male sexual dysfunction	
Desvenlafaxine	50–100	Dry mouth, dizziness, nausea, sweating	None
Duloxetine	30–120	Nausea, dry mouth, constipation, insomnia, male sexual dysfunction	None
Levomilnacipran	20–80	Nausea, dry mouth, headaches, male sexual dysfunction	None
Other Second-Generation and Novel Antidepressants			
Agomelatine[a]	25–50	Dizziness	None
Bupropion	150–450	Insomnia, dry mouth, nausea	Headaches
Mirtazapine	15–60	Dry mouth, constipation, increased appetite, weight gain	Somnolence
Moclobemide[a]	300–600	None	None
Vilazodone	10–40	Diarrhea, nausea, headaches	None
Vortioxetine	10–20	Nausea	None

[a]Not available in the United States.

Data from Kennedy SH, Lam RW, McIntyre RS, et al. Canadian Network for Mood and Anxiety Treatments (CANMAT) 2016 Clinical Guidelines for the management of adults with major depressive disorder: section 3. pharmacological treatments. *Can J Psychiatry*. 2016;61(9):540–560; Kennedy SH, Rizvi SJ. Chapter 246: SSRIs and related compounds. In: Stolerman I, ed. *Encyclopedia of Pharmacology*. Springer; 2010.

Agomelatine is a melatonin 1 and 2 receptor agonist. Additional 5-HT2C antagonist effects facilitate release of dopamine in the prefrontal cortex and may account for its favorable effect on anhedonia and minimal sexual side effects. This drug was also associated with elevation of hepatic enzymes and monitoring of liver function is recommended.

SECOND-LINE APPROACHES TO TREATMENT (OPTIMIZATION, SWITCHING, AND ADJUNCTIVE THERAPIES). When a patient has received at least 4 to 6 weeks of treatment with a first-line antidepressant and has shown no improvement despite a dose increase, the following options should be considered:

- further **dose increase**, particularly when the medication appears to be well tolerated;
- **switching** to a different antidepressant within the same or a different class; and
- **adjunctive therapy** with an established agent such as an atypical antipsychotic, lithium, triiodothyronine, or a second antidepressant with a different neurotransmitter action (e.g., bupropion added to an SSRI).

Invariably, optimization is the first step, particularly when the drug is well tolerated, is at a relatively low therapeutic dose or if past treatment history suggests tolerance for high doses of other medications. Extending the initial trial beyond 4 to 6 weeks is indicated if there is an incremental but slow improvement during the first 4 weeks. In a minority of instances, a dose reduction may optimize effectiveness and tolerability.

Potential advantages of switching from one monotherapy to another are cost, single drug side effects, and simpler dosing regimen. These factors are likely to be associated with improved adherence, compared to adjunctive treatment regimens. Two clinician-monitored methods for switching monotherapies are typically used. The first requires a complete tapering of the initial drug before starting the second drug. This is known as the “V-method.” The second “X-method” involves a cross-gradual tapering of the initial drug while adding the second drug. This method minimizes discontinuation-emergent symptoms and is preferred when there are similar pharmacodynamic drug profiles (e.g., switching from one SSRI to another or from an SSRI to an SNRI); however, it should not be used when the potential for a hazardous drug–drug interaction exists (e.g., switching from an MAOI drug to a TCA or SSRI).

APPLY ADJUNCTIVE STRATEGIES. In clinical practice, most adjunctive treatments are administered sequentially, adding the second agent only after the first has been ineffective or partially effective. This second-line approach was used at several stages in the STAR*D trial. In a few

studies, concurrent combined treatments have been initiated from the outset with inconclusive results. Until there are specific indications for this approach, sequential adjunctive treatments are recommended.

There is a large body of evidence to support the adjunctive use of second-generation antipsychotics (SGAs) also known as dopamine and serotonin modulators in the treatment of MDD, and TRD. Although they share a common dopamine D2 antagonist action, these agents differ in their affinities for D2, D3, and other receptors. This justifies switching from one SGA to another in the absence of a favorable response or if adverse effects of the first agent are intolerable. Based on a series of studies, the combination of olanzapine and fluoxetine was superior to either agent alone for TRD. Although the only SSRI involved in these trials was fluoxetine, it is likely that olanzapine (5 to 10 mg) would also be effective when combined with other antidepressants. Quetiapine (150 to 300 mg) is the only atypical agent to demonstrate antidepressant efficacy as monotherapy in the treatment of MDD and is also effective when combined with a range of antidepressants in patients with previous TRD. Augmentation with risperidone was efficacious in two double-blind, placebo-controlled trials. Aripiprazole (5 to 15 mg) is an effective adjunctive therapy in MDD. Interestingly, patients who either worsened or failed to improve with a first antidepressant treatment still showed significant benefits with adjunctive aripiprazole. Like aripiprazole, brexpiprazole acts as a dopamine and serotonin receptor partial agonist and has shown efficacy as an adjunctive agent in MDD. Despite similar efficacy, brexpiprazole shows improved tolerability (e.g., potentially less akathisia and extrapyramidal symptoms) compared to aripiprazole. Adjunctive treatment with ziprasidone in a TRD trial was not significantly better than continuation of the SSRI (sertraline), supporting the view that SGA adjunct efficacy is not a class effect but depends on the individual receptor profiles of these agents. Cariprazine (see bipolar section) acts as a partial agonist at the dopamine D3, D2, and 5-HT1A receptors, it is an antagonist at the 5-HT2A receptors. Cariprazine is currently approved for both manic and depressive episodes of bipolar disorder and is under investigation as an adjunctive agent for MDD treatment. Although SGAs provide a valuable additional treatment option for TRD, their potential to cause serious side effects, including weight gain, dyslipidemia, hyperglycemia, akathisia, extrapyramidal symptoms, and QTc interval prolongation, is of concern. This is most relevant when long-term

treatment is anticipated. An unanswered question is how long to continue any adjunctive agent particularly when the additional therapy carries a hazardous side effect burden (e.g., weight gain or hyperlipidemia).

Several agents including lithium, triiodothyronine (T3), and buspirone have been displaced as first-line adjunctive agents in favor of SGAs. Most studies of lithium involved augmentation of TCAs and the daily dose varied widely (250 to 1,200 mg); nevertheless, two recent meta-analyses support the efficacy of adjunctive lithium therapy. There is also limited support for the use of T3 at a dose of 25 to 50 μg/day as an augmentation strategy. At the third level of treatment in STAR*D, lithium, and T3 both produced modest increases in remission. Buspirone, a partial postsynaptic 5-HT1A agonist, was also evaluated in the STAR*D trial and was comparable in effectiveness to bupropion in some, but not all, outcome measures in the augmentation of citalopram.

When patients fail to respond to the above strategies, psychotherapy, and various forms of neurostimulation should be considered. Among the psychotherapies, most evidence supports CBT or modified versions including internet-based CBT (refer to section on psychotherapy).

Electroconvulsive therapy (ECT) (refer to neurostimulation section) is very effective in antidepressant treatment-refractory patients with response rates as high as 70% and is specifically indicated for certain groups of patients with depression, including those with acute suicidal ideation or with mood congruent or incongruent delusions. Among subsequent forms of neurostimulation, repetitive transcranial magnetic stimulation (rTMS) has the most evidence to support its role as an adjunctive treatment.

CONSIDER THIRD-LINE ANTIDEPRESSANTS. The use of tricyclic and MAOI antidepressants is limited by their potential for side effects and toxicity. Nevertheless, they should be considered for particularly difficult-to-treat cases of depression. Among the TCAs, amitriptyline is the most evaluated. It has mixed reuptake inhibition effects on both 5HT and NE transporters with additional cholinergic, histaminergic, serotonergic, and noradrenergic receptor actions. These multiple effects are responsible for the wide range of side effects including sedation, weight gain, urinary retention, and cardiac conduction defects. Nortriptyline is a metabolite of amitriptyline that was previously recommended to treat late-life depression due to a less severe side effect profile. Imipramine, desipramine, and

clomipramine are also TCAs that are typically reserved for third-line use, although clomipramine is indicated for the treatment of obsessive-compulsive disorder (OCD) and not MDD in the United States. In all cases, plasma monitoring may be helpful in determining appropriate doses.

Tranylcypromine, phenelzine, and isocarboxazid are irreversible inhibitors of both MAO-A and MAO-B. While this mode of action provides a broad-spectrum inhibition of monoamine reuptake and a favorable antidepressant effect, it also increases the risk of orthostatic hypotension, and in the presence of tyramine-rich foods may produce a life-threatening hypertensive crisis. This necessitates a low tyramine diet during MAOI treatment. Hence, these agents are generally reserved for otherwise treatment-resistant patients. Selegiline is an irreversible inhibitor of MAO-B that has been used as an adjunct therapy for Parkinson disease and is available in both oral and transdermal patch delivery systems to treat MDD. Its use is generally restricted to TRD patients. Moclobemide is a selective and reversible MAO-A inhibitor with a generally safer tolerability profile, although it is not approved for use as an antidepressant in the United States.

Future Directions. Tailoring management to a selective subgroup of patients shows promising results as demonstrated in a precision medicine–based, “fast-fail” approach there is evidence that engaging κ-opioid-receptor antagonism improves reward-circuit dysfunction and anhedonia in MDD. This approach aims to eliminate ineffective therapies at an early phase of clinical trials, thereby avoiding costly large trials that fail to show efficacy.

Ketamine and its enantiomer esketamine, both N-methyl-D-aspartate (NMDA) receptor antagonists display antidepressant efficacy as adjunctive agents in TRD, delivered respectively as intravenous and intranasal formulations. Current practice involves four to six ketamine infusions over 2 to 3 weeks as an initial course of treatment, but there are no clear guidelines on maintenance therapy. In the case of esketamine, continuation treatment once weekly or once every 2 weeks proved superior to antidepressant plus placebo in delaying relapse. There is still a lack of consensus on postketamine/esketamine maintenance treatment. Adverse behavioral (e.g., dissociative symptoms) and physiologic (e.g., hypertension) events require careful monitoring during treatment.

Ketamine has also been administered in oral, intranasal, sublingual, and intramuscular (IM) formulations particularly in combination with psychotherapy, but variability of absorption through these routes makes it difficult to identify appropriate doses for these routes of administration.

Although there is considerable interest in the adjunctive role of anti-inflammatory agents to treat MDD, no single compound has emerged with clear antidepressant benefits. Evidence that proinflammatory cytokines such as interleukin 1 (IL-1) and IL-6 are frequently elevated in depression has stimulated interest in the potential role of anti-inflammatory agents as antidepressants. Celecoxib, minocycline, and infliximab are examples of anti-inflammatory agents with potential antidepressant properties. Pramipexole, a D3 dopamine agonist has been shown to relieve depression in Parkinson disease and at higher doses in patients with TRD, including bipolar disorder.

The past decade has seen a revival in human psychedelic drug research. One of the earlier studies (2016) demonstrated that administering a single, 25-mg psilocybin (magic mushroom) dose with psychotherapy for resistant depression markedly reduced depressive symptoms from 1 week to 3 months after treatment. Since then, trials have continued to expand for wider populations including patients with terminal illness, PTSD, and substance use disorders. In a recent double-blind, randomized controlled trial psilocybin was comparable to escitalopram in reducing depression. Other psychedelic agents including LSD and MDMA are also being investigated.

Maintaining Remission

Address Risk Factors for Relapse and Recurrence. The primary aim of maintenance treatment is to prevent the recurrence of a new episode. It should be considered for patients with MDD who have experienced recurrent episodes or PDD. Maintenance medication is more effective than placebo in virtually all studies to date. Given the high rate of relapse for individuals who have had three or more episodes, maintenance therapy is recommended.

In general, the management of PDD is not significantly different from that of MDD. While there may be differences in the tailoring of treatment plans based on symptom severity, and chronicity, the general principles of pharmacotherapy and psychotherapy remain the same. The cognitive-behavioral analysis system of psychotherapy (CBASP) is typically

recommended for the treatment of PDD, but it has yet to become a standard of care and other evidence-based psychotherapies including cognitive behavioral therapy and interpersonal therapy should also be considered.

Patients who consistently relapse following antidepressant discontinuation, those with recurrent psychotic episodes, persistent residual symptoms, or a strong family history of mood disorders are candidates for prolonged maintenance therapy. In any of these circumstances, clinicians and patients should decide collaboratively whether to initiate maintenance treatment or to maintain contact and rapidly reinstate treatment if there are emergent symptoms. If a new episode develops when the patient is free of treatment, then early intervention shortens the length of the new episode. There are virtually no data to suggest when to discontinue maintenance medication, although a study examining the impact of discontinuing venlafaxine after either 1 year or 2 years of maintenance treatment supported the benefits of longer-term treatment. When the decision to discontinue treatment is made, careful monitoring is required during gradual discontinuation, particularly for the first 6 months as this is a high-risk period for recurrence.

TREATMENT OF BIPOLAR DISORDERS

The discovery of the utility of atypical antipsychotics and some anticonvulsants such as valproate and lamotrigine for bipolar disorder in the 1990s heralded a new era in the pharmacologic treatment of bipolar disorders. The availability of several newer treatments for the management of bipolar disorder has presented clinicians with further options to tailor the treatment to suit individual patient needs based on efficacy, safety, tolerability, and patient preferences. The past two decades have also witnessed significant progress in understanding the adjunctive role of psychological and behavioral treatments in managing bipolar disorder.

This section will address the foundations of the management of bipolar disorder and specific treatment options for the management of mania, bipolar depression, and prophylaxis of bipolar disorder. Clinical recommendations are provided for the management of each phase of bipolar disorder with guidance on first-, second-, and third-line choices, but it is important to acknowledge that these recommendations are mainly

applicable to bipolar I disorder. This section also briefly covers the management of bipolar II disorder as well as the management of comorbidity in bipolar patients. The reader is advised to refer to other sections in the textbook for managing bipolar disorder during pregnancy and the postpartum period as well as in children and adolescents, and older adults.

Foundations of Management

Diagnose and Intervene Early. Although mania is the defining feature of bipolar I disorder, depressive episodes and subsyndromal depressive symptoms are more predominant in the overall course of bipolar I disorder. Indeed, prospective cohort studies suggest that patients with bipolar I disorder spend more time (a ratio of 3:1) experiencing depressive episodes/symptoms than manic episodes/symptoms. Depressive symptoms are even more prevalent in bipolar II patients, with the average patient spending 37 times more days experiencing depressive symptoms than hypomanic symptoms.

Patients with bipolar disorder are also more likely to seek help when they are depressed and often are not aware or do not easily identify information about previous manic/hypomanic episodes. Hence, clinicians must be vigilant to the possibility of bipolar disorder in every patient presenting with depressive symptoms. Studies suggest that about two-thirds of patients with bipolar disorder are misdiagnosed initially, and major depressive disorder is the most common misdiagnosis. While screening instruments such as the Mood Disorders Questionnaire are useful, they do not replace a thorough clinical assessment that systematically probes for a previous history of manic/hypomanic symptoms. The probabilistic approach, which takes into account the presence or absence of certain clinical or disease variables, can also assist in the diagnostic evaluation process. For instance, the probability of depression being part of a bipolar disorder is higher in patients who have a family history of bipolar disorder and if their depressive episode includes psychotic features, reverse vegetative symptoms, or mood lability as a part of their clinical presentation. Management decisions can then be informed based on the level of probability of having bipolar disorder. In the context of diagnostic uncertainty, patients with a very high likelihood may benefit from a focus on treatments used for bipolar disorder, whereas those with a low likelihood of bipolar disorder may be reasonably treated

for nonbipolar depression, but with ongoing monitoring for the emergence of any manic/hypomanic symptoms.

Early intervention has the potential to improve outcomes in bipolar disorder. Indeed, studies in first-episode mania patients suggest that those that remain episode-free after their first manic episode show improvements (reversal of cognitive deficits) in cognitive functioning and minimal decline in age-related gray matter volumes.

Conduct Systems Review, Baseline Investigations, and Implement Safety Monitoring for Psychotropic Medication. In addition to obtaining a comprehensive psychiatric history to diagnose bipolar disorder, clinicians are advised to conduct a systems review of medical history with particular attention to personal and family history of cardiovascular, endocrine, and metabolic disorders as the incidence of medical comorbidities is higher in bipolar patients compared with the general population. Many psychotropic medications have a tendency to cause weight gain, and some are associated with an increased likelihood of metabolic syndrome. Therefore, it is important to conduct some baseline laboratory investigations and obtain weight and waist circumference as early as possible in the treatment course, ideally baseline prior to initiating pharmacotherapy (see Fig. 13.6–1 for details) for bipolar disorder. Patients that require treatment with lithium, valproate, carbamazepine, or atypical antipsychotics need additional specific lab investigations prior to initiating treatment. During follow-up visits, clinicians are advised to routinely monitor for medication-induced adverse events at each scheduled clinical follow-up and institute appropriate strategies to address them. Patients should have weight, appropriate laboratory investigations, and serum levels of lithium, valproate, or carbamazepine measured at regular intervals as outlined in Figure 13.6–1.

FIGURE 13.6–1. Recommendations for treatment monitoring in bipolar disorder. (Adapted with permission from Ng F, Mammen OK, Wilting I, et al. The International Society for Bipolar Disorders (ISBD) consensus guidelines for the safety monitoring of bipolar disorder treatments. *Bipolar Disorders.* 2009;11(6):559–595. © 2009 The Authors. doi: 10.1111/j.1399-5618.2009.00737.x.)

Treat the Disorder and Not Just Acute Episodes. Pharmacotherapy is the cornerstone of the management of bipolar disorder. When initiating treatment of acute episodes, while stabilization of the acute episode is the immediate goal, it is essential for clinicians to bear in mind that bipolar disorder is a recurrent illness, and hence prevention of further mood episodes is an equally important consideration in treatment selection. Therefore, when choosing a medication to treat an acute episode, those options that have proven efficacy in treating not only the index episode but also in preventing the recurrence of both manic and depressive episodes should be considered first before selecting medications that have efficacy for only acute episodes. There is growing consensus that mood episode recurrences are “toxic” to the brain and are associated with cumulative reductions in brain volumes, lower brain-derived neurotrophic factor (BDNF) levels, cognitive impairment, and poorer response to pharmacotherapy, and thus prevention of recurrence of mood episodes is paramount in the management of bipolar disorder. Consensus is growing that prophylaxis should be offered for all patients with bipolar disorder, including for those after the first manic episode, as prospective naturalistic cohort studies suggest that 60% to 75% of first-episode manic patients experience a recurrence within 4 years. Adjunctive psychological treatments such as psychoeducation promote treatment adherence and reduce the risk of relapse of mood episodes in bipolar patients, and hence should be initiated as soon as the patient is amenable to such strategies.

Treat Acute Episodes to Full Remission. Acute manic, hypomanic, and depressive episodes must be treated to full and sustained remission. This is because several studies now suggest that residual subsyndromal mood symptoms not only significantly affect the quality of life and functioning but also strongly predict relapse of subsequent full-blown mood episodes. Patients who recovered from an index mood episode with residual mood symptoms experience a new episode 3.4 times sooner than those that recovered from an index episode with no residual symptoms. Median time to recurrence of a mood episode is five times shorter in those with residual symptoms compared with those with full recovery from an index episode.

Assess for and Treat Comorbidities. Psychiatric and medical comorbidities are common in bipolar disorder. While the estimates of the prevalence vary, at least 75% of patients with bipolar disorder have at

least one-lifetime comorbid psychiatric disorder. Alcohol or substance use disorders are present in at least 40% of patients, and some type of anxiety disorder is present in 50% to 75% of patients. There is evidence that patients with alcohol and substance use disorders or anxiety disorder comorbidities take longer to recover from an index episode and are more likely to relapse compared with those without these comorbidities. Hence, the optimal management of bipolar disorder should include not only treatment of mood symptoms/episodes associated with this condition but also assessing for comorbidities and instituting appropriate pharmacologic/psychological management strategies to address comorbidities in order to improve outcomes. During the maintenance treatment, clinicians should routinely monitor for the onset of new psychiatric, substance, or alcohol use comorbidities and manage them as clinically indicated.

Address Cognitive Impairment. Patients with bipolar disorder often complain of cognitive difficulties. A thorough clinical assessment should be conducted in such patients to address contributory factors such as comorbid substance use (e.g., marijuana), psychotropic medication-induced confusion or sedation, lithium-induced hypothyroidism, valproate-induced hyperammonemia, etc. for cognitive difficulties. Evidence has accumulated over the past 20 years to suggest that cognitive dysfunction can be an inherent part of bipolar disorder for nearly two-thirds of patients. Impairments are seen in several domains, including processing speed, verbal learning, working memory, and executive function, and such impairments are present not only during acute mood episodes but even during euthymic periods. The effect sizes for the magnitude of impairment during euthymia are in the range of 0.6 to 0.8. Cognitive impairments, particularly in the domains of verbal learning and executive function, correlate with functional impairments. There is increasing interest in examining the efficacy of pharmacologic treatments and cognitive remediation to address cognitive dysfunction. While evidence for efficacy is limited, there is early preliminary data supporting the use of lurasidone or nonpharmacologic interventions such as cognitive remediation.

Monitor for Treatment Adherence. While the rates of treatment nonadherence vary depending upon how it is defined, there is evidence that up to 60% of patients with bipolar disorder are nonadherent or poorly adherent to pharmacotherapy. The consequences of poor adherence to

pharmacotherapy include illness destabilization with increased relapse/recurrence of mood episodes, higher suicide risk, increased hospitalization, disability, and poor functioning. Several factors such as poor insight/denial of illness, concerns about or experience of side effects of medications, inadequate efficacy of medications, younger age, low level of education, or cognitive impairment all contribute to poor treatment adherence. It is important for clinicians to be cognizant of demographic variables and explore illness-related factors, attitudes toward illness, and treatment-related factors that predict poor adherence and address them routinely at clinical follow-up visits. There is evidence that psychoeducation improves treatment adherence. More recently, customized treatment adherence programs have been developed that include modules on psychoeducation, substance abuse, medication routines, and communication with providers, and these programs can be tailored to address the specific reasons for the treatment of nonadherence in individual patients.

Monitor for the Emergence of Mood Symptoms and Suicide Risk. There is evidence that bipolar patients with subsyndromal mood symptoms are more likely to relapse into a full-blown mood episode compared with those without such symptoms. Therefore, it is prudent for clinicians to routinely screen for emergent subsyndromal symptoms at each clinical visit. Clinicians may find the Young Mania Rating Scale (YMRS) and MADRS particularly helpful in systematically assessing and quantifying subsyndromal symptoms. The reasons for the emergence of such symptoms may include poor treatment adherence, comorbidity, or partial efficacy of ongoing treatments, which should be identified when possible and addressed with psychoeducation or changes to pharmacotherapy as appropriate in order to rapidly resolve such symptoms. Subsyndromal depressive symptoms can also be treated with psychological strategies such as interpersonal and social rhythm therapy (IPSRT) or CBT.

Clinicians should also routinely monitor for the emergence of suicidal ideation not only when treating acute episodes but also during the maintenance treatment. This is because suicidal ideation is common in patients with bipolar disorder and that between 25% to 50% of patients with bipolar disorder make a suicide attempt at least once during their lifetime. The rates of lifetime risk of suicide deaths in bipolar patients

range from 6% to 19% depending on the sample, with more recent studies in less severely ill populations suggesting lower rates. Regardless, the standardized mortality ratios for suicide in bipolar disorder patients range from 10 to 30, which means that bipolar patients are 10 to 30 times more likely to die of suicide compared with the general population. A recent International Society for Bipolar Disorders (ISBD) Task Force identified several risk factors for suicide attempts and suicide deaths (see Table 13.6–4) in bipolar disorder.

Clinicians should be more vigilant for suicidal ideation and other warning signs of suicide in those with an increasing number of risk factors. The risk of suicide attempt and suicide death is higher early in the course of the illness, during acute mood episodes (especially in the presence of mixed features) or hospitalization, and within 4 to 12 weeks of discharge from the hospital. When suicidal ideation is endorsed, clinicians must take appropriate steps immediately to ensure the safety of the patient, and these may include hospitalization, preventing/reducing access to methods of suicide (e.g., medication overdose, access to firearms), establishing a therapeutic alliance, and involving family members/friends when possible in care, and addressing the illness-related and psychosocial factors that led to the emergence of suicidal ideation.

Table 13.6–4.
Factors Associated with Suicide Attempts and Suicide Deaths in Bipolar Disorder

Variables	Increased Likelihood of Suicide Attempts in Bipolar Disorder	Increased Likelihood of Suicide in Bipolar Disorder
Sociodemographics		
Sex	Female	Male Females have higher SMR
Age	Younger Older age—higher lethality attempts	No clear effect Older age—higher ratio of deaths/attempts
Race	Minorities—specific to youth only	
Marital status	Single, divorced, single parents	
Religious affiliation	Discordant results	
Characteristics of Bipolar Disorder		
Age of illness onset	Younger age	
Duration of illness	Discordant results	
Polarity of 1st episode	Depression Mixed symptoms Mania—more violent attempts	
Predominant polarity	Depressive	
Polarity of current episode	Depressive episodes Mixed states	Depressive episodes Mixed states Manic states with psychotic features
Other mood episode	Mixed features	Hopelessness

characteristics	Greater number and severity of episodes/rapid cycling Anxiety Atypical features Suicidal ideation	Psychomotor agitation
Psychosis at any time	Discordant results	No effect
Bipolar disorder subtype	No clear effect	No clear effect
Comorbidities		
Psychiatric comorbidity	Substance use disorder Cigarette smoking Coffee intake Anxiety disorder Obesity or high BMI Eating disorder	Substance use disorder—no clear effect Anxiety disorder
Personality disorders and characteristics	Personality disorders—including borderline or cluster bipolar disorder in particular Aggression or irritability Impulsivity (discordant results)	
Other Clinical Variables		
First-degree family history	Mood disorders Bipolar disorder Suicide	Mood disorders Bipolar disorder Suicide
Prior suicide attempts	Presence	Presence
Early life trauma	Childhood abuse Higher early-life stress	
Psychosocial precipitants	Interpersonal problems Occupational problems Bereavement	Present within a week prior to death
Sexual	Presence	

dysfunction

SMR, standardized mortality ratio.

A review of factors associated with greater likelihood of suicide attempts and suicide deaths in bipolar disorder: part II of a report of the International Society For Bipolar Disorders Task Force on suicide in bipolar disorder. *Aust N Z J Psychiatry*. 2015;49(11):1006–1020.

Acute Mania: Treatment Options

Lithium. There is robust evidence for the efficacy of lithium in treating acute mania. When adequately dosed, the therapeutic effect of lithium becomes apparent within 7 days as the separation from placebo was seen as early as day 7 in clinical trials. While the response rates to lithium varied between the trials, on average, about 50% of patients met the criteria for response to lithium in these 3-week trials.

Lithium is typically started at 900 mg/day, although lower starting doses may be required for some patients who are more sensitive to side effects. Serum levels should be measured after 5 days of consecutive therapy, 12 hours after the last dose. Serum levels between 0.8 and 1.2 mEq/L are likely required to treat acute mania effectively, although lower levels (0.4 to 0.8 mEq/L) may be appropriate in older adults. Lithium levels of ≥1.5 mEq/L can lead to symptoms of lithium toxicity, and this should be treated as a medical emergency. Patients should be educated and clinically monitored for signs of lithium toxicity that may include gastrointestinal (vomiting and diarrhea), neurologic (coarse tremor, agitation, dysarthria, drowsiness, lethargy, ataxia), renal (polyuria and polydipsia), and cardiovascular (syncope, dizziness, arrhythmias) symptoms.

Anticonvulsants

CARBAMAZEPINE. Carbamazepine is as effective as lithium and typical antipsychotics in treating acute mania. Carbamazepine extended-release (ER) is also effective, with response rates between 40% and 60% that are similar to the aggregate response rates of 52% observed with carbamazepine in older studies.

Carbamazepine is typically started at 100 to 200 mg bid, and the dose is gradually titrated upward to achieve a therapeutic effect. Most patients will need between 400 and 800 mg/day. The therapeutic effect is observed typically within 1 week to 10 days. There is no evidence to suggest a

relationship between serum carbamazepine levels and acute therapeutic efficacy in mania.

OXCARBAZEPINE. While oxcarbazepine may be better tolerated than carbamazepine, the data for its efficacy in treating acute mania is conflicting. While four small controlled studies in adult manic patients support the efficacy, a recent larger clinical trial in children and adolescents with mania that compared oxcarbazepine with placebo found no differences in improvement in manic symptoms between the two groups. Given the lack of larger placebo-controlled trials in adults with modern methodology and a negative trial in children and adolescents with acute mania, further studies are clearly needed to determine the efficacy of oxcarbazepine for acute mania. This statement is consistent with a recent Cochrane review which concluded that there is currently insufficient evidence for the efficacy of oxcarbazepine in treating acute mood episodes in bipolar disorder.

DIVALPROEX/VALPROATE. Divalproex consists of sodium valproate and valproic acid in a 1:1 molar ratio. The landmark trial by Bowden and colleagues (1994) that compared the efficacy of divalproex with placebo and lithium led to the approval of divalproex for the treatment of acute mania. Divalproex is as effective as lithium in adult manic patients. Two out of three studies that compared divalproex with olanzapine showed similar efficacy at 3 weeks. Divalproex has similar efficacy to quetiapine in treating acute mania in adolescents.

The therapeutic effect of divalproex is apparent by day 7, although studies with divalproex oral loading (20 mg/kg/day or 30 mg/kg/day on days 1 and 2 followed by 20 mg/kg/day) suggest a more rapid onset of action with effect apparent by day 5 or sooner. Posthoc analyses of data from these trials suggest that divalproex has a broader spectrum of efficacy with effect in manic patients with and without concurrent depressive symptoms, psychotic symptoms, rapid cycling, and regardless of the number of prior mood episodes.

There is a linear relationship between serum valproate levels and therapeutic efficacy for acute mania, with higher serum levels yielding greater efficacy. The evidence suggests that optimal efficacy may not be obtained when serum levels are below 94 μg/mL. Hence, clinicians should titrate the dose of valproate to achieve serum valproate levels to this

target range. If tolerability is not a concern, the doses could be further increased if necessary as some patients may require higher levels for optimal efficacy.

OTHER ANTICONVULSANTS. Lamotrigine, gabapentin, topiramate, and licarbazepine are not effective in treating acute mania as none are separated from placebo in controlled clinical trials in improving manic symptoms. Lamotrigine or topiramate adjunctive therapies are also ineffective in treating acute mania.

Other anticonvulsants such as tiagabine, pregabalin, levetiracetam, felbamate, and zonisamide have not been assessed in randomized, double-blind controlled trials for acute mania.

Conventional/First-Generation Antipsychotics. Haloperidol is the most widely investigated first-generation antipsychotic for acute mania. Several modern placebo-controlled trials of atypical antipsychotics such as risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole used haloperidol as an active comparator. In all these studies, haloperidol was more effective than placebo, confirming the efficacy of haloperidol in treating acute mania.

The efficacy of haloperidol was apparent at early as day 2 in some trials. The doses of haloperidol used in these trials ranged from 2 to 15 mg per day, although in the ziprasidone trial, up to 30 mg/day of haloperidol was allowed. These studies demonstrated that haloperidol was as effective as risperidone, olanzapine, and aripiprazole and more effective than quetiapine and ziprasidone. Extrapyramidal symptoms are common with haloperidol, and patients with bipolar disorder are more prone to movement disorders such as tardive dyskinesia. Furthermore, more patients treated with haloperidol experienced depression in some of these trials compared with placebo or atypical antipsychotics.

It is believed that the efficacy of haloperidol for acute mania is related to its ability to reduce dopamine transmission through the blockade of dopamine D2 receptors. Since all conventional antipsychotics reduce dopamine transmission through their effects on D2 receptors, they are likely effective in treating acute mania. Chlorpromazine has been compared with lithium and found to have similar efficacy overall, although it appears to be more effective in “highly active” manic patients, which is likely related to its sedating effects, while lithium has better efficacy in

treating core manic symptoms. The loxapine-inhaled formulation is effective y in treating agitation in acutely manic patients and found to be effective, but its utility in treating core manic symptoms has not been assessed in placebo-controlled trials.

Haloperidol in combination with lithium or valproate is more effective than lithium or valproate monotherapy. Similarly, valproate add-on to haloperidol/perphenazine is more effective than monotherapy with haloperidol/perphenazine.

Atypical Antipsychotics

MONOTHERAPY. Several atypical antipsychotics are currently in use for the treatment of psychosis. Of these, risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, paliperidone, asenapine, and cariprazine have proven efficacy and hence approved for the treatment of acute mania in select countries. Cariprazine, a new atypical antipsychotic with D2 and D3 partial agonist properties, is effective and was recently approved by the FDA for the treatment of acute mania. Table 13.6–5 provides a summary of the efficacy of atypical antipsychotics and the dose ranges commonly used in clinical practice. Clozapine and lurasidone are likely effective, but no placebo-controlled trials have assessed their efficacy for acute mania to date. Surprisingly, brexpiprazole was not found to be effective for acute mania in RCTs and hence is not recommended.

The only study that compared two atypical antipsychotics head-to-head found no difference in efficacy between risperidone and olanzapine for acute mania. While other atypical antipsychotics have not been compared directly in double-blind, controlled trials, there is no reason to believe that there are any clinically meaningful significant differences in efficacy between various atypical antipsychotics, given the broad similarity in effect sizes and placebo-corrected response rates.

Table 13.6–5. Atypical Antipsychotics for Bipolar Disorder: Efficacy Summary and Dose Ranges

Drug	Dose Range (mg)	Efficacy: Acute Mania	Efficacy: Acute Depression	Efficacy: Prevents Mood Episodes	Efficacy: Prevents Mania	Efficacy: Prevents Depression	Comments
Olanzapine	5–20	Yes	?Yes[1] (see comments)	Yes	Yes	Yes[2]	[1]Improvement was seen mostly in sleep, appetite and inner tension but not in core depressive symptoms [2]Magnitude of benefit for depression less than for mania
Risperidone	1–6	Yes	No data	[1]Yes	[1]Yes	No	[1]Prophylactic efficacy was demonstrated with Risperdal Consta but no studies with oral risperidone
Quetiapine	300–800[1]	Yes	Yes	Yes	Yes	Yes	[1]For bipolar depression, 300 mg/day is as effective as 600 mg/day (see text for guidance) Appears to have equal efficacy in preventing both mania and depression
Ziprasidone	80–160	Yes	No	[1]Yes	[1]Yes	No	[1]Prophylactic demonstrated for adjunctive therapy but no data for monotherapy
Aripiprazole	15–30	Yes	No	Yes	Yes	No	
Paliperidone	6–12	Yes	No data	[1]Yes	Yes	No	[1]Less effective than olanzapine in preventing mood episodes
Asenapine	10–20	Yes	No data	Yes	?Yes	?Yes	Numerically fewer patients in the asenapine group had relapse of manic and depressive episodes but the differences were not significant
Cariprazine	1.5–12[1]	Yes	Yes	No data	No data	No data	[1]For bipolar depression, 1.5–3 mg/day is recommended, while for mania, up to 6 mg/day is appropriate
Lumateperone	42 mg	No data	Yes	No data	No data	No data	Currently under FDA review
Lurasidone	40–120	No data	Yes	?	?	?	The adjunctive therapy study just missed statistical significance. Posthoc analysis showed efficacy in preventing mood episodes in patients with index depressive episode

If a medication is effective rapidly, it can shorten the duration of the manic episode and the hospital length of stay. When atypical antipsychotics are dosed adequately, some improvement in manic symptoms is apparent typically within the first week with all atypical antipsychotics. While there is a perception that sedating atypical antipsychotic drugs may have a more rapid onset of action, this is not borne out in clinical trials. For instance, although aripiprazole and ziprasidone are less sedating, their therapeutic effects on mania were apparent at first postbaseline measurements of day 4 and day 2, respectively, in clinical trials.

DSM-5 has eliminated the mixed episodes category and introduced mixed features as a course specifier for manic as well as depressive episodes. This is to reflect the fact that the symptoms of opposite polarity are present in nearly two-thirds of patients with acute mania or acute depression. Therefore, it is not surprising that several acute mania trials with atypical antipsychotics have included some patients with various definitions of mixed episodes or symptoms. Posthoc analyses from these trials suggest that asenapine, cariprazine, ziprasidone, aripiprazole, or olanzapine are effective in treating manic symptoms in patients with acute

mania with mixed features, while asenapine, cariprazine, and ziprasidone also have some data supporting treatment of mixed depressive features during acute mania. Further, a meta-analysis suggests that atypical antipsychotics as a group are effective in treating acute mixed episodes, and the effect size for their efficacy in treating mixed episodes is in the medium range which is similar to their magnitude of effect in manic patients. Based on this, it is reasonable to conclude that atypical antipsychotics, unlike conventional first-generation antipsychotics, at the very least do not worsen or induce depressive symptoms in manic patients.

COMBINATION/ADD-ON THERAPY. There is evidence that as many as 80% of manic patients in clinical settings are treated with a combination of a mood stabilizer and an antipsychotic. In some cases, both medications are started at the same time (combination therapy), while in other cases, one medication is started, and the other is added at a later point (add-on therapy).

In clinical trials of add-on therapy, although patients met entry criteria for mania severity, refractoriness to existing therapy was not established prospectively in many studies. Hence, it is unknown if the add-on studies truly assessed the efficacy in refractory manic patients.

Regardless, there is evidence that response rates are greater when manic patients are treated with a combination/add-on of risperidone, olanzapine, quetiapine, aripiprazole, or asenapine with lithium or valproate compared with lithium or valproate monotherapy. On average, 20% more manic patients will respond with combination/add-on therapy compared with lithium or valproate monotherapy. While different combinations of treatments are not directly compared, based on differences in response rates observed between monotherapy and combination therapies in various studies, there does not appear to be any clinically meaningful differences between different combinations of atypical antipsychotic and lithium or valproate. The only exception is ziprasidone adjunctive therapy which was not superior to lithium or valproate monotherapy in the only clinical trial that assessed this strategy.

There is preliminary evidence that adding an atypical antipsychotic to carbamazepine does not confer additional efficacy. For instance, risperidone or olanzapine combined with carbamazepine is no more effective than carbamazepine monotherapy. This is likely because

carbamazepine, through induction of hepatic microsomal enzymes, reduces serum levels of antipsychotics and thus affects their efficacy. In theory, this could be overcome with higher doses of the atypical antipsychotic, but that has not been tested in a controlled fashion.

Some clinicians believe that antipsychotic monotherapy is as effective as the combination strategy. There is preliminary evidence to suggest that this is clearly not the case. For instance, a large double-blind trial suggested that lithium given in combination with quetiapine XR was more effective than quetiapine XR monotherapy. Similarly, valproate in combination with haloperidol/perphenazine was more effective than monotherapy with an antipsychotic.

It is, however, important to note that greater efficacy of combination therapy comes with a trade-off in terms of adverse events as combination therapy is often associated with more adverse events than monotherapy.

Miscellaneous Agents. Tamoxifen, a drug used in the treatment of breast cancer, is a protein kinase c (PKC) inhibitor. There is evidence that treatment with lithium or valproate alters the PKC signaling pathway and, more specifically, reduces specific isoforms of this enzyme. There is evidence from five small double-blind RCTs (two monotherapy and three adjunctive therapies) that tamoxifen is effective in treating acute mania. However, clinicians must be aware that tamoxifen use in patients with breast cancer is associated with a two- to sevenfold increase in endometrial carcinoma. Further, there is no longer-term safety data for tamoxifen in bipolar patients. Similarly, two RCTs demonstrated that endoxifen, an active metabolite of tamoxifen, is as effective as valproate in treating acute mania at doses of 8 mg/day.

Verapamil was reported to be effective in two small earlier controlled trials and some open trials, but a larger double-blind, placebo-controlled trial found no evidence for the efficacy of verapamil in treating acute mania. Two very small trials suggest that nimodipine may be useful in treating manic symptoms, but larger trials are needed before any conclusions about its efficacy can be drawn. There is some evidence that clonazepam is useful in treating acute manic symptoms. While calcitonin was reported to be effective in treating acute manic symptoms in a trial conducted in the 80s, a more recent double-blind trial that compared calcitonin nasal spray versus saline nasal spray in refractory manic

patients found no difference between the two groups. Celecoxib adjunctive therapy has shown efficacy in two small RCTs.

Clinical Recommendations for the Management of Acute Mania

Manic episodes can be a part of bipolar I disorder or secondary to an underlying medical condition, neurologic condition, head injury, substance use disorder (e.g., cocaine or amphetamines), or induced by medications such as steroids. When possible, verbal de-escalation techniques should be tried to calm the manic patient and obtain a thorough psychiatric and medical history. Manic patients are often uncooperative and lack insight; collateral information is vital in such cases. Patients should be assessed for the risk of aggressive behavior, the severity of mania, the presence of psychotic features, and insight, all of which inform the clinician about the treatment setting for further management. Patients with severe mania and aggressive behavior with little insight will require hospitalization, while those with mild-to-moderate mania may be treated in an outpatient setting if adequate family support is available and if the patient has some insight.

A thorough review of medication history should be conducted. If a patient had been taking antidepressant medication, this should be discontinued. Similarly, other medications that might be potentially contributing to manic symptoms, such as stimulants or steroids, should be discontinued. A physical examination and appropriate baseline medical investigations should be conducted before definitive pharmacologic treatment is instituted, although this may not be possible in some cases. If the patient has a history of substance use, this should be simultaneously addressed while mania is being treated. Psychoeducation should commence as soon as the patient is behaviorally stabilized and is amenable.

Management in an Emergency Setting. Patients presenting with a manic episode in an emergency setting are often agitated, irritable, uncooperative, and lack insight. In some cases, they may be verbally or physically aggressive and may escalate to becoming assaultive and violent. Hence, ensuring the safety of the acutely manic patient and those around is a high priority. It is important to move the patient to a low stimulus and comfortable environment as soon as possible.

The severity of agitation and aggressive behavior and the patient's willingness to accept treatment dictate whether medications can be given

orally or in an injectable form. Oral medications are less likely to disrupt the therapeutic alliance and hence are preferable but have the disadvantage of slower onset of action. Further, although oral administration of benzodiazepines such as lorazepam, first-generation antipsychotics such as haloperidol and loxapine, and SGAs (risperidone, olanzapine, quetiapine, aripiprazole, ziprasidone, asenapine) is a common clinical practice in the emergency setting to control agitation and aggressive behavior, they are not widely studied in controlled clinical trials for efficacy in treating agitation and aggressive behavior in mania. Nevertheless, clinicians often employ this strategy in many parts of the world. While haloperidol and several SGAs have proven efficacy in treating acute mania, there is little evidence to suggest that lorazepam is effective in treating core manic symptoms, although this may be useful in controlling agitation and calming the patient. Hence lorazepam monotherapy for controlling agitation in mania is not recommended, but this can be given in conjunction with an antipsychotic and, in particular, first-generation antipsychotics such as haloperidol to reduce the risk of extrapyramidal symptoms and to enhance the calming effect. Clonazepam has shown some efficacy in treating manic symptoms, and this can be given in conjunction with a mood stabilizer or an antipsychotic medication with proven antimanic effects.

While lithium and carbamazepine are effective in treating acute mania, they have not been studied for their efficacy in treating acute agitation and aggressive behavior in acute mania, and hence are not recommended as monotherapy for treating agitation in an emergency setting. Valproate oral loading dose has a similar faster onset of action as the antipsychotics in treating acute mania but has not been studied for controlling agitation. For patients who have a tendency to “cheek” the medication, orally disintegrating tablets (ODT) or liquid form of antipsychotics is preferable. However, there is no convincing evidence to support that these forms of administration have a faster onset of action in comparison to conventional tablet forms.

Two novel forms of oral administration of antipsychotics have shown rapid efficacy in controlling agitation. In a recent clinical trial, sublingual asenapine was shown to rapidly control agitation within 2 hours in psychiatric patients that included manic patients with a number needed to treat (NNT) of 3. Sublingual asenapine bypasses the first-pass metabolism provided that the patient does not drink or eat for 10 minutes

after the administration, and this may explain the rapid effect. Similarly, loxapine aerosol delivered through inhalation with a staccato system is also rapidly effective in controlling agitation in manic patients with an NNT of 3 achieved within 30 minutes. Loxapine inhalation (ADASUVE, 10 mg) is approved by the FDA in the United States as well as by the European Medicines Agency (EMA) for the treatment of agitation in mania. Since ADASUVE can cause bronchospasm that can potentially lead to respiratory distress and arrest, it is approved under the risk evaluation and mitigation strategy (REMS) program to mitigate the risk of bronchospasm. This basically means that ADASUVE can be administered only in an enrolled healthcare facility. Given the risk of bronchospasm, it is contraindicated in patients with a history of respiratory conditions such as asthma, chronic obstructive pulmonary disease (COPD), or other lung diseases associated with bronchospasm.

When rapid control of agitation is required to ensure safety and if a patient is unwilling to take the medication orally, IM administration of an antipsychotic should be considered. Haloperidol and second-generation antipsychotic medications such as olanzapine, aripiprazole, and ziprasidone IM formulations are rapidly effective within 2 hours in controlling agitation with an NNT of 3. Clinicians, however, must recognize that IM administration of medication against patients' wishes can be a very negative experience for the patient and may interfere with the establishment of a therapeutic alliance. Hence, if IM formulations are used to manage agitation and aggressive behavior, patients should be switched to oral medications as soon as the patient is willing to take the medication.

Treatment Selection for Acute Mania. If a manic patient was given an atypical antipsychotic with proven efficacy for mania to control agitation in the emergency setting and if this was well tolerated and improved agitation, this should be continued and the doses adjusted as clinically appropriate to treat acute mania. However, if first-generation antipsychotics such as haloperidol, loxapine, or chlorpromazine were used to control agitation, patients should be switched to a first-line antimanic agent as soon as possible. Although first-generation antipsychotics are likely as effective in treating acute mania, they are not recommended as first-line antimanic agents by most experts because first-generation antipsychotics such as haloperidol have a tendency to

induce depressive symptoms and increase the risk of depressive episodes in bipolar patients.

FIRST-LINE TREATMENTS. Lithium, valproate, and several atypical antipsychotics are all considered first-line agents for treating acute mania (see Table 13.6–6) as they all are effective and the response rates are broadly similar. Although multiple treatment meta-analyses suggest that risperidone may be more effective, this may have been accounted for by variability in study populations included in different trials. Thus it is unlikely that there are any clinically meaningful significant differences in efficacy between these agents, and hence, monotherapy with any of these agents would be considered an appropriate first-line option for acute mania.

Some guidelines, such as the Canadian Network for Mood and Anxiety Treatments (CANMAT) that were published in collaboration with the ISBD, recommend a combination of an atypical antipsychotic with lithium or valproate also as a first-line option. This is because combination therapy in general results in approximately 15% to 20% more patients responding compared with monotherapy. As with monotherapy, there does not appear to be any clinically meaningful significant differences in efficacy between various proven combinations for acute mania. It is, however, important for clinicians to remember that combination therapy is likely associated with more adverse events.

Table 13.6–6.
Recommendations for Pharmacologic Treatment of Acute Mania

First-line	**Monotherapy:** Lithium, divalproex, divalproex ER, risperidone, quetiapine, quetiapine XR, aripiprazole, asenapine, paliperidone ER, cariprazine **Adjunctive therapy with lithium or divalproex:** Risperidone, quetiapine, aripiprazole, asenapine
Second-line	**Monotherapy:** Olanzapine, ziprasidone, carbamazepine, carbamazepine ER, ECT, haloperidol **Combination therapy:** Lithium + divalproex, olanzapine plus lithium or divalproex
Third-line	**Monotherapy:** Chlorpromazine, clozapine, tamoxifen **Combination therapy:** Lithium or divalproex + haloperidol, lithium + carbamazepine, adjunctive tamoxifen
Not recommended	**Monotherapy:** Gabapentin, topiramate, lamotrigine, licarbazepine, zonisamide, valnoctamide, tiagabine **Combination therapy:** Risperidone + carbamazepine, olanzapine + carbamazepine

ECT, electroconvulsive therapy; XR or ER, extended-release.

Which First-Line Treatment?. Given that various monotherapy and combination therapy first-line options are available for treating acute mania, clinicians have to make a choice as to which monotherapy or combination therapy should be used to treat a given patient with acute mania.

Since there are no consistent efficacy differences between various first-line monotherapies and between different first-line combination therapies, physicians should consider clinical presentation, previous history of response/nonresponse, adverse events, and patient preference in deciding which monotherapy or combination to use to treat mania in a

given patient. Patients are more likely to respond to combination therapy compared with monotherapy, but this comes with additional adverse event liability. Therefore, clinicians must carefully weigh the risks and benefits of monotherapy versus combination therapy for each patient before making a decision on the most appropriate strategy.

If a decision is made to use monotherapy, patients presenting with acute agitation and aggressive behavior are commonly started on an atypical antipsychotic given their effectiveness in behavioral control and more rapid onset of action compared with mood stabilizers such as lithium. Lithium is the preferred agent in patients with “classical euphoric grandiose” type of mania, whereas those with dysphoric/irritable mania, mixed features, comorbid alcohol or substance abuse, or brain trauma may respond better to valproate. Similarly, patients with multiple previous mood episodes tend to respond poorly to lithium, while this does not predict poor response to valproate. Atypical antipsychotics, and in particular, olanzapine, asenapine, aripiprazole, and ziprasidone, appear to be equally effective for patients with classical mania as well as those with mixed episodes/mixed features. While clinicians tend to believe that presence of psychotic features may require treatment with an antipsychotic, the evidence from clinical trials suggests lithium, valproate, and atypical antipsychotics are equally effective in treating mania in patients with and without psychosis. However, clinical trial data notwithstanding, if a manic patient who is on lithium or valproate continues to exhibit psychotic symptoms, clinicians should consider adding an antipsychotic. Given that there are clear differences in adverse event profiles between various antimanic agents, this is also a very important consideration in treatment selection. For instance, olanzapine is less appropriate for manic patients who are overweight or obese or have a personal or family history of diabetes. Similarly, for patients with kidney disease with compromised kidney function, lithium is not appropriate.

Since there are no efficacy differences between combinations of different atypical antipsychotics (except ziprasidone) with lithium or valproate, the decision with regard to which combination to use for a given patient is also determined by taking into consideration previous history of response, adverse event profile of medications, clinical presentation, and preference of the patient.

What If a Patient Does Not Respond to a First-Line Treatment? Since several first-line monotherapy and combination treatment options are available, if one first-line treatment is ineffective, it is appropriate to switch the patient to another first-line treatment. Most manic patients who respond to therapy will show some improvement in manic symptoms within the first 2 weeks. If no improvement is observed during this time period, a switch to a different first-line treatment should be considered. For instance, if a patient is not responding to an atypical antipsychotic monotherapy, a switch to lithium or valproate or vice versa might be appropriate. A switch to a different monotherapy or combination could also be considered for tolerability reasons. In real-world clinical practice, it is unusual to encounter a patient who does not respond to one of the several first-line treatment options that are currently available to treat acute mania.

SECOND-LINE TREATMENTS. These should be considered mainly for those patients who have not responded to several first-line therapies.

Haloperidol is an effective treatment of acute mania. However, haloperidol has a tendency to induce depressive symptoms/switch patients into depression. Therefore, despite excellent efficacy for acute mania, haloperidol is recommended only as a second-line option.

Carbamazepine is also as effective in treating acute mania as other first-line antimanic agents, but tolerability is a significant concern with carbamazepine. Further, carbamazepine induces hepatic microsomal enzymes, which results in the induction of its own metabolism as well as the metabolism of other drugs, and this complicates the management of bipolar disorder. Weight gain and metabolic risk, however, are lower with carbamazepine.

The efficacy of lithium and valproate combination for acute mania is not examined in large double-blind, placebo-controlled trials. Nonetheless, given that both lithium and valproate are effective in monotherapy, it is likely that combination may provide some benefit for patients who are refractory to monotherapy with either agent or a combination of either agent with an atypical antipsychotic.

THIRD-LINE TREATMENTS. If a patient is a nonresponder to all first-line and second-line treatments, third-line options should be considered. These include first-generation antipsychotics such as chlorpromazine, the

atypical antipsychotic clozapine, tamoxifen, or neuromodulation treatments such as rTMS.

TREATMENTS NOT RECOMMENDED. Given the efficacy of valproate and carbamazepine for acute mania, clinicians tend to believe that other anticonvulsants are also effective in treating acute mania. However, there is evidence that gabapentin, topiramate, lamotrigine, Licarbazepine, zonisamide, and valnoctamide are ineffective for acute mania and hence should not be used. Brexpiprazole was not effective in RCTs of mania and hence is not recommended for treating acute mania. Similarly, it is not advisable to combine atypical antipsychotics such as risperidone or olanzapine with carbamazepine as no additional benefit in efficacy was identified with this strategy.

ECT in Acute Mania. Although there is a paucity of well-designed studies assessing the efficacy of ECT for acute mania, it is believed that ECT is highly effective for acute mania based on the data from retrospective and some prospective level 3 evidence studies. ECT may be used as a first-line option in the first trimester of pregnancy or in patients with delirious mania where rapid response is required. In other situations, given the cognitive adverse event profile, ECT should be used primarily in only those manic patients who have failed several first and possibly second-line treatments.

Acute Bipolar Depression: Treatment Options

There is a significant unmet need for the treatments of acute bipolar depression as few drugs have proven efficacy.

Lithium. The evidence for the efficacy of lithium monotherapy in treating acute bipolar depression is sparse. Earlier small trials that used cross-over designs with short duration of lithium and placebo periods reported that response rates were significantly higher during lithium periods compared with placebo periods. The mean response rate to lithium in these studies was 76%. About half of the patients experienced a relapse of depression when lithium was substituted with a placebo.

However, the efficacy of lithium was not confirmed in a more recent large double-blind, placebo-controlled parallel design study as lithium was not different from placebo in improving depressive symptoms in bipolar I

and bipolar II patients. The mean serum lithium levels in this study were 0.61 mEq/L, and therefore, it is possible that higher levels might have led to greater efficacy. One study that compared lithium versus lithium plus paroxetine showed that the latter was more effective than lithium alone in patients with low serum lithium levels, but in those that had serum lithium levels ≥0.8 mEq/L, there was no difference in efficacy, lending some support to the notion that higher serum lithium levels are required for lithium to be effective for treating acute bipolar depression.

Studies that compared antidepressant/other-agent adjunctive therapy to mood stabilizer with mood stabilizer monotherapy (that included patients on lithium) in general found no differences in efficacy between the two groups. Based on this, it has been suggested that mood stabilizer (lithium) monotherapy is effective. Lithium has been reported to have an antisuicidal effect beyond its mood-stabilizing properties, although prospective randomized controlled data is still required to confirm this. Furthermore, lithium is effective in preventing relapse of depressive episodes, and based on the efficacy of lithium in various phases of bipolar disorder, CANMAT/ISBD guidelines recommend lithium as one of the first-line treatments for bipolar depression.

Anticonvulsants

DIVALPROEX/VALPROATE. Similar to lithium, the data for the efficacy of divalproex in acute bipolar depression is also sparse. Divalproex was superior to placebo in three out of four small placebo-controlled trials. A meta-analysis of these trials suggests that divalproex is effective and that approximately 40% of patients will respond and meet the criteria for remission. It is currently unknown if there is a relationship between serum valproate levels and therapeutic efficacy for improving depressive symptoms.
