LAMOTRIGINE. Five double-blind, placebo-controlled studies with reasonable sample sizes of 7 to 10 weeks duration failed on the primary measures to demonstrate the efficacy of lamotrigine for treating acute bipolar depression. Since the lamotrigine dose needs to be titrated up gradually due to concerns about the risk of Stevens–Johnson syndrome with rapid up-titration, it is possible that 7- to 10-week study durations were not sufficient to demonstrate the efficacy given that the target dose

of 200 mg was not reached until the beginning of week 5 or 6 in these clinical trials.

A pooled analysis of response rates from these trials suggests that lamotrigine is effective in treating acute bipolar depression, but the magnitude of the effect is small. However, the therapeutic effect was larger in those that had more severe depression.

There is evidence that lamotrigine addition provides a therapeutic benefit in bipolar-depressed patients who fail to respond to lithium monotherapy.

OTHER ANTICONVULSANTS. There is only limited data for carbamazepine as its efficacy was assessed in only three small placebo-controlled trials that had a total of 40 bipolar-depressed patients. The mean response rates to carbamazepine were 68%; relapse occurred in 50% of these patients with placebo substitution.

Gabapentin and levetiracetam are found to be ineffective in small controlled trials. No placebo-controlled data exist for other anticonvulsants.

Atypical Antipsychotics. While all atypical antipsychotics are effective in treating mania, only a few of these have proven efficacy in treating bipolar depression. There is substantial evidence for the efficacy of quetiapine for bipolar I and II depression. However, clinical trials assessed only two fixed doses (300 mg/day and 600 mg/day), and there was no significant difference in efficacy between these two doses. Thus, 300 mg/day of quetiapine is generally considered the target dose for the improvement of depressive symptoms. Although the efficacy of lower doses of quetiapine has not been studied in acute bipolar depression in clinical trials, experience from clinical practice as well as trials in MDD suggests that some bipolar depressed patients are likely to respond to lower doses. Lurasidone monotherapy and adjunctive therapy to lithium or valproate have also been shown to be efficacious in treating acute bipolar depression and have received FDA approval for this indication. While efficacy has been established across the dose range of 20 to 120 mg, the lack of a clear signal for greater efficacy at the higher dose range supports the clinical impression that the 20 to 60 mg dose range may be sufficient for most patients.

Olanzapine was more effective than placebo in clinical trials of bipolar depression, but the magnitude of benefit was small. Olanzapine plus fluoxetine combination is clearly effective and is approved by the FDA for the treatment of acute bipolar depression. Although not tested, it is likely that other SSRIs given in conjunction with olanzapine are also effective.

Cariprazine, a D2 and D3 receptor partial agonist, at 1.5 mg/day was superior to placebo in three double-blind trials and at 3 mg/day in one RCT in improving depression in acute bipolar I depression. Based on these data, cariprazine was recently approved by the FDA for the treatment of acute bipolar I depression. Lumateperone, a novel antipsychotic, has been shown to be effective at 42 mg/day as a monotherapy and in combination with a mood stabilizer in improving depressive symptoms in patients with acute f bipolar I or II depression and the FDA review is currently underway.

Two placebo-controlled RCTs of aripiprazole did not find efficacy for treating acute bipolar depression, although the studies allowed flexible doses between 5 to 30 mg/day, and the mean doses in these studies were around 16 mg/day, which may have been too high. More patients in the aripiprazole group dropped out from these clinical trials, and evidence of aripiprazole efficacy at lower doses for add-on treatment in MDD provides relevant information. Thus, it is conceivable that tolerability related to higher doses may have impacted the efficacy. Ziprasidone monotherapy and adjunctive therapy are not effective in treating acute bipolar depression.

Antidepressants. There is a continuing controversy about the role of antidepressants in treating acute bipolar depression. There is consensus that monotherapy with antidepressant medications is not appropriate for bipolar I depression because of the concerns of manic/hypomanic switch and possible destabilization of the course of bipolar disorder. This advice is consistent with the recent data from a Swedish Registry study which demonstrated that manic switch is about 2.8 times greater in bipolar patients treated with antidepressant monotherapy compared with those taking antidepressants in conjunction with mood stabilizers. There is consensus that the risk of manic/hypomanic switch is higher with TCAs, older MAOIs, and possibly with SNRI antidepressants such as venlafaxine.

While adjunctive antidepressant therapy is widely used by clinicians to treat acute bipolar depression, the evidence for such a strategy from clinical trials is conflicting. Fluoxetine adjunctive therapy to olanzapine is effective, but paroxetine, citalopram, bupropion, and agomelatine adjunctive therapy failed to provide benefit.

However, two out of three meta-analyses support the efficacy of antidepressants. Further, another recent meta-analysis that calculated the NNT for the various treatments of bipolar depression reported an NNT of 5.75 for antidepressants which is in the same range as the NNT of 5.62 for quetiapine and 5.24 for lurasidone. However, these meta-analyses included studies of both antidepressant monotherapy and combination therapy. This limits the applicability of findings from these meta-analyses to real-world practice as most experts do not recommend antidepressant monotherapy for treating acute bipolar I depression. A more recent meta-analysis that specifically examined the efficacy of modern non-SNRI antidepressant adjunctive therapy supports efficacy, but the magnitude of benefit is small. There is uncertainty in the literature regarding the precise switch rates with acute antidepressant use, with results ranging from 0% to 19% in more recent studies and as high as 50% with the TCA desipramine. The ISBD Task Force on Antidepressant Use in Bipolar Disorders provides a balanced consensus view that discourages antidepressant use, especially among patients at higher risk of switch or cycling, but also acknowledges that for some patients, they can play a helpful role in treating acute depressive symptoms. The CANMAT/ISBD Bipolar Guidelines provide a second-line recommendation for add-on antidepressant use in bipolar I depression.

Adjunctive Therapy with Dopamine Agonists/Psychostimulants. There is conflicting evidence for the efficacy of modafinil/armodafinil adjunctive therapy. While modafinil and a phase 2 study of armodafinil were positive, only one out of three phase 3 studies of armodafinil adjunctive therapy supported its efficacy for bipolar depression. Armodafinil was well tolerated in these trials with no increase in manic switches. However, clinical experience suggests that the risk of a switch with modafinil/armodafinil is an important clinical consideration.

Pramipexole adjunctive therapy has been shown to be useful in two small trials of patients with refractory acute bipolar depression, although only one of these included patients with bipolar I depression.

Omega-3 Fatty Acid Adjunctive Therapy. Although there is evidence for the efficacy of adjunctive omega-3 fatty acid therapy in major depression, few studies assessed its efficacy in acute bipolar depression. The results of these studies are conflicting, but a meta-analysis of the data from these trials suggests efficacy. The evidence suggests that potential therapeutic benefits are likely to be derived from eicosapentaenoic acid (EPA) preparation. The omega-3 fatty acid preparations are in general well tolerated; a few patients report gastrointestinal symptoms such as diarrhea and bloating.

Nutritional Supplements as Adjuncts. N-acetylcysteine (NAC) is a glutathione precursor and hence is expected to have protective effects against oxidative stress. There was preliminary evidence that NAC, given at 2 g/day, may provide some benefit in treating depressive symptoms as one out of two studies that initially assessed the efficacy of adjunctive NAC versus placebo reported improvement in depressive symptoms in patients with bipolar disorder that included patients with bipolar I, bipolar II, and bipolar NOS, however recent data have been less promising. There are no significant tolerability issues with NAC.

Glutamatergic Modulators. A growing number of small studies, some of which included treatment-resistant bipolar depressed patients, support the efficacy of the noncompetitive NMDA antagonist ketamine. When infused in subanesthetic doses of 0.5 mg/kg over 40 minutes as adjunctive therapy, ketamine has been reported to rapidly improve depressive symptoms in patients with TRD. A recent systematic review concluded that a single ketamine infusion was associated with higher rates of response and remission on days 1, 3, and 7. The efficacy appears to be greater in those with unipolar depression than in those with bipolar depression. Ketamine may have antisuicidal effects. There is preliminary evidence that the benefits of ketamine could be maintained with further infusions or IM or oral or sublingual or intranasal administration of ketamine. However, the administration of riluzole, another glutamatergic modulator, was not more effective than placebo in maintaining the antidepressant effects of ketamine. Ketamine infusion is associated with transient psychotomimetic effects as well as sedation, dizziness, lightheadedness, incoordination, blurry vision, and feeling “strange or unreal.” The intranasal enantiomer esketamine is now available. However, extensive data on bipolar depression is lacking.

Limited open-label data suggest that riluzole at doses of 50 to 200 mg may be useful in treating bipolar depressive symptoms.

Somatic Treatments

ELECTROCONVULSIVE THERAPY. There is consensus among the experts that ECT is one of the most effective treatments for acute bipolar depression. Response rates to ECT are in the range of 50% to 70% in refractory major depressive disorder and bipolar depression. A recent meta-analysis concluded that there is no difference in efficacy of ECT between major depressive disorder and bipolar depression. There is some evidence that patients with bipolar depression respond faster and require fewer treatments to improve compared with those with unipolar depression. It is not surprising that a recent study found that ECT is more effective than algorithm-based pharmacologic treatments in patients with bipolar depression who have failed at least two previous pharmacologic treatments. Most patients with bipolar depression require six to eight treatments to respond.

Maintenance pharmacotherapy is necessary for the vast majority of patients to prevent relapse of depressive and manic episodes. This should be commenced, when possible, prior to completion of the ECT course. While ECT is very effective, cognitive side effects can often be problematic. Therefore, clinicians need to pay particular attention to various ECT stimulation parameters such as electrode placement, pulse width, and electrical dose in order to minimize cognitive side effects.

MAGNETIC SEIZURE THERAPY. Magnetic seizure therapy (MST) is a relatively new technique that involves inducing seizures through magnetic stimulation of the brain. There is preliminary uncontrolled evidence that MST is effective in treating depression. However, few patients with bipolar depression were included in these reports. Further, while MST appears to be effective, head-to-head comparison with ECT suggests that response and remission rates are better with ECT compared with MST. It is conceivable that further refinements in stimulation parameters of MST might lead to better efficacy. As expected, MST is associated with a much safer cognitive side effect profile as memory, language, and practice seem to be relatively unaffected by MST.

TRANSCRANIAL MAGNETIC STIMULATION. The data with regard to the efficacy of rTMS in acute bipolar depression is limited, although there is extensive literature supporting its efficacy in treating major depressive disorder. A meta-analysis that included data on 181 patients with different subtypes of bipolar disorder and different stimulation parameters concluded that overall, there is support for the efficacy of rTMS in treating bipolar depression with an NNT of 6. However, two small recent RCTs that assessed the efficacy of theta burst stimulation in improving depressive symptoms in bipolar depression failed to support the efficacy, thus raising questions about its utility in treating acute bipolar depression. However, given the small number of studies and differences in methodology, clearly, further controlled trials are needed to fully understand its role in treating bipolar depression.

TRANSCRANIAL DIRECT CURRENT STIMULATION (TCDS). Transcranial direct current stimulation (tCDS) involves the application of low-amplitude direct current to stimulate brain areas through surface scalp electrodes. There is emerging evidence from a systematic review that included seven reports and a recent sham-controlled randomized trial supporting the efficacy of tCDS in treating depressive symptoms in bipolar disorder. The sham-controlled trial showed that response rates were 68% in tCDS group compared with the 30% response rate in the sham treatment group, with an NNT of 2.69. This strategy may be considered for patients with bipolar depression who do not respond to standard first and second-line treatments or those that have difficulties in tolerating the side effects of medications.

Clinical Recommendations for the Management of Acute Bipolar Depression

Treatment goals in a patient with bipolar depression include treating depression to full remission without destabilizing the course of bipolar disorder while ensuring the safety of the patient. The risk of suicide is higher during acute depressive episodes and especially so in depressed patients with mixed features. Therefore, clinicians must carefully assess for suicide risk, and appropriate steps must be taken to ensure the safety of the patient. The severity of depression, presence of mixed features or psychotic features, substance abuse or other psychiatric comorbidities, and the severity of suicidal ideation should guide the clinician with regard

to the most appropriate treatment setting for managing depression in each patient.

Adjunctive psychological treatments such as CBT, IPSRT, and family-focused therapy (FFT) are beneficial in reducing time to recovery, improving treatment adherence and recovery rates, and reducing subsyndromal symptoms in bipolar depressed patients and, therefore, form an important part of the optimal management of bipolar depression.

Treatment Selection for Acute Bipolar Depression. Many patients with bipolar disorder experience breakthrough depressive episodes. This may be because patients had been taking inadequate doses of maintenance medication, were partially or fully nonadherent to medications, or the maintenance medications were ineffective in preventing the depressive recurrence or relapse. A thorough clinical assessment that gathers information about the course of bipolar disorder (e.g., number of previous manic and depressive episodes, their duration, and severity), the treatment history (current and previous medications, what worked and what did not work, tolerability issues), and adherence to treatment should help the clinician in determining the most appropriate treatment choices for each given patient.

First-Line Treatments. The evidence for the efficacy of many commonly used medications for treating depression in bipolar disorder is less robust and often conflicting. Therefore, it is not surprising that there is no general consensus among experts about the most appropriate first-line treatment options for bipolar depression. The CANMAT/ISBD group that published the most recent treatment guidelines took into account several factors such as efficacy from controlled trials, meta-analyses, clinical experience, the safety of the medication, and long-term efficacy in arriving at the first-line treatment recommendations for acute bipolar depression. A modified list of CANMAT recommendations for bipolar depression is provided in Table 13.6–7.

WHICH FIRST-LINE TREATMENT? If a patient had been taking one of the first-line treatments, optimizing the current treatment is the most appropriate first step before other interventions are considered. Similarly, first-line treatment should be commenced in patients who are drug-free or not taking first-line medications. While there is no clear research evidence to guide clinicians between various first-line monotherapy options, previous

treatment history, illness course, symptom profile of depression, side effect profile of medications, and patient preferences are all important considerations in determining treatment choices among the first-line therapies. The 2018 CANMAT/ISBD guidelines also introduced a hierarchical approach that emphasized the importance of long-term treatment planning even for the management of acute episodes. This hierarchical approach encouraged incorporating all aspects of the levels of evidence across all phases of illness, safety and tolerability concerns during the acute and maintenance phases, and risk of a switch when arriving at the sequence of interventions. Given that quetiapine has shown efficacy in acute mania, acute bipolar depression, and prevention of both mania and depression, it is recommended at the top of the hierarchy of first-line treatments. However, patient-specific factors such as certain clinical features, previous history of response or nonresponse, preference for a medication based on the tolerability profile of an agent may override such hierarchy. For instance, lithium monotherapy may be more appropriate for patients with a history of classical manic episodes, an illness course that has mania, depression, and euthymia patterns, and a family history of bipolar disorder. Bipolar I patients with frequent depressions and infrequent mild manias are suitable for lamotrigine monotherapy, while quetiapine is a better option for those with frequent depressions as well as manic episodes. Those with reverse vegetative symptoms such as hypersomnia and hyperphagia may be reluctant to take quetiapine because of its sedating and appetite-stimulating properties, although there is no reason to believe that it is less effective for this population. Lamotrigine dose needs to be escalated gradually due to concerns of skin rash with rapid dose escalation, and hence although it is effective in severely depressed patients, it may not be the most appropriate option given that it takes a few weeks to reach an effective therapeutic dose. Lurasidone is relatively weight-neutral and is preferred by patients who are reluctant to take medications that can cause weight gain. While the pharmacologic profile of this agent suggests that it may prevent mood episodes, given that the only maintenance study failed to demonstrate the efficacy, it may be prudent to consider combining lurasidone with lithium or valproate. Cariprazine has shown efficacy in monotherapy at 1.5 mg daily, which can be the starting and therapeutic dose for this agent, and it appears to have efficacy in treating a broader group of bipolar-depressed patients. As well, it is also relatively weight

neutral and has minimal impact on blood sugar or lipid levels. Thus, it is also an excellent option for bipolar-depressed patients. While the pharmacologic profile of this agent suggests that it might prevent mood episodes, the RCT data are not available as yet; hence, it may be prudent to monitor patients on cariprazine monotherapy closely for the emergence of any mood symptoms and add mood stabilizer therapy as appropriate.

Table 13.6–7.
Recommendations for Pharmacologic Treatment of Acute Bipolar I Depression

First-line	**Monotherapy:** Quetiapine/quetiapine XR, lithium, lamotrigine, lurasidone, cariprazine **Combination therapy:** Lithium or divalproex + lurasidone, adjunctive lamotrigine
Second-line	**Monotherapy:** Divalproex, ECT[a], lumateperone **Combination therapy:** Adjunctive SSRI/bupropion to a mood stabilizer or atypical antipsychotic, adjunctive lumateperone
Third-line	**Monotherapy: Carbamazepine, Olanzapine** **Combination therapy:** Adjunctive aripiprazole, adjunctive armodafinil/modafinil, adjunctive asenapine, adjunctive eicosapentaenoic acid (EPS), adjunctive ketamine (IV), adjunctive light therapy ± total sleep deprivation, adjunctive levothyroxine, adjunctive pramipexole, adjunctive tCDS, adjunctive SNRI/MAOI antidepressant
Not recommended	**Monotherapy:** Antidepressant, Gabapentin, aripiprazole, ziprasidone **Combination therapy:** Adjunctive ziprasidone, adjunctive levetiracetam, adjunctive mifepristone

[a]Can be a first-line treatment of severe depression with suicidal ideation or in the first trimester of pregnancy.

SSRI, selective serotonin reuptake inhibitor; MAOI, monoamine oxidase inhibitor; ECT, electroconvulsive therapy;

Modified with permission from Yatham LN, Kennedy SH, Parikh SV, et al. Canadian Network for Mood and Anxiety Treatments (CANMAT) and International Society for Bipolar Disorders (ISBD) 2018 guidelines for the management of patients with bipolar disorder. *Bipolar Disord.* 2018;20:97–170. doi: 10.1111/bdi.12609. © 2018 The Authors. Published by John Wiley & Sons Ltd.

WHAT IF A PATIENT DOES NOT RESPOND TO A FIRST-LINE TREATMENT? If optimization of monotherapy with a first-line agent is ineffective, a switch to another first-line monotherapy therapy (e.g., a switch from lithium to quetiapine or vice versa or to cariprazine or lurasidone) or combination

therapy (e.g., lamotrigine plus lithium or lurasidone or cariprazine plus a mood stabilizer) is appropriate.

Second-Line Treatments. Lumaterperone has excellent safety and tolerability profile and hence is a good option for patients that have trouble tolerating first-line agents for bipolar depression. The addition of an SSRI or bupropion could be considered for bipolar depressed patients who were unresponsive to optimization of lithium or valproate monotherapy, especially if there is a previous history of response to adjunctive antidepressant therapy. However, antidepressants are not appropriate for patients with a history of rapid cycling or those with mixed features. If antidepressants are used for treating acute bipolar depression, an attempt should be made to taper and discontinue them within 8 weeks of remission of depression.

ECT should be considered for patients who have failed several first-line treatments or for whom the rapid onset of response is paramount (e.g., in the presence of catatonia). ECT may be considered earlier for bipolar depressed patients with psychotic features, those at high risk of suicide, the older adults, and those with rapidly deteriorating physical status due to poor oral intake because of depression.

Valproate monotherapy is appropriate for bipolar depressed patients who had tolerability issues with other first-line monotherapy options. While no data exists, it may also be useful for bipolar depression with mixed features. Olanzapine-fluoxetine combination would also be a reasonable option for patients who remain unresponsive to treatment. Antidepressant adjunctive therapy to other atypical antipsychotics such as aripiprazole or quetiapine may be helpful for some patients.

Third-Line Treatments. These options are only appropriate for patients who failed many first- and second-line options. If these strategies are employed, clinicians need to educate patients and their family members about the limited evidence base to support their use.

Treatments Not Recommended. Treatment with antidepressant monotherapy is not recommended. As noted earlier, aripiprazole monotherapy also has negative data for acute bipolar I depression treatment. However, it can be effective in treating and preventing mania, and hence, adding an SSRI or bupropion to aripiprazole could be an

acceptable strategy in patients who were refractory to all the other first and second-line treatments.

Maintenance Therapy/Prophylaxis: Treatment Options

Lithium. Lithium is still considered the “gold standard” by many experts for the maintenance treatment of bipolar disorder. Lithium is effective in preventing mood episodes not only in bipolar I patients who had responded to lithium during acute episodes (enriched for lithium response) but also in those who had been treated with a different psychotropic medication for acute mood episodes (not enriched for lithium response). Lithium is effective in preventing both manic and depressive episodes, although the magnitude of benefit may be slightly lower for depression than it is for preventing mania. While earlier studies suggested that around 70% of patients with bipolar disorder remained episode-free with lithium, more recent studies suggest that the response rates are probably below 50%. This may be due to several reasons, including the cohort effect and the fact that these studies recruited patients who were responders to other psychotropic medication during acute episodes.

There is evidence that lithium plus valproate combination is more effective than valproate alone in preventing relapse of mood episodes. In bipolar patients who are refractory to therapy with lithium or carbamazepine, the combination appears to be helpful in reducing the risk of relapse of mood episodes.

It is recommended that lithium is given as a single daily dose as there is some evidence that multiple daily doses of lithium are more commonly associated with a greater incidence of renal side effects and pathologic changes in kidneys. Further, treatment adherence is likely better with a single daily dose.

There is evidence that serum lithium levels at or below 0.6 mEq/L are less effective. Therefore, for prophylaxis, serum lithium levels should be maintained between 0.8 and 1.2 mEq/L. For older adults with bipolar disorder, there is expert consensus that lower levels are preferred. Serum levels of 0.4 to 0.8 mmol/L are recommended for those ages 60 to 79 years, and levels of 0.4 to 0.7 mmol/L for those ages 80 or above. Lithium levels should be measured after the target dose has been achieved, in the steady-state (approximately 5 days after the last dose change), about 12 hours after the last dose. Serum levels should be repeated until two

consecutive levels within the therapeutic range are obtained for the same dose.

Patients receiving maintenance lithium therapy should be monitored as per modified ISBD safety monitoring guidelines (see Fig. 13.6–1) or more frequently if clinically indicated.

Patients on maintenance treatment of lithium should be educated about symptoms of lithium toxicity and the preventive measures. Risk factors for lithium toxicity include renal diseases, dehydration, drug interactions, older adults, and those with organic brain syndromes. Lithium toxicity is a medical emergency, and if not treated, can result in irreversible organ damage and death.

If lithium is to be discontinued for any clinical reason in bipolar patients whose serum lithium levels had been in a therapeutic range, it should be tapered and discontinued over a period of several weeks. This is because there is evidence that the time to 50% risk of recurrence of mood episodes is four times shorter with abrupt discontinuation (1 to 14 days) compared with gradual (15 to 30 days) discontinuation of lithium.

Anticonvulsants

CARBAMAZEPINE. There is limited data for the efficacy of carbamazepine from placebo-controlled trials. However, most, although not all, controlled studies that compared carbamazepine with lithium showed similar efficacy. While no study showed that carbamazepine was more effective than lithium, there is some evidence that carbamazepine may be more effective than lithium in patients with “nonclassical bipolar disorder” (i.e., patients with bipolar II disorder/bipolar NOS or with mood-incongruent delusions or with anxiety disorders or substance use comorbidity or mixed states).

The clinical trials have not specifically examined the relationship between serum carbamazepine levels and therapeutic efficacy in maintenance treatment. Hence, it is currently unknown what levels might offer optimal prophylactic efficacy. In clinical practice, serum carbamazepine levels are typically maintained between 4 and 12 μg/L, the same range used for treating patients with epilepsy.

Carbamazepine induces hepatic microsomal enzymes that metabolize carbamazepine. As a result, within the first few weeks of commencing carbamazepine, the clearance of carbamazepine increases by

approximately twofold; hence, dosage adjustments are necessary in order to keep serum carbamazepine levels within the clinically accepted range. Carbamazepine causes leukopenia in 10% to 20% of patients, and it occurs commonly within the first 3 months of commencing treatment and resolves with discontinuation of carbamazepine. Agranulocytosis and aplastic anemia are rare but have a more rapid onset and occur in an unpredictable pattern. Therefore, periodic clinical monitoring is not likely to be of much help. Clinicians need to be vigilant to this possibility when hematologic symptoms emerge clinically.

There are no controlled data to support the efficacy of oxcarbazepine in the maintenance treatment of bipolar disorder.

VALPROATE. In contrast to lithium which has robust data for its efficacy in maintenance treatment, only a single large double-blind, controlled trial assessed the efficacy of valproate in the maintenance treatment of bipolar disorder. In this trial, valproate was not superior to placebo on the primary measure of time to any mood episode. This study was considered a failed trial for a variety of reasons, including the fact that lithium was also not superior to placebo in preventing relapse of mood episodes. Valproate, interestingly, was superior to placebo on some secondary measures, including time to discontinuation for a recurrent mood episode or depressive episode. In the subgroup of patients who were treated with valproate during the open-label phase, valproate was superior to placebo in time to any mood episode. Further, patients randomized to valproate were significantly less likely to drop out for a mood episode and less likely to be prematurely terminated for any reason. Thus, in aggregate, these data suggest that valproate may be beneficial for preventing mood episodes in patients who respond to valproate during acute episodes.

A randomized controlled study found no difference in efficacy between valproate and lithium in patients with rapid cycling bipolar disorder who were stabilized on a combination of valproate plus lithium. Consistent with this, the results of a Cochrane review indicated that valproate was more effective than placebo in preventing study withdrawal due to any mood episode and that there was no difference in efficacy between lithium and valproate. There is evidence that fewer patients drop out of treatment with valproate compared with placebo or lithium. This may explain why valproate is widely used for maintenance treatment.

Although there is a linear relationship between serum levels of valproate and improvement in acute manic symptoms, there is no data to guide the clinicians with regard to serum valproate levels for the maintenance treatment of bipolar disorder. Therefore, it is a common practice to maintain the same valproate dose that was effective in treating mania for maintenance treatment, provided serum levels are within the range used for epilepsy (45 to 125 μg/mL).

Most patients prefer to take valproate as a single bedtime dose. Valproate can cause nausea and vomiting, particularly in the first few days of commencement of therapy. Some patients experience weight gain and hair loss. Women taking valproate should be monitored for polycystic ovary syndrome with questions about menstrual irregularities, fertility issues, hirsutism, and galactorrhea.

LAMOTRIGINE. Lamotrigine is approved for prophylaxis of mood episodes in bipolar I disorder by the FDA. Lamotrigine has robust efficacy in preventing depressive relapses/recurrences, but it only has marginal efficacy in preventing manic episodes. There is no data to suggest a relationship between serum levels of lamotrigine and prophylactic efficacy.

A large randomized open study that compared lamotrigine with lithium found no statistically significant differences in efficacy, but as expected, the hazard ratios for lamotrigine relative to lithium were higher (1.91) for mania and lower (0.69) for depression. In rapid cycling bipolar disorder, lamotrigine was no more effective than placebo on the primary measure of time to additional pharmacotherapy, but lamotrigine patients stayed significantly longer in the study compared with those that received placebo.

Lamotrigine is titrated upward slowly due to concerns about skin rash with rapid titration. Other risk factors for skin rash include younger age, a prior history of rash with another drug, and taking lamotrigine in conjunction with valproate. Rash more commonly occurs within the first few weeks of therapy. The incidence of benign skin rash is about 10% in prospective studies. The incidence of serious skin rash (i.e., Stevens–Johnson syndrome or toxic epidermal necrolysis) is rare (about 1 to 10 per 10,000) with slow dose titration. Nearly 50% of serious skin rash are seen in patients who receive lamotrigine in conjunction with valproate.

If a patient on lamotrigine therapy develops a skin rash, this needs to be evaluated carefully to determine if it is a benign or serious rash. When in

doubt, if immediate dermatologic consultation is not available, lamotrigine should be discontinued, and the patient should be carefully monitored. Those with serious skin rash require urgent medical evaluation and treatment.

Apart from the cutaneous reactions described above, lamotrigine does not cause weight gain and is in general well tolerated.

OTHER ANTICONVULSANTS. Gabapentin is not effective for treating acute mania or bipolar depression. In a small controlled trial, surprisingly, gabapentin adjunctive therapy was beneficial in maintaining mood stability. There are no controlled maintenance data for topiramate, levetiracetam, felbamate, or other anticonvulsants.

Antipsychotics

TYPICAL (CONVENTIONAL) ANTIPSYCHOTICS. Conventional antipsychotics are likely effective in preventing manic episodes. However, there is evidence that conventional antipsychotic therapy is associated with an increased risk of depressive symptoms and depressive episodes. Further, patients with bipolar disorder are at higher risk of developing tardive dyskinesia with conventional antipsychotics. Therefore, therapy with conventional antipsychotics, including depot preparations, should be mainly reserved for those patients who have failed treatment with traditional mood stabilizers and atypical antipsychotics.

ATYPICAL ANTIPSYCHOTICS. Atypical antipsychotics are widely used for treating acute mania or depression, and most available agents in North America have proven efficacy from double-blind, controlled trials. If a manic patient responds to an atypical antipsychotic agent, whether continuation of that atypical antipsychotic is effective in preventing relapse of mood episodes is an important clinical question.

From the longer-term maintenance perspective, both oral aripiprazole monotherapy (10 to 30 mg/day) and aripiprazole once-monthly injection (400 mg) are effective in preventing mood episodes and manic episodes but not depressive episodes. Similarly, aripiprazole adjunctive therapy to lithium or valproate is also beneficial in preventing manic episodes.

Continuation of olanzapine in manic/mixed episode patients who respond to olanzapine is effective in preventing manic, mixed, and depressive episodes, but the magnitude of benefit appears to be greater

for preventing mania and mixed episodes relative to depression. Olanzapine appears to be as effective as lithium and valproate in preventing mood episodes. Olanzapine adjunctive therapy to lithium or divalproex appears to be useful in preventing symptomatic relapse of mood episodes.

While oral risperidone has not been assessed for its efficacy, manic patients who responded to oral risperidone and switched to risperidone long-acting injectable (Risperdal Consta) are less likely to experience a relapse of mood episodes. Like aripiprazole, Risperdal Consta is effective in preventing manic episodes but not depressive episodes. Most patients require about 25 mg of Risperdal Consta every 2 weeks for preventing manic episodes. Risperdal Consta adjunctive therapy is also effective in preventing relapse of mood episodes and manic episodes but not depressive episodes in frequently relapsing bipolar patients.

Paliperidone ER monotherapy (mean dose of 6 mg/day) continuation in manic patients who responded to paliperidone is effective in prolonging time to and reducing the risk of relapse of mood episodes and manic episodes but not depressive episodes. In schizoaffective patients, paliperidone palmitate once-monthly (between 78 and 234 mg monthly) given as either monotherapy or adjunctive therapy is also beneficial in reducing the risk of relapse of manic, depressive, and psychotic symptoms.

Quetiapine is effective in preventing mood episodes, manic/mixed episodes, and depressive episodes in bipolar patients who responded to quetiapine during acute mania or bipolar depression. Quetiapine appears to be equally effective in preventing both mania and depression. The mean doses of quetiapine in the maintenance studies ranged from 527 to 562 mg/day. Quetiapine adjunctive therapy to lithium or divalproex is also effective in preventing both manic and depressive episodes, and the magnitude of benefit of adjunctive therapy for prevention of mania and depression is similar with hazard ratios around 0.3. This means that there is approximately a 70% reduction in risk of manic and depressive episodes with quetiapine adjunctive therapy compared with lithium or valproate monotherapy.

A double-blind placebo-controlled trial showed that asenapine monotherapy was associated with a longer time to recurrence of any mood episode in recently stabilized manic/mixed episode patients. Asenapine was significantly more effective than placebo in preventing

relapse of both manic and depressive mood episodes; however, similar to olanzapine, the magnitude of prophylactic benefit with asenapine was greater for preventing mania than in preventing depression.

Lurasidone adjunctive therapy reduced the risk of recurrence of a mood episode by 29% relative to placebo adjunctive therapy, but this difference just failed to reach statistical significance. Lurasidone adjunctive therapy, however, was superior to placebo adjunctive therapy in those who did not have rapid cycling BD and in patients with an index episode of depression in reducing the risk of recurrence of any mood episode.

While ziprasidone monotherapy is effective in treating acute mania, there is no data to guide clinicians with regard to whether the continuation of ziprasidone in such patients is useful in preventing mood episodes. However, ziprasidone adjunctive therapy to lithium or valproate is effective in preventing mood episodes and manic episodes but not depressive episodes.

There are no long-term data as yet for cariprazine, but a large RCT is currently underway, and the results are awaited in 2022.

Clozapine is likely effective at least in preventing mania, but no controlled studies have been conducted to date. In refractory bipolar/schizoaffective patients, clozapine add-on has been reported to be beneficial in reducing manic and psychotic but not depressive symptom scores on rating scales.

ANTIDEPRESSANTS. There is evidence that TCAs increase the risk of manic switch and are not recommended for treating acute bipolar depression. The maintenance studies that compared imipramine with lithium or lithium plus imipramine confirmed an increased risk of a manic switch with both imipramine mono and adjunctive therapy and hence TCAs are clearly not appropriate for maintenance therapy of bipolar disorder.

If modern antidepressants are used as adjuncts to treat acute bipolar depression, is the continuation of antidepressant therapy beneficial? This issue was addressed in a Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) trial that randomized patients who responded to adjunctive antidepressant therapy to continuation for 1 to 3 years versus discontinuation within 2 weeks. The results showed that the continuation of antidepressant therapy was associated with a trend toward less depressive symptom burden without increasing manic/hypomanic

symptoms. Further, the time to a depressive episode was significantly delayed in the antidepressant continuation group. There was no evidence of an increase in manic episode risk. Interestingly, a rapid-cycling course predicted a threefold increase in depressive episodes in patients who continued antidepressants versus those who discontinued. Therefore, clinicians are advised to carefully assess the risks and benefits of the need for long-term antidepressant adjunctive therapy for each patient and tailor the treatment accordingly.

Clinical Recommendations for Maintenance Treatment/Prophylaxis of Bipolar I Disorder

Most experts agree with the need for long-term prophylaxis in all patients with bipolar I disorder, and that prophylaxis should begin after the first manic episode. This is because bipolar disorder is a highly recurrent illness, frequently characterized by residual symptoms and chronicity. Over 90% of patients have a recurrence of a mood episode within 5 years. A recent meta-analysis suggests that recurrence rates are lower in first manic episode patients, with about 60% experiencing a mood episode within 4 years. Bipolar I patients experience syndromal or subsyndromal symptoms an average of 50% of the time, with depressive symptom periods predominating by a ratio of 3:1 to manic/hypomanic symptoms. There is evidence that subsyndromal symptoms increase the risk of full-blown mood episodes. Multiple mood episodes are more likely to be associated with cognitive impairment, structural brain changes, and functional impairment. Frequent episodes alter the response to treatment such that those that have had multiple mood episodes are less likely to respond to treatment during acute mood episodes as well as to prophylactic pharmacotherapy and adjunct psychotherapy.

Therefore, the goals of the long-term treatment include prevention of mood episodes, prevention of/improvement in subsyndromal symptoms, prevention of suicidal behavior, and improvement in treatment adherence, quality of life, cognitive, social, and work function.

While pharmacotherapy is the mainstay of the long-term prophylactic treatment of bipolar disorder, there is evidence that adjunct psychological treatments are helpful in reducing the risk of relapse in bipolar patients. Group or individual psychoeducation is effective in reducing relapse rates by 25% to 30%. Patients should be educated about the illness, adverse effects of medication, early warning symptoms of mood episodes, triggers

for mood episodes such as substance use and psychosocial stressors, as well as coping strategies. IPSRT and FFT are also effective. Bipolar patients who recovered from mood episodes tend to benefit from adjunct individual CBT that reduces relapse rates and prolongs time to mood episodes. The STEP-BD study reported that recovery rates at 1 year were significantly greater in acute bipolar depressed patients who received CBT, IPSRT, or FFT compared with those that received collaborative care. Thus, adjunct psychological treatments are essential components of the long-term treatment of bipolar disorder to improve treatment adherence and mood symptoms and reduce relapse rates.

Treatment Selection for Maintenance Treatment. Several factors are important in aiding the treatment selection for the maintenance treatment. These include information about the course of the illness in the patient, response (lack of response) and tolerability to various treatments during acute episodes and maintenance treatment, predictors of response to various medications, the predominant polarity of the illness, comorbidity, and whether the most recent episode was manic or depressive and what treatment/s were effective in remitting this episode. Family history of bipolar disorder, if present, and treatment response in family members are also helpful in some cases.

FIRST-LINE TREATMENTS. Lithium, valproate, lamotrigine, and some atypical antipsychotics are effective and are recommended as first-line agents for the maintenance treatment of bipolar disorder (see Table 13.6–8). However, it is important to note that the benefits of these agents in reducing relapse rates have been demonstrated in bipolar patients who were responders to acute therapy with the same agents. The only exception to this is lithium that has been shown to be effective in the maintenance treatment regardless of whether patients were treated for an acute episode with lithium or not.

Which First-Line Treatment? If a patient was recently treated for an acute manic episode with monotherapy with one of the first-line agents listed in Table 13.6–8, it is advisable to continue the same medication for the maintenance treatment. Although risperidone and ziprasidone are first-line agents for acute mania, they are only listed as third-line treatments for maintenance therapy as there are no efficacy data for maintenance therapy of oral formulations with these agents. However,

given that the other atypical agents that are effective in mania are also effective in maintenance treatment, clinicians may choose to continue these agents for the maintenance treatment after discussing the potential benefits and risks with such a strategy. Although paliperidone ER (>6 mg) is effective in maintenance treatment, it was less effective than olanzapine, and hence, it is listed as a second-line treatment for maintenance, but in manic patients who were responders to paliperidone ER, clinicians may also choose to continue this medication for prophylaxis.

Table 13.6–8.
Recommendations for Maintenance Pharmacotherapy of Bipolar Disorder

First-line	**Monotherapy:** Lithium, quetiapine, divalproex, lamotrigine (limited efficacy in preventing mania), asenapine, aripiprazole oral or LAI (mainly for preventing mania) **Adjunctive therapy with lithium or divalproex:** Quetiapine, aripiprazole (mainly for preventing mania)
Second-line	**Monotherapy:** Olanzapine[a], risperidone LAI (mainly for preventing mania), Carbamazepine, paliperidone ER (>6 mg), paliperidone LAI **Combination therapy:** Adjunctive risperidone LAI, lurasidone added to lithium or divalproex, ziprasidone added to lithium or divalproex (mainly for preventing mania), Lithium + divalproex, lithium + carbamazepine, lithium or divalproex + atypical antipsychotic
Third-line	**Monotherapy: Ziprasidone[b], risperidone[b]** **Adjunctive therapy:** Aripiprazole and lamotrigine, adjunctive clozapine, olanzapine plus fluoxetine, ECT
Not recommended	**Monotherapy:** Gabapentin, topiramate, antidepressants, perphenazine

[a]Given the metabolic side effects, use should be carefully monitored.

[b]Manic patients who responded to these, continuation is appropriate as a first-line.

LAI, long-acting injection; ECT, electroconvulsive therapy; ER, extended-release.

Modified with permission from Yatham LN, Kennedy SH, Parikh SV, et al. Canadian Network for Mood and Anxiety Treatments (CANMAT) and International Society for Bipolar Disorders (ISBD) 2018 guidelines for the management of patients with bipolar disorder. *Bipolar Disord.* 2018;20:97–170. doi:10.1111/bdi.12609. © 2018 The Authors. Published by John Wiley & Sons Ltd.

If a patient's illness course is characterized by predominant depressive polarity, clinicians should consider adding lamotrigine or lithium to atypical antipsychotic agents (such as aripiprazole, risperidone, or ziprasidone). Alternatively, they could replace these agents with either lithium, quetiapine, asenapine, or lamotrigine for prophylaxis.

For manic patients who were treated with a combination of lithium or valproate with an atypical antipsychotic, there is evidence that continuation of combination therapy is more effective than lithium or valproate monotherapy for preventing relapse of mood episodes. A recent study that compared different durations of atypical antipsychotic adjunctive therapy with risperidone or olanzapine for the maintenance treatment reported that adjunctive therapy is beneficial for the first 6 months after remission of mania, but continuation beyond this period was associated with significant weight gain liability with no apparent additional benefit in efficacy. Hence, clinicians are advised to carefully assess the need for the continuation of atypical antipsychotic adjunctive therapy beyond 6 months after mania remission. For instance, a longer duration of adjunctive therapy may be appropriate in bipolar patients with a previous history of insufficient prophylaxis with lithium or valproate monotherapy.

Patients who respond to treatment with quetiapine or lithium for acute bipolar depression are advised to continue these agents for maintenance treatment of bipolar disorder. In a bipolar depressed patient treated with lurasidone, clinicians may choose to continue this medication for prophylaxis despite lack of maintenance data given its D2 blockade (likely confers acute and prophylactic antimanic efficacy) properties, especially given the fact that lurasidone adjunctive therapy was effective in preventing relapse of mood episodes in those with an index depressive episode. Lamotrigine monotherapy is effective mainly in preventing depression, and hence in bipolar patients with previous severe manic episodes, clinicians are well-advised to add a prophylactic antimanic agent such as lithium or an atypical antipsychotic for optimal prophylaxis. Bipolar depressed patients who respond to cariprazine are also advised to continue this agent for maintenance treatment given its efficacy in treating acute mania and acute bipolar depression despite lack of maintenance data, while they are being monitored closely for emergence of mood episodes.

If a bipolar depressed patient responded to adjunctive modern antidepressant therapy, is the continuation of adjunctive therapy with antidepressant beneficial? There is preliminary evidence that continuation in nonrapid cycling bipolar patients is beneficial in reducing the risk of depressive relapses without destabilizing mood. The CANMAT/ISBD guidelines recommend tapering and discontinuing antidepressants about 8 weeks after remission of depression, based on the assumption that

antidepressants are primarily needed to cover the natural duration of the depressive episode, and beyond this, there is a risk of potential destabilization. The data from a recently completed Canadian trial are awaited for more definitive guidance on this issue.

In making a decision with regard to the maintenance medication for bipolar patients who are currently not on any treatment, clinicians need to consider several factors outlined in the treatment selection section above. If lithium has not been tried previously, given the robust evidence for efficacy in preventing both mania and depression and possibly suicidal behavior, it is the most appropriate first-line agent for such patients. Quetiapine monotherapy also has a wealth of evidence and clinical experience as a maintenance treatment. Patients with a history of alcohol or substance abuse or mixed features may be more appropriate for valproate therapy. For those with predominant manic polarity, any first-line agent with the exception of lamotrigine would be appropriate.

What If a First-Line Agent Is Ineffective? If a patient experiences breakthrough subsyndromal symptoms or relapse while on monotherapy with one of the first-line agents, a switch to an alternative first-line agent or a combination therapy is appropriate. For instance, if a patient on lithium experiences depressive symptoms, consider adding lamotrigine, lurasidone, or quetiapine. If manic symptoms emerge on lithium, consider adding an atypical antipsychotic or valproate or if there are tolerability issues, consider a switch to an alternative first-line agent. It is recommended that monotherapy or combination therapy with several first-line agents be tried before embarking on second-line strategies for maintenance therapy.

SECOND-LINE TREATMENTS. Olanzapine has strong data supporting maintenance use for the prevention of both mania and depression. However, given greater liability with regard to weight gain and metabolic effects, it should be considered after the series of first-line agents. Given that the evidence for prophylactic efficacy of carbamazepine and paliperidone is less robust, these options are mainly considered for bipolar patients who failed or had tolerability issues to monotherapy with first-line agents. Carbamazepine does not generally cause weight gain and is effective in preventing relapses, particularly in patients with atypical forms of bipolar disorder.

However, many patients who failed several first-line agents are unlikely to respond to monotherapy. Hence, combination therapy strategies outlined in Table 13.6–8 are most appropriate for such patients.

THIRD-LINE TREATMENTS. Given the efficacy of cariprazine for acute mania and depression, the expert opinion is that it is likely effective in maintenance treatment and should be considered if other first and second-line options have failed to prevent mood episodes. Clinical experience and some controlled data suggest that clozapine adjunctive therapy is very effective in refractory bipolar disorder. However, in addition to the risk of agranulocytosis, clozapine is associated with significant weight gain and metabolic side effects, and hence patients need to be monitored closely for these adverse events and treated appropriately. For some refractory patients, maintenance ECT is an option. Aripiprazole and lamotrigine combination has some evidence for maintenance treatment.

Treatment of Bipolar II Disorder

Although bipolar II disorder is common and associated with significant morbidity and mortality, few clinical trials investigated the efficacy of treatments for various phases of bipolar II disorder. The limited data that is currently available is derived from studies of bipolar I disorder or major depressive disorder that had included a few patients with bipolar II disorder. Therefore, in the absence of controlled clinical trial data, by necessity, extrapolation is made from the treatment studies in bipolar I disorder to aid clinical decisions in managing bipolar II disorder.

Treatment of Hypomania. It is generally believed that medications that are effective in treating acute mania are also effective in treating hypomania. Indeed, small placebo-controlled trials or open-label studies demonstrated that valproate, quetiapine, and risperidone are effective in treating hypomanic symptoms. These findings are consistent with the clinical experience of experts in the field.

Thus, bipolar II patients with persistent hypomanic symptoms could be treated with an antimanic agent to rapidly alleviate hypomanic symptoms. Prior history of treatment response, adverse effects of medications, and patient preferences are important considerations in treatment selection. If a patient had been taking a prophylactic antimanic agent, an increase in the dose of that medication might be sufficient in some cases.

Medications that could potentially be contributing to hypomanic symptoms, such as antidepressants, should be discontinued.

Treatment of Bipolar II Depression. The data for the efficacy of various treatments is even more limited for treating acute bipolar II depression relative to bipolar I depression. Quetiapine is the only medication with some evidence for efficacy from placebo-controlled trials with adequate sample sizes in treating acute bipolar II depression. In three out of five studies, quetiapine/(XR) was more effective than placebo in improving depression, with improvement apparent as early as week 1. Hence, quetiapine is an appropriate first-line option for bipolar II depressed patients who are drug naïve or have never tried quetiapine.

Most experts recommend lithium, lamotrigine, valproate, and lurasidone as appropriate monotherapy agents for some patients with bipolar II depression despite limited and conflicting data. Recent lumateperone monotherapy trial suggests that efficacy was robust in bipolar II depressed patients; hence, this should also be considered an appropriate option for bipolar II depressed patients.

Modern antidepressants are widely used to treat bipolar II depression, although the evidence is limited and conflicting. Given the limited effective options for treating bipolar II depression, modern antidepressant adjunctive therapy is appropriate for treating some patients with bipolar II depression. A meta-analysis suggests that the risk of antidepressant mood elevation is lower in bipolar II disorder compared with bipolar I disorder (7% in acute and 14% in maintenance trials vs. 14% and 23%, respectively for bipolar I). Therefore, there is less disagreement among experts about the use of modern antidepressant adjunctive therapy for bipolar II depression. This advice is consistent with the recommendations of a recent ISBD Task Force that endorses its use in bipolar II depression except in patients with rapid cycling bipolar disorder and in those with mixed features. Although a series of small studies suggest that antidepressant monotherapy is effective and is not associated with increased risk of a switch, such a strategy is not recommended for most bipolar II depressed patients.

ECT is an effective treatment for bipolar II depression. Although the evidence is very limited, adjunctive therapy with pramipexole, modafinil, omega-3 fatty acids, or N-acetyl cysteine could be considered for treating bipolar II depressed patients who are refractory to the above strategies.

Maintenance Treatment of Bipolar II Disorder. Syndromal or subsyndromal depressive symptoms comprise the vast majority of symptomatic periods in patients with bipolar II disorder. Therefore, the major challenge in the management of bipolar II disorder is not only to treat depressive episodes to full remission but also to prevent relapse/recurrence of depressive episodes without increasing the risk of a hypomanic switch.

Clinicians typically continue the medication that worked for the acute episode for the maintenance treatment. While such strategy has not been widely studied in bipolar II disorder, there is some evidence that bipolar II depressed patients who respond to quetiapine or lamotrigine benefit from the continuation of the same medication for the maintenance treatment. Lithium is beneficial for maintenance regardless of whether it was used to treat acute episodes or not. If a patient has responded to adjunctive modern antidepressant therapy, the continuation of the combination may be beneficial for some patients. Some studies suggest that patients who responded to fluoxetine monotherapy may benefit from a continuation of this medication for prophylaxis. Although these studies did not report increased hypomanic switch rates, clinicians are well-advised to warn patients about the potential risk of hypomanic/manic switch if such a strategy was chosen. If the above options are ineffective, open-label data and clinical experience support the use of combinations of mood stabilizers or a mood stabilizer and an atypical antipsychotic with or without a modern antidepressant or pramipexole or other agents such as NAC or omega-3 fatty acids.

Treatment of Bipolar Disorder with Comorbidity

Both psychiatric and medical comorbidity is highly prevalent in patients with bipolar disorder and impacts the clinical outcome. In general, bipolar patients with comorbidities tend to have poorer outcomes as they are less likely to respond or take a longer time to respond to treatments and are more likely to relapse. Therefore, the optimal management of such patients includes treating not only symptoms associated with bipolar disorder but also addressing comorbidities without destabilizing bipolar disorder. However, clinical trials conducted for regulatory approval of treatments for bipolar disorder have systematically excluded patients with active comorbidities. Therefore, in the absence of robust evidence-based strategies for the management of patients with bipolar disorder with

psychiatric comorbidity, treatment decisions for the management of comorbidity have to be made by necessity, based on the secondary analysis of data on comorbid symptoms in trials of bipolar disorder and the treatment efficacy data from clinical trials of the other conditions not in the context of bipolar disorder. In choosing treatments for managing comorbidity, clinicians must carefully weigh the risks of adjunctive treatments, such as their propensity to destabilize bipolar disorder and adverse events versus benefits of treating comorbidity and the consequential positive impact on the outcome of bipolar disorder.

Anxiety Disorders. Since several psychological treatments such as CBT have been shown to be effective in treating primary anxiety disorders, their use is preferable in treating the comorbid anxiety disorders in bipolar patients as they pose little risk of illness destabilization.

GENERALIZED ANXIETY DISORDER. GAD/anxiety symptoms are common in bipolar disorder, impact clinical outcomes, and hence must be treated. In addition to psychological treatments, if a patient has been taking an anticonvulsant such as lamotrigine or valproate or an atypical antipsychotic such as quetiapine or olanzapine plus fluoxetine combination for bipolar disorder, these should be optimized as there is some evidence from secondary analysis of clinical trials or open-label data to support their efficacy. If optimization of ongoing pharmacotherapy is ineffective in resolving symptoms, medications that have been shown to be effective in treating primary anxiety disorder should be considered. Among these, pregabalin and quetiapine are preferable as they are not associated with the risk of destabilization of bipolar disorder. Gabapentin is also useful as anecdotal evidence supports its efficacy in treating comorbid anxiety symptoms in bipolar patients. Some SSRI antidepressants (escitalopram, paroxetine, sertraline) are effective and widely used in clinical practice. Similarly, some newer antidepressants such as agomelatine and vortioxetine are also effective in treating GAD; the risk of illness destabilization appears to be lower with agomelatine, while no data are available as yet for vortioxetine. However, it must be remembered that since anxiety disorders/symptoms pose a chronic symptom burden in bipolar disorder, the long-term use of SSRIs or other antidepressants in bipolar patients may pose a considerable risk of illness destabilization. Hence, other strategies outlined above should be tried first

before considering the use of SSRIs. If SSRIs are used on a longer-term basis, patients need to be on an adequate cover with antimanic mood-stabilizing medications (i.e., a combination of two mood stabilizers or a mood stabilizer and an atypical antipsychotic). Although SNRIs such as duloxetine and venlafaxine are effective in primary anxiety disorder, their use in bipolar patients is not recommended due to their potential higher risk of mood destabilization.

SOCIAL ANXIETY DISORDER. While the estimates of a social anxiety disorder (SAD) in bipolar disorder vary, the National Comorbidity Survey reported that 39% of patients with any type of bipolar disorder have SAD. There are virtually no controlled efficacy data in this comorbid population. CBT is very effective in treating primary SAD and likely useful in comorbid patients as well. Among the agents shown to be effective in treating primary SAD, pregabalin and gabapentin are preferred options as they have no propensity to destabilize bipolar disorder. In nonresponders, SSRIs could be considered provided patients with bipolar disorder are on adequate mood stabilization. Beta-blockers such as propranolol and atenolol are not recommended as they do not appear to be beneficial in primary SAD.

PANIC DISORDER. Between 14% to 27% of patients with bipolar disorder have panic disorder, and up to 35% of patients with bipolar disorder report experiencing panic attacks. There is limited open-label data to support the use of valproate in bipolar disorder with comorbid panic disorder. There is posthoc evidence that gabapentin is useful in severe PD. If optimization of anticonvulsant therapy is ineffective, the addition of an atypical antipsychotic such as quetiapine or risperidone may be appropriate. As with other anxiety disorders, SSRIs are effective, but these should be given preferably in conjunction with an atypical antipsychotic and possibly a mood stabilizer in order to minimize the risk of manic/hypomanic switch. Clonazepam, alprazolam, and lorazepam are also effective, and they may be appropriate for short-term use to control panic attacks.

POST-TRAUMATIC STRESS DISORDER. Lifetime post-traumatic stress disorder (PTSD) rates range from 16% to 39% in patients with bipolar disorder. Childhood sexual abuse, adult sexual assault, and adult survival of the

suicide, homicide, or accidental death of a close friend or relative are commonly associated with comorbid PTSD in bipolar disorder.

There are virtually no controlled data on bipolar disorder with PTSD comorbidity. Anticonvulsants are likely beneficial and should be preferred particularly in light of their efficacy in reducing cravings for alcohol, as comorbid alcohol abuse is common in patients with PTSD. Atypical antipsychotic mono or adjunctive therapy has been reported to be beneficial for primary PTSD, particularly in treating symptoms of intrusion, and hence are appropriate options in anticonvulsant nonresponders. As with other anxiety disorders, SSRIs are effective but should be used preferably in conjunction with an atypical antipsychotic. Benzodiazepines are not effective, and there is anecdotal evidence that they may worsen symptoms.

OBSESSIVE-COMPULSIVE DISORDER AND RELATED DISORDERS. About 10% to 25% of patients with bipolar disorder have a lifetime history of OCD. The symptoms of OCD are particularly exaggerated during depressive episodes. Sexual and religious obsessions tend to be more common in bipolar disorder, and their severity tends to wax and wane over a lifetime. Psychological treatments such as CBT should be offered first. There are no controlled data for pharmacotherapy in the comorbid patient population, but there is some evidence that adjunctive treatment with lamotrigine, topiramate, or atypical antipsychotics such as risperidone, aripiprazole, olanzapine, or quetiapine is effective in treating primary refractory OCD. Since these medications, with the exception of topiramate, are effective in treating bipolar disorder, they should be optimized first. In those that continue to manifest OCD symptoms, therapy with topiramate or a combination of an atypical antipsychotic with an SSRI (i.e., escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) may be considered. The need for ongoing SSRI treatment should be evaluated periodically, and the risk versus benefit analysis should determine the duration of SSRI treatment. While clomipramine is effective in primary OCD, it is not recommended in bipolar patients due to the higher risk of a manic switch.

Alcohol and Substance Use Disorders. About 50% of patients with bipolar disorder have alcohol or substance use comorbidity. There is evidence that valproate is effective in reducing various indices of alcohol

use in bipolar patients with comorbid alcohol use, and hence is a preferred option in this population. Lamotrigine is also beneficial for some patients with alcohol comorbidity. Other anticonvulsants such as gabapentin and topiramate have shown efficacy in primary alcoholism and could be used as adjuncts to primary treatments for bipolar disorder in some patients to address alcohol comorbidity. While naltrexone and disulfiram are effective in primary alcohol use disorder, disulfiram is not recommended in bipolar patients given its inhibitory effects on dopamine β-hydroxylase and the potential for worsening of mania. There is some evidence for naltrexone add-on therapy in bipolar patients with alcohol comorbidity. While quetiapine is effective in primary bipolar disorder, it does not appear to have any utility in reducing alcohol-related behaviors.

Valproate, lamotrigine, quetiapine, and risperidone mono or add-on therapy appear to provide some benefit in patients with cocaine abuse. Add-on NAC or modafinil may be useful in some patients.

Attention-Deficit Hyperactivity Disorder. The estimates for the prevalence of ADHD in patients with bipolar disorder range from 9% to 30%, and therefore, all patients with bipolar disorder should be routinely screened for comorbid ADHD. Bipolar patients with ADHD tend to have an earlier age at onset of mood symptoms, more frequent mood episodes, more suicide attempts, and other psychiatric comorbidities. ADHD symptoms persist during euthymia and contribute to impairment in function. The diagnosis of comorbid ADHD in bipolar patients can be challenging, given the overlapping symptoms. Therefore, clinicians need to be aware of the possibility of both under-diagnosis and over-diagnosis of ADHD in bipolar disorder. Persistent impulsivity and the impaired ability for sustained attention despite treatment with mood-stabilizing medications and the absence of other symptoms of mood episodes should raise the index of suspicion for ADHD.

If ADHD symptoms and functional impairment persist despite psychoeducation and behavioral interventions in bipolar patients optimized on mood-stabilizing medications, the institution of specific pharmacotherapy targeting ADHD symptoms is appropriate. However, clinicians must be aware that ADHD treatments can destabilize the course of bipolar disorder. Adjunctive bupropion is often the first choice, particularly in bipolar patients with comorbid ADHD and frequent depressive episodes/depressive symptoms, as it is less likely to induce

manic switch compared with stimulants. In nonresponders, adjunctive modafinil or mixed amphetamine salts, or methylphenidate could be considered. If a patient responds, clinicians are advised to periodically evaluate the need for ongoing treatment with stimulants and offer psychoeducation to patients on monitoring for the emergence of manic symptoms.

FUTURE DIRECTIONS IN THE TREATMENT OF MOOD DISORDERS

An ultimate goal is a stratified approach to the personalized treatment of major depressive disorder, bipolar disorders, and other mood disorders. However, this is limited by the failure of clinical phenotypes to inform the selection of psychotropic medication. While the search for validated molecular, neuroimaging, and other biomarkers to subgroups within the major depressive disorder and bipolar disorders is underway, this has not yet influenced treatment selection or patient outcomes.

Newer therapeutic approaches are also emphasizing the rapidity of response, which matches the acute and severe nature of acute mood episodes. This approach may eventually lead to more discrete care pathways that utilize specific treatment goals at various stages of management, even within acute episodes.

Newer studies are also emphasizing the importance of therapeutic targets beyond only mood symptoms. For instance, clinical trials that utilize cognitive functioning as a primary outcome offer the hope for additional interventions that help patients across the broad spectrum of illness characteristics.

13.7 Mood Disorders: Psychotherapy

John R. McQuaid, Ph.D., and Michael E. Thase, M.D.

Psychotherapy, in various forms, has been one of the cornerstones of therapeutics for mood disorders for decades. Even before controlled studies were available to document the utility of these approaches, there was substantial clinical support or face validity for treating depression psychotherapeutically; depression frequently occurs during times of significant psychosocial stress and often is associated with relevant intra- and interpersonal vulnerabilities. As the field has become more evidence based and awareness of issues such as cost-effectiveness and disseminability has grown, greater emphasis has been placed on models of therapy that are procedurally specified and empirically tested. These trends were first evident in the introduction of shorter-term or time-limited therapies, particularly those that emphasize more pragmatic behavioral, cognitive behavioral, or interpersonal formulations and interventions. More recently, time-limited and manual-based models of psychodynamic psychotherapy have been introduced for the treatment of mood disorders. All of these therapies aim to improve upon the considerable beneficial effects of supportive clinical management, with the potential for theoretically driven, mode-specific benefits in addition to the relief of depressive symptoms. This chapter will review the current status of these therapies.

HISTORY OF PSYCHOTHERAPY FOR DEPRESSION

Psychotherapy for depression arose from psychoanalytic and subsequent psychodynamic models of intervention. Early theories conceptualized depression as an intrapsychic phenomenon stemming from internalized anger that arose from unconscious conflicts. Therefore, treatment was long term and focused on developing awareness of these internal conflicts through identification and interpretation of historical experiences that

reflected such conflicts. Intervention emphasized developing insight into these conflicts through the use of free association and the therapist's interpretations. This treatment also used the patient's projections onto the therapist (the transference neurosis) as a means of studying early object relationships and conflicts.

In contrast to more traditional approaches, behavioral theories of depression treatment emphasized observable factors, such as decreased participation in potentially rewarding or pleasurable activities, and suggested that the negative emotional symptoms of depression could be understood as a consequence of withdrawal of reinforcement. Treatment interventions initially were guided by learning theories, but by the 1970s had broadened to include cognitive components (e.g., to increase self-efficacy or decrease negative thoughts or beliefs about self, world, and future). Some models emphasized social skills or problem-solving strategies, whereas others focused more on increasing positive activities or remediating cognitive symptoms and vulnerabilities. Whatever the differences in specific models of CBT, all emphasize the role of the therapist as a teacher of specific skills that are intended to help the depressed person reduce depressive symptoms and/or improve coping. Moreover, virtually all models of CBT emphasize the importance of homework assignments to enhance mastery and generalization of these skills in "real-world" environments.

Arguably, the most impactful of the models of CBT to emerge from the 1970s was the approach developed by Beck and colleagues. More commonly known as cognitive therapy (CT), this form of therapy focuses more on identifying the negatively valenced automatic thoughts associated with depressed moods and using strategies to both test the accuracy of the negative thoughts and consider more rational (and less depressogenic) alternatives. As many people in the midst of a depressive state evince various kinds of cognitive distortions (e.g., thinking in a more overly general and absolute way or selective recall of negative mood–relevant memories or associations), a skilled CT therapist can help most nonpsychotically depressed people see examples of "cause and effect" relationships between cognition, mood, and behavior within the first hour of treatment.

Whereas early models of behavior therapy either minimized the value of the therapeutic relationship or were silent about its importance, Beck and colleagues emphasized a collaborative approach between the therapist

and the patient, referred to as collaborative empiricism, and specifically structured therapy sessions in discrete 10- to 20-minute segments to ensure that the patient had the opportunity to give feedback (e.g., whether the particular topic was personally relevant or made sense) and express reservations. A collaborative process using Socratic questioning was similarly incorporated to guide and facilitate mastery of techniques for testing and remediating negative thoughts and beliefs, and the patient practices these techniques.

Beyond CT's initial focus on automatic negative thoughts ("surface" cognitions), Beck's model of therapy also emphasized that vulnerability to depression was linked to "deeper" forms of cognition, including dysfunctional attitudes and schema. Schemas are underlying cognitive structures that help the brain organize information in memory, guide awareness, and predispose action. The complex thoughts and actions involved in tying a bow are an example of a simple, nonaffectively relevant schema. Schemas that are associated with depression are often reflected by automatic negative thoughts or abiding beliefs about competence ("I'm just not good enough") or intimacy ("No one will ever really love me"), which may be activated by thematically relevant life events. Thus, another distinguishing feature of CT is a specific stress–diathesis model of vulnerability. As such, schemas are "silent" (i.e., they must be inferred from the predominant themes or beliefs revealed in automatic negative thoughts), and Beck's model of CT did deviate significantly from the zeitgeist of the behavior therapy movement. Nevertheless, the fully developed model of therapy developed by Beck and colleagues incorporated more conventional behavioral strategies such as activity scheduling and graded task assignments.

Interpersonal psychotherapy (IPT), developed by Klerman, Weissman, and colleagues, emerged in the 1980s as the leading alternative to CBT. Drawing upon psychodynamically influenced interpersonal models (Meyer and Sullivan) and attachment theory (Bowlby), IPT incorporated many of the more pragmatic methods used by social workers in case management to develop a time-limited therapy that addresses the common problematic patterns in relationships that plague the lives of people with depression, including unresolved grief, role disputes, role transitions, and interpersonal deficits. Beyond eliciting an interpersonal inventory and identifying the area or areas of interpersonal difficulty of greatest relevance to a particular patient, the interventions used in IPT are

relatively eclectic and can include psychoeducation, nondirective questioning and empathic support, and role-playing and social problem solving. IPT thus may be particularly well suited for more traditionally trained psychotherapists or counselors who find it difficult to implement the structure, activity level, and the more directive posture that characterize most models of CBT. Significantly, IPT was the first psychotherapy outside of CBT to be evaluated in comparison to antidepressant medications using RCT methods.

Several adaptations of IPT have a particular utility for patients with more complex depressive disorders. Frank and colleagues incorporated the importance of social rhythm disruption and the adaptive value of social rhythm stability (i.e., the consistency of regular activities such as bedtime and meal times) in their adaptation of IPT, which was primarily targeted for recurrent forms of affective illness, including bipolar disorder. Known as interpersonal and social rhythm therapy (IPSRT), this approach adds an assessment of social rhythm stability and activity scheduling tailored to strengthen the role of social *zeitgebers* (time givers) in helping patients prevent recurrent affective episodes and promote recovery. Shear and colleagues adapted IPT to focus on complicated bereavement, including clinical presentations in which the thoughts, feelings, and behaviors pertaining to bereavement overlap with the signs/symptoms of PTSD.

More recent innovations in psychotherapy have incorporated techniques from a long-standing meditation tradition and done so using an evidence-based approach. Mindfulness meditation, developed from Buddhist techniques, emphasizes two skills: observing one's perceived sensations and accepting and experiencing those sensations nonjudgmentally. In the application of this technique to depression, sensations include cognition and emotional states, as well as input through the five senses. Segal, Teasdale, and colleagues propose that these techniques are relevant for three reasons. First, the training in observation facilitates gathering evidence, which is a central component of CBT. Second, learning to view thoughts—even the most negative or damning ones—as discrete, limited experiences helps patients dampen affective arousal in response to them, which in turn improves their ability to consider alternate perspectives. Third, the emphasis in meditation on nonjudgmental observing moves the therapy toward a focus on acceptance rather than change per se. For more chronic depressive disorders, a focus on acceptance—rather than change—can offer a novel

therapeutic component, particularly when the ability to tolerate distress has interfered with coping behaviors.

Several models of treatment now incorporate mindfulness techniques and are often referred to as “third-wave” techniques, reflecting the path from behavioral to cognitive to now mindfulness and acceptance-based interventions within the CBT tradition. Mindfulness-based cognitive therapy (MBCT) is a treatment intervention specifically developed to reduce the risk of relapse in individuals who have a history of recurrent depression. Acceptance and commitment therapy (ACT), developed by Steven Hayes and colleagues, emphasizes identifying core values and committing to acting on those values rather than focusing on avoiding suffering. This model was particularly designed for addressing chronic depression. Another closely related therapy, dialectical behavior therapy (DBT), has recently been adapted for working with patients with more treatment-resistant depression. Initially developed by Linehan and colleagues, DBT is a behaviorally oriented system of therapy that also places a strong emphasis on mindfulness and acceptance and has well-replicated effects on the reduction of suicidal ideations and behaviors.

Family support is an important asset in life and is generally a favorable prognostic indicator across mood disorders. Conversely, there is an increased risk of relapse/recurrence for patients whose families show high levels of criticism and emotional expression. Drawing upon these observations, Miklowitz and colleagues developed family-focused therapy (FFT), which has primarily been adapted for the treatment of adolescents and young adults with bipolar disorder. This treatment focuses on educating both patients and family members on the disorder and helping them gain a shared perspective of the disorder. From this shared perspective, the therapist guides the family in developing a relapse prevention plan, including ways that the family can identify symptom exacerbations, an agreement about how they will share this observation with the patient, and an understanding of how the patient will respond to this information. Options for managing symptoms are generated (e.g., visiting the doctor for medication adjustment or increasing structure in the home). Family members are also trained to communicate effectively in ways with the patient and reduce the level of hostility and criticism in the environment.

REVIEW OF RESEARCH FINDINGS

Unipolar Disorders

Individual Psychotherapy. A number of forms of psychotherapy (see Table 13.7–1) have been shown to be either efficacious or probably efficacious for outpatients with major depressive disorder. These treatments have been shown to be effective in outpatients treated in a variety of settings (e.g., psychiatric clinics, psychology clinics, college counseling centers, community mental health centers, and primary care clinics), and meta-analyses suggest that across modes of therapy, differences tend to be modest to nonexistent. By contrast, no form of psychotherapy is indicated as the primary treatment for bipolar disorder, although a growing literature supports the value of several different forms of psychotherapy as adjuncts to ongoing therapy with mood stabilizers.

CBT has been evaluated in numerous RCTs, including placebo-controlled studies that included first- and second-generation antidepressants as active comparators. Although the findings of one very influential early multicenter study, the National Institute of Mental Health (NIMH) Treatment of Depression Collaborative Research Program (TDCRP), suggested that CT may be less effective than pharmacotherapy for the treatment of patients with more severe depressive symptoms, the findings of a number of other RCTs do not support such a relationship. Rather, patients with higher symptom severity scores tend to respond slower or less favorably to many different interventions. In general, depressed patients treated with CBT are as likely to respond/remit across 8 to 16 weeks of treatment as are patients treated with antidepressant medications.

Table 13.7–1.
Efficacious Treatments for Major Depression

Treatment	Conceptualization of Disorder Etiology	Sample Interventions
Behavioral therapy	Deficit of reinforcers, including pleasant activities and positive interpersonal contacts	Increase activity level Structured goal setting Interpersonal skills training
Cognitive behavioral therapy	Interaction of beliefs with matching stressor	Identify and challenge automatic thoughts Engage in activities that provide evidence disproving dysfunctional beliefs Modify core beliefs by reviewing evidence
Interpersonal psychotherapy	Interpersonal vulnerabilities arising from early attachment and learned relationship patterns	Develop awareness of patterns in primary relationships and the therapeutic relationship Interpersonal skills training Communication analysis
Behavioral marital therapy	Marital distress increases stress while impairing support resources	Assertive communication training Active listening exercises Problem-solving skills Increasing reinforcing behaviors toward spouse

A number of studies have likewise demonstrated that IPT also is an effective treatment for depressed outpatients, and there is particularly strong literature supporting the use of IPT for the treatment of depression during and after pregnancy. In aggregate, IPT and CBT appear to be comparably effective across 2 to 4 months of treatment.

The results of several studies suggest that simpler behavioral interventions may be as effective for depressed outpatients as more elaborate models of therapy. The performance of a “pure” behavioral activation (BA) intervention was particularly strong for patients with more severe levels of depression in one study. Whether BA and CT or IPT might be sequenced for patients at increased risk of relapse or recurrence is an interesting topic for future research, particularly because there is growing evidence that CBT and IPT curricula can be provided online, with a relatively modest amount of therapist support.

Although it was once true that there were too few studies of time-limited forms of psychodynamic psychotherapy, there is now a sufficient body of research to conclude that these are efficacious for the treatment of depressed outpatients (as compared to waiting list control conditions) and have outcomes across 8 to 16 weeks that are comparable to other therapies, such as CBT or IPT, or antidepressant medication. To date, no reliable indicators of preferential responsiveness to psychodynamic psychotherapy versus other forms of psychotherapy have emerged.

Across studies and types of psychotherapies, there is evidence that a response to psychotherapy may be more durable or persistent for weeks or months after therapy is stopped than is the case following the withdrawal of antidepressant medications. As a result, differences in the cost of delivering care that might favor pharmacotherapy in the short run may dissipate or actually shift in favor of psychotherapy when the need for continuation and maintenance phase pharmacotherapy is taken into account. Longer-term models of psychotherapy have been developed for patients who do not obtain full remission during a typically adequate course of individual therapy. In one study of incompletely remitted patients judged to be at high risk for relapse, the provision of 8 months of continuation phase CBT had a relapse prevention effect that was comparable to pharmacotherapy. It is less certain that an effective course of time-limited psychotherapy actually reduces the longer-term risks of recurrent depression. In the classic study of maintenance phase therapies conducted by Frank and colleagues, patients with highly recurrent forms of major depressive disorder who recovered with the combination of IPT and imipramine were significantly more like to remain well when their maintenance treatment included the active imipramine than when they received monthly sessions of “maintenance” IPT. Nevertheless, other studies have indicated that the addition of CBT or MBCT during an

ongoing course of continuation or maintenance phase therapy may improve residual symptoms and reduce the risk of recurrent illness after discontinuation of antidepressant medication.

Group and Couples Therapy. A number of studies indicate that cognitive and behavioral therapies are well suited for delivery in groups. Group delivery of CBT may not only be a cost-effective alternative to individual therapy but may have particular value for groups with subsyndromal symptoms, for whom individual treatment might be judged not to be necessary. Depressed individuals with marital discord similarly have been shown to benefit from behavioral marital therapy (BMT). In controlled studies, BMT appears to have an impact on depressive symptoms that is comparable to individual CBT, with the added value of greater improvements in marital functioning than CBT.

Combined Psychotherapy and Pharmacotherapy. Many psychiatrists favor combining psychotherapy and pharmacotherapy, particularly for the treatment of outpatients with more chronic, severe, or treatment-resistant forms of depression. Although the effect sizes typically favoring combined treatment over competently administered monotherapies have tended to be modest, a pooled analysis of participants from a series of studies conducted at the University of Pittsburgh found that the advantage of combined treatment was particularly large for patients with more severe, recurrent depressive disorders. Results of several larger-scale, multicenter studies likewise showed advantages for patients with more severe or chronic depression. Similarly, several studies that have adapted IPT and CBT to inpatient settings have shown that the addition of focused therapy improves outcomes in comparison to treatment as usual conditions that include antidepressant medication and milieu therapies. As noted earlier, sequential studies of pharmacotherapy followed by focused psychotherapy have likewise shown advantages for promoting recovery or facilitating discontinuation of pharmacotherapy.

Bipolar Disorders

In addition to the models of psychotherapy described earlier, group psychoeducation has emerged as a cost-effective form of adjunctive intervention for people with bipolar disorder. As developed by Colom and colleagues in Barcelona, this practical treatment can be conducted in

groups as large as 30 to 50 participants and their families and focuses on risk factors, warning signs, and coping strategies. Although the acute efficacy of psychoeducation has never been studied for bipolar depression, it has been shown in several studies to have a significantly positive effect on treatment adherence and relapse prevention.

With respect to the treatment of bipolar disorder, no form of psychotherapy—provided as a monotherapy—has been shown to be an effective treatment of mania or mixed states. Like group psychoeducation, most formal therapies have been studied as adjuncts to pharmacotherapy with mood stabilizers with the goal of preventing relapses or recurrences. Looking across interventions, the evidence is fairly convincing that adjunctive therapies, including psychoeducation, IPSRT, FFT, and CBT, significantly increase well time and reduce the risk of relapses and recurrence. In fact, the magnitude of benefit for adjunctive psychotherapy, as compared to no adjunctive treatment or treatment as usual alone, is comparable to the prophylactic effects of mood stabilizers such as divalproex or lamotrigine in placebo-controlled trials (see Table 13.7–2).

The evidence for the utility of focused psychotherapies for the treatment of acute bipolar depressive episodes carries the same caveat that pertains to antidepressant pharmacotherapy. In one component study of the large-scale U.S. study known by the acronym STEP-BD, adjunctive psychotherapy with FFT, IPSRT, or CBT had significant effects on both depressive symptoms and social functioning. The nature of this study did not permit valid comparisons among the psychotherapies. Given the hazards of treatment-emergent affective switches and induction of rapid cycling associated with antidepressants, the potential for focused psychotherapies for adjunctive treatment of bipolar I depressive episodes warrants further exploration. Likewise, the use of focused psychotherapy alone for selected patients with bipolar II depressive episodes deserves systematic study.

APPLYING THE RESEARCH TO CLINICAL PRACTICE

There have been important advances in understanding the roles of psychotherapy in the treatment of mood disorders, and several good psychotherapy options for both unipolar and bipolar disorders now exist. Nonetheless, clinicians are often faced with providing treatment to patients who may not match the typical participant in research trials and

need to extrapolate from the available data to develop a treatment plan for their patients. Of course, several important critical questions remain, including which treatment is best for which patient, what are optimal doses (e.g., number and length of sessions), and how best to address comorbid disorders. It is also not clear how critical-specific techniques associated with these interventions are for the successful treatment of mood disorders. A study of the therapeutic process of IPT (i.e., the actual in-session behaviors of the therapist and patient) found that the process was more consistent with ideal CBT than ideal IPT. A meta-analysis examining comparisons between specific psychotherapies and placebo conditions found that the difference between treatments was related to the adequacy of the placebo design. Studies with placebo comparisons deemed adequate (e.g., using nonspecific therapy techniques for the placebo condition and matching for the level of contact with therapists) showed smaller differences between active interventions and placebo than those studies with placebo conditions that were inadequate (e.g., less therapist contact or constraint of topics to issues not related to the patient's disorder). These findings suggest that differences between psychotherapy techniques may be less critical than some of the shared components (e.g., positive therapeutic relationship, shared goals, and facilitated behavior change). There are also no definitive answers regarding the underlying models of depression. Although BA, CBT, and IPT are based on empirical models of psychopathology that all have supportive evidence, the development of these treatments and the conceptualization of depression are extrapolations beyond the available data.

Table 13.7–2.
Efficacious Treatments for Bipolar Disorder

Treatment	Conceptualization of Disorder Etiology	Sample Interventions
Cognitive behavioral therapy	Biologic vulnerability interacting with stress Skills deficits limit ability to manage symptoms	Identify and challenge automatic thoughts that interfere with treatment adherence Engage in rewarding activities that provide increased routine and stability Practice communication skills with providers
Interpersonal and social rhythm therapy	Interpersonal vulnerabilities arising from early attachment and learned relationship patterns, plus disruption of social rhythms	Develop awareness of patterns in primary relationships and the therapeutic relationship Track and stabilize social rhythms Interpersonal skills training Communication analysis
Family-focused therapy	Biologic vulnerability exacerbated by negative expressed emotion in family environment.	Education regarding the disorder, including precipitants, risk factors, and effective treatment Establish relapse prevention plan, agreed upon by all involved family members Communication skills training

Clinicians then are faced with how to use this knowledge in treating patients. One key approach, regardless of the model, is the development of a case formulation to guide treatment.

TREATMENT OF MAJOR DEPRESSIVE DISORDER WITH CBT

CBT is based on the assumption that dysfunctional beliefs, learned in response to life experiences, lead to dysfunctional behavioral and emotional responses. Treatment, therefore, modifies these beliefs to reduce problematic responses and increase functional responses. Patients learn to modify beliefs by first learning to observe their thinking, affect, and behavior and then evaluating how thoughts influence mood and actions. As the patient becomes aware of these processes, the therapist teaches skills in questioning and testing the validity of beliefs and developing alternative, more accurate, functional beliefs. The long-term goal of treatment is for patients to learn the skills to such an extent that they are able to be their own therapist.

Assessment and measurement by the therapist and the patient are central to effective CBT. The therapist teaches the patient to quantify the issues of concern. Patients learn to observe and define their own assumptions that lead to depression and then engage in a series of experiments to improve their mood. Patients learn to measure the effects of these experiments so that they test the previous assumptions and can develop new, more constructive beliefs and actions that reduce depression and other problematic moods and behaviors.

A 23-year-old, never married Black woman presented to the university mental health clinic. She was in the midst of her first semester at law school, and her primary care physician referred her to the clinic after the patient reported frequent crying and feeling hopeless. She also reported that her mood was depressed nearly every day, and she was experiencing anhedonia, early, middle, and late insomnia, decreased appetite and weight loss, difficulty concentrating, and almost daily thoughts of death and life not being worth living.

CBT, like most other psychotherapies, uses a case conceptualization approach to determine the treatment of each patient. In CBT, the conceptualization is developed based on an understanding of how different aspects of cognition are related. Aaron Beck and later, Judith Beck proposed that cognition could be divided into three levels: automatic thoughts, intermediate beliefs, and cognitive schemata. The most accessible, labeled, automatic thoughts represented the conscious response to stimuli. For example, the previously mentioned patient, when studying, often thought, “I’ll never understand this.”

The second level, intermediate beliefs, is assumptions about the self, the world, and the future that lead to the automatic thought occurring in response to a particular stimulus. Using the case of the law student presented here, the patient believed that she was not competent and that she was not good enough; she perceived the world (in this case, professors and classmates) as attacking and critical. She anticipated that the future would be filled with failure. At times when things went well, she was not unduly distressed. However, in the face of failure or criticism, she quickly experienced self-critical thoughts that were consistent with these beliefs.

The content (e.g., the beliefs) and the organization of that content define the third level, cognitive schema. An individual’s schema determines which stimuli are most likely noticed and encoded in memory, which stimuli are ignored or discounted, how encoded information is linked or associated in memory, and which memories are most easily recalled. For the previously mentioned patient, she may suffer from a schema that could be conceptualized as, “I’m not good enough.” She tends to notice information consistent with this belief and tends to ignore or discount other information.

As the therapist completes an initial assessment and establishes a treatment plan, a central goal is to elaborate a case conceptualization that will facilitate treatment. By understanding the unique meaning of experiences to the patient, the therapist can be more effective in identifying interventions that truly test the beliefs and produce meaningful improvement.

Several authors have described models for developing case formulations in CBT, and they generally are based on gathering evidence to propose an underlying schema. Once the automatic thoughts, beliefs, and schema are identified, interventions are chosen based on these hypothesized structures. The therapist continues to gather evidence throughout treatment, refining the formulation over time.

Initial Assessment

Specificity and accurate data gathering are key focus of CBT. In particular, assessment of diagnosis and symptoms is necessary. Primary assessment preferably includes standardized measures, such as the Structured Clinical Interview for DSM-5 (SCID), the Hamilton Rating Scale for Depression, and the Beck Depression Index (BDI). The assessment also needs to include the dimensions of functioning: interpersonal relationships, work and achievement, health, and recreation. As treatment progresses, a formulation is developed regarding the patient's case conceptualization, as well as particular cognitive and behavioral coping strategies that the patient uses.

The previously presented patient experienced impairments in several areas of functioning. The patient had not contacted family or friends for several weeks, which was unusual for her. She had no current close friends at her school and had not had a dating relationship for several years. She reported that she was skipping classes and that she believed she was failing her program. The patient made statements such as, “I’m just a total loser” and “I don’t belong.” Despite excellent grades in college, she believed she was only accepted to law school due to her minority status. She primarily coped with stress by ruminating and had stopped many rewarding activities (e.g., exercise).

She had several relevant experiences from her early childhood. The patient had been adopted shortly after her birth by a White couple and was their only child. She grew up in an almost exclusively White neighborhood. She reported that, although she had some friends, she had no African American friends and that she often felt discriminated against by Whites and the few African Americans with whom she had contact, who criticized her for “trying to be White.” The patient described that, despite having devoted parents, she had a sense of not being good enough and being out of place since approximately 6 years of age, when she first started school.

Course of Therapy

In the initial session, the therapist has several goals, including (1) orienting the patient to the treatment approach, (2) establishing rapport, (3) identifying problems and treatment targets, (4) assessing current symptom and problem severity, (5) providing some initial symptom relief, and (6) introducing an initial homework assignment. In reality, these components tend to overlap. For example, it is often helpful to illustrate the CBT model using the life experience of the patient, and in doing so, to provide a chance at some symptom relief. An example could be processing a situation, such as being late to a first therapy appointment.

Therapist: You mentioned that you were upset because you were late. Can you tell me what you were thinking when you realized you were late?
Patient: I figured you'd be angry.
Therapist: Okay, and when you thought I'd be angry, how did you feel?
Patient: Pretty nervous.
Therapist: So that is what we will focus on in here, how your thinking in different situations influences how you feel. In this case, you were late, thought "he'll be angry," and felt nervous. Our goal is to test out the beliefs, like "he'll be angry," and change them when they aren't healthy or accurate. The great thing is that you sort of implicitly tested out the belief that I'll be angry by showing up. Was I angry?
Patient: You didn't seem angry.
Therapist: How anxious did you feel once we started talking?
Patient: Well, I'm feeling more comfortable.
Therapist: What thoughts do you have now about me being angry?
Patient: I don't think you're angry.
Therapist: So, this is an example of what we're going to be doing in therapy—I'll be helping you to identify thoughts that make you feel bad. We're then going to work together to come up with ways to check them out and change them if they're not true or accurate. You checked out whether I was angry by observing me, and you changed your thought, and now, I get the impression that you feel better.

In this example, the model of CBT is described for the patient and illustrated using her own thoughts, behaviors, and feelings. In particular, the effect of behavioral testing of beliefs (i.e., coming into session late and finding out if the therapist actually was angry) is pointed out. To increase her sense of efficacy, the therapist points out that her current actions can lead to mood change (feeling more relaxed after coming in late) and that she is already demonstrating some of the necessary skills to benefit from CBT.

To facilitate skills, an agenda is explicitly set forth and agreed on by the therapist and the patient every session. In the early sessions, the patient is oriented and trained in thought tracking and activity tracking. The decision of which thoughts or behaviors are targets for intervention is

based on the specific needs of the patient, which the therapist assesses using the case formulation. In the case described, the patient reported feeling “miserable” when she arrived at class. The therapist used the situation to train the patient in using a thought record, as shown in Figure 13.7–1. The specific situation is identified, and the emotional response and the thought or thoughts are recorded as well as the patient’s belief in the thought.

Patients learn techniques for modifying unhelpful thinking, including identifying factual inaccuracies (e.g., “I don’t understand anything” is all-or-nothing thinking) and biased information processing (ignoring evidence that she does know some things) and generating more accurate thoughts by the use of logic and testing beliefs.

Situation	Emotions (strength, 0–100)	Automatic Thoughts (strength of belief, 0–100)	Rational Responses	New Emotion (0–100)
Entering class	Miserable (70–80)	I don’t understand anything going on in this class! (100)	That’s all-or-nothing and emotional reasoning In the past, some things I felt were true didn’t turn out to be true I do know something, or I would not have gotten a B.	Miserable (50)

FIGURE 13.7–1. Thought record example.

Therapist: Okay, in this situation, you are feeling miserable. Now let's check this thought. What problems do you see with the thought, "I don't understand anything?"
Patient: Well, it's pretty all-or-nothing, but it feels like it's true.
Therapist: Can you think of any times when you felt something was true, and it wasn't?
Patient: Sure, I felt sure I wouldn't get into law school or college, for that matter.
Therapist: What does that tell you about this thought?
Patient: Well, it might not be true either.
Therapist: Okay, what would be other evidence that this thought isn't completely true?
Patient: Well, I do know some things.
Therapist: What is your evidence? Have you taken any tests or completed any assignments?
Patient: Yeah—and I got a B on the first test.
Therapist: So, what can we write in the rational responses column?
Patient: It isn't all-or-nothing; I do know some stuff.
Therapist: How miserable do you feel if you tell yourself that?
Patient: Well, a little less.

In this case, the patient experiences several types of distortion, including all-or-nothing thinking and emotional reasoning (i.e., "I feel it is true; therefore, it must be true"). The patient is asked to generate evidence that challenges the negative belief. The evidence reduces but does not eliminate the negative feeling. This is often the case, particularly when working with retrospective examples and patients experiencing significant depression. One approach to increase the efficacy of thought challenging and evidence gathering in CBT is by developing behavioral experiments to test the belief. In this case, the patient later conducted an experiment to test the "I don't know anything" belief. She wrote down her own answers to questions asked in the class, as well as the answers that other students made. She found that her knowledge was on par with her classmates, and she was able to answer most of the questions. This experiment also addressed her "belonging" because she got evidence of her equivalence to her peers.

As treatment progresses, the therapist points out recurring themes and helps the patient to identify and challenge core beliefs. In this example, the patient repeatedly experienced thoughts about not being good enough. She said that she felt this way all her life and attributed this to her sense of being different from her parents and her European American friends and her experience of persistent racism.

One approach to changing schema is to generate alternative core beliefs and to help the patient to identify behaviors and cognitions that are consistent with the new beliefs. In this case, a belief of “I belong just like everyone belongs; others may not believe it or act that way, but I do” was consistent with the patient’s values and overriding experience. The therapist would therefore challenge thoughts by asking, “is that the ‘old self’ or ‘new self’ talking?” This provided a shorthand for identifying dysfunctional thoughts and generating new ones consistent with the alternative schema.

In the final sessions, the tasks shift to reviewing progress, identifying potential future challenges, and learning to administer interventions independently. Returning to the example, the patient showed significant improvement in her mood. Interventions that had been beneficial were attending the university gym on a regular schedule (activity scheduling), joining a study group (activity scheduling, assertiveness training, and social interaction), and gathering evidence regarding beliefs about being good enough and belonging (thought challenging and experiments). In addition, another student had invited the patient on several dates. At the end of therapy, the patient had a depression score on the BDI in the nondepressed range, her school attendance and grades had improved, and she had daily contact with friends and family.

In preparation for termination, it is important to identify the improvements that the patient has made, the skills that have been learned, and potential challenges that may arise in the future. This client identified her risk factors for increased depression as a rejection if she started dating or failure at school. She also noted that, although she now did not fear attending class and she was doing well, she still was not talking in class unless she was called on.

Therapist: Is not answering questions in class a problem?
Patient: Yeah.
Therapist: Okay, you've been doing this a while; what do you think would be a good homework for you?
Patient: Well, I guess I could just plan to answer one or two questions in class and see what happens.
Therapist: When you say "see what happens," what could you track?
Patient: Maybe how many I get right and my thoughts and feelings after each question.
Therapist: Sounds good. What are some things you can do to make that easy in the class setting?

Because CBT is a skills-based model, it is critical that the patient demonstrates an ability to use skills independently of the therapist. In this case, she is able to take on the role of therapist and assign herself a task that can help her to modify her beliefs and behavior.

ADJUNCTIVE PSYCHOTHERAPY FOR BIPOLAR DISORDER

Psychotherapy for bipolar disorder is an adjunct to pharmacotherapy for the management of symptoms. As such, interventions including CBT, FFT, and IPSRT emphasize education about the disorder, learning to track symptoms and warning signs of relapse, and improving adherence to pharmacotherapy. In CBT, additional interventions include identifying thoughts and beliefs that can either (a) exacerbate symptoms or (b) increase the risk of relapse. In CBT and IPSRT, there is an emphasis on establishing stable routines to reduce triggers for mania. Finally, FFT emphasizes the role of educating the entire family system about the disorder and enlisting family members to aid patients with the management of their disorder. The current vignette describes a case from a cognitive behavioral conceptualization that incorporates techniques from other approaches.

A 47-year-old divorced Caucasian man was referred for psychotherapy by his treating psychiatrist. The patient was currently unemployed, although he volunteered 5 hours per week at his church. Although he had a long history of symptoms, this was the first time that he had been referred for psychotherapy. At the time of referral, the patient reported mixed symptoms of depression and mania. Depressive symptoms included depressed and sad mood, feelings of guilt, and suicidal ideation. Currently, the patient reported manic symptoms of irritability, racing thoughts, decreased need for sleep, and impulsive spending. In addition, the patient was preoccupied with religious ideation.

In considering integrative interventions, it is key to have an organizing structure with which to work. In this current case, the psychotherapist starts from a cognitive behavioral framework but then incorporates techniques associated with other approaches based on the formulation.

Initial Assessment

As with a unipolar disorder, an accurate assessment of diagnosis and symptoms is necessary for effective treatment. In addition, it is particularly important in the treatment of bipolar disorder to assess the level of activity, stability of routine, and supportive social networks. This is also an important point in identifying patient beliefs regarding bipolar disorder. These could include beliefs about the benefits of mania, fears that treatment would eliminate these benefits, concerns about medication side effects, or questioning the diagnosis. These issues will be key targets of treatment in any intervention.

The current patient presented for treatment secondary to several significant life events. He reported that he had several arguments with other volunteers at his church. This led to a warning from his pastor that he would not be able to continue volunteering if these conflicts continued. The patient was also under severe financial stress. Although he received disability income, he had spent the entirety of his most recent check on religious memorabilia and charitable donations and was at risk of eviction from his subsidized housing.

The patient had a long history of his disorder. He reported that he was raised in an intact family by his mother and father and had two younger sisters. He reported that his childhood was uneventful, and his parents were loving and supportive. He had done well in high school and had joined the army. He served 4 years in the military as a communications specialist. While in the military, he married a German woman whom he met while stationed in Germany.

His first symptoms occurred while in the military. He reported a manic episode leading to hospitalization, characterized by religious delusions, elated mood, goal-directed behavior (attempting to convert other soldiers to his beliefs), excessive spending, alcohol and drug use, and sexual acting out. This first episode led to his medical discharge from the military and divorce from his wife. After discharge from the hospital, the patient reported ongoing depressive symptoms extending several years, punctuated by periods of mixed depression and mania. He reported three additional hospitalizations, one following an additional manic episode and two following suicide attempts secondary to severe depression.

Course of Therapy

Psychotherapy for bipolar disorder is an adjunctive treatment to pharmacotherapy, and initial sessions reflect this. As with unipolar disorders, treatment included education about the treatment model, establishing rapport, identifying problems and goals, and assessing symptoms. In addition, the therapist assesses knowledge about bipolar disorder and provides education to both expand on that understanding and correct any misconceptions.

Therapist: What do you know about your diagnosis of bipolar one?
Patient: Well, it means I have ups and downs, and they get pretty bad.
Therapist: What else do you know about it?
Patient: Well, my doctor says I have to take my meds or else it will get worse.
Therapist: How do you feel about taking your medication?
Patient: I really don't like to.
Therapist: How come?
Patient: I'm just not me when I'm taking them. I feel like I am slowed down, and I just can't think. I just don't know if they help. I'm taking them now, and I don't feel much better. And they don't fix the real problems I've got.
Therapist: Which are?
Patient: I have no friends, I have no girlfriend, I have no job, I have no money, no one helps me, my family's disowned me. And when I'm taking my medication, I just become a lump, and none of that gets better.
Therapist: That sounds pretty depressing. I am going to write down those things you listed as items for your problem list, including job, money, dating, family, friends, and medications.
Patient: Okay.
Therapist: And one thing that stands out to me is that you aren't happy with taking medications. That is an important thing for us to deal with as well.

In this example, the question about the patient's understanding of his disorder was to actually get information for the problem list. In addition, it elicits information about concerns regarding medication. The therapist here now has the opportunity to both demonstrate the development of the problem list and, over time, educate the patient about medication use.

One issue that complicates treatment when patients are receiving combined pharmacotherapy and psychotherapy is whether the psychotherapist is also the prescribing provider. In the case where there is one provider, coordination of pharmacotherapy and psychotherapy is obviously easier, but frequently the prescriber does not have time and/or expertise to provide psychotherapy. Therefore, frequently separate

providers do psychotherapy and pharmacotherapy, and therefore it is critical for these providers to be in frequent contact and coordinate.

From a CBT perspective, the key aspects of psychotherapy for bipolar disorder will include tracking symptoms and functioning, identifying and modifying cognitions that may exacerbate symptoms or impair functioning, and behavioral interventions designed to increase rewarding activities without producing manic activation. To do this, interventions can include those from other models, including the education and involvement of family or other support resources and stabilization of social rhythms through the establishment of a consistent routine as in IPSRT.

In this situation, identifying warning signs can help the patient apply skills to prevent full symptom exacerbation. However, patients often don't notice as symptoms are worsening, and therefore it is useful to enlist family members or other support to provide feedback. For this to be effective, it is helpful to (a) meet with the support person and educate them about the disorder and the goal of tracking warning signs and (b) to work with both the patient and the support person to agree on how the support person will inform the patient about concerns and how the patient will respond. In the current case, the patient's pastor eventually attended a session with the patient and developed a plan for tracking symptoms and responding when symptoms were exacerbated. This both provided pragmatic support and also challenged the patient's perception that no one cared. In this case, the fact that the support person was the pastor was also beneficial, given that the patient had symptoms of hyperreligiosity when becoming manic. By educating the pastor and patient regarding these symptoms, they could quickly notice when there was a change and intervene through thought challenging, working with structure, attending to medication adherence, and working with the prescribing provider to adjust medications.

This example reviews identifying strategies to reduce the risk of relapse following recent symptom exacerbation.

Therapist: What do you think led to you feeling worse?

Patient: I think that I felt like I had to do all the work for the church to prepare for the holidays. I started doing more and more, and I got really stressed.

Therapist: All right, so taking on too much is a problem. One thing we're going to do today is work on a list of warning signs that your symptoms are getting worse. Then we have to figure out how to help you notice when they come up and do something about them. Do you have anyone around whom you trust who could help you notice when this is happening?

Patient: No. You know that.

Therapist: I was thinking about co-workers, like one of the other volunteers or your pastor. You've mentioned that he has been really supportive, and he knows about your symptoms.

Patient: Yeah, I know he gets worried about me.

Therapist: One thing we can do is practice asking him to give you feedback about your actions and to let you know when he notices warning signs that your symptoms are getting worse.

Patient: I just worry that I'm asking too much.

Therapist: Well, let's practice in here how you would ask. Also, let's generate some other ways to notice warning signs.

During the course of treatment of bipolar disorder, the role of the therapist is to facilitate the patient identifying warning signs, implementing skills practice, and providing support and encouragement (Table 13.7–3).

Table 13.7–3.
Examples of Warning Signs

Warning Signs	Depressed	Warning Sign	Normal	Warning Sign	Manic
Sleep	Sleeping >10 hours	Trouble waking up, sleeping >9 hours	8 hours	>7 hours	No sleep and energized
Energy	Cannot get out of bed	Tired in the evening	Up at alarm clock, able to work through day	Waking up early and energetic	"Superman mode"
Spending	Isolating—not buying necessities	It is an effort to get food	Normal	Start buying treats for friends	Giving away all my money to charity
Mood	Crying easily	Pessimistic	"OK"	Optimistic	Euphoric
Guilt	Thoughts of failure	Sensitive to criticism	"OK"	Flippant, not concerned about others	"I am special in God's eyes"
Religion	Abandoned by God	Feeling cynical and doubting	Comfortable with faith	Wanting to share the good news	"I am God's messenger"—seeking out people to convert
Suicide	Start planning to kill self	Thoughts of being dead	None	None	None ("I will live forever")

Later sessions emphasize not only the continued practice of learned skills but challenging core beliefs that may contribute to the risk of symptom relapse. For the current patient, the belief "I'm damaged and will never be accepted by anyone" was a key theme that came up. He perceived his bipolar disorder as a flaw that meant that he could never have a "normal" life and that others would always reject him. Assumptions that arose from this belief were that he could never have a romantic relationship, that he could never reconnect with his family, and that he could never have paid employment. He also was ambivalent about his treatment (particularly medication), doubting that he could make any improvement. Therefore, the later sessions focused on both challenging unhelpful beliefs and developing alternatives to unhelpful core beliefs.

At the end of treatment, the goals are for the patient to be able to identify symptom changes, have a range of skills with which to respond to those changes, and have improved communication with their pharmacotherapist so that medication adherence is consistent and appropriate changes in pharmacotherapy can be made as needed. In addition, if family members are available, the goal is that the patient and family have developed an improved understanding of the disorder and communication skills so as to facilitate a stable mood.

FUTURE DIRECTIONS

Some basic guidelines can be derived from treatment. In general, it is incumbent on the clinician to apply interventions for which there is empirical support. In the case of mood disorders, there are several psychotherapeutic options that are now available. There are some patient

characteristics that could recommend treatment, including the presence of significant marital distress, amenability to a particular validated treatment modality, and chronic depression.

An important component of good psychotherapy, regardless of the model, is that the therapist has a treatment rationale that guides decisions regarding interventions. This is a shared theme of all of the current validated treatments for mood disorders. However, such a model is not likely sufficient for effective treatment. Psychotherapies generally are built around mediational models of change, with modification of the target symptom (e.g., depressed mood) being achieved through intervention on a more accessible construct (e.g., an irrational belief, a rewarding activity, increase in medication adherence, or a transference reaction in therapy). What distinguishes excellent clinicians, regardless of orientation, is their ability to hold a conceptual framework in mind and to apply that framework to the unique challenges of the patient.

13.8 Mood Disorders: Neurobiology

Michael E. Thase, M.D., Vladimir Maletic, M.D., M.S., and Charles L. Raison, M.D.

It has been thought for centuries that at least some forms of depression are either caused by or maintained by disturbances of brain function and since the 1960s, it has been possible to study selected neurobiologic processes that are linked to the etiology and pathogenesis of mood disorders. Several key sets of observations have informed research in this area. First, the heritability of mood disorders has suggested that the neurobiologic underpinnings of depression may be related to specific genes, of which more than 100 have been identified. Second, a more detailed understanding of the neurobiology of stress response has informed interactive stress-diathesis models of vulnerability. Third, the discovery of the first generation of “somatic” treatments (i.e., ECT and the TCA and monoamine oxidase inhibitor [MAOI] antidepressants) in the 1940s and 1950s pointed to potentially reversible neurobiologic targets for intervention. As the methodology for studying the neurobiology of mood disorders has grown more sophisticated, investigations utilizing indirect indicators of brain function such as the levels of monoamine metabolites or cortisol, urine, plasma, or cerebrospinal fluid (CSF), have largely been

supplanted by translationally guided studies of gene transcripts and proteomics. Likewise, coarse measures of regional brain function, such as recordings of evoked potentials or electroencephalographic (EEG) activity patterns during waking and sleeping, largely have given way to neuroimaging strategies that permit the activity of regions or specific neural circuits to be examined at rest and during provocative challenges. This chapter will survey the neurobiology of mood disorders, emphasizing clinically relevant associations with phenomenology, course of illness, and treatment outcomes.

CLINICAL PHENOMENOLOGY

The signs, symptoms, and subjective experiences associated with depression have long suggested dysfunction of basic central nervous system (CNS) processes. With respect to cortical function, depression involves multiple disturbances of information processing. Most depressed people automatically interpret experiences from a negative perspective, and their access to memory is negatively biased. In more severe depressive states, cognition and problem-solving skills are further compromised by poor concentration and decreased ability to use abstract thought. A virtual monologue of negative thoughts and images seems to run on autopilot, and unlike normal states of sadness, ventilation to a confidante has little beneficial effect. In more extreme cases, delusions or hallucinations, or both, grossly distort reality testing. These neurocognitive changes point to dysfunction involving the hippocampus, prefrontal cortex (PFC), the amygdala, and other limbic structures.

Another biologically based characteristic of depression involves decreased interest and a loss of mood reactivity. Spontaneous, goal-directed activities decrease, and events that *should* improve mood have little or no effect. One correlate of loss of interest is decreased reinforcer salience. Even basic appetitive functions, such as appetite and libido, are diminished in severe depression. Anhedonia and decreased appetitive behavior point to dysfunction of the neural circuits involved in the anticipation and consummation of rewards, which involve the thalamus, hypothalamus, nucleus accumbens, anterior cingulate, and PFC.

Alterations in the initiation, expression, and spontaneity of movement are common in severe depression. A background state of decreased animation, referred to as psychomotor retardation, is sometimes

accompanied by a superimposed state of agitation. In addition to the pacing and frequent postural shifts, stereotypical signs or behaviors, such as a furrowed brow, hair pulling, biting at the lips or nail beds, and compulsive scratching, are observed in severe depressive states. Anhedonia and psychomotor disturbances are more pronounced among older depressed patients and in recurrent depressive episodes, with agitation typically limited to the most severe depressive syndromes. These observable signs point to the dysfunction of subcortical circuits connecting the thalamus, basal ganglia, and striatum.

Almost all depressed people report low energy or fatigue and some difficulty involving sleep. Although insomnia is much more common (prevalence rates of two-thirds to four-fifths in most clinical samples), hypersomnolence is not uncommon, particularly earlier in life. Clinicians have long noted an association of hypersomnia with other “reversed” neurovegetative signs and symptoms, such as increased appetite and weight gain. The classical sleep disturbances of depression, such as difficulty maintaining sleep and early morning awakening, also tend to be more pronounced and severe in older individuals with a history of recurrent illness. Such terminal insomnia is in turn linked to diurnal mood variation, in which morning is the worst time of the day. Disturbances of these normally well-entrained circadian rhythms are indicative of dysregulation of nuclei in the thalamus, hypothalamus, and brain stem.

For decades, clinical researchers have viewed the tendency for these signs and symptoms to coaggregate or cluster together to reflect the neurobiologic basis for the classical subtypes of depression. For example, anhedonia, loss of mood reactivity, and psychomotor disturbance are more commonly associated with weight loss, terminal insomnia, diurnal mood disturbance, or a combination of these. This constellation forms the basis of the syndrome of *melancholia* (also known over the past five decades as *autonomous*, *biologic*, or *endogenous* forms of depression). As these depressions are often recurrent, and discrete episodes can begin without the provocation of a significant stressor, they were proposed to have an *internal* (i.e., neurobiologic) etiology. The fact that such depressions were slow to remit spontaneously, yet were quite responsive to ECT further reinforced perceptions of underlying biologic dysfunction. The stable nature of this syndrome over the centuries has been recognized by the contemporary use of the ancient Greek term

melancholia, even though black bile is no longer implicated in the pathophysiology of severe depressive states.

In contrast to *melancholia*, the depressions more commonly seen in young adult life often seemed inextricably tied to personality problems, interpersonal problems, and maladaptive responses to psychosocial difficulties. The terms *nonendogenous* and *reactive* were used to represent the observation that depression in young adults is almost invariably associated with stressful life events. As suggested by the names, these depressions were presumed to be mediated by nonbiologic factors related to personality and resilience to stress. The association of an early age of onset with co-occurring anxiety (both symptoms and discrete disorders)—coupled with a low incidence of psychotic symptoms (i.e., delusions or hallucinations)—further solidified impressions that younger depressed patients had a *neurotic* disorder. Another hallmark of a putatively neurotic disorder, persistence or chronicity, also characterized by many early-onset depressions. The presumed primacy of psychosocial factors in neurotic or nonendogenous depression was further suggested by the too frequently poor responses to ECT and TCAs. That the onset of depression in early life may, of course, distort personality development, limit one's repertoire of coping skills and diminish resilience, change brain structure and function, and alter drug responsivity (i.e., pathoplasty) was not yet appreciated. It was also not yet known that early-onset depressions are associated with a relatively high familial loading in genetic studies (i.e., a hallmark of a biologically mediated disorder). Likewise, neither the heritability of neuroticism nor the neural basis of the characteristically increased reactivity to emotional stimuli had yet been established.

One historically important subgroup of patients with nonendogenous or neurotic depression was defined in part by *reverse* neurovegetative symptoms (i.e., increased appetite, weight gain, and hypersomnolence). As the patients treated by the hospital-based psychopathologists of the 1940s and 1950s seldom had such symptoms, this presentation was described as *atypical depression*. The notion of atypicality was reinforced by a relatively poor response to ECT and TCAs, and by contrast, a relatively preferential response to MAOIs. Importantly, as clinical research shifted to ambulatory settings, and greater numbers of younger and less severely symptomatic people began to seek treatment for mood disorders, it was recognized that about 15% to 25% of depressed people have

reverse vegetative features, which means that—despite the name—this presentation was not so atypical. Furthermore, contemporary studies used the correlation between polygenic risk scores, functional imaging studies, and phenotypical and metabolic markers in order to “dissect” depression subtypes based on their neurobiologic underpinning. Atypical depression was noted to share risk genes with increased appetite/BMI/obesity, upregulated inflammatory signaling (higher C-reactive protein [CRP]), insulin resistance, elevated leptin and leptin resistance, and increased insula response to appetitive stimuli.

RISK FACTORS

Genetic Influences

Mood disorders and suicide clearly run in families, yet the contributions of nature and nurture have provoked intense debates for decades. It is now well established that bipolar affective disorder is more heritable than other mood disorders; heritability increases in proportion to the amount of shared genetic material, and early age of onset is associated with greater heritability. Thus, identical twins have a greater heritable risk than fraternal twins, who are at approximately the same risk as other first-degree relatives (i.e., siblings and parents). First-degree relatives, in turn, have a greater shared risk than half-siblings, grandparents, or cousins. Research comparing same-sex fraternal and identical twins and studies using the adopted-away paradigm further demonstrated that heritable risk transcends environmental influences. Research using modern molecular genetic methods will eventually lead to the identification of the gene products that transmit this risk. Already, it is clear that a number of alleles are associated with a small but replicable increase in the risk of depression, yet others may be associated with relative resilience. Other genes, while showing no relation to the risk of depression, are relevant to response to specific antidepressants, primarily by increasing or decreasing drug metabolism via Cytochrome P450 enzymes.

Although the significance of genetics cannot be disputed, considerable variability exists within and across groups with comparable heritable risks. For example, identical twins do not have 100% concordance of bipolar affective disorder. Early-onset depressions are more heritable, and conversely, late-onset mood disorders (i.e., after 60 years of age) have the lowest rates of heritability, presumably because of the greater impact

of acquired risk factors, including cerebrovascular disease and selected dementing illnesses. In some pedigrees, men are at greater risk of alcoholism and sociopathy, and women are at greater risk of depression. There is some evidence that different environmental experiences may influence whether a woman develops depression or a generalized anxiety disorder. Conversely, for men, alcohol or drug use disorders may constitute an alternate illness trajectory to early-onset depressive disorders. Genetics thus constitutes just one pathway of vulnerability.

Predispositions to various emotional states (i.e., mood set points or temperament) also appear to be partly heritable. Of particular importance is a temperament characterized by excessive emotional reactivity and behavioral inhibition. Modern theories of temperament and personality converge around several related dimensions, including high levels of harm avoidance (neuroticism) and low levels of novelty seeking (introversion).

These temperaments, which can be recognized in infancy, are associated with increased vulnerability to depression and anxiety, presumably via increased limbic reactivity and heightened sensitivity to the impact of stressful life events. Childhood-onset of dysthymia similarly presages extremely high rates of depression and bipolar disorder in adulthood.

One reason for inconsistency in genetic research is the process known as epigenetics. This term refers to functionally relevant modifications of genes—typically induced by DNA methylation or histone modification—in response to environmental stimulation that do not actually change the DNA sequence of the gene. Epigenetic changes in gene expression, both activating and inhibiting, are typically irreversible (i.e., will last for the life of the cell) and may persist across multiple generations. Intensive ongoing research indicates that some of the changes in brain function attributable to the impact of chronic stress may be mediated by epigenetic changes in key regions of the brain.

Recent synthetic approaches attempting to elucidate common etiologies within the otherwise biologically heterogeneous condition of MDD combined large-scale genome-wide association studies (GWAS) with postmortem cytology and functional and structural imaging studies. Consistent associations were noted between principal neuroimaging findings in depressed patients and downregulated genetic markers for cortical somatostatin (SST)-expressing gamma aminobutyric acid (GABA) interneurons and astrocytes. Polygenic SST interneuron markers were

most expressed in the subgenual anterior cingulate (sgACC), medial PFC (mPFC), anterior insula, and temporal lobes coinciding with brain areas where imaging studies confirmed cortical thinning and aberrant connectivity in depressed patients. By linking specific genetic changes to functional/structural consequences in the brain, these types of combined methodologies may help both identify depressogenic mechanisms and more biologically homogeneous subtypes of depression.

ETIOLOGY OF EMOTIONS

Some consider depression to be an extreme expression of sadness, a normal mood, with elation to be the healthier counterpart of the euphoria of mania. Such continuity between normal and pathologic mood states is illustrated by bereavement. On the one hand, grief is a universal experience, yet, on the other hand, it can segue into a severe and disabling depressive state. Although there are less obvious parallels to mania, the intensity of new romantic love or other peak emotional experiences is associated with changes in perception, cognition, behavior, and judgment that border on manic excitement. The euphorigenic effects of cocaine and other psychostimulants amply document that the hard wiring for manic states exists in many if exposed to the right neurochemical milieu.

There is now considerable agreement that several basic emotions are observed across human cultures. Sadness and crying, for example, may be universally recognized interpersonal distress signals. Moreover, the capacity to recognize the emotional states of others develops at such an early age that innate processes are undoubtedly implicated.

At the risk of anthropomorphizing excessively, basic emotional states are also observable across mammalian species. Behavioral predispositions toward aggressivity (or passivity) and social dominance (or subordination) appear to extend across vertebrate species. However, by virtue of a large neocortex, humans are distinguished by a greater capacity to modify the expression of basic emotional states via abstraction, integration, and synthesis of complex symbolic representations, communication of experiences to others in direct or elaborated forms, and development of self-concepts that guide behavior, both in relation to others and an anticipated future. The domains of competence are similarly broader and diverse. Whereas a highly

competent primate may quickly gain a position of dominance if placed in a new troupe, only the human can intentionally misrepresent their competence, conceal motivations, or be thwarted by archival documentation of past behaviors.

When compared to other mammals, the relatively greater importance and intensity of attachment bonds facilitate the protracted task of human child-rearing and enhance the advantages of kinship. Indeed, for hundreds of thousands of years, the ancestors of man lived in a world in which survival into adulthood was uncommon. Indeed, it is only in the past few centuries that average life expectancy has exceeded 40 years. Young humans are arguably the most vulnerable of mammals and certainly remain dependent on their caregivers for the longest period of time. Certain necessary divisions of labor no doubt increased the chances of viable offspring and may have slowly shaped sex differences in affectivity and affiliative behavior that in turn may help to underpin gender differences in the risk of depressive disorders. Ethologic considerations also may help to explain why rates of depression appear to be increasing. The profound changes in social systems and lifestyles that have taken place in the past several centuries have forced adaptations that are too rapid for natural selection. In relative terms, the breathtaking sociocultural and technologic changes of the past century have taken place in less than 0.00001th of hominid experience! The stressors faced in modern life thus present complexities that despite such a large neocortex and complex social networks, sometimes overwhelm basic adaptive capacities.

FIGURE 13.8–1. The central executive network (CEN). CEN is centered on the dorsolateral prefrontal cortex (dlPFC) and posterior parietal cortex (PPC), and also includes the dorsomedial prefrontal cortex (dmPFC), dorsal ACC (dACC), and inferior temporal gyrus (ITG). (Figure reprinted from Bi B, Che D, Bai Y. Neural network of bipolar disorder: Toward integration of neuroimaging and neurocircuit-based treatment strategies. *Transl Psychiatry.* 2022;12:143. doi: 10.1038/s41398-022-01917-x. EMOTIONAL PROCESSING AND THE BRAIN

Modern affective neuroscience focuses on the importance of four brain regions in the regulation of normal emotions: the PFC, the anterior cingulate, the hippocampus, and the amygdala (Fig. 13.8–1). The PFC is viewed as the structure that holds representations of goals and appropriate responses to obtain these goals. Such activities are particularly important when multiple, conflicting behavioral responses are possible or when it is necessary to override affective arousal. The dorsolateral region of the PFC (dlPFC) and posterior parietal cortex (PPC) are particularly active in the suppression of negative affect and are key constituents of the cognitive control network (CNN), topographically coinciding with the central executive network (CEN), and for the most part with the frontoparietal network (FPN) (see Fig. 13.8–1). In addition to "top-down" regulation of emotions, the CNN/CEN also supports working memory and allocation of attention. The mPFC along with the posterior cingulate cortex (PCC), inferior parietal lobe, and temporal cortical

structures, including the hippocampus (see below), are important hubs in the default mode network (DMN)(Fig. 13.8–2), an interconnected circuit of regions that are active during resting wakefulness, self-referential thinking (i.e., autobiographical memory), processing social information, planning for the future or daydreaming. Contemporary studies have implicated DMN structures in the planning stages of higher cognitive activity and creative processes. The DMN appears to show both hyperconnectivity *and* hypoconnectivity in depressive disorders, which predisposes to negative recall and a failure to inhibit rumination. More recent meta-analyses have investigated the individual roles of DMN subsystems that contribute to MDD. The “Core DMN,” composed of anterior mPFC and PCC, plays a key role in self-referential processing. The “dmPFC complex,” together with the temporoparietal junction (TPJ) and lateral temporal cortex, participates in mentalizing and metacognitive representation of self and others. Finally, the medial-temporal cortex (MTL) subsystem, which also includes the dmPFC, extended hippocampus, and posterior inferior parietal cortex, underpins both reminiscing and projecting one’s future.

FIGURE 13.8–2. The default-mode network (DMN). DMN consists of two core regions: the medial prefrontal cortex (mPFC) and the posterior cingulate cortex/precuneus (PCC/PCU), and the inferior parietal lobule (IPL). The lateral temporal cortex (LTC) and the hippocampal formation (Hip) are often found as being strongly related to the DMN, but likely constitute a subsystem within the DMN. (Figure reprinted from Bi B, Che D, Bai Y. Neural network of bipolar disorder: Toward integration of neuroimaging and neurocircuit-based treatment strategies. *Transl Psychiatry.* 2022;12:143. doi: 10.1038/s41398-022-01917-x. License: https://creativecommons.org/licenses/by/4.0/.)

The largest meta-analyses examining the relationship between MDD and DMN (sample size of several hundred patients) have confirmed that MDD is highly heterogeneous while simultaneously establishing overall hypoconnectivity in the DMN-core as a moderate risk marker of MDD. Global DMN hypoconnectivity has also been linked with severe negative bias and anhedonia. Furthermore, DMN core and dmPFC subsystem dysfunction appear to be responsible for ruminations in a subpopulation of MDD patients. Extending these findings, recent studies have reported an association between greater “internal” DMN connectivity, as well as connectivity between DMN and SMN and FPN with response to antidepressants.

There is also evidence of some hemispherical specialization in PFC function. For example, left-sided activation of regions of the PFC is more involved in goal-directed or appetitive behaviors, whereas regions of the right PFC are implicated in avoidance behaviors and inhibition of appetitive pursuits.

The anterior cingulate cortex (ACC) is thought to serve as the point of integration of attentional and emotional inputs. Two subdivisions have been identified: an affective subdivision in the rostral and ventral regions of the ACC and a cognitive subdivision involving the dorsal ACC. The former subdivision shares extensive connections with other limbic regions, and the latter interacts more with the PFC and other cortical regions. It is proposed that activation of the ACC as part of a CCN facilitates effortful control of emotional arousal, particularly when goal attainment has been thwarted or when novel problems have been encountered. There is evidence that connectivity among the components of the CCN is diminished in depressive states, and if persistent, such decreased connectivity may contribute to relapse/recurrence risk.

The salience network (SAN) attributes emotional meaning to sensory experiences including anxious and depressed feelings. Abbreviation SAN will be used in place of the more commonly utilized SN for the purpose of disambiguation from the substantia nigra (SN). Furthermore, SAN structures are key participants in motivational and reward signaling. Moreover, aberrant connectivity between components of SAN (anterior ACC) and DMN (PCC) has been associated with the intensity of depressive ruminations and the duration of depressive episodes. It is as if the negative affect generated by SAN to fully engage CCN/CEN during cognitive tasks without adequately suppressing DMN activity may hinder cognitive performance due to interference stemming from ruminations and/or daydreaming. This pattern of maladaptive functional activity is more common in individuals with child/adolescent onset of depression. Diminished SAN connectivity has been linked with several clinical correlates of the depressed state, such as inattention, negative emotional bias, anxious avoidance, and anhedonia.

FIGURE 13.8–3. The salience network (SAN). The salience network (SAN) consists of the insular cortex (IC), dorsal anterior cingulate cortex (dACC), amygdala (Amy), ventral tegmental area (VTA), substantia nigra (SN). (Figure reprinted from Bi B, Che D, Bai Y. Neural network of bipolar disorder: Toward integration of neuroimaging and neurocircuit-based treatment strategies. *Transl Psychiatry.* 2022;12:143. doi:10.1038/s41398-022-01917-x. License: https://creativecommons.org/licenses/by/4.0/.)

The hippocampus is most clearly involved in various forms of learning and memory, including fear conditioning, as well as inhibitory regulation of HPA-axis activity. Importantly, the hippocampus is also one of the few sites of the brain capable of neurogenesis (i.e., the process of differentiation of stem cells into potentially functional neurons). Emotional or contextual learning appears to involve a direct connection between the hippocampus and the amygdala.

The amygdala appears to be a crucial way station for processing novel stimuli of emotional significance and coordinating or organizing cortical responses. Located just above the hippocampi bilaterally, the amygdala has long been viewed as the functional center of the limbic system. Although most research has focused on the role of the amygdala in responding to fearful or painful stimuli, novelty and ambiguity can also bring the amygdala “on line.”

Finally, one recent review of intrinsic functional networks includes a sensory-motor or somatomotor network (SMN) (Fig. 13.8–4). The sensory-motor network is composed of the middle cingulate cortex (MCC), dorsal striatum, ventral thalamic nuclei, sensory (postcentral) gyrus, motor (precentral) gyrus, and pre- and supplemental motor areas. The SMN supports sensory processing, as well as planning and execution of

complex motor behaviors. It has been posited that mania is associated with elevated activity of SAN and SMN and diminished DMN-based self-monitoring. In contrast, depressive states may be marked by reduced SMN activity, coinciding with psychomotor retardation and increased DMN function, reflected by internally focused thinking and rumination. The ratio between DMN and SMN activity was found to strongly correlate with the intensity of depression. Psychomotor abnormalities due to aberrant functional network activity may represent a trans-diagnostic phenomenon. Furthermore, "supremacy" of SMN relative to DMN activity is most likely clinically associated with compromised self-monitoring, sensory hyperacuity, emotional reactivity, and psychomotor agitation in the context of mania but also agitated unipolar and bipolar depression. Based on a recent large meta-analysis of the brain's functional connectome involving over 600 MDD patients, internal hypoconnectivity within SMN seems to be the most stable imaging marker of MDD.

Any cogent discussion of functional neural circuits involved in the etiology of mood disorders would be incomplete without mention of the reward circuit and cortico–striatal–thalamo–cortical (CSTC) circuit (see Fig. 13.8–5). Malfunction of the reward circuit, comprised of the dopaminergic ventral tegmental area (VTA), ventral striatum, rostral ACC, and ventromedial (vmPFC)/orbital PFC, likely underpins anhedonia, loss of interest, low motivational states, and even some cognitive manifestations of depressive episodes. The CSTC circuit is a highly integrated "updating" system comprised of three parallel feedback loops. In some ways, CSTC functions as a "backbone" of other major functional networks (SAN, DMN, CEN, SMN) as it shares anatomical locations and pathways with the hubs of these networks and continuously updates them with new multimodal information. The CSTC comprises three parallel loops: (1) the associative/cognitive division, which includes dlPFC, dorsal caudate, pallidum, SN, pars reticulata (SNr), and ventral anterior (VA), and mid-dorsal (MD) thalamic nuclei; (2) the affective/limbic division, which includes vmPFC/ACC, ventral striatum, pallidum, SNr and VA, and MD thalamus; and (3) the sensory-motor division, which encompasses sensory and motor cortical areas, dorsal putamen, pallidum, SNr and ventrolateral (VL) thalamus (see Fig. 13.8–5).

Elevated dopaminergic transmission in the associative striatum and increased activity of the sensory-motor division putatively underpin psychotic symptoms, agitation, and emotional reactivity in bipolar mania,

while diminished activity in the sensory-motor division may coincide with psychomotor retardation in the context of a depressive episode. Inadequate functioning of the associative/cognitive division of the CSTC loop may also be responsible for cognitive and executive function deficits in mood disorders. Moreover, reduced activity in the ventral affective/limbic division of the CSTC loop has been implicated in anhedonia and cognitive/emotional blunting during a depressive episode. Novel approaches to elucidating the role of major functional networks in generating the symptoms of mood disorders have shifted the focus away from stationary connectedness to a more dynamic perspective that highlights disturbance in their adaptive coupling and the relative duration of specific network activity (e.g., level of depression correlated with duration of DMN activity).

FIGURE 13.8–4. The somatomotor/sensorimotor network (SMN). SMN—which comprises the middle cingulate cortex (MCC), dorsal striatum, ventral nuclei of thalamus and postcentral gyrus (somatosensory cortex [SC]), premotor (PMC), and supplemental motor areas (SMAs)—is involved in sensory processing and motor functions. Auditory and visual cortices (AC/VC) are sometimes included. (Figure reprinted from Bi B, Che D, Bai Y. Neural network of bipolar disorder: Toward integration of neuroimaging and neurocircuit-based treatment strategies. *Transl Psychiatry.* 2022;12:143. doi:10.1038/s41398-022-01917-x. STRESS AND ANIMAL MODELS OF DEPRESSION

Studies of smaller mammals and nonhuman primates have demonstrated that acute stress responses involve activation of central and peripheral components of two interactive psychoneuroendocrine systems: the cortical HPA axis and the sympathomedullary (SM) axis. Acute responses to stress are phenomenologically and neurobiologically more akin to fear and anxiety than depression. However, whereas stress initially signals threat, it is the anticipation of loss and the meaning of the loss—as well as the loss of hope—that can provoke the transition from anxiety to sadness and despair.

Acute stress activates cell bodies of norepinephrine (NE) neurons in the locus coeruleus (LC), whose ascending axons signal noradrenergically-mediated increases in cortical arousal and whose descending axons signal increased adrenergic (predominantly epinephrine) output by the sympathetic nervous system and adrenal medulla. Behaviorally, the perception of acute stress elicits perceptual vigilance, preparedness for response, and inhibition of appetitive activities, such as foraging and pursuit of sexual activity.

Stress simultaneously triggers and releases corticotropin-releasing hormone (CRH) from neurons in the hypothalamus and cerebral cortex. Hypothalamic CRH activates the synthesis and release of adrenocorticotropic hormone (ACTH) from the anterior pituitary, which in turn, triggers the release of cortisol and other glucocorticoids (from the adrenal cortex). CRH also synergistically increases LC activity, and directly or indirectly, increases the synthesis of other stress-reactive gene products and anti-inflammatory responses, and decreases the synthesis of key neuropeptides such as brain-derived neurotrophic factor (BDNF). The excitatory amino acid glutamate may synergistically heighten CNS arousal in response to stress. The acute response to stress is counterbalanced by homeostatic or adaptive mechanisms. These include feedback inhibition by glucocorticoid receptors in the hippocampus and pituitary, downregulation of postsynaptic noradrenergic receptors, and inhibitory auto- and heteroreceptors on presynaptic NE neurons. As is discussed subsequently, parallel input from serotoninergic, GABA, and glycinergic neurons exert dampening or inhibitory effects.

Exposure to prolonged, inescapable stress is associated with numerous adaptations in neurobehavioral responses. Although CRH levels in the brain and corticosteroid levels in the periphery may remain elevated, levels of NE, 5-HT, dopamine (DA), and GABA in the brain stem and forebrain eventually decrease. Animals trapped in such a state eventually cease trying to resist or to escape and show decreased grooming and appetitive behavior. The behavior persists outside of the experimental situation. There are significant individual differences in the development of such learned helplessness, as well as differences across pedigrees, strains, and species. Like other forms of chronic stress, the negative behavioral effects of learned helplessness may be sustained by epigenetic changes in key regions of the brain. Importantly,

antidepressant drugs have been shown to prevent, attenuate, or reverse learned helplessness across species.

Studies of the experiences of primates in the wild, of course, are more relevant to the stresses faced by people than a rat's response to an inescapable, painful electric shock. These naturalistic studies demonstrate not only that central 5-HT activity is partly under genetic control, but also that loss of a dominant role within a primate social hierarchy results in decreased 5-HT neurotransmission and increased HPA. In the wild, animals with low levels of the serotoninergic metabolite 5-hydroxyindoleacetic acid (5-HIAA) are likely to be more aggressive, more socially subordinate, and less sexually active. When social status is manipulated by creating a new troupe from a cohort of subordinate primates, a new dominance hierarchy emerges, and the more dominant animals experience a corresponding increase in 5-HT function. Conversely, during times of adversity, such as drought or famine, it is the socially dominant primates that experience the largest increases in HPA activity.

MALTREATMENT AND EARLY ADVERSITY

Physical, verbal, and sexual abuse and parental neglect have an indelible effect on one's life trajectory. Although it has been known for decades that such maltreatment plays a key role in the pathogenesis of PTSD and borderline personality disorder, it is now clear that such a history results in a two- to threefold increase in the risk of depression and is associated with important phenomenologic and biologic differences in depressive states.

Studies of animal models confirm that lasting alterations in neuroendocrine and behavioral responses can result from severe early stress. Animal studies further indicate that even transient periods of maternal deprivation can alter subsequent responses to stress. This vulnerability has been shown to be the result of enduring changes in gene expression. For example, protracted stress thus can induce changes in the functional status of neurons via inducing epigenetic changes and may suppress neurogenesis in the hippocampus. Recent studies in depressed humans indicate that a history of early trauma is associated with long-lasting changes in responsivity of the HPA axis, including accompanied by

structural changes in the hippocampus and perhaps other focal regions within the cerebral cortex.

MONOAMINE SYSTEMS: FUNCTION AND DYSFUNCTION

An area of scientific inquiry is chosen in part because of the knowledge base and experimental paradigms available to investigators. In the early 1960s, nobel prize-winning research had just elucidated the importance of monoamines in neurotransmission. Moreover, it was possible to measure the metabolites of the catecholamine NE in various body fluids and 5-HIAA, the principal metabolite of 5-HT, in CSF. Visualization of the functional brain, by contrast, was essentially limited by the low sensitivity of recording neuronal activity from the surface electrodes used for EEGs. Specifically, whereas the paroxysmal spikes in electrical activity caused by epileptogenic foci or the diffuse slowing associated with delirium could be documented by EEGs, the more subtle changes in brain activity or regional cerebral metabolism associated with affective states could not.

In addition, there were multiple lines of evidence from pharmacologic studies implicating perturbations of monoamine systems in the therapeutic and iatrogenic effects of various medications. The relevant pharmacotherapies of the time, the TCAs and MAOIs, were known to increase the amount of neurotransmitter available at monoamine synapses. Conversely, the monoamine-depleting compound reserpine was known to cause depression as a side effect during the treatment of hypertension. Intoxication with potent noradrenergic agonists, such as amphetamine and cocaine, also was known to induce states of sleepless euphoria and activated psychosis, followed by a crashing, depression-like withdrawal.

The early monoamine hypotheses—formulated by many of the pioneers of the first generation of psychopharmacologists, such as Joseph J. Schildkraut, Alexander H. Glassman, Arthur J. Prange Jr., John Davis, and Herman van Praag, are now obsolete as it is known that these ancient neuromodulatory systems comprise only a small fraction of the brain's neurons. Nevertheless, NE and 5-HT neurotransmission is still thought to play a role in the pathophysiology of mood disorders, and most antidepressant medications initiate their actions through these neurons. A third monoamine, the catecholamine DA, was thought to play a greater

role in the pathophysiology and treatment of schizophrenia and thus received less emphasis. Nevertheless, evidence of DA dysfunction in at least some forms of depression has emerged. Knowledge about monoamine receptor families, second messengers, neurokinins, excitatory amino acids, and gene transcription factors has added layers of complexity to the original monoamine hypotheses. As a result, there has been a progressive shift away from focusing on disturbances of single neurotransmitter systems in favor of studying neurobehavioral systems, neural circuits, and more intricate neuroregulatory mechanisms.

Supporting this shift away from a single neurotransmitter focus, recent clinical studies and meta-analyses correlating CSF monoamine metabolites with clinical diagnosis, as well as GWAS and studies using pharmacologic probes to evaluate monoamine transmitter/receptor function in MDD have cast further doubt on the primacy of monoamine dysfunction in MDD. A meta-analysis involving 11 individual studies comparing CSF levels of the NE metabolite 3-methoxy-4-hydroxyphenylglycol (MHPG) and the 5-HT metabolite 5-HIAA found no significant difference between controls and MDD patients. Another study evaluating altered monoamine signaling in MDD by using various pharmacologic “probes” found that approximately 40% of MDD patients had no measurable aberrations of NE and 5-HT signaling. Similarly, a GWAS study found no evidence of involvement of monoamine-related genes in the etiology of MDD.

When considered together, recent studies indicate two more indirect relationships between monoamine and the pathogenesis and treatment of MDD. In regard to pathogenesis, it is increasingly clear that monoamines play an important role in “fine-tuning” the activities and coupling of functional brain networks. Such an explanatory model recognizes the “two-pronged” influence that monoamine projections may exert on functional networks involved in the regulation of affect, cognition, and motoric activity. Monoamine projections emanating from the brainstem directly innervate the hubs of major functional networks (SN, DMN, CEN, and SMN), primarily regulating their basal activity and connectivity. In addition, monoamines moderate a more dynamic influx of “updating signals” originating from the CSTC loop. Dopaminergic fibers originating from the SN exert an influence on the associative/cognitive and motor striatum, while the VTA provides input to the limbic/affective section of the striatum. DA fibers also project to the dorsomedial thalamus, thereby

regulating ascending glutamatergic projections (final branch, closing the CSTC loop) from the basal ganglia and thalamus to the cortical components of major functional networks. In a similar fashion, noradrenergic fibers from the LC and serotoninergic fibers from the nuclei raphe primarily provide input into thalamic sections (limbic/affective, associative/cognitive, and sensory/motor) of the CSTC loop. These specialized thalamic areas are the origin of glutamatergic fibers projecting to the cortical SAN, CEN, DMN, and SMN hubs. In conclusion, even in circumstances where primary monoamine dysfunction is not a key etiologic factor in mood disorders, their balance, and influence on local glutamate and GABA circuits still have an important role in managing baseline activity of major functional networks and the dynamic of their adaptive coupling and uncoupling, and can therefore be a relevant target for pharmacotherapeutic interventions in mood disorders.

These "fine-tuning" modulatory activities of monoamine neurotransmitters are consistent with multiple findings suggesting that altered monoamine signaling reflects a potential compensatory response rather than a primary pathophysiologic basis of mood disorders. For example, several studies have reported elevated levels of 5-HT and NE metabolites in untreated MDD patients, which were "normalized" after successful antidepressant treatment. This notion is further supported by the fact that monoamine-enhancing antidepressant interventions produce a delayed clinical response (measured in weeks), despite the rapid elevation of brain monoamines (measured in hours), directly registered by in vivo microdialysis in animal models. In summary, the monoaminergic systems are thus now viewed primarily as broader neuromodulatory systems, and disturbances are as likely to be secondary or epiphenomenal effects as they are directly or causally related to etiology and pathogenesis.

NORADRENERGIC SYSTEMS

The cell bodies of almost all noradrenergic neurons in the brain are located in the LC of the brain stem and project rostrally to the thalamus, hypothalamus, ventral striatum, limbic system, and cerebral cortex (see Fig. 13.8–6). There are significant gender-related differences, as females relative to males have approximately 20% more NE fibers emanating from the LC on each side of the brain, as well as much richer axonal

arborization at the termination points for these projections. Noradrenergic projections from the LC have a modular organization, subserving HPA/endocrine regulation, emotional modulation, cognition, and sensory and motor functions. This diffuse distribution belies NE's role in initiating and maintaining limbic and cortical arousal, as well as modulation of other neuronal systems. Noradrenergic projections to the amygdala and hippocampus are implicated in emotional memory, and behavioral sensitization to stress and prolonged activation of the LC contributes to the state of learned helplessness. The medial forebrain bundle (MFB) is the key ascending NE pathway to anterior cortical structures. Stimulation of the MFB elicits increased levels of goal-directed and reward-seeking behavior. Sustained stress eventually results in decreased MFB neurotransmission, which may account for anergia, anhedonia, and diminished libido in depression. The LC also is the origin of neurons that project rostrally to interact with the cell bodies of the sympathetic nervous system, and hence, the adrenal medulla. The LC is phasically active (see Fig. 13.8–7). Increased activity is provoked by the perception of novel stimuli; decreased activity accompanies eating and sleeping. As noted previously, there is an additive interaction (i.e., positive feedback loop) between noradrenergic neurons in the LC and CRH from the hypothalamus, as well as cortical regions. Other negative feedback loops must exert inhibitory control over this alerting synergism to prevent sustained pathologic activation. For example, increased noradrenergic output stimulates α_2 heteroreceptors on colocalized inhibitory 5-HT neurons, and a sustained increase in CRH drives results in a decreased hypothalamic release of ACTH which blunts HPA activity. Changes in cognitive processing of sensory input can further dampen corticolimbic and sympathoadrenal responses to sustained threatening or painful stimuli.

FIGURE 13.8–6. Noradrenergic projections. Noradrenergic cells are mainly concentrated in the pontine nucleus *locus coeruleus* (LC) that projects diffusely to the entire cortex (mostly prefrontal cortex and cingulum) and the limbic system (mainly hippocampus and amygdala), thalamus/hypothalamus, cerebellum, and spinal cord. (From Carandini T, Cercignani M, Galimberti D, Scarpini E, Bozzali M. The distinct roles of monoamines in multiple sclerosis: a bridge between the immune and nervous systems? *Brain Behav Immun*. 2021;94:381–391.)

Recent functional imaging studies have reported a high degree of functional connectedness between noradrenergic-LC and hubs of the CEN, sensory-motor network (SMN), and SAN. In contrast to its presumed regulatory role in CEN and SMN function and connectedness, LC/NE seems to have a rather limited role in influencing DMN function. Given the primary internal focus of the DMN, this finding supports conclusions from the literature proposing a primary role of NE in

“externally directed processes.” Given extant literature implicating disruption in adaptive shifting from internal self-preoccupation to externally focused adaptive coping in MDD, NE/glutamate dysfunction is a likely candidate.

Although past literature has predominantly qualified MDD as a “low norepinephrine” condition, accumulating evidence points in the opposite direction. A study that measured CSF concentration of MHPG in patients suffering from treatment-refractory mood disorders discovered a significant correlation between the “accumulated mood burden,” a composite measure based on the number and severity of mood episodes, and increased NE turnover, reflected by MHPG CSF concentration. Another study found an association between saliva MHPG levels and intensity of depression measured by a standardized scale. Moreover, several studies report “normalization” of elevated CSF and plasma NE levels in patients suffering from severe melancholic depression following successful ECT and antidepressant treatment. A hyperaroused subgroup of MDD patients identified by an automated EEG analysis, exhibited perhaps surprisingly, prominent concentration difficulties and fatigue. Other studies have found increased LC, ascending reticular activating system (ARAS), amygdala, and ACC activity in MDD patients suffering from insomnia (ACC and amygdala are hubs of SAN).

FIGURE 13.8–7. Reflective to reactive: Catecholamine regulation of prefrontal cortex, limbic and paralimbic areas. Anterior cingulate cortex BA24; BA25 (subgenual cingulate); BA10, frontopolar or dorsomedial PFC; dlPFC, dorsolateral PFC; BA32, dorsal anterior cingulate; SNc, substantia nigra pars compacta, supplies striatum with dopamine. (Figure reprinted from Yang S, Seo H, Wang M, Arnsten AFT. NMDAR neurotransmission needed for persistent neuronal firing: potential roles in mental disorders. *Front Psychiatry.* 2021;12:654322. Copyright © 2021 Yang, Seo, Wang and Arnsten. doi: 10.3389/fpsyt.2021.654322. License: https://creativecommons.org/licenses/by/4.0/)

How does one reconcile these apparently contradictory findings? Persistently elevated LC activity/hyperarousal has been shown to disrupt the function of PFC areas associated with CEN and motor cortical areas associated with SMN. Therefore, disrupted regulation of the LC/arousal system in MDD, which would generate excessive NE signaling, is likely to produce disturbance of cognitive/executive function, including “top-down” regulation of emotions and sensory/psychomotor modulation. This imbalance could underpin impaired concentration, executive function, working memory, and psychomotor retardation. Moreover, a high frequency of LC firing promotes the release of a “cotransmitter” galanin, which acts as a functional antagonist of NE and DA transmission. Consistent with common manifestations of MDD, increased NE signaling in the amygdala and ventral portions of the ACC (SAN) has been linked with negative affect, anxiety, and diminished motivation and reward

response. Therefore, it is plausible that in terms of arousal/LC/NE signaling, MDD patients may be a heterogeneous group. While some experience hyperarousal, it is also possible that some may be hypoaroused, while others have no disturbance in NE signaling. In addition, NE/LC transmission acts as a “master switch,” providing a smooth transition between the patterns of connectedness of major functional networks in order to successfully adapt to changes in the environment. It still remains to be ascertained if malfunction of the LC/arousal system may be responsible for the failure of MDD patients to pivot from their inwardly focused ruminative mode to an externally focused actively coping mode.

FIGURE 13.8–8. Main serotoninergic projections. Serotoninergic neurons are concentrated in the brainstem in two functional groups: (1) the caudal raphe nuclei (raphe magnus, raphe obscurus, and raphe pallidus) project to the lower brainstem and spinal cord; (2) the rostral raphe nuclei (median raphe [MR] and dorsal raphe [DR]) project to the entire neocortex, as well as to the thalamus and basal ganglia. The rostral raphe nuclei send a large contingent of fibers to the cerebellum and spinal cord. (From Carandini T, Cercignani M, Galimberti D, Scarpini E, Bozzali M. The distinct roles of monoamines in multiple sclerosis: a bridge between the immune and nervous systems? *Brain Behav Immun*. 2021;94:381–391.)

Aberrations in NE transmission have also been noted in bipolar disorder. Elevation of CSF-NE levels correlates with the manic state as well as associated mixed symptoms, such as anxiety and anger, typifying the state of “dysphoric mania.” Moreover, research has established a

correlation between plasma levels of MHPG and the intensity of manic symptoms as well as their response to treatment.

SEROTONINERGIC SYSTEMS

Serotoninergic neurons project from the brain stem dorsal raphe nuclei to the cerebral cortex, hypothalamus, thalamus, basal ganglia, septum, and hippocampus (see Fig. 13.8–8). The 5-HT pathways have inhibitory (mediated by 5-HT1 and 5-HT5 receptors) and facilitatory functions (mediated by 5-HT3,4,6 and 7 receptors) in the brain. Both in cortical and subcortical areas, 5-HT neurons synapse with GABA and glutamate neurons, thereby regulating the balance between excitation and inhibition. Furthermore, the 5-HT system interfaces with acetylcholine (ACh), cortisol, prolactin, oxytocin, substance P, and vasopressin. Emphasizing its ubiquitous role, some authors point out that virtually all neurons and glial cells in the CNS express some type of 5-HT receptors. For example, much evidence suggests that 5-HT is an important regulator of sleep, appetite, body temperature, metabolism, energy homeostasis, stress response, anxiety, pain regulation, cognition, memory, reward processing, and libido. Moreover, 5-HT inhibits aggressive behavior across mammalian and reptilian species. Serotoninergic neurons projecting to the suprachiasmatic nucleus (SCN) of the hypothalamus help regulate circadian rhythms (e.g., sleep–wake cycles, body temperature, and HPA-axis function). The 5-HT also permits or facilitates goal-directed motor and appetitive behaviors in conjunction with NE and DA.

FIGURE 13.8–9. The role of serotonin in regulation of functional networks. DMT, dorsomedial thalamus; pACC, perigenual anterior cingulate cortex; PCC, posterior cingulate cortex; vmPFC, ventromedial prefrontal cortex; SM, sensorimotor; RNi, raphe nuclei; dACC, dorsal anterior cingulate cortex; SMN, sensorimotor network; DMN, default-mode network; SN, salience network. (Modified from Conio B, Martino M, Magioncalda P, et al. Opposite effects of dopamine and serotonin on resting-state networks: Review and implications for psychiatric disorders. *Mol Psychiatry.* 2020;25:82–93. doi:10.1038/s41380-019-0406-4.)

As noted previously, there is some evidence that 5-HT neurotransmission is partly under genetic control. The 5-HT "tone" also shows a seasonal fluctuation and shows a characteristic temporal response to stress. Specifically, acute stress increases 5-HT release transiently, whereas chronic stress eventually causes decreased 5-HT activity and depletion of 5-HT stores. Chronic stress may also increase the synthesis of 5-HT_{1A} autoreceptors in the dorsal raphé nucleus, which further decreases 5-HT transmission. Elevated glucocorticoid levels tend to enhance 5-HT functioning and thus may have significant compensatory effects in chronic stress. In addition, 5-HT has an important role during

neurodevelopment when it participates in synapse formation, regulation of adhesion molecules, and neural network construction and connectivity.

Generally speaking, 5-HT and DA appear to have opposing roles in the regulation of major functional networks in healthy subjects. Serotonin tends to attenuate activity in the SMN network while catecholamines elevate it (see Fig. 13.8–9). This is in line with reports that 5-HT-enhancing psychotropics cause a sense of fatigue and blunted sensory experience, while catecholamine-boosting agents (e.g., stimulants) may produce a state of agitation and increased sensory acuity. Diminished DA transmission from the SN, along with lower 5-HT output from nuclei raphe, may underpin psychomotor retardation in mood disorders, while excessive DA output from SN and inadequate 5-HT transmission may be responsible for psychomotor agitation, observed both in depressive and manic states (see Fig. 13.8–10). In terms of 5-HT modulatory influence on the DMN network, the situation appears much more complex.

In healthy individuals, suppression of 5-HT transmission induced by acute tryptophan depletion (ATD) paradigm compromised the function of several DMN hubs. This change may be associated with the onset of depressed mood, anger/hostility, and diminished vigor. It is plausible that disturbance of 5-HT transmission in MDD may be related to a reduction of functional connectivity and perfusion within DMN, as well as aberrant DMN connectedness with other limbic and paralimbic formations. In line with this hypothesis, intravenous citalopram (an SSRI) “reintegrated” the precuneus with other DMN components in MDD patients while diminishing its connectivity with the amygdala (an SN component). Other studies have noted that aberrant connections between DMN and sgACC in MDD may be associated with ruminative tendencies and disease duration. Failure of DMN areas to “decouple” from CEN areas during cognitive tasks may be the basis for impaired working memory in MDD, which often manifests clinically as self-focused thoughts that interfere with externally oriented problem-solving. In conclusion, 5-HT elevation due to SSRI treatment may attenuate connectedness between core DMN areas in MDD (supporting more accurate self-assessment and adaptive future planning).

An increase in 5-HT activity may reduce aberrant connections between DMN and SAN and CEN brain structures, which might help to explain antidepressant effects on depressive symptomatology. Surprisingly, 5-HT influence on DMN may not be unidirectional, and recent dynamic imaging studies suggest that core DMN areas exert top-down regulation of 5-HT

and DA release. In apparent contradistinction to SSRI effects, psychedelic drugs with putative antidepressant effects, such as potent 5-HT2A agonists LSD and psilocybin, have been noted to produce acute disruptions in DMN connectivity. Disruption of typical DMN connectedness has been associated with “self-dissolution” and altered social perception, commonly associated with psychedelic use. It is difficult to ascertain how much of the psychedelic effect is directly attributable to 5-HT2A agonism in DMN because these agents also disrupt the activity of SAN.

FIGURE 13.8–10. Psychomotor balance, functional networks and monoamine neurotransmitters. SN, substantia nigra (DA); RN, raphe nucleus (5-HT); BG, basal ganglia, Thal thalamus; SMN, sensorimotor network; DMN, default-mode network; GA, global activity. (From Northoff G, Hirjak D, Wolf RC, et al. All roads lead to the motor cortex: Psychomotor mechanisms and their biochemical modulation in psychiatric disorders. *Mol Psychiatry.* 2021;26(1):92–102. doi:10.1038/s41380-020-0814-5.)

Serotonin influence on the SMN is more straightforward. Increased 5-HT transmission from the nuclei raphe has been consistently associated with suppressed activity in the SMN, consistent with the high expression of inhibitory 5-HT1A receptors in the sensory and motor cortical areas. Serotoninergic regulation of the SMN is of utmost clinical importance since compromised SMN resting and dynamic connectedness appears to

be one of the central features of MDD, most likely underpinning psychomotor retardation. SSRI treatment of MDD may be a mixed blessing because it is often associated with complaints of fatigue and blunted sensory experience, phenomena consistent with down-regulated SMN function. Moreover, meta-analyses have revealed that SNRIs and a DNRI agent (bupropion) provide greater relief of psychomotor symptoms of MDD compared to SSRIs, which are either minimally effective or a hindrance.

Functional imaging studies have consistently implicated aberrant activation of SAN components, such as dACC, insula, dorsomedial thalamus, nucleus accumbens, and amygdala (some authors also include VTA and ventrolateral PFC), in the pathophysiology of depression. Functional connectivity between serotoninergic nuclei raphe and SAN hubs, insula, mid-ACC, and amygdala, has been reported to be altered in MDD patients compared to controls. Successful SSRI treatment tends to “normalize” amygdala activity. As a reminder, the degree of amygdala activity and its connectedness with the sgACC has been associated with the duration and intensity of negative affect in MDD. Greater amygdala, insula, and dorsal ACC response to emotional stimuli in MDD patients are noted to be a positive predictor of SSRI response. Administration of an SSRI was associated with greater suppression of nucleus accumbens response to an erotic stimulus in healthy individuals relative to placebo and bupropion. This finding may explain some aspects of the SSRI-induced sexual dysfunction. Moreover, SSRI administration in preclinical studies has been associated with the suppression of VTA dopaminergic neurons, hypothetically mediated by 5-HT2C receptors. Extending these findings, the use of the antidepressant agomelatine, a melatonin receptor agonist and 5-HT2C antagonist, resulted in the rapid improvement of anhedonia in MDD patients, measured by a standardized scale.

FIGURE 13.8–11. Main dopaminergic projections. (1) the *substantia nigra* (SN) that projects to the dorsal striatum (DS) via the nigrostriatal pathway, which is part of the basal ganglia loop; (2) the ventral tegmental area (VTA) that is the origin of the mesocorticolimbic pathway. The mesolimbic portion projects from the VTA to the ventral striatum (VS)/nucleus accumbens (Nacc) and limbic system (mainly hippocampus and amygdala). The mesocortical part connects the VTA with the prefrontal cortex and the entire neocortex. (From Carandini T, Cercignani M, Galimberti D, Scarpini E, Bozzali M. The distinct roles of monoamines in multiple sclerosis: a bridge between the immune and nervous systems? *Brain Behav Immun*. 2021;94:381–391.)

Finally, diminished connectivity between the serotoninergic nuclei raphe and basal ganglia/thalamus (BG/THAL), with a resulting decrease in DMN activity, has been associated with bipolar mania. Compromised DMN activity also may underpin decreased self-monitoring in mania.

DOPAMINERGIC SYSTEMS

There are four relatively discrete DA pathways in the brain (see Fig. 13.8–11). The tuberoinfundibular system projects from cell bodies in the hypothalamus to the pituitary stalk, exerting inhibitory control over prolactin secretion. The nigrostriatal system originates from cell bodies in the SN and projects to the basal ganglia, regulating involuntary motor activity. Recent studies have also reported sparse projections from SN to lateral aspects of PFC. The cell bodies of the mesolimbic pathway are located in the ventral tegmentum and project diffusely to the nucleus accumbens, amygdala, hippocampus, medial dorsal nucleus of the thalamus, and cingulate gyrus. This pathway modulates emotional expression, learning and reinforcement, and hedonic capacity. The fourth DA pathway, also originating in the ventral tegmentum, is the mesocortical pathway, which projects to the orbitofrontal and the prefrontal cortical regions and helps to regulate motivation, concentration, and initiation of goal-directed and complex executive cognitive tasks. Decreased mesocortical and mesolimbic DA activity has obvious implications for the cognitive, motor, and hedonic disturbances that are associated with depression and are a target for action for some investigational compounds. Across pathways, increased DA activity is potentiated by nicotinic inputs and glucocorticoids, and DA levels are inversely correlated with indices of brain 5-HT activity. The nigrostriatal pathway innervates important striatal relay structures, which are components of the corticostriatal–thalamo–cortical (CSTC) loop. While the VTA provides dopaminergic input for the limbic/affective division of the striatum, the cognitive/associative and sensory-motor striatum are innervated by SN. Excessive DA release in the associative striatum has been linked with psychotic symptoms in the context of bipolar mania.

Dopaminergic signaling and its balance with other monoamines is a key determinant of the activity of major functional networks, and by extension, regulation of affect, motor behavior, and cognition. One of the indicators of CNS DA signaling is the CSF concentration of its principal metabolite, homovanillic acid (HVA). In a recent study, severely depressed patients had significantly reduced CSF concentration of HVA compared to controls. Furthermore, depression scores were inversely correlated with CSF-HVA levels in depressed patients, suggesting that severe MDD may in part be a hypodopaminergic state.

In contrast, increased dopaminergic input into BG/THAL CSTC relay structures is associated with increased activation of the (SMN), which most likely underpins psychomotor agitation in the context of bipolar mania. It is plausible that increased activity of the SMN, combined with inadequate DMN-based self-monitoring, maybe the neurobiologic basis for transdiagnostic manifestations of psychomotor agitation. In support of this theory, functional imaging studies have reported increased connectivity between the dopaminergic VTA and the motor cortex in MDD patients. On the other hand, attenuated DA and 5-HT signaling in the BG/THAL may translate into decreased SMN activation and ensuing psychomotor retardation, a prominent feature of depression. In aggregate, data support what we observe clinically; a major depressive episode may have two separate biotypes with matching phenotypes: agitated depression and depression with psychomotor retardation.

FIGURE 13.8–12. Dopamine transmission and functional organization of the striatum. (See eBook for color images.) (Reprinted from McCutcheon RA, Abi-Dargham A, Howes OD. Schizophrenia, dopamine and striatum: From biology to symptoms. *Trends Neurosci.* 2019;42(3):205–220; Basile GA, Bertino S, Bramanti A, et al. Striatal topographical organization: bridging the gap between molecules, connectivity and behavior. *Eur J Histochem.* 2021;5(s1):3284. doi:10.4081/ejh.2021.3284. License: https://creativecommons.org/licenses/by/4.0/.)

As a general rule, DA transmission, predominantly mediated by D1 receptors in the hubs of the CEN, has an inverted “U” shaped relationship with alertness, sustained attention, working memory, and executive

function. Both inadequate and excessive D1 signaling may result in distractibility, inattentiveness, and impaired working memory, as well as impairment of the executive function. Excessive stress and MDD may act synergistically via dysregulated catecholamine input into the DLPFC to compromise CEN-related top-down regulation of emotion (see Fig. 13.8–12). Indeed, increased DA signaling in the amygdala (a key SAN area) has been associated with an increased response to negative emotional stimuli and excessive preoccupation with internal bodily processes in MDD. It is possible that increased stress contributes to the elevation of negative emotionality in MDD, both by increasing catecholamine activity in limbic and paralimbic SAN regions and by reducing the DLPFC-mediated top-down regulation. Indeed, functional imaging studies have observed increased connectedness between the VTA and insula (key SAN hub) in MDD patients. Such increased connectedness between the insula, a focal target of all interoceptive inputs, and the VTA may be responsible for the over-attribution of emotional salience to internal stimuli in MDD patients. Indeed, imaging findings support the over-activation of brain areas related to interoception and relatively attenuated brain responses to exteroceptive stimulation. On the other hand, lower functional connectivity between the dopaminergic VTA and the dACC (a SAN hub) is reflected in more pronounced somatic symptoms of MDD, such as appetite disturbance, fatigue, and loss of sexual interest. Furthermore, multiple studies have reported decreased response of the nucleus accumbens (another major SAN node) to positive and rewarding stimuli in depressed individuals relative to controls. As a matter of fact, compromised NAcc response to positive stimuli has been deemed a predictor of response to bupropion (a DA/NE modulating antidepressant). Moreover, contemporary imaging studies have provided new insight into the relationship between DLPFC and the regulation of mesolimbic DA transmission stemming from VTA. Not only does VTA via mesocortical pathway provide innervation for DLPFC, a CEN hub, but in a retrograde fashion, the DLPFC via polysynaptic connections also modulates dopaminergic influx into the nucleus accumbens, possibly explaining how our interest can drive motivated behaviors. In addition, decreased DA signaling in the ventral striatum/ventral pallidum via D2/D3 receptors has been noted to correlate with higher anxiety in MDD patients.

Finally, the elevation of striatal DA signaling has been consistently associated with suppression of the DMN and an increase in SAN

connectedness in healthy individuals (see Fig. 13.8–13). Dysregulated DA signaling in BG/THAL structures of the CSTC loop with resulting increase in glutamatergic flow from the thalamus to the CEN and SMN regions, along with reduced serotoninergic input in BG/THAL and diminished activation of the DMN network, has been associated with mania. The above-described pattern of major brain network activity/connectivity may underpin clinical manifestations of mania, such as inattentiveness, impaired executive function, problematic decision-making and working memory (all CEN-related), and affective reactivity due to compromised top-down emotional regulation. Pathologically enhanced SMN activation may be associated with hyperactive behavior and increased sensory acuity, while compromised DMN function may be clinically reflected in inadequate self-monitoring, planning, and maladaptive processing of social cues, all common clinical features of the manic state.

Opposite effects of dopamine and serotonin on resting-state networks: Review and implications for psychiatric disorders. *Mol Psychiatry.* 2020;25:82–93. doi:10.1038/s41380-019-0406-4.)

SUMMARY OF RESEARCH ON MONOAMINES IN DEPRESSION

After nearly 50 years of research, it can be said that some depressed people manifest one or more abnormalities of monoamine neurotransmission. Decreased central NE activity can be inferred, in part, from decreased urinary excretion of the metabolite MHPG, although a

partly overlapping subgroup of patients manifests elevated circulating levels of NE and its metabolites. This suggests a dissociation of NE activity in the MFB and SM systems. As reviewed in earlier editions of this chapter, 5-HT dysfunction has been documented in overlapping subgroups of patients using a variety of methods, ranging from low CSF levels of 5-HIAA to decreased regional cerebral metabolism in response to 5-HT agonists, such as D-fenfluramine, and as discussed subsequently, decreased 5-HT neurotransmission also can be inferred from the findings of HPA and EEG sleep studies. Low levels of the DA metabolite HVA have been implicated in psychomotor retardation. Some evidence suggests that increased DA activity may contribute to the development of delusions and hallucinations.

Burgeoning evidence from biochemical, neuroimmunologic, endocrine, and functional imaging studies implicates either primary or secondary malfunction of monoamine signaling in the pathophysiology of mood disorders. Moreover, monoamine projections have an established role in regulating the connectedness and function of major functional networks involved in the regulation of mood, cognition, motoric activity, and sensory processing (SAN, SMN, DMN, and CEN). Furthermore, dysfunction of major functional networks closely correlates with symptoms of mood disorders, offering these theories good face validity. In addition, monoamine signaling has a prominent role in regulating the “updating” function of the CSTC loop. One can conceive of harmonious and adaptive monoamine signaling as the basis for maintenance of dynamic homeostasis (allostasis) involving major brain functional networks and their dysfunction as a principal contributor to a disequilibrium underlying the “allostatic overload” in mood disorders. Finally, decades of research have established an important role of agents modulating monoamine metabolism, reuptake, and receptor activity in the treatment of mood disorders.

OTHER NEUROTRANSMITTER DISTURBANCES

ACh is found in neurons that are distributed diffusely throughout the cerebral cortex. Cholinergic neurons have reciprocal or interactive relationships with all three monoamine systems. Abnormal levels of choline, which is a precursor to ACh, have been found at autopsy in the brains of some depressed patients, perhaps reflecting abnormalities in cell

phospholipid composition. In an animal model of depression, strains of mice that are super- or subsensitive to cholinergic agonists have been found to be prone to or more resistant to developing learned helplessness. Cholinergic agonists can induce changes in HPA activity and sleep that mimic those associated with severe depression. Indeed, some remitted patients with mood disorders, as well as their never-ill first-degree relatives, have a trait-like increase in sensitivity to cholinergic agonists. Decades ago, a theory was put forth whereby a high cholinergic/adrenergic ratio represents a risk for depression, whereas a low ratio may be linked with the manic state. Cholinergic agonist and antagonist drugs have differential clinical effects on depression and mania. Agonists can produce lethargy, anergia, and psychomotor retardation in normal subjects, can exacerbate symptoms of depression, and can reduce symptoms of mania. These effects generally are not sufficiently robust to have clinical applications, although some recent research has suggested that parenteral scopolamine can have rapid antidepressant effects. Presumably, scopolamine blocks M1 muscarinic receptors on GABA interneurons, thereby decreasing their signaling and diminishing the ensuing inhibition of glutamatergic neurons. The resulting increase in the glutamatergic transmission is putatively associated with the observed rapid antidepressant response. More conventional antidepressants that target serotonergic or adrenergic neurons also indirectly decrease cholinergic tone.

GABA interneurons have an inhibitory effect on ascending monoamine pathways, particularly the mesocortical and mesolimbic systems. Furthermore, mPFC GABA interneurons modulate the signal-to-noise ratio of the incoming transmission and the output volume of cortical pyramidal glutamatergic neurons. While the signal-to-noise ratio of incoming signals is primarily regulated by somatostatin-expressing (SST) GABA interneurons, the glutamatergic output is modulated by parvalbumin-expressing (PV) GABA interneurons. Long glutamatergic projections from the mPFC to brainstem nuclei have a cardinal role in the modulation of ascending monoamine fibers. Reductions in GABA have been observed in plasma, CSF, and brain GABA levels in depression. Animal studies have also found that chronic stress can reduce and eventually deplete GABA levels. By contrast, GABA receptors are upregulated by antidepressants, and some GABAergic medications have weak antidepressant effects. The most compelling evidence of GABA involvement in the pathophysiology of

MDD comes from ENIGMA consortium studies which integrated mega-GWAS findings with functional and structural imaging studies, postmortem cytologic findings, and clinical data from tens of thousands of MDD patients. Two cell types that were most closely associated with MDD etiopathogenesis were astrocytes and cortical SST GABA interneurons. Downstream effects of PFC SST GABA interneuron dysfunction include diminished transmission from pyramidal neurons to the amygdala, thalamus, hypothalamus, BNST, and brainstem monoaminergic nuclei. Therefore, deficits in descending glutamatergic transmission, emotional regulation, endocrine control, arousal modulation, autonomic function, and monoamine signaling in mood disorders can all be potentially traced back to altered SST GABA interneuron density and function. Recent functional imaging studies have discovered that rapid GABA and glutamate circuits have a central role in “switching,” establishing, and shifting connections between major functional networks, such as SAN, CEN, and DMN. It is plausible that altered GABA signaling may have repercussions on the previously described disruption of the major functional network dynamics in mood disorders. Clinical studies have established a link between reduced size, density, and neurotransmitter synthesis in dlPFC GABA interneurons and MDD. In addition, the synthesis of allopregnanolone, a naturally occurring neurosteroid ligand of GABA-A receptors has been reported to be lower in DLPFC of depressed patients relative to controls. Moreover, other studies reported a correlation between ACC GABA levels and anhedonia scores in young patients suffering from MDD. In addition, lower GABA ACC levels are also associated with reduced hippocampal volumes in treatment-resistant MDD patients but not ones who have responded to treatment. Furthermore, inadequate GABA neuronal activity in the ACC combined with structural changes in the hippocampus may interfere with the HPA stress response and contribute to the endocrine manifestations of MDD. Moreover, altered GABA synthesis has also been reported in the amygdala of MDD patients compared to controls. This finding may have implications for increased amygdala response to negatively valenced stimuli, frequently observed in individuals suffering from MDD. Extending these findings, synthetic neurosteroids are being developed for the treatment of MDD. Unlike benzodiazepines which predominantly modulate the gamma-subunit containing synaptic GABA-A receptors involved in phasic signaling, neurosteroids also bind to extrasynaptic GABA-A receptors, containing the delta-subunit involved in

tonic regulation of GABA signaling (see Fig. 13.8–14). Brexanolone, a synthetic neurosteroid that functions as a positive allosteric modulator of GABA-A receptors, is already approved for the treatment of major depressive episodes with peripartum onset. Another similar agent, zuranolone, is in the late stage of development for the treatment of MDD.

In the CNS, two amino acids—glutamate and glycine—are respectively the major excitatory and inhibitory neurotransmitters. Glutamate and glycine bind to sites associated with the *N*-methyl-D-aspartate (NMDA) receptor, and an excess of glutamatergic stimulation can cause neurotoxic effects. It appears that glutamate binding to extra-synaptic NMDA receptors, containing the N2B subunit, with glycine as a coagonist produces excitotoxicity and suppression of BDNF synthesis. In contrast, activation of synaptic NMDA receptors containing the N2A subunit, with d-serine as a coagonist, promotes BDNF synthesis and is neuroprotective. In addition to NMDA receptors, glutamate binds to two other ionotropic receptors: α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPA) and kainate receptors.

While ionotropic receptors rapidly mediate rapid glutamate transmission, eight subtypes of metabotropic glutamate receptors (mGlu) are involved in slower (i.e., seconds to minutes) signaling. Importantly, the hippocampus has a high concentration of NMDA receptors. Glutamate may thus work in tandem with hypercortisolemia to mediate the deleterious neurocognitive effects of severe recurrent depression. Aberrant glutamate transmission may be proximally implicated in atrophic changes documented in some regions of the cerebral cortex, perhaps by first reducing the connectivity of neurons and volume of supporting glia. Indeed, imaging studies have confirmed glutamate markers in hippocampi of chronically depressed patients compared to healthy controls; such changes are evident even among people suffering their first-lifetime depressive episode. Furthermore, another study has noted a reduction of glutamate in the vmPFC, a key area in emotional regulation of patients suffering from recurrent or chronic forms of depression but not in controls or first-episode depressed patients. Interestingly, there is also a significant correlation between the duration of depressive illness and the reduction of vmPFC glutamate concentrations. Glutamate levels in ACC also are lower in both unipolar and bipolar depression compared to controls. Altered glutamate transmission was also noted in the basal ganglia of MDD patients relative to controls. Elevated glutamate levels in this key

component of the CSTC loop were associated with both anhedonia and psychomotor retardation in MDD patients. The potential significance of aberrant glutamate signaling via NMDA receptors in the pathophysiology of depressive states is suggested by growing evidence that subanesthetic doses of ketamine and esketamine, which noncompetitively antagonizes NMDA receptors, exert large and rapid antidepressant effects. Studies of continued therapy (e.g., weekly or every other week) with intranasal esketamine indicate that treatment benefits persist for months or even years. Both racemic ketamine and esketamine show a preference for N2B containing extrasynaptic NMDA receptors. Theoretically, antagonism at NMDA receptors located on GABA interneurons reduces their input, thereby promoting glutamatergic bursts from the postsynaptic neurons.

FIGURE 13.8–14. Relationship between GABA and neuroactive steroids. NAS binding to $GABA_A$ receptors resulting in potentiation of both synaptic and extrasynaptic $GABA_A$ receptor populations and leads to increased $GABA_A$ receptor surface expression. Extrasynaptic $GABA_A$ receptors containing delta subunits are insensitive to benzodiazepines.[1-8] HSD, hydroxysteroid dehydrogenase; StAR, steroidogenic acute regulatory; MBR, mitochondrial benzodiazepine receptor. (See eBook for color images.) (Data from Jacob TC, Moss SJ, Jurd R. GABA(A) receptor trafficking and its role in the dynamic modulation of neuronal inhibition. *Nature Rev Neurosci.* 2008;9:331–343; Reddy DS, Estes WA. Clinical potential of neurosteroids for CNS disorders. *Trends Pharmacol Sci.* 2016;37:543–561.)

Increased glutamatergic signaling via AMPA receptors has been associated with inhibition of eukaryotic elongation factor 2 (eEF2) and consequently enhanced synthesis of BDNF. Moreover, elevated BDNF signaling activates an intracellular cascade supporting mTOR (mammalian

target of rapamycin) synthesis and a downstream increase in synaptogenesis. In contrast to intrasynaptic NMDA receptor activation, extrasynaptic NMDA activation is associated with mitochondrial dysfunction, suppression of BDNF synthesis, and ultimately, cell death. Therefore, extrasynaptic NMDA inhibitors such as esketamine and ketamine are likely to support BDNF synthesis via the reduction of extrasynaptic NMDA-mediated glutamate transmission (see Fig. 13.8–15).

Subanesthetic doses of ketamine and esketamine influence the activity of major functional networks both in healthy volunteers and depressed patients. An MRI study compared ketamine infusion with placebo in a group of healthy volunteers. Ketamine infusions produce a significant increase in dACC activity, suggesting positive modulation of a key SAN hub. However, a study comparing depressed patients and healthy controls found that ketamine infusions increased activity in the CEN and reduced activity in the DMN and SAN relative to the placebo group. The impact of ketamine on burst firing in the lateral habenula (LHb) has been a recent focus of interest. Burst firing of LHb has been associated with suppression of monoamine release and intense negative affect in MDD patients.

Convergent lines of evidence implicate changes in glia function and density in the pathohistology of mood disorders. Large-scale studies of mood disorders incorporating genetic data, postmortem cytology, and functional and structural imaging studies have found that transcriptional signatures related to astrocytes, microglia, pyramidal neurons, and SST-expressing GABA interneurons have the greatest correlation with a decreased thickness of cortical areas in mood disorders. Furthermore, postmortem cytology in MDD demonstrated a reduction of glial density and numbers in several brain areas involved in mood regulation and the stress response. A substantial decline in both numbers and density of astroglia and oligodendroglia has been reported in the sgACC, DLPFC, orbitofrontal cortex, and amygdala of unmedicated bipolar and MDD patients relative to controls. In addition, a recent transcriptional study of MDD patients discovered the aberrant expression of 17 genes related to oligodendroglia function, suggesting that reduced oligodendroglia numbers may be a consequence of genetic vulnerability. A 29% reduction of oligodendroglial density was reported in the DLPFC of bipolar patients compared to controls. Given the oligodendroglia's role in myelination of long white matter tracts, these cytologic findings may underpin imaging

reports of disrupted functional and structural connectivity between key prefrontal and limbic areas involved in emotional regulation.

Postmortem studies using immunohistochemistry evaluated microglia density in the DLPFC, ACC, mediodorsal thalamus, and hippocampus of mood-disordered patients. Significant microgliosis (i.e., increased number of microglia) was noted in affective disorder patients who committed suicide but not in depressed individuals who died due to other causes. Microgliosis in this study was interpreted as a marker of stress prior to suicide. Microglial pathology may interact with dysregulated peripheral inflammatory signaling in MDD and bipolar disorder. In response to excessive peripheral inflammatory signaling in mood disorders, a pathogen-associated molecular pattern (PAMP) occurs in the CNS. Specifically, activated microglia respond by releasing copious amounts of IL-1, IL-6, TNF-alpha, PGs, NO, and H_2O_2, which in turn prompts astrocytes to release more of the similar inflammatory molecules. Due to aberrant astroglia-microglia communication, oligodendroglia are likely to suffer oxidative damage related to overexposure to reactive oxygen and nitrogen species (ROS and RNS) and maladaptive activation of its NMDA receptors. Furthermore, TNF-alpha released by microglia and astrocytes, combined with reduced BDNF support, has a toxic effect on oligodendroglia. The sum of these aberrant activities likely contributes to demyelination and compromised communication within and between mood-modulatory networks. Moreover, aberrant microglia function in mood disorders may be related to inflammatory, neurotrophic, and neurotransmitter disturbance. Proinflammatory cytokines and prostaglandins jointly induce indoleamine 2,3-dioxygenase (IDO), an enzyme that converts tryptophan to kynurenine and quinolinic acid (QUIN), thereby reducing its availability for 5-HT and melatonin synthesis (see Fig. 13.8–16). In addition, proinflammatory cytokines accelerate 5-HT and DA reuptake from the synaptic cleft, further disrupting their role in neurotransmission. Moreover, QUIN is a robust NMDA agonist and stimulator of glutamate release, most likely contributing to excitotoxicity by binding to extrasynaptic NMDA receptors. In vitro studies have provided evidence that activation of microglial NMDA receptors drives the release of inflammatory cytokines. It is conceivable that there is a vicious circle present in mood disorders, whereby microglial activation induces increased extrasynaptic NMDA signaling, which in turn perpetuates microglial proinflammatory activity. Although the use of translocator

protein (TSPO) as a marker of microglial activation is not without controversy, imaging studies (PET) have reported increased TSPO in the PCC, ACC, insula, and hippocampus of MDD patients compared to controls. Furthermore, the duration of untreated depression correlates with TSPO elevation in the PFC, ACC, and insula, while the duration of antidepressant treatment is counter-correlated with TSPO concentration in the same brain areas. Extending these findings, imaging studies have reported a correlation between PFC TSPO binding and cognitive dysfunction in MDD. Interestingly, ketamine may reduce microglial inflammatory signaling.

FIGURE 13.8–15. Hypothetical mechanism of action of NMDA modulating medications. (Reprinted from Delfino RS, Surjan J, Bandeira ID, et al. NMDA antagonists and their role in the management of bipolar disorder: A review. *Curr Behav Neurosci Rep.* 2020;7:76–85. doi:10.1007/s40473-020-00201-w.)

Only indirect evidence of altered astrocyte function in mood disorders is available. Elevated inflammatory signaling in mood disorders precipitates activation of IDO in astrocytes, which propagates conversion of tryptophan into kynurenic acid (KA), a known antagonist of dopamine and NMDA receptors. Furthermore, astrocyte dysfunction may alter GABA/glutamate balance in another important way. Recent research has identified astrocytes as an important source of GABA in the CNS. In

addition to its role in transmission, GABA may act as an anti-inflammatory molecule by attenuating microglial and astrocytic release of inflammatory cytokines. In this manner, astrocytes, via autocrine signaling mediated by GABA-A receptors, can reduce their own inflammatory signaling. Accumulation of inflammatory and oxidative compounds in MDD may cause astrocytic apoptosis (established by postmortem studies) and precipitate a shift in the microglia/astroglia balance, favoring microglial activity, thus producing excessive glutamatergic transmission relative to GABA output further perpetuating a proinflammatory milieu. In addition, since microglia and astrocytes are principal sources of BDNF, their compromised function and numbers may contribute to alterations in neurotrophic signaling in MDD. Due to histologically established astrocytic apoptosis in MDD, their processes no longer effectively seal off synaptic space, allowing glutamate spillover where it binds to extrasynaptic NMDA receptors. In contradistinction with activation of synaptic NMDA receptors, which leads to enhancement of BDNF synthesis and release, glutamate binding to extrasynaptic NMDA receptors robustly suppresses BDNF synthesis.

FIGURE 13.8–16. Interactions at the glia–synaptic junction in mood disorders NMDA-R, *N*-methyl-D-aspartate receptor (glutamate); QA, quinolinic acid; KA, kynurenic acid; 3HK, 3-hydroxy-kynurenine; BDNF, brain-derived neurotrophic factor; GDNF, glial-derived neurotrophic factor; TGF, transforming growth factor; ATP, adenosine triphosphate; Glu, glutamate; GABA, gamma aminobutyric acid. Unlike widespread and prominent glial abnormalities, changes in neuronal morphology and density in MDD appear to be more subtle and regionally limited. A number of postmortem studies noted a greater reduction in pyramidal cell size in the hippocampus, ACC, DLPFC (BA 9), and OPFC (BA 47) of MDD patients relative to controls. The distribution of neuronal pathology remarkably mirrors glial reductions and findings from structural imaging studies. Furthermore, changes in pyramidal neuron morphology and density were also reported in bipolar disorder.

Morphologic changes are predominantly related to neuronal apoptosis and thinning of interneuronal neuropil. Nevertheless, a postmortem study reported a 16% to 22% reduction of pyramidal neuron density in the DLPFC of bipolar patients relative to controls. This finding is particularly intriguing since affected pyramidal neurons are targets of ascending thalamic glutamatergic fibers and represent a cortical destination of the CSTC loop. In addition, DLPFC pyramidal neurons provide top-down feedback to the ACC and amygdala. Therefore, one can plausibly speculate that morphologic and ensuing functional changes in these pyramidal neurons may be related to cognitive difficulties and compromised top-down emotional regulation in bipolar disorder. Moreover, a significant decrease in ACC neuronal size and hippocampal neuronal density separated bipolar patients from controls. It is likely that these postmortem findings in bipolar patients have repercussions regarding affective modulation, declarative and spatial memory, and possibly HPA regulation.

NEUROPLASTICITY AND NEUROTROPHIC CHANGES IN MOOD DISORDERS

Changes in several neurotrophic factors have been detected in patients suffering from mood disorders. Probably, the best studied is BDNF. BDNF has an important role in neuronal maturation, differentiation and survival, synaptic plasticity, long-term memory consolidation, HPA activity regulation, slow-wave sleep modulation, as well as regulation of serotonin, glutamate, and GABA release. Several convergent factors present in MDD converge to impede BDNF synthesis and signaling, such as unfavorable genetic polymorphism, epigenetic methylation of BDNF promoter gene, loss of diurnal rhythm of cortisol secretion, elevation of inflammatory signals, and impaired astroglia function. Burgeoning research has detected a reduction in CSF levels of BDNF in MDD patients relative to controls and an association between the CSF BDNF levels and suicidal ideation in depressed patients. Although the majority of studies reported lower peripheral BDNF levels in MDD patients, particularly in suicidal individuals and ones with the persistent disease form, compared to healthy controls, the correlation between the severity of depression and disease recurrence has been inconsistent. Different antidepressant treatments, including tricyclic and heterocyclic antidepressants, MAOIs,

SSRIs, SNRIs, selective norepinephrine uptake inhibitors (NRIs), and ketamine, as well as nonpharmacologic interventions such as ECT, repetitive transcranial magnetic stimulation (rTMS), exercise, and psychotherapy. Peripheral BDNF levels may be an indicator of antidepressant response. A recent study reported that an increase in serum BDNF levels to 126% from baseline, following a week of antidepressant treatment, combined with a 50% reduction in their HAMD-17 over the same time period, predicted the ultimate treatment response with 100% specificity! However, despite successful antidepressant treatment, peripheral BDNF levels in remitted depressed patients most often lag behind BDNF concentrations in healthy controls. A number of clinical studies have noted diminished peripheral BDNF levels in depressed and manic bipolar patients. Furthermore, low BDNF levels have been associated with the clinical severity of depression and mania. One study reported normalization of BDNF levels in conjunction with a successful treatment outcome. A reciprocal relationship between BDNF and inflammatory mediators is an important marker of the progression of bipolar disease.

Glia-derived neurotrophic factor (GDNF) plays an important role in the maintenance of neuronal health, neuroplasticity, microglia function, GABA, and monoamine transmission and cognition. Research has discovered reduced serum levels of GDNF in depressed patients compared to healthy controls. Furthermore, 8 weeks of antidepressant treatment was associated with a significant increase in serum GDNF in depressed patients relative to controls. Both elevated and reduced levels of GDNF have been reported in mania. Unlike the scenario in MDD, bipolar depression does not appear to have a meaningful impact on peripheral GDNF levels. Pharmacologic studies have detected a “normalizing” effect of antipsychotic and mood-stabilizer treatment in manic patients.

SECOND MESSENGERS AND INTRACELLULAR CASCADES

The binding of a neurotransmitter and a postsynaptic receptor triggers a cascade of membrane-bound and intracellular processes mediated by second messenger systems. Receptors on cell membranes interact with the intracellular environment via guanine nucleotide-binding proteins (G proteins). The G proteins, in turn, connect to various intracellular enzymes

(e.g., adenylate cyclase, phospholipase C, and phosphodiesterase) that regulate the utilization of energy and formation of second messengers, such as cyclic nucleotide (e.g., cAMP and cyclic guanosine monophosphate [cGMP]), as well as phosphatidylinositols (e.g., inositol trisphosphate and diacylglycerol) and calcium–calmodulin.

Second messengers regulate the function of neuronal membrane ion channels, neurotransmitter synthesis and release, and protein kinase activity. Protein kinase, for example, catalyzes phosphorylation, an energy-liberating process involved in the synthesis and degradation of receptors, ion channels, G proteins, gene transcription, and translation factors. Some studies have reported abnormalities in platelet adenylate cyclase activity, phosphoinositide hydrolysis, intracellular calcium metabolism, and G-protein function in depressive disorders. Moreover, the synaptic effects of antidepressants initiate a series of intracellular reactions that ultimately alter gene activity, resulting in the downregulation of selected monoamine receptors and increased synthesis of BDNF. There is increasing evidence that mood-stabilizing drugs similarly act on G proteins or other second messengers.

ALTERATIONS OF HORMONAL REGULATION

HPA Activity

As noted previously, elevated HPA activity is a hallmark of mammalian stress responses and one of the clearest links between depression and the biology of stress. Elevated HPA activity in depression has been documented via excretion of urinary free cortisol (UFC), 24-hour (or shorter time segments) IV collections of plasma cortisol levels, salivary cortisol levels, and tests of the integrity of feedback inhibition. A disturbance of feedback inhibition is tested by administration of dexamethasone (0.5 to 2.0 mg), a potent synthetic glucocorticoid, which normally suppresses HPA-axis activity for 24 hours. Nonsuppression of cortisol secretion at 8:00 AM the following morning or subsequent escape from suppression at 4:00 PM, or 11:00 PM is indicative of impaired feedback inhibition. Hypersecretion of cortisol and dexamethasone nonsuppression are imperfectly correlated (approximately 60% concordance), suggesting that they may measure overlapping but different aspects of HPA dysfunction. Hypercortisolemia in depression

suggests one or more of the following central disturbances: decreased inhibitory 5-HT tone; increased drive from NE, ACh, or CRH; or decreased feedback inhibition from the hippocampus. About 20% to 40% of depressed outpatients and 40% to 60% of depressed inpatients have some evidence of increased HPA activity. Older patients, particularly those with highly recurrent or psychotic depressive disorders, are the most likely to manifest increased HPA activity. Although hypercortisolism is one of the best-replicated biologic correlates of melancholia or endogenous depression, it is hardly a specific abnormality. For example, a short period of starvation or several weeks of partial sleep deprivation can induce hypercortisolism in otherwise healthy people. Neither the sensitivity nor the specificity of these tests of feedback inhibition is sufficient for use as a diagnostic test, and adrenocortical hyperactivity (albeit usually less prevalent) is observed in mania, schizophrenia, dementia, and other psychiatric disorders.

Elevated HPA activity in depression is typically not associated with the physical stigmata of Cushing syndrome but is sufficient to be implicated in the genesis of neurocognitive and neuroimmunologic disturbances. Patients with increased HPA activity are typically less responsive to attention placebo interventions and psychotherapy. Hypercortisolemic depressed patients thus may have a relatively greater need for active pharmacotherapy or ECT. Hypercortisolism usually resolves with effective treatment. When persistent despite effective treatment, increased HPA activity is associated with a high risk of relapse. This is presumably a consequence of the incomplete resolution of the pathophysiology of the depressive episode. One implication of these relationships is that interventions that suppress HPA activity, including dexamethasone and the cortisol synthesis inhibitor ketoconazole, are sometimes used to treat patients with more refractory depressive disorders. Attempts to develop antidepressant medications that directly antagonize central CRH receptors have to date been unsuccessful.

Thyroid Axis Activity

Approximately 5% to 10% of people evaluated for depression have previously undetected hypothyroidism, as reflected by low levels of circulating thyroid hormone, an elevated basal TSH level, or an increased TSH response to a 500-mg infusion of the hypothalamic neuropeptide thyroid-releasing hormone (TRH). Such abnormalities are often

associated with elevated antithyroid antibody levels, and unless corrected with hormone replacement therapy, may compromise response to antidepressant medication. A larger subgroup of depressed patients (20% to 30%) shows a blunted TSH response to the TRH challenge. This type of response would usually suggest hyperthyroidism, yet few depressed patients have clinically significant elevations of thyroid hormones. A blunted TSH response in a euthyroid person thus may result from pituitary downregulation consequent to increased TRH "drive." As neurons containing TRH have been identified in a variety of cortical regions, this abnormality may have a suprahypothalamic origin. Increased central TRH secretion, in turn, could result from a homeostatic response to decreased noradrenergic neurotransmission. The therapeutic benefits of adjunctive therapy with 1-tri-iodothyronine (T_3) or other thyroid hormones may be mediated by a dampening of this failed homeostatic response. This abnormality may be most common in individuals who have reduced ability to convert thyroxine to T_3. The major therapeutic implication of a blunted TSH response is evidence of an increased risk of relapse despite preventive antidepressant therapy. Of note, unlike the dexamethasone suppression test (DST), blunted TSH response to TRH often does not normalize with effective treatment.

GROWTH HORMONE (GH)

Growth hormone (GH) is secreted from the anterior pituitary after stimulation by NE and DA. Secretion is inhibited by SST, a hypothalamic neuropeptide, and CRH. Pulsatile GH secretion follows a 24-hour circadian rhythm with a characteristic secretory surge during the first few hours of sleep. The most consistent finding in depression is a blunted GH response to clonidine, an α_2-receptor agonist. Secretory responses after the onset of sleep or the administration of nonselective adrenergic agonists such as desipramine are also blunted in depression. Although the hypothalamus has the highest concentrations of SST, significant concentrations are also found in the amygdala, hippocampus, nucleus accumbens, PFC, and LC. In addition to inhibition of GH release, SST inhibits release or antagonizes the effects of CRH, GABA, and TSH. Decreased CSF SST levels have been reported in depression, and increased levels have been observed in mania.

Prolactin

Prolactin is released from the pituitary by 5-HT stimulation and inhibited by DA. Most studies have not found significant abnormalities of basal or circadian prolactin secretion in depression, although a blunted prolactin response to various 5-HT agonists has been described. This response is uncommon among premenopausal women, suggesting that estrogen has a moderating effect.

ALTERATIONS OF SLEEP NEUROPHYSIOLOGY

Sleep is regulated by complex, temporally, and environmentally cued interactions between the monoamine systems, neuroendocrine secretion, and neuropeptides. At the broadest levels, there is a seasonal tendency for longer and deeper sleep in winter and a circadian propensity for the onset of sleep (i.e., after dark and after midday). The onset of sleep is promoted by a surge in the secretion of the pineal hormone melatonin (after the onset of darkness). Sleep onset is followed by the nocturnal surge in GH secretion, which occurs within the first 90 minutes of sleep onset. A reduction in core body temperature and diurnally low levels of cortisol secretion further promote the maintenance of sleep. Orchestrated across each 24-hour period is an oscillating, 90-minute, infradian cycle defined by rapid eye movement (REM) sleep. Within each cycle, there is a characteristic progression from light to deeper levels of sleep (defined by different types of EEG activity), culminating in the paradoxical central activation of REM sleep, during which most of the night's dreaming occurs. An 8-hour night of sleep thus typically includes four or five cycles consisting of nonrapid eye movement (NREM) sleep and REM sleep. The propensity for deep sleep is greatest within the first 3 hours after sleep onset. REM sleep periods, by contrast, tend to become longer and more intense as the night of sleep progresses.

Prefrontal cortical metabolism is normally decreased during NREM sleep, a time of physical and metabolic rest. The frontal cortex is essentially offline during deep sleep, and the characteristic rhythm of brain activity consists of slow (delta) desynchronized waves of thalamocortical origin. REM sleep, by contrast, is characterized by fast, low-amplitude electrical activity and increased glucose metabolism in the limbic system. REMs are under the direct control of cholinergic neurons in the pons, which is tonically inhibited by the reticular activating system

(predominately by histaminergic and noradrenergic neurotransmission) during wakefulness. During sleep, inhibitory 5-HT projections from the dorsal raphe nuclei phasically suppress REM. Pharmacologic manipulations that increase central cholinergic activity lighten sleep and increase phasic REM activity. Dietary depletion of 5-HT and exogenous administration of glucocorticoids similarly can increase phasic REM indices. Injections of CRH and ingestion of potent noradrenergic agonists decrease total sleep time, reduce slow-wave sleep, and suppress REM sleep.

Depression is associated with decreased deep (slow-wave) sleep and an increase in nocturnal arousal. The latter is reflected by four types of disturbance: (1) an increase in nocturnal awakenings, (2) a reduction in total sleep time, (3) increased phasic REM sleep, and (4) increased core body temperature. The combination of increased REM “drive” and decreased slow-wave sleep results in a significant reduction in the first period of NREM sleep, a phenomenon referred to as reduced REM latency. Results of family and twin studies suggest that these related abnormalities are partly heritable. Consistent with the expected behavior of a heritable trait, reduced REM latency and deficits of slow-wave sleep typically persist after recovery from a depressive episode. Blunted secretion of GH after sleep onset is associated with decreased slow-wave sleep and shows similar state-independent or trait-like behavior. Difficulties maintaining sleep and increased phasic REM sleep are associated with hypercortisolism and increased limbic blood flow and glucose metabolism; although some forms of pharmacotherapy can distort sleep profiles, recovery from depression usually is accompanied by at least a partial reversal of these abnormalities. The combination of reduced REM latency, increased REM density and decreased sleep maintenance identifies approximately 40% of depressed outpatients and 80% of depressed inpatients. False-negative studies are commonly seen in younger, hypersomnolent patients, who may actually experience an increase in slow-wave sleep during episodes of depression. Approximately, 10% of otherwise healthy individuals have abnormal sleep profiles, and like dexamethasone nonsuppression, profiles associated with depression are seen in patients with other psychiatric disorders.

Despite clear limitations as a diagnostic test, EEG sleep recordings continue to be an important research tool. For example, patients manifesting a characteristically abnormal sleep profile have been found to

be less responsive to psychotherapy and to have a greater risk of relapse or recurrence, and may benefit preferentially from pharmacotherapy. Most antidepressants suppress REM sleep, probably by directly or indirectly activating postsynaptic 5-HT_{1A} receptors. The efficacy of several antidepressants that do not suppress REM sleep, including bupropion, nefazodone, and agomelatine, in patients with pathologically increased REM sleep, warrants further study. The effects of antidepressants on sleep maintenance and slow-wave sleep are more variable and are largely mediated by antihistaminic effects and antagonism of 5-HT_2 and possibly melatonin receptors.

STRUCTURAL AND FUNCTIONAL BRAIN IMAGING

Modern magnetic resonance imaging (MRI) scans permit visualization of the living brain, with high resolution of cortical structures such as the hippocampus and anterior cingulate, as well as white matter lesions. One abnormality commonly observed in depressive disorders is an increased frequency of hyperintensities in subcortical regions such as periventricular regions, the basal ganglia, and the thalamus. More common in bipolar I disorder and among older adults, these hyperintensities appear to reflect atherosclerotic change, and as such, illustrate the deleterious effects of the interaction of aging and recurrent affective episodes. Ventricular enlargement, cortical atrophy, and sulcal widening have been observed in some studies of patients with more severe recurrent affective illness. More recent studies utilizing higher-resolution MRI scans have documented reduced volume in a number of relevant regions, including the hippocampus, medial orbital cortex, and anterior cingulate. Diffuse and focal areas of atrophy have been associated with increased illness severity and increased cortisol levels. In several studies, the hippocampal volume reduction has been associated with measures of illness chronicity, such as lifetime days of untreated depression. Volume reduction is thought to partly result from a reduction in the glial matter that supports neurons; suppression of BDNF-mediated connectivity, and ultimately, neurogenesis also may be implicated. Nevertheless, the reduced hippocampal volume has been documented in younger individuals experiencing a first depressive episode and has been shown to be partly under heritable control in primates.

Positron emission tomography (PET) and functional MRI (fMRI) scanning are now widely used for research aimed at visualizing brain activity during rest and various states of activation. Normal sadness is associated with an increase in blood flow and neuronal activity in the thalamus and mPFC, which may be thought of as a nonspecific change associated with diverse emotional responses. More specific activation is seen in the left amygdala, hippocampal formation, and parahippocampal gyrus. Sadness generated by one's own thoughts (as opposed to a video scenario) and anticipatory anxiety are associated with a relative increase in blood flow to the anterior insular cortex. The most widely replicated fMRI findings associated with depression pertain to resting-state connectivity, which is abnormally increased in the DMN and decreased connectivity within the CNN.

FIGURE 13.8–17. Key brain regions involved in affect and mood disorders. **A:** Orbital prefrontal cortex and the ventromedial prefrontal cortex. **B:** Dorsolateral prefrontal cortex. **C:** Hippocampus and amygdala. **D:** Anterior cingulated cortex.

The most widely replicated PET finding in depression is decreased anterior brain metabolism, which is generally more pronounced on the left side. Thus, depression may be characterized by a relative increase in nondominant hemispheric activity. Decreased cerebral blood and reduced glucose metabolism in regions such as the dorsolateral PFC appear to be severity-dependent and are correlated with difficulties inhibiting negative affective expression, reduced abstraction, and impaired executive problem-solving skills. Abnormalities of regional cerebral metabolism have been observed in unipolar and bipolar depressions and appear to be somewhat state-dependent. Furthermore, hypofrontality tends to reverse in concert with shifts from depression into hypomania, such that there are greater left-hemisphere reductions in depression compared to greater right-hemisphere reductions in mania. Other studies have observed more specific reductions in reduced cerebral blood flow or metabolism, or both, in the dopaminergically innervated tracts of the mesocortical and mesolimbic systems in depression. Again, there is evidence that antidepressants at least partially normalize these changes.

In addition to a global reduction in anterior cerebral metabolism, increased glucose metabolism has been observed in several limbic regions, particularly among patients with relatively severe recurrent depression and a family history of mood disorder (see Fig. 13.8–17). During episodes of depression, increased glucose metabolism is correlated with intrusive ruminations. Of note, increased metabolic activity in the amygdalae and decreased activity in the dorsolateral PFC appear to be independent dysfunctions. Increased paralimbic metabolism appears to be reversible with effective pharmacotherapy, but, in one study, the abnormality re-emerged when recently remitted patients were restudied off medication. State-dependent or trait-like paralimbic hypermetabolism has been proposed to be an “emotional amplifier” that helps to distort the signal of various stressors in those at high risk of depression.

IMMUNOLOGIC DISTURBANCE

Overview

Although long conceptualized as separate systems with different biologic goals, it is now widely understood that the CNS and immune system are better conceptualized as an interconnected network tasked with protecting organismal integrity from threats, both internal (i.e., infectious, cancer)

and external (i.e., predators, threatening conspecifics). In addition to sharing the capacity to learn from experience, the CNS and immune system are biologically interdigitated in ways that would have astounded both neurologists and immunologists practicing their crafts in the mid-20th century. Initial findings linked depression with immunosuppression, as measured by reduced adaptive immune responses to immune stimuli. Subsequent studies highlighted associations between activation of the innate immune system (i.e., inflammation) and the development of depression. In general, these studies have carried the day in terms of scientific focus, but more recent research is again highlighting important and complex associations between adaptive immunity (especially T-cell function) and stress-related conditions such as MDD. In this section, we focus on the more robust literature linking inflammatory processes to the pathogenesis and treatment of depression.

Evidence that Inflammation Is Associated with MDD: Cross-Sectional and Inflammatory Stimulation Studies

Given our general failure to identify unequivocal biologic alterations associated with MDD, it is quite striking that the top contender for such an alteration may be increased peripheral inflammation. Hundreds of studies and multiple meta-analyses confirm that, as a group, individuals with MDD demonstrate increased circulating levels of a number of inflammatory mediators, with the most reliable increases seen for the proinflammatory cytokines interleukin (IL)-6 and tumor necrosis factor (TNF) and the acute phase reactant CRP. Gene expression studies suggest these inflammatory molecules likely derive from activated peripheral blood immune cells, given findings that MDD is associated with activation of canonical inflammatory signaling pathways, such as nuclear factor-kappa-beta and the NLRP3 inflammasome which activates the potent proinflammatory cytokine IL-1-beta. MDD has also been repeatedly associated with increased inflammatory activity in the CNS, as evidenced by increased levels of inflammatory mediators in CSF and activation of microglial cells, which are the resident immune cells in the CNS. A robust literature also reports increased inflammatory mediators in the brain parenchyma of individuals with depression in postmortem studies, especially in depressed individuals who died by suicide.

These types of cross-sectional and postmortem studies can report association but are only suggestive of causation. However, two other lines

of research provide strong support for the ability of inflammatory processes to produce depression and related emotional states, such as anxiety, fatigue, and irritability. The first line of evidence comes from many longitudinal studies showing that individuals with increased inflammatory biomarkers are more likely than others to develop depression in the future. Related literature from large population-based datasets finds that the occurrence of serious infectious or autoimmune illness (both of which are associated with inflammatory activation) predicts the later development of depression, with infections serious enough to require hospitalization being associated with a 42% increase risk of subsequent suicide.

The second line of evidence supporting the depressogenic potential of inflammation comes from very consistent literature showing that inflammatory stimuli induce symptoms commonly seen in depression, as well as closely related symptoms such as anxiety and irritability. Of these inflammatory stimuli, the most extensively studied is treatment with the inflammatory cytokine interferon (IFN)-alpha, which was widely used for many years as a treatment for certain cancers (e.g., malignant melanoma) and infections (e.g., hepatitis C). Because patients would voluntarily expose themselves to IFN-alpha on a long-term basis, this treatment modality provided a natural experiment in the behavioral and neurologic effects of chronic inflammation. Depending on the dose, chronic exposure to IFN-alpha produces the full syndrome of MDD in 30% to 50% of individuals not depressed prior to commencing the treatment and induces far higher rates of subsyndromic mood disturbance. That inflammatory processes are responsible for these behavioral changes comes from many lines of evidence, including the observation that increased induction of the inflammatory second messenger p38 mitogen-activated protein kinase in response to the first injection of IFN-alpha predicts the development of depression a month later with a high degree of accuracy. Evidence that the behavioral state induced by IFN-alpha is a “true” depression comes from studies showing a high degree of symptom overlap between IFN-alpha-induced depression and depression in the general population, as well as from studies showing that the depressive state induced by IFN-alpha can be prevented and/or treated with standard antidepressant medications. In addition to IFN-alpha, other shorter-term immune stimuli, such as typhoid vaccine and lipopolysaccharide, have been shown to induce time-limited depressive symptoms. Intriguingly,

females appear to be more vulnerable to the depressogenic effects of these brief inflammatory stimuli, which may contribute to the higher rate of depression seen in females worldwide.

It is important to note that the degree of inflammatory activation seen in populations of medically healthy individuals with depression is typically mild, with mean values frequently in the upper range of normal for biomarkers such as CRP, which have standardized values. Nonetheless, because individuals living in industrial societies tend to demonstrate fairly stable levels of inflammation across time (in contradistinction to individuals in hunter-gatherer societies who show far more intraindividual variation), even these mild increases in inflammatory biomarkers are known to significantly increase the risk for a range of medical conditions (e.g., diabetes, cardiovascular disease, dementia). Given this, it shouldn't be surprising that the modest increases observed in depression are also able to produce profound alterations in mood, cognition, and behavior.

Inflammation Causes Depression, But Depression Is Not an Inflammatory Condition

The finding that groups of depressed people have elevated inflammation compared to nondepressed comparison groups could imply two very different possibilities. It might be that almost every person with MDD has mildly increased inflammation, which would be consistent with being a "final common pathway for the development of MDD." Under this scenario, MDD would be reconceptualized as an inflammatory condition. On the other hand, it might be that the average increase in inflammation seen in groups of depressed individuals reflects the effect of a subgroup of depressed individuals with more markedly increased inflammation who are pulling up the mean value for the depressed group as a whole. In fact, it is now established that this latter scenario is the case: only a subgroup of depressed individuals demonstrate increased inflammation (as measured by a CRP >3 mg/L), with this group typically comprising 30% to 45% of the larger depressed population, depending on a variety of other factors independently associated with inflammation, including obesity, childhood adversity, socioeconomic disadvantage, and treatment resistance. This means that the majority of depressed individuals do not show signs of elevated peripheral inflammation. While it is possible that inflammation may contribute to depressive pathogenesis in some individuals with normal inflammatory biomarkers but enhanced

downstream sensitivity to their effects, most current data argue against this. As we discuss below, depressed patients with increased inflammation show differences in brain functional connectivity, metabolism, and response to anti-inflammatory medications and standard antidepressants. All of this points to the fact that inflammation likely only contributes substantially to depression in individuals with increased inflammation, whereas other brain–body pathways, either separate or downstream from inflammation, are more relevant to pathogenesis in individuals with MDD but lower levels of peripheral inflammation.

Inflammation Promotes Specific Symptoms with Transdiagnostic Implications. Just as MDD is not always caused by inflammation, inflammation does not appear to be an “equal opportunity” promoter of depressive symptoms. Indeed, convergent data indicate that inflammation is especially likely to induce the interrelated symptoms of anhedonia and psychomotor slowing, as well as suicidal behavior. Deficits in anhedonia and psychomotor activity have been repeatedly linked to the tropism of inflammatory mediators for the basal ganglia, where cytokines have been shown to impair dopamine signaling directly and indirectly while promoting glutamatergic excitotoxicity, leading to reduced basal ganglia functionality and impaired connectivity, both internally within the striatum and between the striatum and other areas implicated in depression such as vmPFC. Anhedonia is a complex phenomenon, and inflammatory processes do an admirable job of deconstructing it into its more basic and homogeneous elements. Studies in animals and humans indicate that inflammation impairs effort-based motivation, reinforcement learning, and reward anticipation without impacting the capacity to experience reward while it is occurring. Anyone who has experienced the difficulty of making an effort or looking forward to things while depressed will understand this constellation of effects.

It is increasingly recognized that associations between inflammation and depression in the modern world might be a legacy of adaptive advantages in pathogen-host defense conferred by depressive symptoms and biology across hominid evolution. However, the fact that inflammation increases the risk of suicidal ideation and behavior is a challenge that all immune-based and other types of adaptive explanations for depression will have to address. It is hard to imagine many scenarios in which suicide, especially early in life, might advance survival and reproduction.

Findings in support of an association between inflammation and suicide come from several sources. Postmortem studies have observed increased levels of inflammatory mediators in the brains of depressed individuals who died by suicide versus depressed and nondepressed individuals who perished from other causes. Postmortem studies also indicate that patients with either depression or schizophrenia who die by suicide have increased microgliosis, a marker of increased inflammatory microglial activation. Markers of increased inflammation in postmortem brain samples have been found in both adults and adolescents who died by suicide. Suicidal thoughts and behavior in living individuals have been repeatedly associated with increased CNS and peripheral inflammatory cytokines when compared to patients with similar disorders without suicidal issues. Finally, suicidal ideation was among the most reduced depressive symptoms in medically healthy patients with MDD and elevated inflammation (CRP >5 mg/L) treated with the TNF antagonist infliximab.

Of all the contributions that inflammation has made to our understanding of depression, perhaps none is more intriguing than the critique it offers to current psychiatric diagnostic nosology. On the one hand, inflammatory processes have more causative power over certain depressive symptoms than others, thereby providing what may be the field's best evidence for a subtype of depression more biologically homogeneous than the disorder as a whole. On the other hand, inflammation promotes symptoms that are strikingly transdiagnostic, suggesting that immune-driven depression has deeper ties with elements of other psychiatric conditions than would be apparent from their current nosologic status as separate disorders. This is clearly the case with anhedonia, which is a prominent component of the negative symptom complex of schizophrenia and is common in individuals struggling with post-traumatic stress disorder. That inflammation simultaneously promotes specific symptoms that are not specific to any particular psychiatric condition may help explain the well-established observation that most psychiatric conditions (e.g., schizophrenia, bipolar disorder, PTSD) show as strong—or stronger—associations with increased inflammation as does MDD.

Mechanisms by which Inflammation Promotes Depressive Symptoms

Overview. A good rule of thumb for understanding the role of peripheral inflammation in the pathogenesis of MDD is that inflammation can cause any and all biologic effects that have been observed to differ between depressed and nondepressed individuals. Indeed, the breadth of depression-relevant CNS changes induced by inflammation contributed to earlier conceptualizations of MDD as an inflammatory disorder. As we discuss below, we now know this is not true, and that in fact, inflammation is probably only directly relevant to a subgroup of depressed individuals. Nonetheless, the range of depressive signatures induced by inflammation is impressive and includes; (1) glucocorticoid resistance, (2) flattening of the diurnal cortisol rhythm, (3) changes in sleep architecture, (4) alterations in monoamine and glutamatergic neurotransmission, and (5) loss of glial cell numbers and function. Recent research suggests that changes in neurotransmission and impairment of glial cell function, with resultant effects on functional brain circuits, may be especially relevant for depressive symptoms, such as anhedonia, and are therefore the focus of what follows.

Pathways by which Inflammatory Mediators Access the CNS. Given the centrality of the brain to cognition, emotion, and behavior, one would de facto assume that peripheral inflammatory mediators must have pathways by which they impact CNS activity, and indeed this is the case. It has long been known that inflammatory cytokines can access the brain via fenestrated capillaries in circumventricular organs, via saturable transporters, and via stimulation of peripheral sensory afferent nerves, which project to the nucleus of the solitary track, with subsequent activation of catecholaminergic projections to higher brain areas. Recent years have identified other mechanisms that speak to an even more intimate and profound connection between peripheral immunity and the brain. We now know that the brain can respond to an infectious and noninfectious threat by the release of chemokine (C–C motif) ligand 2 (CCL2), which results in monocytic and T-cells being released from bone marrow that subsequently traffic to the CNS. Depending on the initial stimulus, these cells can either cross into the brain parenchyma or congregate in the meninges, from which they secrete cytokines that influence aspects of CNS function highly relevant to depression. It appears that the behavioral effects of this immune cell trafficking depend, at least to some measure, on whether the cells involved demonstrate an

inflammatory (e.g., “M1 type monocytes, CD8 effector T-cells) or an anti-inflammatory (e.g., “M2 type” monocytes, regulatory T-cells [Treg]) phenotype. Studies in rodents demonstrate that stress resilience (as well as learning from stressors) requires the trafficking of immune cells into the subarachnoid space, from whence they secrete the cytokine IL-4, which crosses into the CNS to induce BDNF in the hippocampus. Importantly, a wide range of antidepressant modalities likewise increase BDNF in the hippocampus. A final mechanism by which peripheral inflammation can signal the CNS is via disruption of the blood–brain barrier (BBB), allowing cytokines direct access to the brain parenchyma. Recent animal work indicates that rather than promoting wholesale BBB disruption that would indicate random pathology, psychological stressors that activate peripheral inflammation produce targeted BBB disruption in areas in which cytokines have specific behavioral effects that—while contributing to depression—likely served adaptive purposes across evolutionary time. In particular, stress-induced inflammation has been shown in animal models to reduce the expression of claudin 5 with resultant BBB disruption in the area of the nucleus accumbens, a brain region known to play a key role in the ability of inflammation to induce anhedonia. Similar decreases in claudin 5 have been found in the nucleus accumbens of postmortem brains of individuals with depression.

Effects of Inflammation on CNS. This chapter provides various perspectives on the relevance of monoamine neurotransmitters to the pathogenesis of depression. An immunologic point of view comports with the idea that monoaminergic signaling may not be the *sine qua non* of biologic abnormalities that produce depression but still may play an important role in subgroups of depressed individuals, in this case, individuals with increased inflammation. Of the monoamines impacted by inflammation, dopamine stands out as the most effected and best studied for its role in contributing to anhedonia and psychomotor slowing, both symptoms common to depression and other mental illnesses (e.g., negative symptoms of schizophrenia). Multiple lines of evidence in animals and humans demonstrate that inflammatory mediators target all aspects of dopamine signaling. Inflammation attenuates the production of dopamine via the oxidative stress-induced destruction of tetrahydrobiopterin (BH4), a cofactor essential for the conversion of precursors such as phenylalanine to monoamines, including dopamine. In

humans, IFN-alpha administration increased the phenylalanine/tyrosine ratio (a marker for decreased BH4 activity), which was associated with increased fatigue and lower concentrations of CSF dopamine and the dopamine metabolite HVA. Inflammation antagonizes dopamine release from presynaptic nerve terminals via reductions in VMAT2, which packages neurotransmitters for release across the synaptic cleft. Finally, inflammation has been shown to impair postsynaptic D2 receptor function.

While recent attention has turned to dopamine, earlier studies tended to focus more exclusively on the effects of inflammation on serotonin metabolism. Inflammatory cytokines such as TNF and IFN-gamma induce the enzyme indoleamine 2,3-dioxygenase (IDO), which plays a key role in constraining immune activation by shunting tryptophan from the production of serotonin to the production of kynurenine. A number of studies found that increased peripheral IDO activity predicted depression in response to IFN-alpha treatment, raising the possibility that inflammation vitiated serotonin availability in the CNS. However, studies of the CFS showed that tryptophan levels were normal during IFN-alpha treatment and showed no association with depressive symptoms, whereas kynurenine levels were markedly increased and were associated with the development of depressive symptoms. Kynurenine is actively transported into the CNS, where it is metabolized into several neuroactive compounds, especially the neurotoxic metabolite QUIN, which has been associated with depressive symptoms in patients receiving IFN-alpha and in medically healthy patients with MDD and elevated levels of inflammation. Increased CNS QUIN in medically healthy patients with MDD has also been associated with volume loss in the striatum and treatment resistance.

In the well-functioning brain, glutamatergic neurotransmission is tightly controlled and generally restricted to synaptic signaling, where it plays an essential role in long-term potentiation and other processes necessary for learning, memory, and other cognitive functions. This control is required given the excitotoxic/neurotoxic potential of glutamate when present in excessive amounts or in inappropriate locations within the CNS. Glial cells, which surround neural synapses, play a definitive role in this regulatory control. In particular, astrocytes are responsible for removing 90% of synaptic glutamate via excitatory amino acid transporters (EAATs). Even before the advent of ketamine as a treatment for MDD, which operates by antagonizing the glutamatergic NMDA receptor, significant

evidence implicated alterations in glutamate, and its metabolites in the pathogenesis of depression and reductions in astrocytes and oligodendrocytes as well as EAATs are among the most consistent findings seen in postmortem brains of individuals with MDD. Inflammatory mediators have been found to induce all these changes. TNF and IL-1 beta have been shown to decrease the expression of EAATs on glial cells, reverse the polarity of the transporters such that glutamate is released instead of taken up and via these processes promote astroglia and oligodendrocyte death, further reducing the capacity of these cells to regulate glutamate levels. By enhancing the function of cystine/glutamate (xCT) transporters on glial cells and by inducing the binding of adenosine triphosphate (ATP) to purinergic P2X7 receptors, inflammatory mediators (and related processes such as oxidative stress) further extrude glutamate into extracellular spaces. This process allows glutamate to engage with extrasynaptic NMDA receptors located in postsynaptic cell processes. Unlike synaptic NMDA receptors, which stimulate growth factor release, stimulation of extrasynaptic NMDA receptors attenuates growth factors such as BDNF, with subsequent loss of neurotrophic support for the relevant neural elements. QUIN has also been shown to stimulate extrasynaptic NMDA receptors, highlighting the relevance of this neurotoxic pathway to the depressogenic effects of inflammation. Neuroimaging studies also point to a role for glutamatergic signaling in the capacity of inflammation to induce depression. Studies using magnetic resonance spectroscopy have observed increased glutamate in the left striatum, and dorsal anterior cingulate gyrus in patients undergoing treatment with IFN-alpha, and medically healthy individuals with MDD and increased inflammation also demonstrate increased left striatal glutamate. In both cases, increased striatal glutamate was associated with features of anhedonia and psychomotor performance.

The effects of inflammation on neurochemical functioning in CNS can be seen writ large in neuroimaging studies showing associations between immune activation and changes in patterns of functional brain activity. Studies of individuals receiving either chronic (IFN-alpha) or acute (LPS, typhoid vaccine) immune stimulation are concordant with studies in patients with MDD and increased inflammation in showing reduced activity in the basal ganglia and increased activity in areas of the cingulate cortex important for modulation of mood, assessment of risk, and error detection.

Multiple imaging modalities have demonstrated altered/impaired basal ganglia activity in patients receiving IFN-alpha, and these changes reliably track with anhedonia (ventral striatum) and psychomotor slowing (motor areas of basal ganglia). fMRI studies in healthy volunteers receiving an endotoxin challenge show a similar blunting of ventral striatal activity in anticipation of reward, with this blunted response associated with the emergence of depressive symptoms. Typhoid vaccination was found to decrease functional connectivity within mesolimbic circuits, including the nucleus accumbens and sgACC cortex, with these changes associated with increased IL-6 and depressive symptoms. In unmedicated medically healthy patients with MDD, increased concentrations of plasma CRP are associated with decreased functional connectivity between the ventral striatum and vmPFC, which correlated with increased anhedonia. In the same population, decreased functional connectivity between the dorsal striatum, vmPFC, and the presupplementary motor area was associated with psychomotor slowing. Inflammatory stimuli (e.g., IFN-alpha, endotoxin) have also been shown to activate brain areas comprising threat circuitry, including the posterior-anterior cingulate, amygdala, insula, and hippocampus. For example, treatment with IFN-alpha in patients with chronic hepatitis C virus infection increased right amygdala reactivity to sad faces. Interestingly, pharmacologic blockade of TNF signaling in patients with rheumatoid arthritis produced the opposite effect. Taken as a whole, an important implication of the imaging studies is that inflammation produces regional and circuit-level alterations in brain function that are associated with symptoms that are also most prominently induced by inflammatory stimuli (i.e., anhedonia, psychomotor slowing, anxiety) but that likely cut across currently recognized psychiatric conditions.

Treatment Implications

If inflammation causes depression, the obvious conclusion is that reducing inflammation should reduce depression in patients with elevated inflammation. Multiple lines of evidence suggest that this is true. However, because MDD is not an inflammatory condition per se, it is not true that all patients with depression will benefit from pharmacologic strategies for reducing inflammation. Moreover, because inflammation promotes some depressive symptoms more than others, anti-inflammatory medications would be predicted to show a larger benefit for these symptoms than for

symptoms less robustly induced by inflammation. Again, evidence suggests this is the case.

It is a paradox that the most extensively studied anti-inflammatory agents are the least informative in terms of evaluating the value of reducing inflammation as a depression treatment strategy. Taken together, many studies have examined the antidepressant potential of nonsteroidal anti-inflammatory drugs (NSAIDs), cyclooxygenase 2 (COX 2) inhibitors, omega-3 fatty acids, minocycline, and other agents that–while having anti-inflammatory properties–also have a range of off-target effects. These off-target effects have been shown in various studies to have both anti- and prodepressant properties, thereby confounding any observed associations between these nonspecific anti-inflammatories and effects on depression. Not surprisingly, studies of these agents as antidepressants paint a mixed picture. Several meta-analyses suggested benefits, but these included studies with effect sizes likely to be unrealistic. More recent large randomized, placebo-controlled trials have generally not shown that these agents have consistent antidepressant effects in general populations of medically healthy individuals (i.e., in depressed populations not enriched for increased inflammation).

Fortunately, a number of studies have examined the antidepressant effects of cytokine antagonists. These medications block specific cytokines with minimal or no off-target effects, making the establishment of causality between blocking inflammation and any subsequent behavioral effects tractable. Moreover, these agents are large molecules that do not readily cross the BBB. Because of this, any behavioral effects can likely be ascribed to the modulation of peripheral inflammation, thereby providing a new line of evidence that bodily inflammation can drive brain function in ways productive of mental illness.

The antidepressant properties of cytokine antagonists have been examined in patients with primary autoimmune conditions and in medically healthy patients with MDD, and the results provide consistent evidence for an antidepressant effect in patients with elevated inflammation and no antidepressant signal in those with normal levels of inflammatory biomarkers. A mega-analysis of studies in autoimmune conditions (10, 743) that examined antagonists against IL-6, Il-12/23, and TNF found an overall modest antidepressant effect (d = 0.29), with the strongest benefits for IL-6 and IL-12/23 antagonists (trend level for TNF). These effects were only observed in the substratum of patients with elevated depressive

symptoms, and results were attenuated when adjusted for improvements in the underlying medical condition.

While suggestive, results in patients with autoimmune conditions are confounded by low rates of depression prior to treatment and improvements in the underlying medical disease, which can secondarily improve depression. The obvious resolution to these limitations is to examine cytokine antagonists in medically healthy individuals with depression. Two studies with the TNF antagonist infliximab and one study with the IL-6 antagonist sirukumab have done this and provided remarkably consistent findings. These agents do not show an antidepressant effect in general populations of medically healthy individuals with depression (either unipolar or bipolar) but do provide a modest benefit in patients with elevated inflammation prior to treatment and perhaps in individuals with early life adversity, which has been repeatedly observed to be associated with increased inflammation (at rest and in response to stress) in adulthood. However, the level of inflammation required to expose the antidepressant effect is quite high (CRP >5 mg/L for infliximab and >8 mg/L for sirukumab), suggesting that the majority of depressed patients will not benefit from anti-inflammatory treatments. In fact, results from the two studies of infliximab indicate that TNF blockade may be counter-productive in patients with depression and lower levels of inflammation. In 60 patients with treatment-resistant depression, those with pretreatment CRP less than 5 mg/L showed a significantly larger antidepressant effect following treatment with saltwater placebo than treatment with the TNF antagonist. Numerically similar results were found in a study of infliximab for bipolar depression. Interestingly, the largest randomized trial of omega-3 fatty acids as monotherapy for MDD found a similar pattern: patients with lower levels of pretreatment inflammation responded better to placebo than the fatty acid. Similarly, a large randomized, placebo-controlled trial of omega-3 fatty acids as a preventive measure in adults 50 years and older found an increased prevalence of depression over time in those who received the fatty acid.

The literature is mixed on whether standard antidepressants (and antidepressant augmenting agents such as atypical antipsychotics) have anti-inflammatory effects and whether any such effects might contribute to their therapeutic efficacy. More consistent have been studies showing that increased pretreatment inflammatory biomarkers are associated with a

poorer response to both antidepressants and psychotherapy, but even here, there is a wrinkle. More recent studies suggest a picture more in line with results from studies of anti-inflammatory agents, which is that patients with higher and lower levels of inflammation likewise respond differently to standard agents. Although based on post hoc findings as of this writing, several studies indicate that patients with elevated peripheral inflammation (often measured as CRP >1 mg/L) respond less well to serotonergic antidepressants and preferentially to agents with catecholaminergic–and especially dopaminergic–activity. This pattern has also been observed for the dopaminergic modulating agent lurasidone in bipolar depression, where response showed a linear relation with CRP concentrations, and only patients with elevated CRP showed a benefit of lurasidone over placebo. Some evidence suggests that increased inflammation may also predict response to ketamine. Taken as a whole, these results are conceptually gratifying, given convergent evidence that inflammatory processes preferentially disrupt dopaminergic and glutamatergic signaling while being less relevant for serotonin activity in the CNS.

Future Directions. Despite remarkable progress over the last 20 years, many key questions remain regarding the role of peripheral and CNS immunity in the pathogenesis and treatment of MDD. Most studies to date have examined innate immune processes, in particular inflammation, with far less work being done to clarify the extent to which adaptive immune functions may also contribute to depression or behavioral resilience. The relevance of this gap in our knowledge is highlighted by recent animal studies showing that T-cells directly interact with CNS processes to promote behavioral processes of direct relevance to stress resilience, learning, and memory—all of which are important for MDD. When it comes to the role of innate immune inflammation in the pathogenesis of depression, data increasingly suggest that inflammation might be best considered as akin to climate and its effects on downstream mediators as akin to weather. Inflammatory molecules are among the most ancient of life's inventions, and their effects on mood are likely the result of producing a background climate conducive to depression driven more immediately by downstream mediators, such as monoamine neurotransmitters, glutamate, and kynurenine pathway metabolites. The degree to which these downstream mediators are specific for

inflammation or relevant to depression more broadly is also a key question, as this will influence the search for optimal predictive biomarkers, or collections of biomarkers, to identify subgroups of depressed patients most likely to benefit from anti-inflammatory treatment strategies. A better understanding of the pathophysiology of an immune-based subtype of depression will also likely help identify optimal anti-inflammatory treatment strategies and whether some of these strategies are most effective broadly or whether even more fine-grained subtypes of inflammatory depression will be identified and found to respond to the targeting of specific inflammatory mediators. Finally, the recurrent observation that anti-inflammatory agents may be harmful compared to placebo in patients with MDD and low levels of peripheral inflammation deserves more attention and study, both for the obvious pragmatic reason of patient safety and because it might suggest that immune processes are relevant for these patients also, but in ways that are different and would require different treatment approaches than in those with high inflammation.

SUMMARY

More severe and persistent depressive states, including those classified as major depressive disorder, are associated with a wide range of neurobiologic disturbances, which in turn are linked to at least some of the differences observed in clinical presentations and response to specific treatments. Some of the disturbances are better understood as *traits*, which may be either inherited or acquired, whereas others are clearly state-dependent and are reversible by treatment or spontaneous remission. Some of the state-dependent abnormalities associated with major depressive disorder, which occur more commonly in older patients with more severe symptomatology, include increased phasic REM sleep, poor sleep maintenance, hypercortisolism, impaired cellular immunity, reductions in anterior cerebral blood flow and glucose metabolism, and increased glucose metabolism in the amygdala. Together, these changes appear to reflect the progressive effects of otherwise adaptive short-term responses to sustained stress. Once manifest in this form, such severe or melancholic depressive episodes tend to be longer, more disabling, more prone to relapse, and more likely to benefit from pharmacotherapy or ECT (vis-à-vis nonspecific or psychotherapeutic interventions).

More trait-like abnormalities may include decreased slow-wave sleep, reduced REM latency, blunted nocturnal GH secretion, and increased connectivity within the DMN. These abnormalities are associated with an early age of onset and increased vulnerability to recurrent illness. The heritability of these abnormalities, which at least partly reflects decreased 5-HT inhibition of responses to stress or threat, is both inferred from family studies and other at-risk paradigms and has been linked to inheritance of the *s* allele of the 5-HT transporter.

Examples of more persistent but acquired abnormalities may include global and focal changes, such as volume reduction in the hippocampus and anterior cingulate, hypertrophy of the adrenal cortex, periventricular hyperintensities, and alterations in CRH synthesis. Blunted TSH response (to a TRH infusion) and dexamethasone nonsuppression may represent *hybrids* in that these abnormalities can be slow to normalize, and when persistent after remission, convey high risk of relapse. Aging and the accumulating consequences of recurrent depressive episodes are inextricably connected. However, the diseases of aging that ravage brain function definitely increase the risk of depression and decrease responsivity to conventional forms of treatment. The late-onset form of depression associated with cerebral atherosclerosis illustrates the subtle interplay between brain function and mood disorder.

There is no doubt that vulnerability to mood disorders is partly heritable. This type of heritability is most likely polygenetic, and in all likelihood, will be best understood through models that include gene-environment interactions. Nevertheless, increased heritability is associated with an earlier age of onset, greater comorbidity, increased risk of recurrent illness, and an increased likelihood of hypomanic or manic episodes. Is it ironic that two of the more heritable forms of mood disorder, early-onset chronic depressions, and bipolar depression, are relatively less likely to be associated with state-dependent neurobiologic disturbances? Different genetic vulnerabilities, different clinical presentations, and age-dependent differences in the effects of depression on brain function depression are likely to explain this apparent paradox.

Ultimately, depression remains a fundamentally human experience, partly because people can all relate to sadness, grief, and the heartbreak of lost love and partly because of the contrived nature of experiments that subject animals to prolonged, inescapable stress. Strong and sustaining affective bonds and an enduring sense of self-worth and competence are

simply too important, and assaults on these fundamental aspects of well-being are too frequent for some humans to withstand without becoming depressed. That some are more vulnerable to depression than others is without question, as is the association of stress, depression, and numerous reproducible changes in brain function. Understanding the mechanisms of successful and unsuccessful adaptation and elucidating the alterations in brain function that predispose to and maintain depressive disorders represent the best hope to prevent and relieve the misery and suffering of tens of millions of people.

Anxiety Disorders

14.1 Anxiety Disorders: Introduction and Overview

Kathleen Ries Merikangas, Ph.D.

The anxiety disorders are the most prevalent psychiatric syndromes in the U.S. population. Nearly one-fifth (17%) of adults report a lifetime history of one of the major anxiety disorders, and 1 in 10 suffer from a current anxiety disorder. Anxiety disorders are associated with intense subjective distress and social impairment, and their childhood and adolescent onset can interfere with the accomplishment of social, educational, and occupational functioning. The most recent estimates of the Global Burden of Anxiety reveal that anxiety disorders explain 10% of the disability-adjusted life years for all mental, neurologic, and substance use disorders, second only to major depression. Despite their high burden, anxiety disorders have the lowest proportion of professional treatment of all of the classes of mental disorders. The sections of this chapter document the phenomenology and classification of anxiety disorders in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), epidemiology, risk factors and impact, biologic correlates including biochemical, neuroimaging, and genetics factors, and somatic and behavioral treatments.

BACKGROUND ON FEAR AND ANXIETY

Fear and anxiety can be conceptualized as two key core negative emotions. As such, definitions of “fear” and “anxiety” must be based on broader definitions of emotions in general. For the current set of sections, the term “emotion” refers to the brain state associated with the perception of a motivationally salient stimulus, a stimulus that creates a need for the organism to act. Motivational stimuli can, in turn, be divided into “rewards” and “punishments,” where a “reward” refers to a stimulus for which an organism will expend effort to approach, and a “punishment” refers to a stimulus for which an organism will expend effort to avoid.

“Fear” refers to the specific set of emotions or brain states that are elicited in an organism when it confronts danger. Many current approaches refer to “fears” in the plural because “fears” are viewed as a collection of closely related but distinguishable brain states, as opposed to one single state. This view reflects the fact that different forms of danger elicit different neural responses and associated differences in information processing and behavior: The response to a conspecific or some other form of innately dangerous stimulus can be distinguished, and both of these can, in turn, be distinguished from the response to objects that are viewed as dangerous through the effects of learning from experience. The term “danger,” in turn, refers to any stimulus or situation that is capable of producing harm to the organisms. The act of encountering a specifically dangerous object, such as a predator, can also be conceptualized as a “threat.” Moreover, because organisms tend to exert effort to avoid virtually all threats or dangerous scenarios, “threats” and “dangerous scenarios” can also be conceptualized as “punishments.”

The term “fear” can be distinguished from the term “anxiety” in a few respects. “Fear” is typically taken to refer to brain states associated with presentations of overtly dangerous stimuli. For example, fear is the emotion aroused when an organism immediately confronts a predator or a dangerous conspecific appearing in close proximity directly in front of the organism. As such, “fear” represents an acute, immediate reaction manifest in abrupt encounters with highly salient threats. In research with rodents, this definition has, at times, been used to model “normal” responses in humans to dangers. For example, this type of “fear” response in the rodent is often modeled with the classic conditioning paradigm in which a rodent is placed in a cage and exposed to a cue,

such as a tone or a light, that predicts the immediate occurrence of an unconditioned aversive stimulus (UCS), such as a shock. In this fear-conditioning paradigm, the cue is conceptualized as a conditioned stimulus (CS+), and the organism's response to the cue can be viewed as an analog of "fear."

Unlike "fear," from this perspective, "anxiety" refers to brain states elicited by signals that predict impending but not immediately present danger. Thus, unlike "fear," "anxiety" involves a more sustained change in the brain, manifesting when a threat is still relatively removed from the organism in a spatial or temporal context. For example, "anxiety" might be conceptualized as the emotion aroused when an organism enters a deserted, isolated context where an encounter with a predator appears likely, despite the isolated nature of the context and the absence of any overt cues indicating that the predator is lurking. In the fear-conditioning experiment, "anxiety" is considered an analog of pathologic reactions to danger in humans, as occurs in anxiety disorders. This view reflects the relatively pervasive, chronic state of negative affect in clinical syndromes. In rodent experimental studies using fear conditioning, "anxiety" can be contrasted with "fear," which manifests on the immediate confrontation of the CS+; "anxiety" typically is considered as manifesting in the general context of the fear-conditioning experiment. Thus, anxiety might be elicited when the organism is placed in the cage where the fear-conditioning experiment was previously conducted.

Thus, "fear" and "anxiety" have been distinguished on both temporal and spatial grounds. From the temporal perspective, fear refers to the acute, immediate response to suddenly appearing, imminent danger, whereas anxiety refers to the sustained, insidious response to danger, as might manifest when the degree to which a threat is present remains ambiguous. From the spatial perspective, fear refers to the acute response to proximal threats, whereas anxiety refers to the response to distal threats. As such, "fear" in rodents can be considered an analog of "normal" human emotions elicited by thoughts about danger. "Anxiety" can be considered an analog of "abnormal" human emotions in similar scenarios. Parenthetically, when an acute, proximal threat is particularly dangerous, however, the emotional state elicited in the organism might better be characterized as "panic" as opposed to "fear."

Conceptualizations of "normal" and "abnormal" fears and anxieties emerging from research directly among humans differ somewhat from

conceptualizations in rodent-based or other basic research. Definitions in humans rest heavily on the presence of impairment, a disruption in normal functioning, or the presence of “clinically significant” distress. Basing definitions of abnormal anxiety on impairment or clinical judgments about distress does create some problems for attempts to conduct cross-species and neuroscience-focused research. The degree to which impairment or distress might manifest can be heavily influenced by the environmental circumstances to which the individual is exposed. Thus, two individuals manifesting identical neural responses to a dangerous stimulus might be classified differently in terms of the degree to which their associated anxiety can be considered “normal.” If one individual faces hurdles not encountered by the other due to the nature of their environment and associated resources, these two individuals, who function identically from a neuroscience perspective, will be classified differently from a clinical perspective.

Thus, as delineated in the chapters pertaining to etiology, particularly those on neurophysiology, neurochemistry, and brain circuitry, the field is entering a period in which ongoing research in basic brain function and its cross-talk with the environmental context and stimuli will enhance our understanding of the pathophysiology of disturbances in fear and anxiety. This knowledge has major future implications in its future potential for treatment and prevention.

DSM-5 MODIFICATIONS IN ANXIETY DISORDERS

The major subtypes of anxiety disorders in the DSM-5 include panic disorder (with or without agoraphobia), agoraphobia (without a history of panic disorder), specific phobia, social phobia, and generalized anxiety disorder (GAD). Revisions to the classification of anxiety disorders in the DSM-5 involve removing obsessive-compulsive disorder, and post-traumatic disorder have been subsumed under newly created “obsessive-compulsive and related disorders” and “trauma- and stressor-related disorders” categories, respectively. Therefore, both obsessive-compulsive disorder and post-traumatic stress disorder are not considered in this chapter. Other modifications to the proposed DSM-5 anxiety disorders category include the addition of separation anxiety disorder (contained under disorders usually first diagnosed in infancy, childhood, or adolescence in the DSM-IV), the identification of agoraphobia as a distinct

and codable disorder (diagnosed only with reference to panic disorder in the DSM-IV), minor revisions to criterion language to enhance clarity, objectivity, and consistency across the anxiety disorders, and the relabeling of social phobia as social anxiety disorder (SAD). As such, the term “social phobia” will now be replaced by “social anxiety disorder.”

ASSESSMENT OF ANXIETY

Anxiety may be assessed at the symptom or disorder level. Among adults, the most commonly used symptom measures include self-report checklists of both state and trait anxiety, fears, phobias, and avoidance, as well as clinician-administered symptom checklists. Anxiety disorders among adults are assessed by structured and semistructured diagnostic interviews designed for administration by either lay interviewers (e.g., the Composite International Diagnostic Interview [CIDI], the Diagnostic Interview Schedule for DSM-IV [DIS-IV]) or experienced clinicians (e.g., the Structured Clinical Interview for DSM Disorders [SCID], the Anxiety Disorder Interview Schedule-Revised [ADIS-R]). The ADIS-R is the most comprehensive diagnostic interview for the assessment of the diagnostic criteria of anxiety and affective disorders.

Assessment of symptoms and disorders of anxiety among children can involve obtaining information from the child alone or, more routinely, from individuals who observe the child in multiple contexts (i.e., caregivers and/or teachers), in addition to the child themself. There are also several structured and semistructured diagnostic interviews of child anxiety disorders, including the Diagnostic Interview Schedule for Children (NIMH-DISC-IV), the CIDI modified for adolescents, the Schedule for Affective Disorders and Schizophrenia for School-Age Children (KSADS-PL); and the Anxiety Disorders Interview Schedule for Children (ADIS-IV-C and P).

Several psychophysiological indicators of anxiety have also been used to examine both human and animal anxiety. Experimental models which induce stress and measure autonomic output to test the human “fight or flight” response to threat have been used to study the range of triggers, correlates, and responses to fear-provoking situations. Behavioral tasks, such as giving a speech or receiving the threat of shock, have been used to experimentally induce anxiety states in unaffected individuals as well as those with ongoing anxiety disorders. Measures of changes in pulse, skin

conductance, heart rate, and temperature regulation, as well as self-reported observations of facial expression, blushing, and other overt signs of anxiety, are presumed to provide a more accurate depiction of anxiety than self-reports or interviews about typical response patterns to stress.

OVERVIEW OF ANXIETY DISORDERS SECTION

The Anxiety Disorders section of this textbook covers the topics of phenomenology, epidemiology, genetics, neuroimaging, neurochemical aspects, and treatment of anxiety disorders.

In Chapter 14.2, Ryan J. Kimmel and Peter Roy-Byrne delineate the key **Clinical Features of the Anxiety Disorders**. The authors keep in line with the changes in the DSM-5. The DSM-5 removed post-traumatic stress disorder and obsessive-compulsive disorder but continues to link panic, generalized anxiety, and phobic anxiety together. This section summarizes the key symptoms and discusses differential diagnosis as it pertains to delineating presentations that appear to occur in multiple disorders. The authors provide the historical background and possible implications of the changes (or the lack thereof) to each disorder in the DSM-5.

Chapter 14.3 on the **Epidemiology of Anxiety Disorders** by Kathleen R. Merikangas and Michelle Theodory provides an update on the magnitude of anxiety disorders in adults and children in community surveys across the world. They show anxiety disorders are the most prevalent of the classes of mental disorders across the world and are associated with substantial individual and societal impact. They also document the large gap between the high magnitude of impairing anxiety disorders and low mental health treatment rates remains a serious challenge in public health, despite the efficacy of behavioral and pharmacologic treatments.

Chapter 14.4 provides an extensive summary by Costi, Feder, Iacoviello, Murrough, and Charney of the **Neurobiology and Neuroscience of Anxiety Disorders.** They summarize evidence from preclinical and clinical research that has implicated a range of neural systems through interactions with cortical and subcortical neural circuits involved in fear responses in the etiology of fear and anxiety responses. They review the role of neurochemical systems involved in anxiety disorders and their treatment targets, including the norepinephrine and

serotonin systems, but also neurosteroids, opioid peptides, neuropeptide Y (NPY), and other neurochemicals involved in the modulation of anxiety. They further describe the growing number of studies that investigate target-selective agents that may enhance the benefits of exposure-based or other forms of psychotherapy. They highlight the importance of continued close collaboration between basic and clinical researchers required to advance the current understanding of the neurobiology of anxiety disorders.

In Chapter 14.5, Drs Kitt, Cohodes, and Gee present a detailed review of **Neuroimaging and the Neuroanatomical Circuits in Anxiety Disorders**. They provide an excellent summary of the prevailing models of anxiety disorders and their relevance to each of the anxiety disorders. They show that the application of neuroimaging technology to investigations of the neurobiologic basis of anxiety disorders is yielding seminal information about the functional anatomical and neurochemical correlates of both normal and pathologic anxiety and fear states. Neuroimaging data from studies of panic disorder, specific phobias, SAD, and GAD support disease models that depend on altered interactions among the amygdala, hippocampus, and medial and orbital prefrontal cortex (PFC). They further highlight the growing effort to delineate the neurodevelopmental processes associated with anxiety disorders in childhood and adolescence and characterize the heterogeneity of anxiety states through approaches that integrate imaging data with genetic and neurochemical information.

A review of the current state of **Cognitive-Behavioral Therapy of Anxiety Disorders** is presented by Jonathan D. Huppert and Edna B. Foa (CBT) in Chapter **14.6**. There is evidence for the efficacy of CBT programs in the treatment of all anxiety disorders across children, adolescents, adults, and geriatric populations. Exposure in vivo to feared but otherwise safe stimuli and imaginal exposure to unwanted and upsetting thoughts are essential components of most CBT programs for anxiety. The cessation of safety behaviors or other subtle avoidance behaviors is essential for the anxiety disorders in order to disconfirm the patients' erroneous perceptions. The addition of interoceptive exposure appears to make a significant contribution to the treatment of panic disorder. In addition, exposure is typically conducted in the presence of cognitive challenging or discussions, helping the patient to attend to the corrective information. Anxiety management training and cognitive therapy

have also been shown to be effective in the treatment of GAD. Cognitive therapy that includes behavioral experiments, which inherently involves in vivo exposure, is also an effective treatment for panic disorder and SAD. Overall, it seems that the integration of exposure therapy with discussions that increase the attention of patients to the disconfirmation of their expectations of negative outcomes to exposures to the feared stimuli is the best method for optimizing treatment outcomes.

In Chapter **14.7**, Drs Ravindran and Stein review the current evidence for the application and evidence for specific **Somatic Therapies for Anxiety Disorders.** Aside from reviewing evidence for specific pharmacologic agents in treating each of the subtypes of anxiety disorders, they also highlight the importance of the diagnostic process and comprehensive evaluation of comorbidity, laboratory studies, and contextual life factors in treatment decision making. Physical examination and laboratory tests contribute to a comprehensive evaluation. They further describe methods to maintain treatment adherence, minimize side effects, and manage discontinuation of these medications when indicated. They also highlight the growing role of the specialty psychiatrist in consulting with primary care about the treatment of anxiety disorders.

In summary, these sections provide an update on the current state of knowledge on the magnitude, clinical presentations, impact, etiologic factors, and treatments of anxiety disorders. There has been substantial progress in each of these domains since the last edition of this textbook. However, the challenges of etiologic and phenotypic heterogeneity, lack of validity of diagnostic thresholds that distinguish the disorder from basic human emotions of fear and anxiety, indistinct boundaries within specific anxiety subtypes and between anxiety disorders, and mood and other emotional and behavior disorders continue to complicate our understanding of their causal mechanisms.

14.2 Clinical Features of the Anxiety Disorders

Ryan J. Kimmel, M.D., Joseph M. Cerimele, M.D., M.P.H., and Peter Roy-Byrne, M.D.

With the shift from anxiety neurosis in early conceptualizations of anxiety, three different spheres of anxiety have been delineated by clinicians: phobias (context-dependent fears), generalized anxiety (context-independent fears), and panic. Research that began in the 1960s suggested that obsessive-compulsive, phobic, nonspecific anxiety, and panic symptom subsets could be grouped together in part due to their common, positive response to various antidepressants. In the 1970s, interest in postcombat stress reactions rose as veterans returned from the Vietnam War. The cumulative research from the preceding decades led the authors of the DSM-III to organize an “Anxiety Disorders” section that included phobic disorders, generalized anxiety disorder (GAD), panic disorder, obsessive-compulsive disorder (OCD), and post-traumatic stress disorder (PTSD).

Though the DSM-IV refined the existing criteria and added a few new diagnoses, its overarching organization of the “Anxiety Disorders” section did not depart from the DSM-III nomenclature. The DSM-5, on the other hand, divided the DSM-IV’s anxiety spectrum into three pieces by separating out PTSD and OCD. Moreover, the DSM-5 asserted a close relationship between the classical anxiety disorders and a number of diagnoses that had been in other, nonanxiety classifications. Thus, the DSM-5’s “Anxiety Disorders” section contains separation anxiety disorder, selective mutism, specific phobia, social anxiety disorder, panic disorder,

agoraphobia, GAD, substance/medication-induced anxiety disorder, anxiety disorder due to another medical condition, other specified anxiety disorder, and unspecified anxiety disorder.

The DSM-5 subsumed PTSD, reactive attachment disorder, disinhibited social engagement disorder, acute stress disorder, and adjustment disorder into a section entitled "Trauma- and Stressor-Related Disorders." The final grouping is codified within the DSM-5 as the "Obsessive-Compulsive and Related Disorders" and includes OCD, body dysmorphic disorder, hoarding disorder, trichotillomania, and excoriation disorder.

With PTSD and OCD removed from the DSM-5 anxiety disorders section, modern nomenclature has made an interesting circuit. Emil Kraeplin, Anna Freud, John Bowlby, and other anxiety theorists from the prior century might recognize the logic behind the DSM-5's decision to recircumscribe its "anxiety disorders," gathering together panic, generalized anxiety, phobias, and separation anxiety. Every generation, however, has researched, argued, and reshuffled the anxiety spectrum to see if drawing new parallels and new divisions would yield improved insight and enhanced treatment efficacy.

Keeping in line with the current nosology, the following material describes the contents of DSM-5's anxiety disorders section, whereas the trauma-related and obsessive-compulsive spectra are detailed in other chapters. Etiology and treatment are briefly referenced but are more extensively covered in other sections of this book. Differential diagnosis is discussed, especially as it pertains to delineating between presentations that appear to straddle multiple disorders in the DSM-5's anxiety disorder grouping. However, given that anxiety-like symptoms appear in most of the diagnostic clusters in section II of the DSM-5, this section cannot provide an exhaustive differential diagnosis. The references included at the end of this section are a good source of cataloged confounders, as is the DSM-5 itself. Moreover, the reader should refer to the DSM-5 available in order to cross-reference the specific diagnostic criteria and their descriptions that could not be repeated verbatim in our text below.

PANIC DISORDER AND THE PANIC ATTACK SPECIFIER

Definition, Diagnosis, and Clinical Features

The DSM-5 defines a panic attack as a sudden, time-limited (minutes to an hour) burst of extreme anxiety accompanied by at least four of a cluster of cardiorespiratory, gastrointestinal, otoneurologic, autonomic, or cognitive symptoms (the specific symptoms are listed in Criterion A of Table 14.2–1). Culture-specific symptoms may be characteristic of panic attacks experienced by patients in other regions or communities, but typical panic symptoms are usually present, as well. Thus, the culture-specific symptoms do not supplant the need for four symptoms from the DSM-5's list of panic attack criteria.

A single panic attack is not necessarily indicative of a psychiatric disorder. More importantly, panic attacks can be a feature of a wide variety of psychiatric and medical diagnoses. Thus, DSM-5's Panic Attack Specifier may be added to other diagnoses to describe the experience and possible impairment in a given patient.

Panic disorder involves recurrent panic episodes accompanied by either a persistent fear of future panic attacks or a change in behavior designed to avoid panic triggers or situations. The behavior focuses on situations where the impact of a panic attack would be especially disconcerting or efforts to gain reassurance that nothing is wrong medically (by making ER visits or having repetitive medical testing) (see Table 14.2–1). At least some panic attacks have to "come out of the blue" without an obvious trigger, but many will be the result of a specific trigger or associated with situations where a specific trigger is anticipated.

Table 14.2–1.
Criteria for Panic Disorder

A. Recurrent unexpected panic attacks. A panic attack is an abrupt surge of intense fear or intense discomfort that reaches a peak within minutes, and during which time four (or more) of the following symptoms occur:

Note: The abrupt surge can occur from a calm state or an anxious state.

1. Palpitations, pounding heart, or accelerated heart rate.
2. Sweating.
3. Trembling or shaking.
4. Sensations of shortness of breath or smothering.
5. Feelings of choking.
6. Chest pain or discomfort.
7. Nausea or abdominal distress.
8. Feeling dizzy, unsteady, light-headed, or faint.
9. Chills or heat sensations.
10. Paresthesias (numbness or tingling sensations).
11. Derealization (feelings of unreality) or depersonalization (being detached from oneself).
12. Fear of losing control or “going crazy.”
13. Fear of dying.

Note: Culture-specific symptoms (e.g., tinnitus, neck soreness, headache, uncontrollable screaming or crying) may be seen. Such symptoms should not count as one of the four required symptoms.

B. At least one of the attacks has been followed by 1 month (or more) of one or both of the following:

1. Persistent concern or worry about additional panic attacks or their consequences (e.g., losing control, having a heart attack, “going crazy”).
2. A significant maladaptive change in behavior related to the attacks (e.g., behaviors designed to avoid having panic attacks, such as avoidance of exercise or unfamiliar situations).

C. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism, cardiopulmonary disorders).

D. The disturbance is not better explained by another mental disorder (e.g., the panic attacks do not occur only in response to feared social situations, as in social anxiety disorder; in response to circumscribed

phobic objects or situations, as in specific phobia; in response to obsessions, as in obsessive-compulsive disorder; in response to reminders of traumatic events, as in posttraumatic stress disorder; or in response to separation from attachment figures, as in separation anxiety disorder).

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:235, 236.

The requirement that at least some panic attacks seem to be unexpected helps separate the definition of panic disorder from, for example, the definition of a specific phobia of heights with a panic specifier. While an exposure to heights may predictably trigger a panic attack, unless there are context-independent panic attacks, the patient would not meet criteria for panic disorder.

History and Comparative Nosology

Though the term “panic attack” is a 20th-century construct, descriptions of what is now referred to as “Panic Disorder” date back to prior centuries. The disorder was identifiable enough that several decades before DSM-III, psychopharmacology researchers were able to clearly identify patients with recurrent panic attacks who experienced therapeutic benefit in early studies of the efficacy of antidepressants.

The biggest debate over the last 20 years regarding the panic disorder diagnosis has been in its relation to agoraphobia. The DSM-IV contained diagnoses of panic disorder with agoraphobia and panic disorder without agoraphobia. This framed agoraphobia as a fear of public situations that developed as the result of panic attacks. However, the high prevalence of agoraphobia alone, without panic attacks, in community surveys worldwide led the DSM-5 committee to include agoraphobia distinctly from panic disorder. This newly independent agoraphobia diagnosis will be discussed later in this chapter.

Epidemiology

Successive iterations of the DSM have consistently distinguished single panic attacks from panic disorder because only about 1 in 25 people will meet criteria for panic disorder in their lifetime, whereas at least 1 in 7 (with some measurements closer to 1 in 3) will have a panic attack. Panic

disorder has a high rate of comorbidity with affective disorders, substance use disorders, and other anxiety and trauma-related disorders. The age of onset of panic disorder peaks in the late teens and early 20s. Twice as many women as men are affected.

Differential Diagnosis, Etiology, Course, and Treatment

A variety of medical conditions may produce panic attack–like symptoms. These include brain tumors and epilepsy involving temporal lobe and adjacent subcortical structures; certain endocrinopathies such as hyperthyroidism and pheochromocytoma; and cardiopulmonary conditions causing chest pain, palpitations, or respiratory distress (e.g., myocardial infarction, cardiac arrhythmias, asthma, and pulmonary emboli). A number of medications can induce panic symptoms, including corticosteroids, stimulants, certain hormones, and some asthma medications. Illicit stimulants and hallucinogens can induce panic symptoms, as can caffeine and marijuana.

While family and twin studies clearly suggest that panic disorder has a heritable component (estimated at 35% to 40%), there is insufficient information to direct diagnosis or treatment. There is an increased frequency and intensity of stressful life events just prior to the onset of panic disorder, suggesting they serve as triggers of an underlying genetic vulnerability. Certain “anxious temperaments,” as well as childhood trauma, have been linked to higher rates of panic disorder in adulthood.

Panic disorder tends to be chronic, though the course is often fluctuating. Even after treatment to remission, the rate of relapse is high. For example, naturalistic studies often demonstrate a >50% relapse rate within 12 months of discontinuing an effective antidepressant. Given the impact of panic disorder on psychosocial functioning, as well as the increased rate of suicide attempts in these patients, ongoing monitoring is warranted if the patient chooses to disengage from active treatment.

Serotonergic antidepressants are the mainstay of pharmacologic treatment. Several benzodiazepines have FDA approval for panic disorder, and their efficacy and associated risks are discussed elsewhere in this book. There is also significant data to support treatment with cognitive behavioral therapy (CBT) and emerging, though still limited, evidence that other psychotherapies, such as psychodynamic and acceptance and commitment therapies, may be effective.

AGORAPHOBIA

Definition, Diagnosis, and Clinical Features

In DSM-5, agoraphobia is characterized by fear (imminent), anxiety (anticipated), and avoidance of multiple public situations where the individual feels that help is either not available or where escape would be difficult if they were to experience panic, anxiety, or other distressing or embarrassing symptoms. The fear or anxiety is “out of proportion” to the real threat, resulting in avoidance of the situation. The emotions (fear or anxiety) or behavior (avoidance) must persist for at least 6 months.

Patients with agoraphobia may develop “panic-like” symptoms, per DSM-5, without meeting full criteria for the panic attack specifier. Patients also may have other psychosomatic symptoms, often gastrointestinal or autonomic, associated with the fear or anxiety. Older individuals with multiple medical comorbidities may develop agoraphobia related to distressing symptoms of their medical condition (e.g., Parkinson disease). This combination of fear and psychosomatic symptoms leads to major life dysfunction. In some cases, patients may avoid all employment and in-person social interactions.

History and Comparative Nosology

In DSM-IV, agoraphobia was subsumed under panic disorder and thought only to develop in someone suffering from panic attacks. Clinicians thus had the option of coding for panic disorder with or without agoraphobia. However, more recent evidence has shown that many people with agoraphobia, perhaps over half, do not suffer from discernable panic attacks. Moreover, agoraphobia is not uncommon in children and adolescents who have never reported a panic attack. This difference has been shown to emerge from differences in clinical and nonclinical samples because many individuals with agoraphobia alone fail to seek treatment because of their extreme avoidance.

Epidemiology

Similar to panic disorder, more women than men have agoraphobia. The age of onset peaks in the late teens to early 20s. The measured prevalence of agoraphobia in specific clinical settings may evolve as the DSM-5’s recognition of agoraphobia without panic disorder spurs

clinicians to screen and consider the disorder in patients who do not present with panic attacks. Other anxiety disorders are seen alongside agoraphobia in comorbidity rates that often exceed 50%. Comorbid depressive disorders are seen in 33% to 52% of cases, with some suggestion that the presence of comorbid panic attacks increases the risk of comorbid depressive episodes.

Differential Diagnosis, Etiology, Course, and Treatment

Although many of the other anxiety disorders are marked by severe anxiety and even panic, consideration of the specific context triggering panic–anxiety can help with differential diagnosis. Specific phobia is limited to one stimulus, whereas agoraphobia's diagnostic criteria require at least two situations. Determining the reason for avoidance can provide further clues. For example, a patient who is loath to walk across a bridge may be afraid of heights (specific phobia) or may perceive the bridge to be an exposed, open area with limited exits should some frightening event occur (agoraphobia). Similarly, patients with separation anxiety disorder may refuse to leave home because of fear of permanent separation from an attachment figure, patients with PTSD may avoid specific stimuli that trigger traumatic memories in certain community situations, patients with social anxiety disorder may prefer home to situations where they might be judged and embarrassed, and patients with OCD may be effectively homebound due to specific obsessions about contamination when outside. Thus, these disorders can usually be distinguished from agoraphobia by the breadth of the avoidance and the motivation for the behavior.

Twin studies have suggested that agoraphobia may be slightly more heritable than panic disorder. Similar to panic disorder, there are certain personality factors, such as anxiety sensitivity, that serve as risk factors. Agoraphobia tends to persist if not treated. It is presumed, based on the improvement in agoraphobia symptoms in DSM-IV era studies of panic disorder with agoraphobia, that the same pharmacotherapies that are efficacious for panic disorder would also be efficacious for agoraphobia. DSM-5's designation of agoraphobia as an independent diagnosis will help spawn prospective trials and retrospective, naturalistic studies that will test this assumption. In contrast to the pharmacotherapy literature, a number of studies already document the efficacy of behavioral treatment for agoraphobia independent of panic disorder.

SOCIAL ANXIETY DISORDER

Definition, Diagnosis, and Clinical Features

Social anxiety disorder is a fear of one or more social situations where for a period lasting longer than 6 months, an individual is concerned about being harshly judged and evaluated for their performance or interpersonal interactions. There is an out-of-proportion fear of being shamed or negatively evaluated. In many cases, the social situation(s) is avoided altogether or tolerated only with significant anxiety. Many people describe increased anxiety in social situations, but a key to the social anxiety diagnosis, per DSM-5, is a "significant impairment" in an important facet of life functioning.

Disabling performance anxiety when speaking in front of a crowd is a common example of social anxiety disorder, as is severe anxiety at having to meet and engage with new people. However, patients can also fear having to do simple, everyday tasks in any setting that could be loosely described as "social." That is, unlike speaking in front of a crowd, the feared situations in social anxiety disorder need not be ones where it would be common and reasonable to expect some level of judgment. An example would be a fear of writing one's signature in front of others out of concern that the manner of writing, no matter how ordinary, will be a source of derision. This fear may be compounded with anxiety about appearing anxious.

History and Comparative Nosology

The formulation of social anxiety disorder evolved from DSM-III to DSM-5. Prior classifications included distinguishing between "specific" and "generalized" social anxiety. Because most individuals with social anxiety disorder fear and avoid multiple social situations, the "specific" specifier was rarely used clinically and subsequently omitted from classification. The DSM-5 conceives the generalized pattern to be the norm, and the only specifier is "performance only," which is by far the most common type of circumstance-specific social anxiety.

The other nosology debate that has impacted this diagnosis over the last several decades is whether the old, "generalized" subtype of social anxiety disorder could be distinguished from avoidant personality disorder. At times, avoidant personality disorder has been considered a severe

form of social anxiety disorder. While there is an unusually high rate of comorbidity between the two disorders as currently defined, it is notable that less than half of those with avoidant personality disorder have concurrent social anxiety disorder. Moreover, some theories align avoidant personality disorder closer to schizophrenia than social anxiety. The DSM-5 thus characterizes avoidant personality as phenomenologically distinct from the anxiety spectrum, though debates remain.

Epidemiology

Estimates of social anxiety disorder in the United States include a 12-month prevalence of 8% and a lifetime prevalence of 13%. Peak incidence occurs in the early teenage years (often in association with puberty and the transition from junior high school to high school or another increase in social context complexity). The prevalence is higher in women compared to men. Depressive episodes and substance use are common in those with social anxiety disorder.

Differential Diagnosis, Etiology, Course, and Treatment

Avoiding social interactions is central to social anxiety disorder but can also occur in other conditions, suggesting a need to consider a broad differential diagnosis. Alternate explanations for avoiding social interactions include other anxiety disorders such as panic disorder (differentiated by the presence of panic attacks and associated avoidance) or GAD (where the worry is broad), avoidant personality disorder (differentiated by avoidance of more than social interactions), development disorders such as autism spectrum disorders (where communication skills are more limited), and psychotic disorders (where insight is generally low). As mentioned above, avoidant personality disorder has been the subject of debate over whether it is distinct from social anxiety disorder, with the DSM-5 separating the two.

Individuals with social anxiety disorder have an elevated risk of comorbid mood and anxiety disorders. Commonly, individuals with social anxiety use nonprescribed anxiolytic and sedative medications and alcohol and cannabis for self-medication. The comorbidity between social anxiety disorder and selective mutism is discussed elsewhere in this chapter. Social anxiety disorder is frequently associated with autism spectrum disorder. Social anxiety disorder also occurs at rates above the population baseline in patients with schizophrenia.

Risk factors for social anxiety disorder include female gender, family history, and childhood signs of behavioral inhibition. There is insufficient data on specific genetic factors mediating the increased familial risk, but parenting styles may also contribute to this familiality. The Mini-Social Phobia Inventory (Mini-SPIN) is an appropriate screening tool for adults.

Agoraphobia symptoms can resemble social anxiety disorder or PTSD, though the context-dependent fears in the same situation would be different. For example, a patient with social anxiety disorder might dislike a crowded party due to feeling that many people are passing judgment. A patient with agoraphobia might avoid the same crowded party out of concern that, were they to develop anxiety, it would be difficult to sprint for the exit. A patient with PTSD might find their desire for hypervigilance is overwhelmed by the multiple stimuli in a crowded room.

The risk of suicide attempts is elevated in patients with social anxiety disorder. This, along with the significant functional impairment associated with this disorder, should motivate clinicians to initiate and monitor treatment for these patients. CBT and IPT have demonstrated efficacy for social anxiety disorder, with greater effect from CBT. The first-line pharmacologic treatments are serotonergic agents, though PRN medications, especially for the performance subtype (beta-blockers), have been used effectively. Social anxiety disorder is a chronic condition with a high rate of symptom re-emergence after symptom remission is achieved via SSRIs, for example. However, durable remission, even after cessation of CBT and/or antidepressants, has been seen in a small proportion of patients.

SPECIFIC PHOBIA

Definition, Diagnosis, and Clinical Features

Specific phobias are fears of specific objects or situations, such as spiders or blood draws, that go beyond the true threat of the stimulus and cause avoidance and functional impairment (Table 14.2–2). To meet criteria, the individual must experience fear during nearly every confrontation with the phobic stimulus. The phobia, by rule, lasts longer than 6 months. Many individuals have multiple phobic stimuli, in which case each would be coded separately. ICD-10 has specific codes for phobias of animals, natural environment (heights, storms, water), fear of blood, fear of injections, fear of transfusions, fear of other medical care, fear of injury,

fear of a specific situation (elevators, airplanes, enclosed spaces, etc.), and fear of other (anything that does not fit into one the above).

History and Comparative Nosology

Circumscribed phobias have long been recognized. They are amenable to nonpharmacologic interventions and, as such, have been central to the delineation of developmental theories and psychotherapy strategies for over a century. A significant development over the course of the DSM iterations has been the separation and diagnostic refinement of social anxiety disorder (formerly social phobia), agoraphobia (formerly subsumed under panic disorder), and specific phobia (formerly simple phobia). The number of subcategories of specific phobia, as well as the value of trying to group the various phobic stimuli, continues to evolve in successive DSM iterations. Determining how much distress and impairment is necessary to separate the range of normal from the range of pathologic remains a nosologic challenge.

Table 14.2–2.
Criteria for Specific Phobia

A. Marked fear or anxiety about a specific object or situation (e.g., flying, heights, animals, receiving an injection, seeing blood).
Note: In children, the fear or anxiety may be expressed by crying, tantrums, freezing, or clinging.
B. The phobic object or situation almost always provokes immediate fear or anxiety.
C. The phobic object or situation is actively avoided or endured with intense fear or anxiety.
D. The fear or anxiety is out of proportion to the actual danger posed by the specific object or situation and to the sociocultural context.
E. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.
F. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
G. The disturbance is not better explained by the symptoms of another mental disorder, including fear, anxiety, and avoidance of situations associated with panic-like symptoms or other incapacitating symptoms (as in agoraphobia); objects or situations related to obsessions (as in obsessive-compulsive disorder); reminders of traumatic events (as in posttraumatic stress disorder); separation from home or attachment figures (as in separation anxiety disorder); or social situations (as in social anxiety disorder).

Specify if:

Code based on the phobic stimulus:

300.29 (F40.218) Animal (e.g., spiders, insects, dogs).
300.29 (F40.228) Natural environment (e.g., heights, storms, water).
300.29 (F40.23x) Blood-injection-injury (e.g., needles, invasive medical procedures

Coding note: Select specific ICD-10-CM code as follows: **F40.230** fear of blood; **F40.231** fear of injections and transfusions; **F40.232** fear of other medical care; or **F40.233** fear of injury.

300.29 (F40.248) Situational (e.g., airplanes, elevators, enclosed places).

300.29 (F40.298) Other (e.g., situations that may lead to choking or vomiting; in children, e.g., loud sounds or costumed characters.

Coding note: When more than one phobic stimulus is present, code all ICD-10-CM codes that apply (e.g., for fear of snakes and flying,

F40.218 specific phobia, animal, and F 40.248 specific phobia, situational).

Reprinted with permission from the American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:224, 225.

Epidemiology

Lifetime prevalence estimates in the United States are from data that is over 20 years old. At that time, the lifetime prevalence of specific phobia was estimated at approximately 9%. The highest prevalence occurs in the teenage years. Female gender and younger age were associated with increased risk of specific phobia. Most individuals experienced multiple fears.

Differential Diagnosis, Etiology, Course, and Treatment

Delineating between the context-dependent phobias can be challenging in clinical practice, specifically when eliciting a history from a patient. Though some patients develop a specific phobia only after a traumatic event involving a threatening phobic stimulus, these patients, by definition, do not develop the breadth of symptoms that meet criteria for PTSD. Similarly, patients can develop a specific phobia to an event following a panic attack, but panic disorder requires that at least some panic attacks that are unexpected rather than just a consequence of a known phobic stimulus. As articulated previously, agoraphobia and specific phobia may be difficult to distinguish if the phobic stimulus is in a specific, public location. However, patients with agoraphobia ought to fear multiple public situations. Moreover, patients with agoraphobia specifically fear the panic or shame that can develop in public situations.

Some specific phobias, such as animal phobias, have a unique age of onset, suggesting a nontraumatic etiology perhaps more based in evolutionary preparedness. Other specific phobias, such as blood–injury–illness phobia, have a unique physiology (i.e., bradycardia and hypotension as opposed to the usual tachycardia and hypertensive reaction) and a greater rate of familiality that suggest still another distinct etiology.

Twin and family studies have demonstrated that there is an elevated familial/genetic risk for phobic disorders in general but not for the type of specific phobia. For many phobias, environmental factors, such as

trauma, may be more important. As with other anxiety disorders, cognitive factors and conditioning may also be involved in their development.

Many individuals experience a chronic course of specific phobia. However, effective treatments exist. Patients often recognize that their anxiety exceeds the true threat of the stimulus, and this insight can often motivate treatment seeking. The treatment of choice for specific phobia is a behavioral therapy series that includes exposure-based, systematic desensitization. New evidence suggests efficacy for exposure therapy delivery through virtual reality in some circumstances. There are small, placebo-controlled studies involving serotonergic antidepressants, but the data is very limited. A recent meta-analysis of trials augmenting exposure-based psychotherapy for anxiety disorders with D-cycloserine included n = 124 individuals with specific phobia and showed a small short-term augmentation effect independent of antidepressant treatment status across all trials, though it did not report subgroup results for specific phobia. The data requires ongoing interpretation and study replication in more individuals with specific phobia to avoid harm via administration of this medication in the wrong context. There is limited long-term data on the durability of remission in pharmacologic studies.

GENERALIZED ANXIETY DISORDER

Definition, Diagnosis, and Clinical Features

GAD is characterized by an uncontrollable worry, more days than not, lasting greater than 6 months, and causing significant impairment. Accurate classification of GAD includes the worry being associated with at least three of the following six symptoms: “restlessness or feeling keyed up or on edge; being easily fatigued; difficulty concentrating or mind going blank; irritability; muscle tension; or sleep disturbance” (Table 14.2–3). All three symptoms need not be present simultaneously every day. The worry usually involves several to many domains of everyday life, such as usual daily activities, timeliness, finances, or health. These are issues that may concern the average person on a daily or weekly basis. However, patients with GAD tend to exaggerate the likelihood and severity of the stressor to the point where negative outcomes or catastrophe seems possible, likely, and imminent. Another key to the GAD diagnosis is that individuals have difficulty prioritizing more pressing matters that pop up on a day-to-day basis over other worries and concerns. This inappropriate prioritization of

certain anxieties contributes to the pathologic effect that GAD has on psychosocial functioning.

Table 14.2–3.
Criteria for Generalized Anxiety Disorder

A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
B. The individual finds it difficult to control the worry.
C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms having been present for more days than not for the past 6 months):
   Note: Only one item is required in children.
   1. Restlessness or feeling keyed up or on edge.
   2. Being easily fatigued.
   3. Difficulty concentrating or mind going blank.
   4. Irritability.
   5. Muscle tension.
   6. Sleep disturbance (difficulty falling or staying asleep, or restless, unsatisfying sleep).
D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
E. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism).
F. The disturbance is not better explained by another mental disorder (e.g., anxiety or worry about having panic attacks in panic disorder, negative evaluation in social anxiety disorder [social phobia], contamination or other obsessions in obsessive-compulsive disorder, separation from attachment figures in separation anxiety disorder, reminders of traumatic events in post-traumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder).

History and Comparative Nosology

The definition and diagnostic criteria of GAD have been iteratively changed over time since its inclusion in DSM-III. Alterations have ranged from broadly theoretical, such as whether GAD is a diagnosis of exclusion for patients whose anxiety does not seem to meet criteria for another anxiety disorder, to empirically detailed, such as how many concurrent symptoms are necessary over what duration of time. The high rate of comorbidity of GAD with other anxiety disorders and major depressive disorder makes it difficult to isolate GAD for the purposes of evaluating the fidelity of the criteria, limits tracking the durability of the diagnosis prospectively, and complicates evaluation of treatment effects. In the last 15 years, the pace of the nosologic evolution of GAD has slowed dramatically, as evidenced by the diagnostic agreement between DSM-IV and DSM-5. This may reflect a lack of consensus on proposed changes to the diagnostic criteria and/or indicate an awareness of the value of maintaining nosologic stability for the purposes of treatment efficacy research.

Epidemiology

The estimated lifetime prevalence of GAD is approximately 5%. Incidence is elevated in early adulthood and older adulthood. GAD is more common in women than in men. The high lifetime psychiatric comorbidity has led some to view GAD as a prodromal or residual phase of a major depression, though there is insufficient empirical support for this view. Other common comorbidities include a broad range of anxiety spectrum disorders and substance use disorders. Clinical epidemiology commonly involves presentation in primary care settings, often with physical symptoms.

Differential Diagnosis, Etiology, Course, and Treatment

For some individuals, GAD distinguishes itself from other anxiety diagnoses with its relatively high severity and persistent symptoms rather than the episodic course seen in the more context-dependent anxiety disorders. However, GAD may still fluctuate in severity over time. The biggest challenge, given the comorbidity between GAD and major depressive disorder, can be distinguishing whether an individual's high anxiety during a major depressive episode represents a symptom of that individual's depression or whether they have an independent, comorbid disorder. The easiest way to determine this would be to evaluate the

anxiety during periods of euthymia, though this often requires a long period of observation.

Studies have identified genetic associations with GAD, though these are not specific enough to guide diagnosis or treatment. As with many other anxiety disorders, childhood maltreatment and abuse are associated with an increased incidence of GAD. The wide variety of neurologic, medical, medication, and chronic substance etiologies listed in the differential for panic disorder can also present with GAD-like symptoms. Beyond maintaining a high index of suspicion, presentations that include a marked change in intensity of GAD symptoms, a marked decline in functioning, an atypical age of symptom onset, or lack of response to standard treatments may prompt a broad medical assessment. The evolving criteria associated with successive DSM iterations complicates medication efficacy comparisons. For example, buspirone garnered FDA approval under a pre–DSM-IV set of GAD diagnostic criteria. Placebo-controlled efficacy trials of benzodiazepines, similarly, were studied in the DSM-III and pre–DSM-III eras. It would be difficult to replicate the depth and breadth of these trials with every new DSM. One of the original motivations to delineate generalized (context-independent) fears and panic was early data suggesting a difference in the efficacy of antidepressants between the two. However, over the last 30 years, a variety of antidepressant medications including tricyclics, SSRIs, and SNRIs, have demonstrated efficacy for both panic disorder and GAD.

Multiyear, naturalistic studies of GAD show that relapse is common. Factors associated with persistence of GAD include higher symptom severity, longer duration of avoidance behavior, and high behavioral inhibition. Thus, studies that follow patients for only a few months after cessation of an effective treatment modality may give clinicians and patients the false expectation of sustained remission. Clinical population-based strategies, such as those involving routine identification of individuals with GAD and subsequent symptom monitoring, stepped care strategies starting with monitoring and lower intensity treatments, treatment intensification for individuals not responding to initial steps in treatment, and case review by psychiatrists, are associated with significantly improved outcomes. The GAD-7 scale is a brief instrument validated for screening and treatment monitoring of individuals with GAD. Patients with GAD are at an increased risk for suicide attempts, and thus, screening for and responding to suicidal ideation is recommended.

Long-term studies of GAD symptom relapse rates following discontinuation of antidepressants after treatment response have led to recommendations that pharmacologic treatment continue for longer than 6 months, though longer follow-up studies are needed. Given that context-independent anxiety disorders have long been formulated as separate from panic and context-dependent phobias, there is a significant body of literature on psychotherapy for the GAD spectrum, including CBT, relaxation, imagery exposure, and various meditation modalities. Studies with follow-up after treatment completion longer than 12 months show that treatment with CBT is associated with better outcomes compared to control conditions.

SELECTIVE MUTISM

Definition, Diagnosis, and Clinical Features

Selective mutism is a disorder wherein children are unable to speak in certain social situations. These children are capable of speaking and do so when at home. Though the lack of speech at school is what often leads to an evaluation with a mental health provider, the disorder can be evident during other interactions between the child and less-familiar adults. The mutism must impact social or educational functioning for greater than a month in order to meet DSM-5's diagnostic criteria. The social situation wherein the symptoms manifest must not be one where a relative mutism might be expected, such as just after starting school or while integrating into a setting with a new language.

History and Comparative Nosology

In order to reframe the discussion of this disorder toward themes of anxiety and phobia, DSM-III's "Elective Mutism" term was switched to "Selective Mutism" in the DSM-IV, thus removing the implication that the symptoms were born of defiance. DSM-5's placement of selective mutism in the anxiety disorders section stems from evidence that anxiety (most often an element of social phobia) is often present. However, selective mutism's age of onset, as well as its heterogeneity in terms of comorbid social anxiety symptoms, developmental disorders, communication disorders, and many other symptom subsets, argue that it is a distinct diagnosis from social phobia.

Epidemiology

The rarity of selective mutism makes it a challenge to quantify, but most studies of children find a prevalence in the range of 1%. While some studies suggest a higher prevalence in girls, others suggest a more even distribution between boys and girls. Social anxiety disorder is likely the most common comorbidity, though social anxiety disorder has an average age of onset in the early teens, whereas selective mutism usually presents by age 5.

Differential Diagnosis, Etiology, Course, and Treatment

Communication disorders, autism spectrum, and developmental delay would be important etiologies to rule out when making the diagnosis of selective mutism. If there is a broader autism spectrum diagnosis with prominent communication symptoms that better explains the symptoms, the selective mutism diagnosis is not applied. Selective mutism should prompt further consideration and screening for comorbid anxiety disorders. A wide variety of genetic, temperament, environmental, and neurodevelopmental contributors have been suggested to contribute to the etiology of selective mutism.

CBT and behavioral therapies have shown efficacy in various studies. Programs that include parental and school-based interventions may have the most promise. These CBT studies also demonstrate that the course of this disorder need not be chronic. Following CBT interventions, long-term studies often report that >50% of children demonstrate full remission. However, long-term follow-up studies have also suggested that children and young adults who had selective mutism go on to demonstrate a higher-than-population-baseline rate of phobic disorders. Some SSRIs have demonstrated partial efficacy, though the studies are small, and there is a low rate of full remission. Overall, the field continues to make strides with regard to selective mutism, with the formulation of this diagnosis as an anxiety disorder appearing to accelerate the development of effective interventions.

SEPARATION ANXIETY DISORDER

Patients with separation anxiety disorder experience excessive distress when anticipating separation or when physically apart from figures of meaningful attachment. These patients ruminate on the possibility of any

harm that might befall them or their loved ones. This worry then leads to the avoidance of activities outside of the presence of the attached figure. Patients can also fear sleep, manifesting a kind of vigilance to reduce the possibility of a separation event. Even when they do manage to sleep, patients with separation anxiety disorder often have nightmares regarding separation. Finally, the excessive worry can be associated with somatic symptoms of anxiety. Symptoms of separation anxiety disorder in children need only persist for 4 weeks to meet criteria. Symptoms must persist longer than 6 months to meet criteria for the adult-onset variant.

History and Comparative Nosology

The epidemiologic evidence documenting a high rate of onset occurring after 18 years old led to a removal of DSM-IV's age-of-onset restriction. The inclusion of the adult-onset formulation moved separation anxiety disorder from DSM-IV's "Disorders Usually First Diagnosed in Infancy, Childhood or Adolescence" to DSM-5's "Anxiety Disorders." The prominent symptom of worry ties separation anxiety disorder to the other classical diagnoses in the anxiety disorders section.

Epidemiology

In a recent worldwide study, the lifetime prevalence was 4.8%, with 43% of these patients experiencing onset after age 18. The prevalence of childhood-onset separation anxiety disorder is more common in girls than boys, but the female:male ratio in adult-onset separation anxiety disorder is closer to even. More than half of patients show a remission of their disorder within the first 10 years after onset. Over the course of the lifetime, separation anxiety disorder is associated with an increased risk of a broad range of comorbid mood and anxiety disorders, including major depressive disorder, bipolar disorder, panic disorder, OCD, social anxiety disorder, and specific phobia. The data on the relative rates of the various comorbidities will likely continue to evolve as DSM-5's recognition of the adult-onset variant dramatically expands the population cohort available for research participation. Prevalence data and improved screening tools for the adult-onset group are important because the presence of comorbid separation anxiety disorder predicts reduced efficacy for CBT in studies of panic disorder, GAD, and social phobia. CBT interventions may need to be specifically tailored to include addressing separation anxiety symptoms when this diagnosis is comorbid with other anxiety disorders.

Differential Diagnosis, Etiology, Course, and Treatment

Patients with separation anxiety disorder have emotional experiences and behaviors when out alone in public that overlap with agoraphobia, though the fear in separation anxiety disorder is that something bad will happen to the attachment figure during the separation. The fear in agoraphobia, on the other hand, involves one's own safety and is secondary to the unavailability of timely help or escape should a frightening or embarrassing event occur. Similarly, patients with separation anxiety disorder might experience panic-like symptoms, or even symptoms meeting full criteria for the panic attack specifier. However, panic disorder requires that some of the attacks be context independent and "out of the blue," whereas panic symptoms in separation anxiety disorder would have their origins in a very specific theme of separation. While fear about the well-being of a loved one could be a theme in GAD, the worries in GAD involve a broader spectrum of subject matters and situations, rather than the more circumscribed worry about separation in separation anxiety disorder. There are adult-onset courses of separation anxiety disorder that seem, at least initially, to be features of a complicated bereavement process, suggesting an overlap with either PTSD or complicated grief. Whether this yields treatment modalities that target trauma- or grief-related symptoms in patients with adult-onset separation anxiety disorder remains to be seen.

Separation anxiety disorder aggregates in families, though what portion of this is genetic and what portion may be due to environmental modeling is not clear. Various biologic correlates are being pursued, including studies of oxytocin receptor polymorphisms, serotonin transporter variants, platelet 18 kDa translocator protein density, and dopamine D4 receptor polymorphisms, to name a few. Interestingly, both separation anxiety disorder and panic disorder are associated with carbon dioxide sensitivity in adults.

The lifetime prevalence of traumatic experience is significantly associated with the lifetime prevalence of separation anxiety disorder. There are no large-scale, controlled intervention studies to guide treatment in adult-onset separation anxiety. Given the efficacy of CBT in childhood-onset separation anxiety disorder, this modality is usually the first intervention in the adult-onset variant. However, it is not known whether CBT interventions, or which facets of these interventions, are

efficacious for the adult-onset variant. The data on pharmacologic interventions in adult-onset separation anxiety are still preliminary.

In childhood-onset separation anxiety disorder, studies show benefit for CBT, as well as for programs that include a component of education for parents and a focus on social skills. CBT strategies often have to be modified based on the age of the child, and there are few studies that include patients under the age of 7, for example. The data on pharmacotherapy for children with separation anxiety is mixed, with SSRIs sometimes employed for CBT nonresponders. While there are children who appear to be refractory to current treatment programs, the format and targets of CBT interventions for separation anxiety disorder continue to evolve and demonstrate improved efficacy.

SUBSTANCE/MEDICATION-INDUCED ANXIETY DISORDER AND ANXIETY DISORDER DUE TO ANOTHER MEDICAL CONDITION

Substance/medication-induced anxiety disorder can manifest as either generalized anxiety or panic. In order to meet criteria, there must be a temporal association between the symptoms and either intoxication or withdrawal from the substance or medication. In addition, the substance or medication in question must be known to be associated with the production of these symptoms. The DSM-5 contains documentation of specific ICD-10 codes for individual inciting agents, including alcohol, caffeine, cannabis, phencyclidine, other hallucinogen, inhalant, opioid, sedative/hypnotic/anxiolytic, amphetamine (or other stimulant), cocaine, and other (or unknown) substance. The “other” substances known to produce anxiety symptoms include a wide range of endocrine and neuromodulatory agents. The ICD-10 mandates a comment about whether there is a comorbid substance use disorder, as well as a comment on the severity of the substance use disorder. There are also coding specifiers regarding whether the symptoms were the result of intoxication, withdrawal, or medication initiation.

Ideally, the anxiety symptoms resolve with the removal of the offending agent or the resolution of the withdrawal. If the anxiety disorder persists for many months after the inciting incident, one may need to consider whether the patient would merit the diagnosis of a primary anxiety disorder. This point is interesting and part of a longer-lasting debate about

whether, for example, there is a prolonged withdrawal syndrome from benzodiazepines that can last months to years. In general, there is not good evidence for toxic or withdrawal effects of any substance lasting for durations longer than the physiologic duration of the withdrawal and, perhaps, the duration required to cognitively and psychologically "readjust."

Anxiety disorder due to another medical condition can similarly present with anxiety or panic, though the symptoms are temporally related to the onset or exacerbation of a diagnosed medical condition whose pathophysiology is known to yield anxiety symptoms. As was noted in the panic disorder section, there are numerous endocrine, metabolic, oncologic, cardiopulmonary, infectious, and neurologic etiologies that can manifest anxiety or panic symptoms.

FUTURE DIRECTIONS

The development of the nosology for anxiety disorders began with organized, direct observation. Differential responses to various psychotherapy and psychopharmacology interventions have contributed in part to our current delineation of the disorders, though there is substantial overlap between psychopharmacologic efficacy among the disorders, and even the specific CBT packages for distinct disorders may not be as necessary, with transdiagnostic (unified) CBT protocols now shown to have efficacy across disorders. Epidemiologic studies that help identify course, comorbidity, cultural differences, and biases have also helped shape the modern nomenclature. Biomarkers, genetic studies, gene–gene interactions, epigenetics, pharmacogenetics, neuroimaging, and the other developing tools of neuroscience have yet to be incorporated into successive iterations of the DSM but will hopefully contribute in the future to the increasingly detailed nosology of the anxiety disorders. It is interesting that, with the culling of the trauma-associated and obsessive-compulsive spectra, DSM-5's anxiety disorders diagnostic grouping appears more neatly bound. However, the extraordinarily high rate of comorbidity between the component diagnoses of the anxiety disorders, trauma-associated disorders, and OCDs argues that anxiety disorder etiology and treatment should not be viewed in isolation. Moreover, anxiety symptoms, or at least end-symptom presentations that look strikingly similar to facets of the anxiety disorders, appear in nearly every

diagnostic cluster of Section II of the DSM-5. Thus, while there is diagnostic and treatment research value in the demarcation of the anxiety disorders, there is also value in seeing the forest through the trees.

14.3 Epidemiology of Anxiety Disorders

KATHLEEN RIES MERIKANGAS, PH.D., AND MICHELLE M. THEODORY, B.A.

Population-based studies across the world have shown that anxiety disorders are the most common class of mental disorders. Epidemiology has made a valuable contribution to our understanding of anxiety disorders by documenting the prevalence, correlates, and natural history of anxiety disorders and highlighting the gap between untreated anxiety disorders in the general population compared to cases seen in clinical settings. During the past few years, more valid estimates of the global burden of anxiety disorders have also become available.

The aims of this chapter are: (1) to describe the general methods of epidemiology that have contributed to our understanding of anxiety disorders; (2) to summarize the prevalence and correlates of DSM-IV anxiety disorders in adults and children from community samples; and (3) to describe the individual and societal impact of anxiety disorders.

BACKGROUND: PSYCHIATRIC EPIDEMIOLOGY

Epidemiology is the study of the distribution and determinants of diseases in human populations. Epidemiologic studies are concerned with the extent and types of illnesses in groups of people and with the factors that influence their distribution. Epidemiologists investigate the interactions that may occur among the host, agent, and environment to produce a disease state. Although the tools of epidemiology were developed to identify causes of infectious diseases, their application to chronic diseases such as cancer, heart disease, and mental disorders has also enhanced our understanding of their multifactorial etiology.

The ultimate goal of epidemiologic studies is to identify the *etiology* of a disease in order to prevent or intervene in the progression of the disorder. To achieve this goal, epidemiologic studies generally proceed from studies that specify the prevalence and distribution of a disease within a population by person, place, and time (*descriptive* epidemiology) to more

focused studies of the determinants of disease in specific groups (*analytic* epidemiology). Descriptive epidemiologic studies are important in specifying the rates and distribution of disorders in the general population. Identification of differential distribution by sex, age, ethnicity, geographic site, or exposure to particular risk factors provides clues that may be tested systematically. Case-control studies generally proceed from retrospective designs and define cases and controls by the presence or absence of a disease in order to identify the disease's potential associations with a particular risk factor or set of risk factors. Cohort studies identify exposure to a putative risk factor in a group of people at baseline and then follow them retrospectively or prospectively to examine the differential incidence of the disease over time.

Community study data can be examined to identify biases that may exist in treated populations and to construct case registries from which persons may serve as probands for analytic epidemiologic studies. Such attention to sampling issues is a major contribution of the epidemiologic approach, as individuals identified in clinical settings often constitute the tip of the iceberg of the disease and may not be representative of the general population of similarly affected individuals with respect to demographic, social, or clinical characteristics.

Application of Epidemiology to Psychiatry

The traditional contributions of the application of the tools of epidemiology to psychiatry include (1) methodological developments, including the introduction of structured and semistructured diagnostic interviews; (2) estimation of the prevalence and correlates of mental disorders across the world; and (3) identification of risk factors for the development of mental disorders.

Community studies of mental disorders have also highlighted the need to expand the categorical diagnostic criteria for mental disorders to collect information on the spectra of expression of their underlying domains. For example, findings from the National Comorbidity Survey-Replication (NCS-R) demonstrated the validity of the spectrum concept of bipolar disorder that had been proposed by clinicians for more than a decade. Prospective follow-up of community samples of youth has also demonstrated the heterogeneity of different patterns of developmental manifestations of anxiety subtypes and their underlying dimensions of fear and anxiety. Therefore, the imposition of arbitrary thresholds in the

contemporary categorical diagnostic system may lead to an inaccurate classification of these conditions. Likewise, the tendency for individuals to meet criteria for more than one condition both at the same time and across their lifetimes, or comorbidity, has been consistently demonstrated in community samples, highlighting the lack of distinct boundaries between classes of mental disorders, particularly anxiety and mood disorders.

One of the most important contributions of epidemiology to our understanding of mental disorders is the identification of the large number of individuals who suffer from one or more of these conditions yet have not received a clinical intervention. There is a growing gap between cases seen in specialty mental health settings and people with anxiety in the general community. As expected, clinical samples have a disproportionate representation of severe cases with multiple comorbid conditions and substantially greater impairment than those who do not receive mental health treatment. Below, we provide updated estimates of the prevalence of anxiety disorders.

MAGNITUDE OF ANXIETY DISORDERS

Adults

Anxiety disorders have emerged as the most prevalent mental disorders in both adult and child populations. The accumulating literature suggests that the prevalence of anxiety disorders in youth is similar, if not higher, to that reported in adults, thereby indicating the importance of a life-course approach to the study of anxiety. During the past decade, the results of several large-scale studies of cross-national and cross-cultural samples have emerged. The largest global collaboration to date is the aforementioned WHO World Mental Health 2000 Initiative (WMH2000), which encompasses a collection of nationally or regionally representative surveys on the prevalence, risk factors, correlates, and service patterns for mental disorders from over 25 countries, representing all regions of the world, with a total sample size exceeding 130,000 individuals. There has also been progress in descriptive epidemiology in countries outside of the United States and Europe that have been traditionally the sole source of population-based data on mental disorders. Below, we provide an update on the prevalence of both the aggregate rates of anxiety as well as those of specific anxiety disorders.

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* criteria removed post-traumatic stress disorder and obsessive-compulsive disorder from the anxiety disorder section, so we limit our review to the major subgroups of anxiety disorders, including DSM-5 anxiety disorders. Separation anxiety disorder and selective mutism are now included as anxiety disorders, and the former's diagnostic criteria no longer specify the age of onset. Other major changes include the separate diagnoses of panic disorder and agoraphobia, the removal of the requirement that individuals over age 18 must recognize that their anxiety is excessive or unreasonable, and the extension of the 6-month duration criterion. However, because the DSM-5 was introduced during the past year, not all studies have updated prevalence rates based on the new criteria. Several studies suggest that modifications in the anxiety disorders section of the DSM-5 will not have a substantial impact on the prevalence rates of specific subtypes of anxiety.

Table 14.3–1 presents an overview of recent national and international community studies of *DSM-IV* and *DSM-V* anxiety disorders in adults.

Panic Disorder. The prevalence of DSM-5 panic disorder has been examined across the globe, and the rates remain fairly consistent across studies. Most studies yield 12-month prevalence rates between 0.2% and 1.1%. The highest rate was reported in the NESARC-III Study in the United States (3.1%), whereas the lowest 12-month prevalence was reported by the WMH in Nigeria (0.1%). The lifetime prevalence rates of panic disorder range from 0.2% in Nigeria to a high of 4.7% in the United States, with most studies falling between 1% and 2%.

Generalized Anxiety Disorder. Generalized anxiety disorder (GAD) has also been extensively examined in samples from several continents. Whereas the 12-month prevalence rate of GAD falls between 4.0% and 5.3% in both large-scale studies in the United States (WMH and NESARC-III), the rates in other areas of the world ranged from 0% in Nigeria to 4.3% in Spain (Murcia). The lifetime prevalence rates of GAD were even more variable, with the lowest rate reported in Nigeria (0.1%) and the highest in Australia (8.0%).

Agoraphobia. Apart from an elevated 12-month prevalence of agoraphobia reported in South Africa (4.8%), the rates of agoraphobia were remarkably consistent across regions. Nine separate international

studies reported estimates ranging from 0% (China) to 0.8% (United States). The lifetime prevalence estimates were similarly consistent, with the lifetime prevalence of DSM-IV agoraphobia ranging anywhere from 0.2% (China) to 2.9% of the population (Brazil) and a median of 0.9%.

[a]WMH prevalence rates derived from various sources based on WHO data.

Social Anxiety Disorder. The 12-month prevalence of social phobia varied across regions, with the highest rates reported in the United States in the WMH survey (7.1%) and the lowest appearing in Nigeria (0.2). However, it cannot be determined whether differences in these rates are the result of methodological or translation inconsistencies or true cross-cultural differences in defining social fears. Even within the United States, the 12-month prevalence dramatically differed, with the WMH study reporting 7.1% in comparison to the 2.9% prevalence reported from the NESARC-III study that was based on DSM-5. The estimates of the lifetime prevalence of *DSM-IV* social phobia were also inconsistent across studies, with a range spanning from 1.2% in East Mediterranean countries to a high of 9.5% in New Zealand and 12.1% in the United States.

Specific Phobia. Similar to the estimates reported for social anxiety disorder, the 12-month and lifetime prevalence rates of DSM-IV-specific phobia varied across studies. The 12-month prevalence estimates, according to the NCS-R, ranged from 1.9% (China) to 9.1% (United States). Estimates for lifetime-specific phobia were lowest in Italy (1.5%) and highest in New Zealand (10.8%), with a median of 6%. As with other

disorders, the reasons for these inconsistencies need to be examined further in order to distinguish between true differences in prevalence and those attributable to methodological differences between studies.

Separation Anxiety Disorder. The *DSM-5* criteria no longer include an age-at-onset restriction because a substantial number of adults report onsets after age 18. The 12-month prevalence rate averaged 1.0% across 20 countries in the WMH survey. The lowest was 0.0% in Nigeria and Italy, and the highest was 2.7% in Colombia. The lifetime prevalence rate averaged 3.1%, and the rates ranged from 0.1% (Nigeria) to 7.9% (Colombia).

Children and Adolescents

Estimates of prevalence rates of anxiety disorders in children have been much more variable than those of adults because of substantial differences in study methods and developmental manifestations of anxiety and fear that may influence prevalence estimates. The chief differences include the age and sex composition of the samples, methods for assessing anxiety disorders (i.e., self-report vs. diagnostic interview); informant source (i.e., parent, child, teacher), number and type of anxiety disorders included in the study, and definition of diagnostic criteria for each disorder. A sophisticated meta-analysis of 41 studies conducted in 27 countries by Polanczyk yielded a pooled worldwide 12-month prevalence of any anxiety disorder of 6.5% (CI 95% 4.7 to 9.1).

The only study that included the full range of anxiety disorders in US adolescents was the National Comorbidity Adolescent Supplement (NCS-A), which was an extension of the NCS-R, using the same diagnostic methodology (Table 14.3–2). These studies yielded high aggregate lifetime prevalence rates of anxiety in adults (28.8%) and youth (31.9%). However, lifetime prevalence rates of disorders with severe impairment were substantially lower than lifetime DSM-IV disorders: GAD-0.9%; social phobia-1.3%, and 0.6% of those with separation anxiety and specific phobias. The finding that the prevalence rates in youth approximate those of adults suggests that the onset of most anxiety disorders occurs in childhood and adolescence. In fact, the rates of aggregate anxiety were actually higher in adolescents than in adults in the NCS-R for both 12-month (24.9% vs. 18.1%) and lifetime (31.9% vs. 28.8%) prevalence (see Table 14.3–2). By contrast, the rates of GAD

(5.7%), panic disorder (4.7%), and social anxiety disorder (12.1%) in adults were greater than those in adolescents, with lifetime rates of 2.2%, 2.3%, and 9.1%, respectively.

Data from several prospective community studies have followed community samples of children and young adults for more than a decade. These studies provide information on the cumulative incidence and stability of anxiety disorders in early and middle adulthood. The Zurich Cohort Study of a community sample of 19- to 20-year-old adults from Zurich, Switzerland, provides unique information on the prevalence and continuity of anxiety disorders across 30 years as they progressed from early to middle adulthood. The cumulative prevalence rate of anxiety disorders across the lifetime was 30%. Similar to cross-sectional studies, specific phobia was the most common disorder (26.9%), followed by GAD (20.8%), social anxiety (12.6%), agoraphobia (6.8%), and panic disorder (6.1%). Classification of the spectrum of disorders in the Zurich Cohort Study has further shown that there are a large proportion of people from the community whose symptoms fall below the diagnostic thresholds for mood and anxiety disorders but nevertheless exhibit impairment and/or distress. Consideration of subthreshold manifestations of anxiety disorders leads to further elevation of the rates of these conditions in the general population.

Table 14.3–2.
12-Month and Lifetime Rates of DSM-IV Anxiety Disorders in the National Comorbidity Survey Replication (Adults) and Supplement (Adolescents)

			NCS-A (Adolescents)			
	NCS-R (Adults)		Lifetime by Sex (%)			
Anxiety Disorder Subtype	12 months (%)	Lifetime (%)	Female	Male	12 months (%)	Lifetime (%)
Agoraphobia	0.8	1.4	3.4	1.4	1.8	2.4
Generalized anxiety disorder (GAD)	3.1	5.7	3.0	1.5	1.1	2.2
Panic disorder	2.7	4.7	2.6	2.0	1.9	2.3
Separation anxiety disorder	6.6	5.2	9.0	6.3	1.6	7.6
Social anxiety disorder	6.8	12.1	11.2	7.0	8.2	9.1
Specific phobia	8.7	12.5	22.1	16.7	15.8	19.3
Any anxiety disorder	18.1	28.8	38.0	26.1	24.9	31.9

Similar prevalence rates emerged from The Early Developmental Stages of Psychopathology Study (EDSP), a 10-year prospective longitudinal study of a community sample of youth ages 14 to 24 to age 33. Cumulative incidence rates were: total anxiety disorders—31.3%; specific phobia—7.0%; social phobia—6.0%; GAD—4.3%; and panic—

3.3%. Projected rates to age 33 were almost double those at the initial interview, demonstrating that the peak period for the onset of anxiety disorders is in late adolescence and early adulthood. Another prospective study of youth that assessed 1,420 participants in the southeastern United States up to 11 times between ages 9 and 26 was the Great Smoky Mountain Study (GSMS). The cumulative incidence rates of anxiety across the study were 22.7% for all anxiety, 9.7% for GAD, 6.1% for agoraphobia, 5.0% for separation anxiety disorder, 4.8% for panic disorder, 4.2% for social phobia, and 2.2% for specific phobia.

A recent follow-up of about 14,000 participants in the Avon Longitudinal Study of Parents and Children (ALSPAC) birth cohort in the United Kingdom identified sources of heterogeneity in the long-term trajectories of different anxiety disorders over time. They further identified that parental mood and anxiety disorders and sleeping difficulties in childhood were associated with the persistence of anxiety disorders from childhood to adulthood. Some of these differential correlates are described in the section below.

CORRELATES AND RISK FACTORS

Sex Differences

The results of community studies in adults reveal that women have greater rates of almost all anxiety disorders. Despite differences in the magnitude of the rates of specific anxiety disorders across studies, the sex ratio is strikingly similar. Women have an approximately twofold elevation in lifetime rates of panic disorder, GAD, agoraphobia, and simple phobia than males in nearly all of the studies. Studies of youth also report that girls tend to have more of all subtypes of anxiety disorders, irrespective of the age composition of the sample.

Epidemiologic surveys of adults reveal that the female preponderance of anxiety disorders is present across all stages of life but is most pronounced throughout early and mid-adulthood. The rates of anxiety disorders in males are also rather constant throughout adult life, whereas the rates in females peak in the fourth and fifth decades of life and decrease thereafter. The increased rates in females are present across all ages and do not diminish as the rates of anxiety decrease in late life.

Age of Onset

Retrospective reports of adults and adolescents with anxiety disorders suggest that the onset generally occurs in childhood or adolescence. For example, results of the NCS-R reveal that anxiety disorders have the earliest age of onset of all of the major classes of mental and behavioral disorders, with a median onset by the age of 12. The NCS-A found an even earlier median onset at age 6. The onset is far earlier than the onset of mood disorders or substance use disorders and comparable to that of impulse control disorders. The prospective GSMS found a U-shaped age prevalence curve for any anxiety disorder in which a sharp decrease in mid-childhood is followed by increasing levels from early adolescence to young adulthood.

Although there is substantial variation across studies, the results of prospective community-based research reveal differential peak periods of onset of specific subtypes of anxiety: separation anxiety and specific phobias in middle childhood; social anxiety disorder in middle adolescence; agoraphobia, and panic disorder from late adolescence to young adulthood; GAD in young adulthood.

Several follow-up studies of children and adolescents have shown that there is stability in both social anxiety disorder and simple phobia, whereas GAD and panic symptoms and disorders are more variable and tend to overlap with episodes of depression.

Social Class and Ethnicity

Community studies have consistently found that rates of anxiety disorders, in general, are greater among those at lower levels of socioeconomic status and education levels, but the associations might be more complex due to the significant interactions among the sociodemographic characteristics. For example, anxiety disorders were negatively associated with income and education levels in the NCS. There was almost a twofold difference between lifetime rates of anxiety disorders in individuals in the highest income bracket over the lowest and those who completed over 16 years of school versus less than 11. However, the association with education was not found in the NCS-R, and the association with income was not found in the NCS-A.

Certain anxiety disorders also seem to be elevated in specific occupations. According to the NEMESIS study, anxiety disorders were higher in homemakers and those unemployed or with a disability.

Similarly, the NCS found higher levels of GAD and phobias in homemakers, students, and other unemployed persons.

The research on how race/ethnicity and social class impact the prevalence of anxiety disorders is inconclusive. While several community studies have yielded greater rates of anxiety disorders, particularly phobic disorders, among African Americans, others have shown the opposite. For example, a recent study on 5,424 Hispanics, non-Hispanic Blacks, and non-Hispanic Whites in the NCS-R showed that both minority groups had a lower risk for GAD and social anxiety disorder, and non-Hispanic Blacks specifically had a lower risk for panic disorder. There was also a lower risk among Hispanics, relative to non-Hispanic Whites, but only among the younger cohort. The interaction between race/ethnicity and education may also be important as they identified that this lower risk among minorities was more pronounced at lower levels of education. In contrast, the NCS-A showed that non-Hispanic black adolescents had higher rates of anxiety disorders than non-Hispanic White adolescents, and no two-way interaction for anxiety disorders was found. The reasons for ethnic and social class differences have not yet been evaluated systematically; however, both methodological factors and differences in exposure to stressors have been advanced as possible explanations.

Patterns of Comorbidity

Subtypes of anxiety disorders tend to co-occur both cross-sectionally and across the lifetime. Comorbidity between anxiety disorders and other mental disorders is already apparent in childhood and adolescence. Anxiety disorders are associated with all of the other major classes of disorders, including mood disorders, disruptive behaviors, eating disorders, and substance use disorders. The co-occurrence of anxiety disorders and mood disorders is so common that there is emerging evidence that anxiety disorders may be part of the developmental sequence in which anxiety is expressed early in life, followed by depression in adulthood.

Both family and twin studies have been used to examine sources of overlap within the anxiety disorders and between the anxiety disorders and other syndromes, including depression, eating disorders, and substance abuse. Family studies have demonstrated the independence of familial aggregation of panic and phobias. With respect to comorbidity, panic disorder, GAD and depression have been shown to share common

familial and genetic liability, whereas there is substantial evidence for the independent etiology of anxiety disorders and substance use disorders. Similar results have emerged from studies of symptoms of anxiety and depression in both youth and adults in which anxiety and depression were found to result from a common genetic diathesis.

Familial and Genetic Factors

The familial aggregation of all of the major subtypes of anxiety disorders has been well-established, and the substantial role of genetic factors underlying familial transmission has been well-documented. However, the relatively moderate magnitude of heritability also strongly implicates environmental etiologic factors. Components of anxiety that may be inherited include somatic manifestations of anxiety such as physiologic responses, which include pulse, respiration rate, and galvanic skin response. There is also substantial evidence for shared genetic risk factors for mood disorders and anxiety disorders that may manifest differentially across developmental stages. Increased rates of anxiety symptoms and disorders have also been found among offspring of parents with anxiety disorders which suggests that there may be underlying psychological or biological vulnerability factors for anxiety disorders in general which may already manifest in children prior to puberty. Children at risk for anxiety disorders throughout life are characterized by behavioral inhibition, autonomic reactivity, somatic symptoms, social fears, enhanced startle reflex, and respiratory sensitivity. These findings suggest that anxiety and fear states are highly heterogeneous and that future studies need to investigate the extent to which the components of anxiety result from common versus unique genetic factors and the role of environmental factors, either biological or social, in either potentiating or suppressing their expression.

Temperament/Personality

One of the earliest indicators of vulnerability to the development of anxiety is behavioral inhibition, characterized by increased physiological reactivity or behavioral withdrawal in the face of novel stimuli or challenging situations. Behavioral inhibition may be a manifestation of a biological predisposition characterized by both overt behavioral and physiologic measures.

Likewise, anxiety sensitivity is another potential sensitive and specific trait marker for the development of anxiety disorders. Anxiety sensitivity is characterized by beliefs that anxiety sensations are indicative of harmful physiological, psychological, or social consequences (e.g., fainting or an impending heart attack). Anxiety sensitivity has been shown to precede the development of anxiety symptoms and disorders and to have specificity in predicting the development of anxiety as opposed to depression.

Medical Symptoms/Disorders

There has been a striking increase in studies of anxiety disorders among a range of medical conditions, including diabetes, cardiovascular disease, respiratory disorders, and neurologic disorders (i.e., epilepsy, migraine, multiple sclerosis, Parkinson's disease). Medical comorbidity is far more strongly associated with GAD and panic disorder than phobic disorders. There is heterogeneity in the explanations for comorbidity that may reflect common underlying diatheses, anxiety disorders as complications of disability from the medical condition, or anxiety as a side effect of medications used to treat the disorder. Community studies have also provided an important basis for identifying the extent to which clinical samples are biased by increased treatment-seeking among those with comorbid medical or mental disorders. These findings highlight the importance of a comprehensive evaluation of concurrent medical conditions in the treatment of people with anxiety disorders.

Exposure

The role of life experiences in the etiology of anxiety states, particularly phobias and panic disorders, has been widely studied. Life events have often been designated a causal role in the onset of phobias, which are linked inherently to particular events or objects. More broadly, life experiences that are likely to trigger specific future problems with safety and security are perceived to predict the onset of anxiety disorders. While it is likely that exposure may trigger the fear response, there is compelling evidence for the evolutionary tendency toward fear and avoidance of potential predators. Therefore, phobic states may first become apparent without exposure. The ability to extinguish such fears may be protective against the development of clinically significant phobias. Recent research suggests such life experiences that also trigger immediate distress (e.g.,

parental divorce or unemployment) might also more broadly precipitate the onset of comorbid depression and anxiety. In evaluating the evidence on the causal role of life experiences, it is critical to consider the subtypes of anxiety disorders separately. Moreover, stressful life events may interact with other risk factors, such as a family history of depression precipitating episodes of panic.

COURSE AND PERSISTENCE

There has been limited information on the persistence of anxiety disorders across the lifespan. Several prospective studies have also shown that the specific subtypes of anxiety fluctuate over time, particularly generalized anxiety and panic attacks. By contrast, phobic states, particularly social anxiety, tend to be more stable across the lifespan. A recent review of predictors of persistent anxiety disorders that included nearly four dozen studies and 30,000 patients with anxiety disorders found that poor treatment response, greater severity and duration of anxiety disorders, and a profile of specific clinical and psychological characteristics were associated with greater persistence of anxiety. Finally, there is also evidence that anxiety disorders may be associated with increased mortality, likely attributable to respiratory and cardiovascular correlates of these conditions.

IMPACT OF ANXIETY DISORDERS

Although the individual impact of anxiety disorders has been well-recognized, early estimates of the global burden of disease tended to neglect anxiety disorders as a significant source of lifetime disability. Recent studies of the global burden of disease have employed the concept of Disability Adjusted Life Years (DALYs) as an index of the impact of particular diseases on mortality and disability. Earlier estimates were based on a limited number of anxiety disorders, particularly obsessive-compulsive disorder and post-traumatic stress disorder (PTSD), that are no longer included in the class of anxiety disorders. Estimates of both person-years lived with disability (YLDs) and years of lost life (YLL) are used as a measure of the societal impact of anxiety disorders. The most recent global estimate of YLDs is 370/100,000 population for all anxiety disorders, and the total DALY for all anxiety

disorders is about 459 for females and 282 for males. The peak disability occurs in the adolescent and young adult age group from 10 to 24 years. Anxiety is the eighth leading cause of YLDs after low back pain, depressive disorders, headaches, diabetes, hearing loss, other musculoskeletal disorders, gynecological diseases, and neck pain and falls, with similar patterns across country-specific income levels. These findings highlight the significant public health impact of anxiety disorders, particularly when coupled with other comorbid conditions.

Evidence for the impact of anxiety on the life course of individuals who suffer from one or more of these conditions has emerged from prospective follow-up studies of children with anxiety into adulthood. The most important consequences are comorbid mental and physical conditions, substance use disorders, and in a small proportion, suicide. The 15-year follow-up of the Smoky Mountains study revealed that youth with anxiety disorders during childhood had substantial impairment in one or more of the domains assessed, including health, financial, and interpersonal functioning in adulthood. Results also showed that youth with GAD tended to have poor functioning across all domains, whereas those with social phobia only displayed impairment in the interpersonal domain, and those with separation anxiety had more health problems than other youth. These studies illustrate that the burden of anxiety disorders is attributable to both their childhood and adolescent-onset and to their continuity across the lifespan. In consideration of their association with the subsequent development of substance use disorders, behavior and mood disorders, these findings indicate the critical need for intervention at the early stages of these conditions.

FUTURE DIRECTIONS

This chapter provides an update on the magnitude of anxiety disorders in adults and children in community surveys across the world. Epidemiology is expanding beyond the North American/European boundaries of earlier work to achieve greater representation of the global prevalence and impact of mental disorders. The most consistent finding across studies is the high prevalence of anxiety disorders and the consistency in correlates of anxiety disorders across geographic settings and methods of assessment. Estimates of global disability associated with anxiety disorders document the substantial individual and societal impact of

anxiety disorders. The impact of anxiety disorders on lower educational and occupational attainment, missed days in one's role, and comorbid associations with other mental and physical disorders highlight their public health relevance. The huge gaps between the high magnitude of impairing anxiety disorders and low mental health treatment rates remain a serious challenge in public health. This is of even greater significance because of the well-established efficacious behavioral and pharmacologic treatments for these conditions. The growing integration of pediatrics and medicine with psychiatry may facilitate efforts to provide treatment to a larger segment of the population and enhance recognition of comorbidity as an important source of disability from anxiety disorders.

The population surveys described herein have been supplanted to some extent by the increasing focus on biobanks, treatment registries, and pharmacologic and insurance databases that are becoming increasingly available. This work will require new tools to derive estimates of the generalizability of these data and may lead to increased efforts to move beyond diagnostic codes in determining population prevalence. In addition, as neuroscience and genetics inform knowledge regarding neural processes underlying anxiety disorders and the role of genetic and environmental factors in their evolution, studies of treatment and prevention strategies will assume increasing importance in reducing the magnitude and burden of this major source of mental disorders.

14.4 Anxiety Disorders: Neurobiology and Neuroscience

Sara Costi, M.D., Adriana Feder, M.D., Brian Iacoviello, Ph.D., James W. Murrough, M.D., Ph.D., and Dennis S. Charney, M.D.

Anxiety disorders encompass a heterogeneous group of conditions, and our understanding of their underlying neurobiologic basis continues to evolve. Evidence from preclinical and clinical research has implicated a range of neural systems in the etiology of fear and anxiety responses. Dysfunction in these systems also plays a key role in the development of anxiety disorders through interactions with cortical and subcortical neural circuits involved in fear responses. In animals, threat detection and defense responses rely on nonconscious mechanisms, which in turn lead to responses in the brain and body that eventually result in conscious fear. Although threat responses have been extensively studied in animals and continue to inform the understanding of anxiety disorders in humans, they cannot inform on the subjective experience of fear and anxiety that are uniquely humans. Thus, continued close collaboration between basic and clinical researchers is required to advance the current understanding of the neurobiology of anxiety disorders. Advances in functional neuroimaging have also allowed for greater understanding of key brain regions in humans with and without anxiety disorders and during emotion, learning, or anxiety-inducing tasks. In addition, progress in genetics allows for increased understanding of vulnerability to anxiety disorders or a poorer treatment response.

NEUROCHEMICAL BASIS OF FEAR AND ANXIETY

The human body responds to perceived threats and fear-inducing stimuli by activating the release of specific neurotransmitters and neuropeptides located in key brain regions (Fig. 14.4–1). The “fight-or-flight” reaction can be adaptive in that increased vigilance, recall of potentially dangerous elements, and rapid physiologic response (evidenced by increased pupillary dilation, increased heart rate, and rapid breathing) prepare the organism for impending danger before quickly subsiding once the fear-inducing trigger is no longer present. On the other hand, overgeneralization of fear-learning to harmless stimuli is thought to characterize anxiety disorders.

Neurochemicals released during stress or periods of prolonged anxiety can result in chronic alterations to a range of neurobiologic systems. Severe stress can also have maladaptive consequences when it causes biologic systems to be chronically activated. Based on preclinical and clinical models of anxiety, there is evidence that exposure to early-life stressors or trauma may result in predisposition to the development of anxiety disorders later in life, by alterations in neuroendocrine systems or perhaps by direct neurotoxic effects. Identification of mechanisms underlying individual differences in susceptibility versus resilience to stressors is an area of active investigation. This chapter reviews current knowledge regarding the neurobiologic systems involved in anxiety and fear response, including neurotransmitters, neuropeptides, and hormones, and summarizes the main findings pertinent to anxiety disorders from animal models of anxiety and from human studies. A figure showing the brain’s key regions involved in response to fear and anxiety is included below (see Fig. 14.4–1).

NORADRENERGIC SYSTEM

Norepinephrine (NE) is a catecholamine released in the central nervous system (CNS) primarily from the locus coeruleus (LC), which is located in the pons. NE is a product of hydroxylation of dopamine, which is a metabolite of tyrosine. NE has several functions, including regulation of CNS cells and circuits. Acute threats result in the release of NE, a key neurotransmitter involved in the “fight-or-flight” response, characterized by coordinated physiologic and behavioral responses. Both “fight” and “flight” are characterized by increased arousal and a higher level of vigilance, critical for assessing threat and reacting quickly in a dangerous situation.

While fight or flight is adaptive responses to a potential threat, overactivity of the NE system is associated with an aberrant response to threat and a prolonged anxious state.

At the brain level, the NE system receives input from and sends projections to a variety of regions, modulating neurons that release a range of other neurotransmitters, including dopamine, serotonin, glutamate and γ-amino butyric acid (GABA). Neurons in the LC and projections from the LC to cortical and limbic regions are involved in the response to fearful or threat stimuli and adaptation to acute and chronic stress. NE is also released by sympathetic nervous system ganglia and via synaptic vesicles in the adrenal medulla. It is responsible for regulating the body's behavioral and physiologic responses to stress through activity of the adrenergic receptors or adrenoreceptors. These receptors are G-protein–coupled and are responsible for controlling NE release, in part via a negative feedback mechanism. α-1 adrenergic receptors are postsynaptic, whereas α-2 adrenergic receptors are presynaptic. Animal studies of these receptors have led to a greater understanding of the role of NE in anxiety disorders. Agonists of the α-2 adrenergic receptors, such as clonidine and guanfacine, are antiadrenergic, whereas α-2 antagonists, such as idazoxan and yohimbine, result in increased NE release. In addition, certain environmental stressors in animal studies, such as acute cold restraint and inescapable stress, cause a reduction in α-2 adrenergic receptors density in the hippocampus and amygdala. Mice lacking the α-2 receptor exhibit heightened autonomic activation and concomitant anxiety behaviors after administration of D-amphetamine.

FIGURE 14.4–1. Schematic representation of the major brain systems involved in response to fear and anxiety. Projections from the thalamus regulate the autonomic and endocrine responses; projections from the hippocampus and amygdala modulate salience detection and associative learning; projections from the locus coeruleus innervate the cortex for regulation of attention, arousal, and pain evaluation. (See eBook for color images.) (Printed with permission from © Mount Sinai Health System.)

Proxy measures of NE system activation can be measured during a state of anxiety or threat in humans. Activation of the sympathoadrenal system can be measured with either plasma or urine sample since circulating levels of NE have been shown to correlate with its concentration in the urine. While 24-hour urinary epinephrine excretion

has been found to positively correlate with anxiety symptom severity, 24-hour urinary NE excretion did not correlate with anxiety or depression in subjects with untreated high blood pressure. Similarly, pupil dilation and 3-methoxy-4-hydroxyphenylglycol (MHPG)—a major metabolite of NE—can be measured in plasma and urine, in both humans and animals, in response to a threat. Specifically, dysfunction of the NE system has been demonstrated in panic disorder (PD) and phobias. There has been longstanding clinical evidence that propranolol, a nonselective β-adrenergic receptor-blocking agent, is useful in the management of social anxiety disorder (SAD), particularly performance anxiety, although it has no direct impact on anticipatory anxiety. Beta-blockers reduce peripheral autonomic symptoms such as hand tremors and tachycardia, often associated with social anxiety. Further, proadrenergic agents such as yohimbine have been reported to be panicogenic in animal and human models of anxiety. Yohimbine is known to precipitate panic attacks in patients with PD but not in healthy subjects. In a study of children with various anxiety disorders, yohimbine caused greater anxiety responses than in the healthy control group. A more selective α-2 receptor antagonist than yohimbine, idazoxan, has been shown to provoke panic attacks in healthy subjects. Patients with PD also have an abnormal response to the α-2 receptor agonist clonidine, with greater decreases in blood pressure and plasma MHPG compared to controls. However, CSF concentration of MHPG has not been found to significantly differ in PD patients compared to non-PD depressed subjects.

Studies of phobic individuals have demonstrated higher baseline rates of NE and other catecholamines and increased release of NE in response to anxiety-inducing triggers. This is not surprising, given the role that NE plays in fear conditioning and how repeated exposure to a stressful stimulus causes a potentiated release of NE, reflecting a process of sensitization. Patients with generalized anxiety disorder (GAD) also show higher plasma levels of NE and MHPG than healthy controls. Their response to yohimbine, however, is generally similar to that of healthy controls. Guanfacine, aα-2 receptor agonist approved in extended-release form for attention-deficit/hyperactivity disorder (ADHD), has been primarily tested for post-traumatic stress disorder (PTSD) but showed no difference compared to placebo in clinical trials. In a trial of guanfacine in children and adolescents aged 6 to 17 years with anxiety disorders including GAD, SAD, and separation anxiety disorder, no differences were observed

between treatment groups on anxiety, although a higher proportion of subjects receiving guanfacine showed greater clinical improvement as judged at the investigator compared to placebo.

To summarize, patients with different types of anxiety disorders exhibit symptoms consistent with an exaggerated noradrenergic system output, including excessive worry, avoidance, heightened arousal, and startle, along with increased autonomic and sympathetic activation. Drugs that act to attenuate this effect by decreasing the firing of NE neurons, including substances such as alcohol, opioids, and benzodiazepines, are commonly used and abused by patients with anxiety disorders as a form of self-medication. Drugs that increase NE signaling, such as SNRIs and tricyclic antidepressants, are thought to treat anxiety via eventual adaptive changes in NE (and serotonin) receptors occurring weeks later.

HYPOTHALAMIC–PITUITARY–ADRENAL AXIS

Cortisol is a glucocorticoid synthesized in the adrenal glands. It contributes to increased arousal, vigilance, focused attention and memory formation, inhibition of the growth and reproductive systems, and containment of the immune response. It is also known to regulate, marshal, and replenish energy stores. There is ample support for the notion that many types of psychological stress increase the synthesis and release of cortisol. Cortisol is a principal contributor in regulating hippocampus, amygdala, and prefrontal cortex (PFC) activity. It has been shown to enhance amygdala activity, increase corticotropin-releasing hormone (CRH), messenger ribonucleic acid (mRNA) concentrations in the central nucleus of the amygdala (CEA), increase the effects of CRH on conditioned fear, and facilitate the encoding of emotion-related memory. Of interest, this glucocorticoid-mediated facilitation of emotional memory encoding has been found to be contingent on endogenous arousal-induced activation of NE in the amygdala. In addition, glucocorticoids such as cortisol have biphasic effects on cognitive function, hippocampal excitability, and memory. Such effects may account, at least in part, for the adaptive role of cortisol in modulating behavior in response to acute stress.

The stress-induced increase in cortisol release is regulated through a complex negative feedback system mediated via moderate-to-low-affinity glucocorticoid receptors (GRs) and high-affinity mineralocorticoid

receptors (MRs). The hippocampus has a very high concentration of GR receptors and possibly also MR receptors and plays an important role in the negative feedback of the HPA axis. If stress-induced cortisol secretion is not contained, persistently elevated cortisol levels can cause diverse harmful effects both peripherally and in the CNS. Peripheral adverse effects include hypertension, osteoporosis, immunosuppression, insulin resistance, dyslipidemia, coagulation abnormalities, and ultimately atherosclerosis and cardiovascular disease. The hippocampus is particularly sensitive to many types of insults. High glucocorticoid levels impair cell survival, alter cell metabolism, and induce changes in cell morphology. The stress-related impairment in hippocampal-dependent cognitive and memory function may be a consequence of this cellular damage. Furthermore, there is accumulating evidence that the amygdala may play an important role in mediating the negative effects of stress on the hippocampus.

A large number of studies have investigated the role of the HPA axis in anxiety disorders, examining plasma, urine, or saliva samples either in basal conditions or after pharmacologic or behavioral stressor tests. Tests used to probe HPA axis function in patients with anxiety disorders have included examination of cortisol suppression after administration of low-dose dexamethasone (DEX), the response of adrenocorticotropic hormone (ACTH) after CRH administration, and the DEX/CRH challenge test, a sensitive and specific technique for assessing HPA axis function. Results of these studies are summarized below. In patients with PD, analyses of plasma cortisol levels have yielded mixed findings, with elevated daytime or nighttime levels observed in some studies but not others. Similarly, urinary-free cortisol has been reported to be within range or elevated. Plasma ACTH has been found to be elevated in patients compared with controls. Blunted ACTH responses to CRH have been reported in PD patients in some but not all studies. While circulating cortisol levels marginally increase during naturally occurring panic attacks as measured with indwelling catheters in patients resting in bed, a significant increase in salivary cortisol concentration has been reported in PD patients during spontaneous panic attacks compared to levels measured on panic-free days on the same subjects, at a similar time of the day.

To further understand the relationship between panic attacks and cortisol, several trials have employed panic provocation tests. Although in

the majority of studies, patients who developed a panic attack following lactate infusion generally did not show elevations in ACTH or cortisol, one study found that cortisol levels dropped during lactate-induced panic in both patients and controls. By contrast, patients who developed panic attacks following yohimbine administration showed a significant increase in plasma cortisol levels compared to healthy volunteers. Oral administration of the partial serotonin agonist meta-chlorophenylpiperazine (mCPP) or oral caffeine was associated with an increase in plasma cortisol in both patients and controls. However, recent evidence from a placebo-controlled study suggests that increases in plasma cortisol, ACTH, and dehydroepiandrosterone sulfate (DHEAS) observed after a 400-mg caffeine challenge administered as instant coffee in PD patients are not associated with the occurrence of panic attacks. Cognitive intervention in PD has been shown to significantly reduce the elevation of cortisol and ACTH by pentagastrin challenge, although it had no effect on panic symptoms per se. Thus, HPA axis hypersensitivity in PD may be activated by environmental contextual cues such as novelty, whereas baseline activity might remain normal. Finally, while most studies found a normal response to the DEX suppression test in PD subjects, results from the CRH stimulation test have been discordant, with some studies reporting a reduced ACTH response and ACTH/cortisol ratio, and others showing inconclusive findings.

Despite some discrepancies in the literature, most evidence suggests that GAD is also associated with HPA axis abnormalities. Specifically, it is still unclear if GAD is associated with elevated cortisol levels. While some studies report similar levels of baseline cortisol and cortisol responses to challenge tests, others report abnormal (increased or decreased) HPA axis activity in these patients. The DEX suppression test showed a reduction in negative feedback sensitivity of the HPA axis in GAD patients. Interestingly, cortisol levels, as well as severity of anxiety symptoms, were demonstrated to decrease after treatment, independently from the kind of therapy provided, benzodiazepine, SSRI, or psychotherapy. Studies analyzing cortisol concentrations in hair (a measure of long-term cortisol levels) showed 50% to 60 lower hair cortisol concentrations in GAD patients compared to healthy volunteers, supporting the hypothesis that chronic anxiety is associated with a downregulation of the HPA axis.

As the HPA axis has been found to play a pivotal role in social interactions in animal studies, the role of cortisol in the regulation of

behavioral responses to social stressors has been investigated in SAD. Several studies reported no abnormalities in basal HPA axis function in adult subjects suffering from SAD by measuring urinary free cortisol levels, free cortisol/creatinine ratio, and the 24-hour excretion of urinary free cortisol. While a study found lower basal plasma cortisol levels during morning hours in patients with SAD compared to healthy controls, a recent study failed to confirm the association between SAD and baseline saliva cortisol during morning hours in a large epidemiologic cohort of 1,050 subjects aged 14 to 21 years old. In the same study, baseline hair cortisol was inversely correlated to SAD in males but not females. Further, longitudinal analyses available in a subgroup of the sample (n = 605) showed a positive association between hair cortisol change between baseline and 1 year follow-up. Overall, this data suggests that both gender and age may mediate the relationship between cortisol and SAD.

Another study found no differences in the level of cortisol following DEX test in SAD subjects. Data from studies in children and adolescents with SAD confronted with a psychosocial stressor show conflicting results, with some reporting similar salivary cortisol levels compared to controls and others increased salivary cortisol levels in children and adolescents with SAD. A recent study conducted on 35 adults with SAD and 35 healthy controls showed a blunted plasma cortisol in SAD subjects compared to matching healthy volunteers, while no difference emerged for ACTH levels between groups.

Finally, HPA axis abnormalities have also been reported in patients with specific phobias (SPs), wherein exposure to the phobic object resulted in an increase in cortisol levels. Interestingly, one study reported a decrease in salivary cortisol levels collected in the afternoon hours following an intensive course of psychotherapy in individuals with SP from the first assessment (following a 2-minute exposure) to the final assessment (following a 15-minute exposure).

There has been ongoing research on the use of glucocorticoids in the treatment of anxiety disorders. In preclinical and clinical studies, glucocorticoids have been shown to block the recall of traumatic memories. Cortisol was also found to reduce the activation of fear responses in patients with SAD and spider phobia. In one of these studies, the oral administration of cortisone shortly before a social stressor significantly reduced social fear prior to, during, and in the aftermath of a stressor in individuals with SAD; cortisol levels correlated with fear ratings

in the placebo group, suggesting a role for glucocorticoids in reducing the intensity of phobic fear. In a double-blind placebo-controlled study, oral cortisol administration was shown to enhance therapeutic response to in vivo exposure-based group therapy in patients with SP of spiders. In preclinical studies, RU-486 (mifepristone), a GR antagonist, impaired the recall of stressful memories in rats. In a pilot study conducted in older adults with anxiety disorder (GAD, PD, or anxiety disorder not otherwise specified) and cooccurring cognitive dysfunction, administration of mifepristone was associated with improvements in memory, executive functions, and severity of worry in patients with elevated cortisol levels at baseline. PH94B, an intranasally administered neurosteroidal aerosol, has been investigated for the treatment of SAD in a randomized, double-blind, placebo-controlled study, wherein adult females with SAD were randomized to placebo or PH94B nasal spray 15 minutes prior to a laboratory-simulated public speaking and social interaction challenge. PH94B was associated with significant improvement in anxiety symptoms compared to placebo. Another study assessed the use of PH94B for SAD in a randomized, double-blind, placebo-controlled trial where males and females with SAD were randomized to either placebo or PH94, and self-administered the nasal spray prior to a distressing social interaction or performance. PH94B was superior to placebo in decreasing symptoms of anxiety. Further studies of glucocorticoids in humans are underway.

CORTICOTROPIN-RELEASING HORMONE

CRH, often referred to as corticotropin-releasing factor (CRF), is also a principal component of the response to stress, coordinating the adaptive behavioral and physiologic responses that occur after stress exposure. Driven by stress, hypothalamic levels of CRH are increased, and the HPA axis becomes active or perhaps even hyperactive, resulting in increased levels of cortisol and DHEA. CRH also exerts extrahypothalamic effects, which may be no less important than those mediated by the HPA axis. CRH-containing neurons are broadly distributed within the brain and can be found in the prefrontal and cingulate cortices, the CEA, the bed nucleus of the stria terminalis (BNST), the nucleus accumbens (NAc), the periaqueductal gray (PAG) matter, and brainstem nuclei such as the LC and dorsal and median raphe. The activation of amygdala CRH neurons triggers fear-related behaviors, and the engagement of cortical CRH

neurons may lessen reward expectation. CRH is also involved in the regulation of diverse neurovegetative functions, such as food intake, sexual activity, and growth and reproduction. In most cases, the administration of CRH inhibits these behaviors, whereas the administration of CRH antagonists increases them.

It has been shown that early-life stress may bring about long-term alterations in brain CRH concentration. Furthermore, both CRH secretion and the individual response to heightened CRH levels apparently depend on numerous environmental factors such as current and/or past social environment, current and/or past trauma history, and behavioral dominance. Continuous high levels of both hypothalamic and extrahypothalamic CRH strongly contribute to psychobiologic allostatic load. Preclinical studies have demonstrated that basal cerebrospinal fluid (CSF) CRH is higher in primates that have experienced early-life stress. The association between CRH and behavior occurs in a context-dependent manner. Exposure to excessive levels of CRH in early life is associated with hippocampal damage later in life. Of interest, intracerebroventricular injection of CRH to the hippocampus produces an increase in MR levels, suggesting that CRH is an important regulator of HPA axis function. A study found that an SNP in the CRH gene was associated with behavioral inhibition, a childhood trait that predicts adult anxiety. Still, the exact functional impact of the SNP on the manifestation of the CRH gene is yet to be determined.

It has been suggested that CRH-1 and CRH-2 receptors have a major role in the regulation of anxiety. Both types of receptors are found in the pituitary and throughout the neocortex (especially in prefrontal, cingulate, striatal, and insular cortices), amygdala, and hippocampal formation in the primate brain. However, other regions of the brain display predominantly one type of CRH receptor: CRH-1 receptors can be found within the LC, nucleus of the solitary tract, thalamus, and striatum, whereas CRH-2 receptors are chiefly located in the choroid plexus, certain hypothalamic nuclei, the nucleus prepositus, and the BNST. The varied distribution of these receptors suggests that each has a distinct role within the primate brain.

In rodents, CRH-1–deficient mice exhibit less anxiety-like behavior and a dampened response to stress. Conversely, CRH-2–deficient mice show more anxiety-like behavior and an exaggerated response to stress. Thus, the activation of CRH-1 receptors may contribute to increased anxiety-like

responses, whereas the stimulation of CRH-2 may be pivotal in mediating anxiolytic behavior. Maintaining the appropriate functional equilibrium in the contribution of each of the two CRH receptor subtypes to brain CRH pathways might be essential to maintain the protective and adaptive psychological and physiologic response to stressors. Although the study of CRH receptor function in humans is limited, genetic investigations have reported an association between nucleotide polymorphisms of the CRH-1 receptor gene and PD. There are also ongoing efforts to develop CRH receptor ligands for single-photon emission tomography (SPECT) and PET imaging. In light of the anxiogenic effects of CRH-1–receptor stimulation described previously, CRH-1 antagonists have been developed. To date, however, no CRH-1 receptor antagonist has demonstrated safety and efficacy in phase III trials for a stress-related psychiatric disorder. A large multicenter clinical trial failed to demonstrate superiority of the selective CRH-1 receptor antagonist pexacerfont over placebo in patients with GAD. Clinical trials of CRH-1 receptor antagonists verucerfont and emicerfont for SAD have been completed, but results have not been published yet.

DOPAMINERGIC SYSTEM

Dopamine, a catecholamine, is involved in goal-directed and reward-seeking behaviors. Dopamine, however, is also released in response to acute stress in a number of specific brain areas important in the regulation of affective behavior, including the basolateral nucleus of the amygdala, the NAc, and the medial prefrontal cortex (mPFC). The dopamine innervation of the mPFC appears to be particularly vulnerable to stress. Thus, low-intensity stress (such as that associated with conditioned fear) or brief exposure to stress increases dopamine release and metabolism in this region, even without any notable changes in other mesotelencephalic dopamine regions. This sensitivity of dopamine receptors in the mPFC is supported by animal studies showing that low-intensity electric foot shock increases in vivo tyrosine hydroxylase and dopamine turnover in the mPFC but not in the NAc or striatum. In other areas receiving dopamine innervation, stress can enhance dopamine release and metabolism, provided that greater-intensity or longer-duration stress is applied. Thus, sensitivity and response of different brain regions to dopamine activation differ, with mPFC dopamine innervation activated prior to mesolimbic and

nigrostriatal systems, and mesolimbic dopamine innervation more sensitive to stress than striatal dopamine innervation.

There is preclinical evidence that the extent of activation of the mesocortical dopamine system to stress may be, in part, genetically determined. It has been further suggested that extreme mesocortical dopamine release by stressful events may represent a vulnerability to depression and may lead to helpless reactions through an inhibition of subcortical dopamine transmission. Lesions of the amygdala before and after training in a conditioned stress model block stress-induced mPFC dopamine metabolic activation, suggesting amygdala control of stress-induced dopamine activation and a role in integrating the behavioral and neuroendocrine components of the stress response. On the other hand, lesions of mPFC dopamine neurons delay extinction (no effect on acquisition) of the conditioned fear response, indicating that prefrontal dopamine neurons are involved in facilitating the extinction of the fear response. One way to reconcile these two seemingly contradictory sets of data is to suggest that there is an optimal range for stress-induced increases in mPFC dopamine release to facilitate adaptive behavior responses. Too much mPFC dopamine release produces cognitive impairment, and an inhibition in NAc dopamine activity results in abnormalities in motivation and reward mechanisms. Insufficient prefrontal cortical dopamine release delays the extinction of conditioned fear. In humans, preliminary studies have reported a reduced density of the dopamine transporter and D_2 receptors in patients with SAD. Notably, increased anxiety is among the symptoms usually associated with dopamine agonist withdrawal in patients treated for conditions like Parkinson disease or restless legs syndrome.

One research group found a higher concentration of the dopamine metabolite HVA in plasma in PD patients with high levels of anxiety and frequent panic attacks. PD patients were also shown to have a larger growth hormone response to the DAT agonist apomorphine than patients with depression. Although no direct alteration in CSF HVA level has been demonstrated in PD patients, and no correlations between anxiety severity and panic attacks have been found, another study conducted on patients suffering from PD with concomitant SAD found lower CSF HVA levels.

SEROTONERGIC SYSTEM

Serotonin (5-HT), the release of which is regulated by the dorsal raphe nuclei, is secreted in response to stress and has been studied extensively in the context of anxiety disorders. Serotonin has been shown to have a dual role in anxiety. The serotonin hypothesis of anxiety suggests that 5-HT may be anxiogenic through its action on the PFC and amygdala, causing a heightened awareness of threats, and anxiolytic by its action on the dorsal periaqueductal gray (dlPAG), thereby inhibiting fight-or-flight behaviors. This model helps to explain the role of serotonin in producing panic and anticipatory anxiety, as well as excessive worry associated with generalized anxiety.

Various serotonin receptor subtypes have been shown to be involved in anxiety, in particular, 5-HT_{1A} and 5-HT_{2A}. The 5-HT_{1A} receptor density is high in the cortex, hippocampus, amygdala, dlPAG, and raphe nuclei (presynaptic). Animal models initially suggested a role of 5-HT_{1A} receptors in the development of chronic anxiety and helped to generate animal models of anxiety-related disorders. However, it is not clear whether these models constitute relevant models for PD in humans. The development of highly selective 5-HT_{1A} receptor radioligands such as [^{18}F] *trans*-4-fluoro-*N*-2-[4-(2-methoxyphenyl) piperazin-1-yl]ethyl]-*N*-(2-pyridyl)cyclohexanecarboxamide (FCWAY) made it possible to assess central 5-HT_{1A} receptor binding in PD using PET. In PD patients, including those who also had depression, receptors were reduced by an average of nearly one-third in the anterior cingulate in the front middle part of the brain, the posterior cingulate, the rear middle part of the brain, and the raphe, as well as in the midbrain.

Preclinical studies of the genetic expression of the 5-HT_{1A} receptor have shown that rodents lacking the receptor exhibit higher levels of anxiety. The opposite has also been shown in mice that have greater expression of 5-HT_{1A}. Of interest, animal studies using models of early-life stress, such as maternal separation, have shown that alterations to the 5-HT_{1A} receptor that occur early in life, such as the prenatal period, can cause persisting changes to the anxious phenotype, even after the restoration of the receptors at a later time. There is no such long-term effect if the receptors are reduced and then reinstated later in adult animals. These findings may be due to the effects of increased CRH and cortisol caused by the early stress, which thereby downregulate the number of 5-HT receptors. There may also be a genetic component.

Studies in humans have used 5-HT_{1A}–binding ligands with neuroimaging to determine receptor density; they have reported reduced receptor binding in patients with PD and SAD. Interestingly, antidepressants may exert their anxiolytic effects through different receptor subtypes depending on the anxiety disorder involved. Chronic treatment with SSRIs in PD patients is thought to suppress panic attacks by enhancing the responsiveness of 5-HT_{1A} and 5-HT_{2A} receptors in the dorsal PAG matter, while in patients with generalized anxiety, SSRIs might act through the desensitization of 5-HT_{2C} receptors and, possibly, through stimulation of 5-HT_{1A} receptors in the forebrain.

Analysis of peripheral levels of 5-HT has led to mixed results. Two studies have found lower plasma levels of 5-HT in individuals with PD compared to healthy volunteers. The majority of studies of 5-HT reuptake binding sites in platelets of patients with PD reported no differences compared to controls, while it appears to be decreased in GAD. In individuals with SAD, the density of platelet 5-HT_2 receptors has been found to be similar compared to controls, and it was associated with anxiety symptom severity. Levels of 5-HT and its metabolite 5-hydroxyindoleacetic acid (5-HIAA) were also measured in CSF in PD patients and healthy volunteers and did not appear to differ between the two groups.

One method of ascertaining the role of 5-HT in anxiety disorders has been to use pharmacologic challenges such as tryptophan depletion (TD), in which an amino acid mixture deficient in l-tryptophan, a precursor of serotonin, is administered, thereby resulting in an acute decrease in tryptophan and thus a decrease in brain serotonin levels. TD has also been shown to trigger depressive symptoms even in individuals with a family history of depression. While more consistent in individuals with a history of depression, the results of TD challenges in individuals with anxiety disorders have been mixed. In studies of PD patients, TD reduced tryptophan levels and increased anxiety and was associated with a heightened panicogenic effect of CO2 challenge compared to controls. There are, however, studies of patients with PD in which TD did not produce anxiety, including a study using a cholecystokinin-4 (CCK-4) panic challenge. Another pharmacologic challenge of the serotonin system involves the 5-HT agonist mCPP, used as a probe of the 5-HT_2 receptor. Some but not all studies of oral and intravenous mCPP have

shown increased anxiety in PD after the administration of the drug. Patients with SAD on SSRIs were also reported to have greater sensitivity to TD challenges, whereas another study found that mCPP did not induce a greater rate of panic attacks than in healthy controls.

Serotonergic agents, such as SSRIs, serotonin–norepinephrine reuptake inhibitors (SNRIs; venlafaxine and duloxetine), mirtazapine, and buspirone remain effective treatments for PD, social phobia, and GAD. Recently, novel compounds acting on 5-HT receptors with more favorable tolerability profiles have been tested. For instance, some trials explored the efficacy of vilazodone, an SSRI with partial agonistic properties on 5-HT1A, for GAD. However, evidence from a recent meta-analysis appears to not support the use of vilazodone in GAD. Conversely, one randomized, double-blind, placebo-controlled trial of vilazodone in SAD showed potential efficacy. Gepirone, a selective 5-HT1A receptor partial agonist, has been shown to have anxiolytic properties, and other 5-HT1A agonists have been investigated for the treatment of anxiety disorders. A clinical trial of PRX-00023 was conducted in GAD patients, but it failed to differentiate from placebo. Studies of other selective 5-HT1A partial agonists are underway.

γ-Amino Butyric Acid and the Benzodiazepine System

GABA is the primary inhibitory neurotransmitter in the brain and a metabolic product of glutamate, the excitatory neurotransmitter. There are two subtypes of GABA receptors: GABA-A and GABA-B. GABA-B receptors are slow-acting channels and are agonized by agents such as baclofen (a drug used as a muscle relaxant). GABA-A receptors are fast-acting, ligand-gated channels made up of five protein subunits and consisting of multiple families of receptors. A wide range of drugs act as agonists of the GABA-A receptor, including barbiturates, benzodiazepines, alcohol, anesthetics, neuroactive steroids, and several anticonvulsant medications. Not surprisingly, all of these agents have been shown to have anxiolytic effects. In particular, benzodiazepines have long been used in the treatment of anxiety disorders, in particular PD, phobias, and GAD.

Central benzodiazepine receptors have also been found in the human brain. They form a complex with GABA-A receptors and have different

binding sites but positive allosteric effects on one another. The presence of these benzodiazepine receptors led to reports of endogenous benzodiazepine receptor ligands, also called endozepines, in the brain and speculations that they might function in the modulation of fear and learning. The exact role of these compounds in anxiety, however, is yet to be fully understood.

The role of GABA and benzodiazepine receptors in anxiety is well-documented in animal studies. It has been reported that benzodiazepine partial agonists reduce anxiety-like behaviors in rats, whereas GABA inverse agonists produce anxiety in certain learning and behavioral tasks. There is also ample supporting evidence in humans. Studies using benzodiazepine antagonists have shown these agents to be anxiogenic. Flumazenil, an antagonist used in emergency settings to treat benzodiazepine overdose, has been shown to be a panicogenic agent in patients with PD but not in healthy controls. Clinical studies of GABA levels in the blood of patients with anxiety disorders have been limited. Studies of patients with PD compared to healthy controls have failed to show a change in plasma GABA at baseline and after a CCK-4 challenge.

Neuroimaging studies have enabled the visualization of GABA and benzodiazepine receptors in the human brain. Several studies of PD patients have shown reduced GABA-A and benzodiazepine binding, using PET and SPECT imaging, in areas such as the cortex, hippocampus, and insula when compared to controls. A study of PD patients taking medications (antidepressants and/or benzodiazepines) using proton magnetic resonance spectroscopy showed reduced GABA levels in the anterior cingulate and basal ganglia. Although benzodiazepines continue to be among the most widely prescribed medications worldwide, they are no longer considered first-line treatment for PD, SAD, or GAD, having been replaced with SSRIs, cognitive-behavioral therapy, and other types of therapy. Part of this change in prescribing practices is due to concerns about the risk of tolerance, the potential for abuse or dependence, sedative properties, and potential long-term effects on cognition and memory. Despite these concerns, there has been consistent evidence that benzodiazepines are safe and effective in the treatment of anxiety when prescribed appropriately.

Despite the fact that several GABA-A receptor subtype agonists failed to reach the market due to lack of efficacy, evidence from preclinical studies has yielded several agents that are currently in development,

including SAGE-217, a GABA-A positive allosteric modulator. While SAGE-217 failed to distinguish itself from placebo for treatment-resistant depression, it is currently being studied for the treatment of GAD. Further, newer agents that enhance GABA function have been explored for the treatment of anxiety disorders. These drugs include several anticonvulsants that work in part as GABA agonists, including tiagabine (Gabitril), a selective GABA reuptake inhibitor (SGRI), and vigabatrin, an inhibitor of GABA transaminase (the latter is not approved for use in the United States). Although controlled studies of tiagabine reported equivocal findings in GAD patients and did not show a difference from placebo in PD, tiagabine appeared effective in improving symptoms of anxiety in a small sample of SAD patients (eight adults aged 21 to 39 years old). Results from clinical trials of other anticonvulsants, such as topiramate, in PD have been mixed. Further studies using larger sample sizes are indicated before the efficacy of these agents as primary treatments for anxiety disorders can be fully ascertained. Gabapentin and pregabalin, although structurally related to GABA, do not act on GABA receptors but instead, bind to a subunit of voltage-sensitive calcium channels.

Neurosteroids, such as allopregnanolone and pregnanolone (see separate section below), have been demonstrated to act as modulators of GABAergic neurotransmission mainly through a stereoselective interaction with GABA-A receptors. In animal models, studies of a synthetic analog of allopregnanolone reported an anxiolytic effect similar to benzodiazepines in the absence of tolerance phenomena. Targeting GABA-A receptors, and in particular the development of compounds selective for GABA-A receptor subtypes, appears to be an intriguing pharmacologic approach for the treatment of anxiety disorders. This approach, also taking advantage of the rapid turnover of GABA-A receptors, could yield a potential drug with high selectivity and reduced adverse effects. To date, results from animal trials appear promising, but further investigations in patients with anxiety disorders are required.

GLUTAMATE SYSTEM

Glutamate is the primary excitatory neurotransmitter of the CNS, is the precursor compound of GABA, and modulates pathways that mediate panic and defensive responses. Results from human and animal studies suggest that panic might arise from an imbalance between tonic

GABAergic inhibition and glutamate-mediated excitation, with predominance of the latter. For example, reduced GABAergic tone has been reported in patients with PD. Further, glutamate is known to regulate other neurotransmitters involved in PD, including serotonin and NE.

Glutamate binds to two families of receptors: metabotropic and ionotropic receptors. Metabotropic receptors (mGluRs), which are G-protein–coupled membrane receptors, are made up of eight subtypes and are believed to serve as allosteric modulators. Ionotropic receptors, which are ligand-gated channels, include *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methylisoxasole-4-propionic acid (AMPA), and kainate receptors. These receptors have become a focus of investigation in the area of anxiety disorders, primarily PD.

Preclinical studies have shown anxiolytic properties of group-2 and group-3 mGlu-receptor agonists, and, more recently, of selective group-2 receptor type 2 (mGluR2) agonists. Systemic infusion of these glutamate receptor agonists prevented panic-like responses after infusion of sodium lactate in panic-vulnerable rats, showing efficacy against panic similar to that of comparison drug alprazolam in this animal model of panic. Despite several studies showing the anxiolytic effect of mGlu modulators in animal models, trials on human samples have not been as promising. With regard to human studies, a small randomized, double-blind clinical trial of an mGluR2/3 agonist, LY354740, in patients with PD, failed to show treatment effects compared to placebo. Similarly, JNJ-40411813 (ADX-71149), an mGluR2 positive allosteric modulator, was studied in an RCT for anxious depression but did not show efficacy. Another randomized, double-blind, placebo-controlled trial of the mGluR2/3 agonist, LY354740, in patients with GAD showed greater improvement in anxiety scores compared to placebo, but the study was discontinued due to findings of convulsions in animal studies of the compound. This is an understandable risk, given that glutamate-enhancing drugs have neuroexcitatory properties and that glutamate inhibitors are commonly used as anticonvulsants. Similarly, there are studies of mGlu1, mGlu5, and mGluR7 antagonists and AMPA/kainate–receptor blockers showing antianxiety properties in animals. Further studies in humans are needed before the safety and tolerability of these compounds can be better understood.

NMDA receptors are prominently involved in the conditioning of fear learning via entry of calcium through the receptors and voltage-gated

calcium channels. Blockade of the NMDA receptor with antagonists such as (2R)-amino-5-phosphonovaleric acid (APV) can block fear acquisition, and some studies show that it may even block expression. In panic-prone rats, injection of NMDA antagonist MK-801 into the dorsomedial/perifornical hypothalamus blocked panic-like behavior induced by sodium lactate in a dose-dependent fashion. The NMDA receptor antagonist ketamine, which at subanesthetic doses has demonstrated efficacy in patients with treatment-resistant depression, has shown efficacy for PTSD in recent studies and mixed results in patients with obsessive-compulsive disorder, both conditions formerly classified as anxiety disorders. A recent randomized clinical trial investigating the effect of repeated ketamine infusions compared to the active control midazolam for chronic PTSD showed a significantly greater improvement in PTSD symptoms severity in the ketamine group from baseline to week 2 (following the six infusions), with a median time to loss of response of 27.5 days following the last infusion. Similarly, few studies have explored the effect of ketamine in patients with conditions currently classified as anxiety disorders. Two small preliminary studies (one open-label and the other exploratory double-blind, compared to midazolam) evaluated the efficacy of ketamine in patients with treatment-refractory SAD and/or GAD without current depression, using an ascending dose design (0.25, 0.5, 1 mg/kg subcutaneously), administered weekly; in both studies, ketamine was associated with a quick reduction in anxiety symptoms, lasting up to 7 days. A double-blind, proof-of-concept RCT with a crossover design tested the effect of intravenously administered ketamine (0.5 mg/kg) compared to saline (administered 28 days apart) in patients with SAD. In this study, ketamine was associated with significantly greater improvement in anxiety than saline in the first 2 weeks following infusion, measured with the Liebowitz Social Anxiety Scale.

NMDA receptors are also critical for fear extinction, with preclinical studies showing that blockade of this pathway inhibits extinction. These findings were supported by animal research showing that a partial agonist at the glycine modulatory site on the NMDA receptor, D-cycloserine (DCS), a drug previously used for the treatment of tuberculosis, could facilitate extinction learning. D-cycloserine is among the most widely studied glutamatergic agents in anxiety. Healthy volunteers receiving DCS during a stressful learning task had less stress and better performance than those receiving placebo. In addition, a small study using functional

magnetic resonance imaging showed that healthy volunteers receiving DCS had a more blunted amygdala response to fearful faces compared to those receiving placebo. Several studies have shown the efficacy of DCS as an adjunct to exposure therapy or cognitive behavioral therapy (CBT) in patients with acrophobia (fear of heights), SAD, and PD. Negative studies have also been reported, including a study of DCS in spider phobia. A recent review reported no difference between DCS and placebo in augmentation of psychotherapy for anxiety disorders in children and adolescents. Overall, results from DCS augmentation have been inconsistent, with initial trials showing promising results that have not been replicated in larger studies.

Another potential strategy consists of inhibiting the glycine transporter, thereby increasing the availability of glycine at the NMDA receptor complex glycine modulatory site. Glycine transporter inhibitor Org 25935 was evaluated in a multicenter clinical trial as augmentation to CBT in patients with PD; panic symptoms decreased in every treatment group, but there was no statistically significant difference between Org 25935 and placebo.

Other glutamate-modulating agents, such as pregabalin, tiagabine, and lamotrigine (Lamictal), have been studied for GAD and SAD. Although pregabalin demonstrated efficacy in several randomized controlled trials in patients with GAD, it has not received formal approval by the U.S. Food and Drug Administration (FDA) for the treatment of this condition. Pregabalin, however, is recommended as a first line of treatment for GAD comorbid with epilepsy. Riluzole (Rilutek), a drug approved for amyotrophic lateral sclerosis, was studied in an 8-week, open-label trial in patients with GAD and found to be effective in lowering anxiety scores. Functional neuroimaging studies of open-label riluzole in patients with GAD showed changes in hippocampal volumes and N-acetylaspartate (NAA) concentrations that correlated with improvement in anxiety symptoms in patients compared with healthy volunteers. More recently, an analog of riluzole, troriluzole (BHV-4157), failed to differentiate from placebo in a large Phase III 8-week trial in GAD. The study of glutamate in larger-scale human studies should continue to provide novel therapeutic agents for anxiety disorders.

NEUROSTEROIDS

Baulieu introduced the term “neurosteroid” in the 1980s to describe endogenous steroids synthesized in the CNS from cholesterol or sterols. Neurosteroids act on neuronal function and regulate neuronal excitability. They are highly selective and positive allosteric modulators of the GABA-A receptor, thereby making them potential anxiolytic agents, a finding that has been supported in animal models. Neurosteroids are thought to act on the amygdala by affecting intracellular receptors in a process involving NMDA receptors. They additionally regulate CRH gene expression, thereby reversing the anxiogenic effects of CRH. The progesterone metabolites believed to be involved in fear and anxiety include 3α,5α-tetrahydroprogesterone (THP) and 3α,5β-THP (pregnanolone).

Preclinical studies have shown that progesterone is anxiolytic, likely due to its effect of increasing allopregnanolone. Progesterone is increased during pregnancy, and it has been shown in animal studies that this is associated with a reduction in anxiety behaviors and that this anxiolytic effect is reversed by finasteride, an inhibitor of the 5α-reductase enzyme that is involved in steroid biosynthesis. One study in humans reported that pregnant women had higher levels of progesterone, allopregnanolone, and tetrahydrodeoxycorticosterone (THDOC), which were believed to be protective against maternal anxiety. A study of pregnant women with preexisting PD found a reduction in anxiety symptoms during the pregnancy and rebound anxiety during the postpartum period, which is consistent with a rapid drop in hormone levels. The effect of hormone levels on anxiety has been studied during the menstrual cycle as well. One study reported that women with PD had elevated peripheral concentrations of allopregnanolone both during the follicular and premenstrual phase and suggested that neurosteroids may be a protective factor against spontaneous panic attacks. Of note, the FDA-approved brexanolone for postpartum depression, a condition characterized by a rapid decrease in the concentration of allopregnanolone and progesterone after childbirth, especially in women with postpartum “blues.” A single infusion of brexanolone showed rapid antidepressant effects, as documented in an open-label and two double-blind, randomized clinical trials (RCTs).

Patients with PD have been found to have increased allopregnanolone levels and decreased isopregnanolone levels. In a study of panic attacks induced by CCK-4 and lactate, patients with PD showed a decrease in allopregnanolone and pregnanolone, suggesting decreased GABA tone

not found in healthy controls. It is possible that alterations in neurosteroid levels might be related to the pathophysiology of panic attacks in PD and not simply reflects state anxiety. No data are available concerning alteration of neurosteroid levels during spontaneous panic attacks. Studies investigating the impact of pharmacotherapy on allopregnanolone levels in PD patients revealed conflicting results, with one trial showing no effect of paroxetine on allopregnanolone levels or concentrations of other neuroactive steroids, but another one showing a significant increase in allopregnanolone levels after 2 months of treatment with paroxetine.

Studies of neurosteroid levels in patients with other anxiety disorders have yielded inconsistent findings. Two small-scale investigations reported low pregnanolone sulfate levels in both SAD and GAD in both cases when compared to healthy controls. One group, however, demonstrated no difference in levels of DHEA, DHEA sulfate (DHEAS), or ALLO in patients with SAD compared to healthy volunteers. Two compounds with neurosteroidal activity, mifepristone (RU486) and PH94B, have been investigated for the treatment of anxiety symptoms (see "Hypothalamic–Pituitary–Adrenal Axis" section for more details). Studies of synthetic analogs of neurosteroids are underway, with no published studies in anxiety disorders to date.

ARGININE VASOPRESSIN

Arginine vasopressin (AVP) is released by the parvocellular neurons found in the paraventricular nucleus (PVN). AVP is best known for its effects on the control of body fluid levels, blood pressure, and blood sugar. Vasopressin is used as a treatment for nocturnal enuresis as well. It has also been linked to pain sensitivity, circadian rhythms, regulation of sleep, and learning and cognition. AVP exerts its effect through two receptors, V1a and V1b, located throughout the brain, including the septum, cortex, and hippocampus.

Although CRH is believed to be the critical factor in controlling the release of ACTH, AVP serves as an important mediator. The release of ACTH during periods of acute stress, as in rat studies using the forced swim test, can be suppressed by simultaneous administration of a CRH receptor 1 antagonist and an AVP V1b antagonist. Mice with the V1a receptor knock-out showed reduced anxiety on similar stress tasks. Similarly, mice with overexpression of the V1a receptor exhibited

heightened anxiety-like behaviors. The role of AVP in anxiety is supported by a human genetic study, which found an association between an SNP within the AVP V1b receptor gene and PD, compared with healthy controls. With regard to treatment, preclinical studies have yielded mixed results of AVP V1b antagonists on anxiety-like behaviors. Clinical studies investigating a V1b antagonist in patients with GAD failed to demonstrate clinical efficacy. A few studies testing the effects of SRX246, an AVP V1a receptor antagonist, have yielded initial encouraging results. In one of these, a 7-day treatment with SRX246 was associated with a reduction of amygdala response to angry faces following an acute intravenous administration of vasopressin in a sample of 29 healthy males.

In addition, there are limited reports of AVP administration in anxiety disorders. A trial in healthy male and female volunteers found that the administration of intranasal AVP reduced skin conductance and heart rate responses during an angry-faces paradigm and that there was a difference between men and women in the social recognition paradigm, supporting the preclinical findings of sex differences in AVP.

OXYTOCIN

Oxytocin, a 9–amino acid peptide hormone synthesized in the paraventricular and supraoptic nuclei of the hypothalamus, and released from neurons within the hypothalamus and also into the bloodstream via the posterior pituitary, has been shown to interact with central reward processing regions, modulate social-emotional functions, and attenuate stress responses via interaction with the HPA axis. The anxiolytic, stress-attenuating, and prosocial effects of oxytocin were first discovered in rodents. Anxiogenic and stressful stimuli activate the synthesis and release of oxytocin, which modulates the HPA axis and anxiety behaviors.

In human studies, circulating plasma oxytocin level has been associated with anxiety, while the CSF level of oxytocin appears to be negatively associated with anxiety in children and adult subjects. Additional support for the role of oxytocin in anxiety is also suggested by a report of an association between polymorphisms in the oxytocin receptor gene and increased risk for anxiety, stress, and depression in individuals with early-life stress exposure. Further, intranasal administration of oxytocin has been associated with increased prosocial behavior and improvement in emotion recognition and social memory. Its anxiolytic and

stress-attenuating effects have stimulated significant interest in its potential therapeutic effect for anxiety disorders. A study using intranasal oxytocin in healthy male volunteers reported reduced amygdala activation to fearful faces, lower anxiety scores, and improved social cognition compared to intranasal placebo. In another study of men with early parental separation, a risk factor for anxiety and depressive disorders in adults, intranasal oxytocin administration attenuated decreases in salivary cortisol compared to placebo, thus dampening the HPA axis alteration associated with early separation.

A series of studies in healthy and anxious volunteers have shown decreased anxiety symptoms during variations of the Trier Social Stress Test (TSST) after intranasal oxytocin administration. In one study of patients with GAD, daily oxytocin administration over 3 weeks was beneficial, especially in male patients. Oxytocin facilitates extinction of social fear. In patients with SAD, intranasal oxytocin alone or as augmentation of exposure therapy was associated with more positive self-evaluation after public performance. In a recent neuroimaging study in patients with SAD, oxytocin administered intranasally was associated with greater enhancement of amygdala-frontal resting state connectivity in patients with higher social anxiety. Oxytocin also enhanced functional connectivity between the amygdala and other brain regions (insula, cingulate gyrus) in patients with SAD but not in healthy controls in response to fearful faces. Oxytocin has also been shown to attenuate the neural response to a negative social interaction task toward other same-sex humans in men, within the amygdala and anterior insula, as measured with fMRI, suggesting a potential effect of oxytocin in reducing the stress of negative social interactions among healthy men. Interestingly, this effect was not detected in female participants. A study in patients with SAD and healthy controls found that decreased methylation of the oxytocin receptor gene was associated with SAD, increased cortisol response to the TSST, and increased amygdala reactivity during processing of words relevant to social anxiety. A trial is currently underway to explore the levels of oxytocin prestressor and after-stress exposure using the TSST in children and adolescents with anxiety disorders. Further studies of oxytocin administration in patients with SAD are necessary to develop this intervention for potential use in clinical practice.

NEUROPEPTIDE Y

Neuropeptide Y (NPY), a 36–amino acid peptide, is one of the most abundant and highly evolutionarily conserved polypeptides found in the brain. Its highest concentrations are in the LC, hypothalamus, septum, and PAG, with moderate levels in the hippocampus, amygdala, and brainstem. NPY is linked with various roles in humans, such as feeding, sleep, and anxiety regulation, although via distinct mechanisms. There is ample preclinical evidence that NPY has anxiolytic effects. Of the five NPY receptor subtypes found in mammals (Y1 to Y5), the NPY-Y1 receptor has been most closely studied in anxiety. Studies of Y-1–receptor knockout mice and administration of Y-1 antagonists increased anxiety-like behaviors in the animals. In addition, NPY has been shown to be involved in fear consolidation, with preclinical studies showing that the administration of NPY impairs the retention of traumatic memories and reduces anxiety during stressful tasks. NPY also mediates the response to chronic stress by increasing expression of amygdala NPY mRNA. A study of rats exposed to maternal separation reported that treatment with acupuncture increased NPY expression in the basolateral amygdala and reduced anxious behaviors. Recent evidence from preclinical studies also suggests a role for NPY in mood regulation. Mice with decreased NPY gene expression in the NAc exhibited behavioral despair. Anxiety-like behavior appeared significantly increased following toxin-mediated ablation of NAc NPY neurons, while chemogenetic activation of NAc NPY neurons reduced anxiety behavior in mice. These data suggest that NPY may play a role in the psychobiology of stress responses and resilience.

Few studies have investigated the effects of NPY administration in clinical samples. The susceptibility of NPY to gastrointestinal degradation and the limited transportation through the blood–brain barrier had implications on the chosen route of peptide administration. Thus, an intranasal direct nose-to-brain route may represent the most clinically relevant procedure to explore the effect of NPY on the clinical population. The only study to date on NPY administration for anxiety was conducted in individuals with chronic PTSD. In this study, 26 subjects were randomized to receive either intranasal NPY or placebo using a cross-over, ascending dose design. The study sample was divided into five cohorts reflecting the single ascending dose study: 1.4 mg (n = 3), 2.8 mg (n = 6), 4.6 mg (n = 5), 6.8 mg (n = 6), and 9.6 mg (n = 6). Each subject received intranasal NPY or intranasal placebo saline on separate treatment days 1 week apart. Assessments were conducted pretreatment

and following a trauma script symptom provocation procedure after receiving the study drug or placebo. Safety and tolerability of NPY represented the primary outcome of the study, while NPY efficacy on anxiety and PTSD symptoms severity as a function of dose were explored as secondary outcomes. Twenty-four subjects completed both treatments, and NPY was well-tolerated up to the highest dose. Higher doses of NPY were associated with greater improvement in anxiety symptoms compared to placebo, as measured with the Beck Anxiety Inventory, immediately following symptom provocation. Other measures of anxiety (State-Trait Anxiety Inventory–State Form) and PTSD (Impact of Event Scale-Revised) symptoms did show a statistically significant difference between NPY and placebo, although the pattern of the dose-response relationship was similar. Recently, a small trial showed potential benefit of intranasal NPY administration for individuals with depression. In this study, 30 subjects with major depressive disorder (MDD) on a stable dose of a conventional antidepressant received 6.8 mg NPY (n = 12) or placebo (n = 18) in a double-blind, randomized fashion. Effects on depressive symptoms severity were collected at several time points (baseline, 1, 5, 24 and 48 hours following administration) using clinician-administered rating scales (Montgomery-Åsberg Depression Rating Scale). NPY was superior to placebo at the 24-hour time point and showed similar a trend 1- and 5 hours following administration, albeit not reaching significance. However, the improvement in depression severity at 48 hours was no longer significant. While there are currently no active trials of NPY administration for GAD, PD, or SAD, the encouraging initial findings in PTSD and MDD suggest the need for further studies in individuals with mood and anxiety disorders.

GALANIN

Galanin, a 30–amino acid peptide, has a wide variety of functions in humans, including modulation of pain, learning, feeding and gastrointestinal motility, and cardiovascular control. Galanin, which is coexpressed with NE neurons in the LC, and thus projects to structures involved in the fear pathway (including the amygdala, hippocampus, and PFC), has been linked to regulation of mood and fear response. It also acts as an autoreceptor to reduce firing of the LC. Galanin acts on three subtypes of receptors: Gal-R_1, Gal-R_2, and Gal-R_3. Although preclinical

data are inconsistent, the three receptors have been shown to have differing effects on anxiety-like behaviors. Mice lacking the Gal-R_1 receptor exhibited anxiety-like behaviors, whereas the injection of receptor agonists produced a reduction of such behaviors. Similarly, studies of Gal-R_3 antagonists in rodents showed them to have antidepressant and anxiolytic properties in several behavioral tasks. Overall, increases in central galanin, either by overexpression or via intracerebral administration, have been demonstrated to regulate anxiety behaviors in rats. More recent studies suggest that galanin might have anxiolytic effects under high stress/high noradrenergic activation. A trial in mice using galnon, a nonselective galanin-receptor agonist, showed that the drug reduced anxiety during certain stressful tasks, such as the forced swim test and the elevated zero maze, and that this effect was reversed by administration of a galanin-receptor antagonist. This finding has also been reported in another animal study using forced swim, a model of depression. The reports suggest that galanin's effects on mood and anxiety may be through its inhibition of hippocampal serotonin receptors.

There are very few human studies of galanin in patients with anxiety disorders. A genetic study of men and women with PD found an association between two of six haplotypes of a galanin gene polymorphism and severity of illness, but only in women; this finding was later replicated in a larger sample. Despite the therapeutic potential of galanin, there are no known published trials of galanin modulators as potential therapeutic agents in anxiety disorders.

CHOLECYSTOKININ

CCK is a neuropeptide derived from a 112–amino acid precursor compound and is classified by its various fragment peptides, of which CCK octapeptide (CCK-8) is the most abundant. CCK helps regulate the digestion of proteins and lipids in the gastrointestinal system. However, CCK is also found in the brain, in key regions of the fear network (amygdala, hypothalamus, periaqueductal grey), and interacts with several neurotransmitters and neuropeptides such as serotonin, noradrenaline, GABA, endocannabinoids, and NPY. CCK acts via two types of receptors, CCK-1 and CCK-2 (also referred to as CCK_A and CCK_B, respectively). Specifically, CCK-2 has been linked with anxiety-like behaviors in mice and with panic attacks in humans. Further, while CCK-8

acts on both receptor subtypes, CCK tetrapeptide (CCK-4) is a primary agonist of CCK-2 receptors. CCK has its highest levels in the cerebral cortex, hippocampus, amygdala, caudate, and putamen, with intermediate levels in the thalamus and hypothalamus. CCK receptors are found in greatest density in the cortex, hypothalamus, substantia nigra, and PAG.

It has been shown in various preclinical studies that CCK-4 is anxiogenic and that this effect is blocked by CCK-2 antagonists. CCK-8 has shown a similar effect on inducing anxiety in rats, but only after intracranial administration, suggesting that the drug does not cross the blood–brain barrier as effectively as CCK-4. Studies in humans have also shown similar results. Studies of both healthy subjects and patients with PD have shown the panicogenic effects of CCK-4 and of CCK-5, or pentagastrin. These effects could be blocked by the administration of CCK antagonists or by treatment with GABA agonists such as vigabatrin or tiagabine. In addition, patients with PD have been shown to have lower CSF levels of CCK versus healthy controls, although it is unclear whether this is due to higher CCK turnover or greater receptor sensitivity. In addition, a recent study of healthy volunteers undergoing a CCK-4 challenge reported that cardiovascular changes may not be correlated with subjective panic, which suggests that this may not be an ideal model for studying the effect of anxiolytic drugs on panic unless strict criteria are used.

The aforementioned studies supported the role of CCK in anxiety and prompted the investigation of CCK-2–receptor antagonists as potential antianxiety drugs. Although several CCK-2 receptor antagonists have been developed, none have been demonstrated to be effective in improving anxiety symptoms in humans. In a randomized, double-blind, placebo-controlled study, the effect of CI-988, a CCK-2 antagonist, on anxiety scores in GAD patients did not differ from placebo. Another study in GAD patients found that CI-988 failed to abate the anxiogenic effects of mCPP, and a similar study showed that it failed to treat the anxiety symptoms induced by CCK-4 in patients with PD. Trials of CCK-2 antagonists in PD showed that they were not significantly better than placebo. This has led to the suggestion that the preclinical data were not as clear-cut in defining the significance of CCK-2 in anxiety modulation. The role of CCK as a possible target of novel therapeutics remains an area of investigation.

ENDOCANNABINOID SYSTEM

Preclinical studies have stimulated a growing interest in the endocannabinoid system, involved in modulating sleep, appetite, pain, emotional memory, and fear responses, as a potential therapeutic target in patients with anxiety disorders. This system comprises polyunsaturated fatty acid endogenous ligands, anandamide (AEA), 2-arachidonoylglycerol (2-AG), and two G-coupled receptors, cannabinoid receptors 1 (CB1) and 2 (CB2). CB1 and CB2 receptors are widely distributed in the frontal cortex and subcortical structures, including the amygdala, basal ganglia, hippocampus, and other structures. In particular, CB1 agonists show a biphasic effect characterized by anxiolytic properties at low doses and anxiogenic properties at high doses.

Findings from preclinical studies suggest that basal endocannabinoid levels are low and increase during exposure to threatening stimuli, counteracting fear responses under conditions of threat. In humans, new studies are focusing on targeting this system in patients with PTSD, which is no longer classified as an anxiety disorder. Cannabidiol (CBD), a cannabis sativa constituent, binds to the CB1 receptor and several others, including the serotonin 5-HT_{1A} receptor. CBD has been studied in animal models of general anxiety and stress-induced anxiety. In human studies, CBD significantly reduced anxiety during simulated public speaking in healthy volunteers and patients with SAD. Conversely, rimonabant, a CB1 antagonist/inverse agonist, increased anxiety in anticipation and during simulated public speaking in healthy volunteers. Further, in a recent study of adolescents with SAD, CBD was associated with an improvement in anxiety symptoms compared to placebo. Currently, a clinical trial exploring the effect of flexible dosages of CBD in patients with PD, GAD, SAD, or agoraphobia is in progress.

While direct CB receptor modulators might potentially worsen anxiety or depression, inhibitors of fatty acid amide hydrolase (FAAH), the principal catabolic enzyme for AEA, show promise. Reduced FAAH expression has been associated with enhanced extinction learning in animal and human neuroimaging studies. Knock-in mice with a polymorphism associated with reduced expression and activity of FAAH exhibited enhanced fronto-amygala connectivity, increased fear extinction learning, and decreased anxiety-like behaviors. However, the role of cannabinoid receptors in mediating memory consolidation and reconsolidation processes appears

to be complex, considering that both endocannabinoid agonists and antagonists have been involved in fear memory reconsolidation. Further, administration of FAAH inhibitors to rodents was associated with decreased anxiety-like behaviors during experimental tasks designed to increase anxiety, such as the elevated-plus maze and the light-dark box. Clinical trials of these novel compounds are needed in social anxiety and other anxiety disorders.

The implication of endocannabinoids in anxiety is in accordance with dense expression of CB1 receptors in brain regions related to anxiety, fear, and aversion, including the mPFC, hippocampus, amygdala, and PAG. As one example supporting the role of the endocannabinoid system in anxiety, CB1 receptor availability in the amygdala was found to mediate attention bias to threat cues in a sample of PTSD patients. A partial agonist of CB1, delta-9-tetrahydrocannabinol (THC), appears to have anxiolytic effect in low doses but can induce anxiety and panic attacks in high doses. Similarly, nabilone is a synthetic cannabinoid with high affinity to CB1 and CB2 receptors. Studies in humans assessing the effect of nabilone on pain and anxiety symptoms showed discordant results, with some trials reporting an improvement in pain symptoms and a decrease in anxiety severity and others that did not show an effect on anxiety symptoms. Two trials studied the effect of nabilone in patients with anxiety symptoms. One enrolled eight anxious volunteers who received placebo and three dose levels of nabilone at 1-week intervals using a single-blind design and showed anxiolytic effects only in a small subgroup, while in another small open-label study, patients with anxiety were treated with nabilone for 28 days and had significant improvement in anxiety symptoms. Finally, preclinical studies showed that anxiogenic-like effects of CB1 antagonists tend to be more evident when animals are subjected to high levels of aversion. Anandamide-hydrolysis inhibitors are more efficacious as anxiolytic drugs when tested in a highly aversive environment. The basal levels of endocannabinoid synthesis and release tend to be low; however, the activity of this system is enhanced in response to neural activation when experimental animals are exposed to threatening stimuli when endocannabinoids would work to counteract.

INFLAMMATORY AND IMMUNOLOGIC FACTORS

Recent evidence suggests a role of inflammatory processes in the pathophysiology of anxiety, with few studies reporting elevated levels of circulating inflammatory markers in anxiety disorders. Stress leads to activation of the HPA axis and the sympathetic nervous system, with the resulting release of catecholamines, which in turn modulate the release of inflammatory mediators (such as cytokines) through α- and β-adrenoceptors displayed on immune cells. Although some studies have observed higher circulating levels of cytokines in individuals with PD, others have failed to replicate this finding and instead showed reduced plasma levels of some cytokines (such as Interferon-γ), similar to findings in animal models. While a few studies have observed higher levels of C-reactive protein (CRP) in GAD patients, CRP levels appear reduced in SAD patients, especially in females. However, the limited number of studies conducted in individuals with anxiety disorders and the presence of multiple confounding factors (age, gender, BMI) that may interfere with the concentration of circulating cytokines preclude any final conclusions on the role of inflammation in the pathophysiology of these disorders. Further studies in this area are warranted.

FUTURE DIRECTIONS

Knowledge about anxiety disorders has arisen from various animal models of stress and fear, using primarily Pavlovian fear conditioning as a basis of understanding. Although such studies have provided invaluable information about the mechanisms of the fear response, translating this work to humans remains challenging. Anxiety disorders are highly unique in their etiology, susceptibility, presentation, treatment, and prognosis. Preclinical research will continue to refine the current understanding of the role and integration of neurochemical systems both in producing fear responses and in modulating anxiety responses in animal models. Additional progress will come from optimizing current animal models of anxiety and incorporating emerging understandings of the intricate and fine-grained neural circuits involved in the experience of anxiety. Further, animal studies are employing novel techniques including in vivo chemogenetics and optogenetics, coupled with retrograde tracing to probe neuro-biologic systems involved in anxiety. New insights from basic research can then be applied to human studies in the search for novel biomarkers of anxiety disorders and new treatment approaches. A

compelling example that has recently emerged involves the identification of a neural circuit in the amygdala, and the cellular mechanisms within this circuit, that give rise to anxiety. Through a series of experiments in mice, researchers have identified this circuit within the central amygdala as critical to the emergence of anxiety and have begun to elucidate the role of dynorphin in reducing inhibition of somatostatin-expressing (SOM+) neurons in the central amygdala. This work has begun to reveal the potential role of dynorphin in the aberrant functioning of these neurons within the central amygdala circuit as well as the role of these SOM+ neurons' aberrant activation in the experience of anxiety. An increased understanding of these circuits is likely to inform the treatment potential of dynorphin inhibition for anxiety in humans.

Future research in humans will benefit from continued fine-tuning of intermediate phenotypes for anxiety disorders, yielding a more refined clinical categorization of disorders that will facilitate translational research. During the last two decades, a growing number of studies have investigated target-selective agents to enhance the benefits of exposure-based or other forms of psychotherapy. Mechanistically novel compounds targeting glutamate, neuropeptide, and endocannabinoid systems are already under development and will continue to be tested in clinical trials. In addition to the neurochemical systems reviewed in this chapter, potentially promising avenues for future research include the neurotrophin, renin–angiotensin, and acetylcholine systems, as well as the immune system, among others. Finally, a new wave of studies in humans that integrates neural circuitry data with burgeoning work in psychiatric genomics promises to expand the current understanding of anxiety disorders. This work is likely to yield novel and more specific biomarkers of anxiety disorders that can lead to more tailored treatment interventions for these highly common and debilitating mental disorders.

14.5 Neuroimaging and the Neuroanatomical Circuits Implicated in Anxiety Disorders

Elizabeth R. Kitt, M.S., M.Phil., Emily M. Cohodes, M.S., M.Phil., and Dylan G. Gee, Ph.D.

Convergent advances in techniques for examining the biological correlates of emotional behavior in animals (i.e., neurophysiological, lesion, and molecular techniques) and fear and anxiety in humans (i.e., neuropharmacological and neuroimaging approaches) have exponentially improved understanding of the neuroanatomical, cellular, and molecular correlates of fear and anxiety. By capitalizing on the unique advantages of these two streams of knowledge, prior research has elucidated the neural circuitry involved in adaptive fear and anxiety. Building off this foundation, a growing body of research has begun to explicate how dysfunction in these circuits may contribute to maladaptive anxiety in the form of anxiety disorders. Embedded in this research is a growing understanding of the neurodevelopmental processes that may contribute to risk for pediatric anxiety disorders.

Originally extrapolated from fear-conditioning research in animals, prevailing models of neural circuitry underlying anxiety disorders in humans may now be directly examined through advances in techniques of in vivo human imaging. These models emphasize interactions within limbic circuitry (especially the prefrontal and sensory cortical regions), the amygdala, hippocampus, hypothalamus, bed nucleus of stria terminalis (BNST), and periaqueductal gray (PAG). This section reviews prevailing models of neuroanatomical circuits implicated in fear and stress-related disorders. Through an emphasis on human neuroimaging studies, this section further demonstrates how modern human neuroimaging approaches provide essential insight into the development and dysfunction of neural circuitry underlying these disorders.

BRIDGING FROM PHENOMENOLOGY TO NEUROCIRCUITRY

Characterizing the neural circuitry underlying anxiety disorders involves a series of stepwise progressions in understanding that ultimately bridge knowledge about phenomenology with growing insight into abnormalities in neurocircuitry. Specifically, previous work has identified neural circuitry underlying these disorders by: (1) examining the phenomenology of the disorder to identify functional domains that appear to be affected; (2) establishing the mediating anatomy of these functional domains in unaffected individuals; (3) investigating whether abnormalities exist at nodes within those circuits in individuals with the disorder; and, finally, (4) demonstrating associations between such abnormalities and the clinical features of the disorder. In the context of anxiety disorders, several key functional domains have emerged, including persistent or enduring learning about threat-related stimuli, exaggerated fear responses, impaired extinction learning or retention, difficulty suppressing attention and emotional and/or behavioral responses to disorder-relevant stimuli, overgeneralization of possible threat, perceptual hypersensitivity to threat-related stimuli, and heightened anxiety sensitivity. These functional domains and their associated neural circuitry will be discussed in detail in the following sections of this chapter.

In general, two parallel lines of research have proved particularly valuable for this process of investigating the neural circuitry involved in anxiety disorders. First, classic fear conditioning paradigms used in both animal studies and neuroimaging studies of humans without psychiatric disorders have elucidated the neuroanatomical circuits mediating anxiety, fear, and stress. Second, neuroimaging studies of individuals with anxiety disorders have begun to provide convergent evidence suggesting how these mediating neuroanatomical circuits are altered in the context of these disorders.

PRECLINICAL STUDIES OF FEAR LEARNING

Capitalizing on the large degree of cross-species conservation in the neural circuitry underlying fear learning, preclinical work in animals has laid the foundation for the design and interpretation of functional imaging studies of fear and anxiety in humans. Preclinical work in this area has

commonly examined the anatomical correlates of fear learning in the context of Pavlovian fear conditioning, fear-potentiated startle (FPS), and other theoretically anxiety-related paradigms, such as the open field paradigm, most typically in rodents.

Classic fear conditioning paradigms present a highly influential and pertinent example through which to discuss the impact of preclinical work on our understanding of neurocircuitry implicated in anxiety, fear, and stress-related disorders. In these paradigms, an animal is exposed to a sequence of intrinsically neutral sensory stimuli (e.g., auditory tones). These stimuli are conditioned over the course of numerous trials, with one of these stimuli paired with an inherently aversive stimulus called the unconditioned stimulus (UCS) (e.g., a shock), and others presented without the UCS. The conditioned stimulus (CS) that is associated with the UCS is referred to as the CS+, whereas the CS that is presented without the shock is referred to as the CS-. Following conditioning via repeated exposure to these stimuli, exposure to the CS+ alone (i.e., without the UCS) provokes defensive behaviors or actions that otherwise suggest preparation for an expected aversive event. These behaviors, such as increased startle or freezing in rodents, resemble expected behaviors associated with fear and anxiety.

Some research paradigms follow this fear conditioning with extinction learning. In extinction paradigms, a sequence of CS+ stimuli is presented without an accompanying UCS, thus suggesting that the CS+ no longer predicts the UCS. After a temporal delay (e.g., the following day), the animal's response to the CS+ is investigated as an indicator of the retention of this extinction learning. Previously extinguished fears may return due to a variety of reasons. Importantly, extinction does not erase the memory of the original pairing between the CS+ and the UCS; rather, extinction leads to the creation and bolstering of a competing safety memory. Thus, previously extinguished fears can return due to the competition between the new learning with the original fear memory. In addition, the fear response can return following the presentation of unsignaled UCS (i.e., *reinstatement*) or following the passage of time or presentation of the CS+ after extinction (i.e., *spontaneous recovery*).

Paradigms that investigate contextual fear learning offer particular relevance for the phenomenology of situation-specific anxiety. For instance, the initial fear conditioning might occur in a specific context (Cx+; e.g., a chamber with particular features) and the extinction learning

in a different context (Cx−; e.g., a different chamber). In this circumstance, testing the day after extinction training reveals differential extinction retention depending on the context of the testing trials. Specifically, extinction learning is typically preferentially exhibited in the Cx− (the extinction context), whereas the conditioned fear response is typically larger in the Cx+ (the conditioning context).

Expanding upon prior work in classic extinction, recent work has examined the role of memory reconsolidation in the reduction of fear. When memories are retrieved, they return to a labile state before they restabilize. Memory reconsolidation rests on this dynamic state of memories; recalling a memory and thereby making it modifiable allows for updating this memory with new information. In the process of memory reconsolidation, extinction thus occurs within a specific temporal window of reconsolidation starting approximately 10 minutes after retrieval and continuing for at least 1 hour. In contrast to classic extinction, in which the new extinction memory competes with the original fear memory, memory reconsolidation involves updating the original fear memory such that the old fear response is no longer expressed.

Findings from preclinical studies of fear learning have important implications for the nature and treatment of anxiety disorders in humans. Individuals with anxiety disorders may show perturbations in functional domains linked with fear learning and extinctions, such as heightened learned-fear responses, limited extinction learning or retention of extinction memories, or limited recognition of safe contexts. Furthermore, this work has important implications for treatment. Exposure-based behavioral therapies for anxiety disorders explicitly build on the principles of fear extinction. Moreover, the effectiveness of behavioral therapies and interventions may rely on extinction learning, retention, and generalization across contexts.

ANATOMICAL CORRELATES OF FEAR AND ANXIETY

Preclinical studies have afforded the mapping of neural circuits that support core functions implicated in the emotional states of fear and anxiety (Fig. 14.5–1). Emotional processing can be divided into four components: evaluation, expression, experience, and modulation. *Emotional evaluation* involves assessing a stimulus's valence (e.g., positive or negative) and its relation to prior experiences and

environmental contexts in which the stimulus occurs. *Emotional expression* comprises the array of behavioral, endocrine, and autonomic manifestations of the emotional response. *Emotional experience* conveys the subjective feeling accompanying the response. Importantly, this subjective experience has primarily been addressed in humans due to their capacity to verbally describe their emotional experiences. Each of these components of emotional processing is *modulated* by complex neurobiological systems that prevent emotional responses from becoming persistent, excessive, or maladaptive.

Fear Circuitry

In general, the anatomical systems underlying fear are organized to permit both rapid responses to basic perceptual elements of potentially threatening stimuli and longer latency responses to more complex sensory stimuli and environmental contexts. The amygdala plays a critical role in fear learning, including the formation of learned-fear associations and the organization of fear responses. The amygdala responds to the inherently emotionally salient UCS and, in a learning-dependent manner, to the CS that predicts the UCS.

The amygdala is comprised of numerous subnuclei, collectively referred to as the amygdaloid complex, each of which serves a distinct function. The lateral nucleus of the amygdala (LA) acts as the primary sensory interface of the amygdala, receiving sensory information from the thalamus and cortex. Single neurons within the LA respond to auditory, visual, and somatic stimuli, with information about the CS and UCS within these domains converging in the LA, whereas neurons in the cortical and medial nuclei of the amygdala respond to olfactory stimuli via direct projections from the olfactory bulb. By bypassing cortical processing, the projections from the sensory thalamus to the LA are posited to support rapid conditioning to simple auditory or visual stimuli, thus permitting unconscious fear responses. In line with this theory, lesions in the auditory cortex do not prevent conditioning to single auditory tones. Conversely, projections from the primary sensory and sensory association cortices to the LA may be critical for aspects of conditioned responding to increasingly complex sensory stimuli. These relations are domain-specific (e.g., disruption of the projections from the auditory thalamus and cortex to LA specifically impedes fear conditioning to auditory stimuli and learned-fear responses to previously conditioned auditory stimuli).

After sensory input enters the LA, the neural representation of the stimulus is distributed in parallel to other amygdaloid nuclei, where it is modulated by numerous diverse functional systems. The most extensive amygdalar projections of the LA include reciprocal projections to the basal (BA) and accessory basal nuclei, as well as the central nucleus of the amygdala (CE). The direct projection from LA to CE may be sufficient to mediate conditioning to simple sensory stimuli, as lesions to either the LA or CE (but not other amygdalar nuclei) inhibit fear conditioning to a tone CS. Projections from LA to BA are also involved in forming long-term memory traces for fear conditioning. Functional inactivation of the LA and BA prior to Pavlovian fear conditioning interferes with learning, whereas inactivation immediately following conditioning does not affect memory consolidation. The BA nuclei have widespread intranuclear connections and also project to other amygdalar nuclei, including the LA and CE. The BA nuclei may also modulate neuronal responses of both the prefrontal cortex (PFC) and the LA and CE via their extensive reciprocal projections with the orbital and medial PFC.

FIGURE 14.5–1. Neuroanatomical circuitry underlying fear and anxiety, organized by systems that evaluate the salience of potentially threatening stimuli (to the left) and systems that organize and mediate the expression of fear and anxiety behaviors (to the right). BNST, bed nucleus of the stria terminalis; OFC, orbitofrontal cortex; PVN, paraventricular nucleus. (Reproduced with permission from Charney DS, Drevets WC. The neurobiological basis of anxiety disorders. In: Davis K, Charney DS, Coyle J, Nemeroff CB, eds. *Neuropsychopharmacology. The Fifth Generation of Progress*. Lippincott Williams & Wilkins; 2002:901.)

Both the amygdala and cortical areas are implicated in plasticity-related fear learning. Rapid conditioning of fear responses to potentially dangerous stimuli depends on amygdala plasticity, which involves long-term potentiation. Conversely, learning involving higher cognitive (i.e., attentional or mnemonic) processing of fear experiences may rely on cortical neuronal plasticity, which is influenced by the amygdala. Cortical regions are believed to establish explicit or declarative memories about the fear-related event through interactions with the medial temporal lobe memory system. The amygdala appears to influence cortex-based memories via late plastic components of the auditory cortex neuronal responses to a CS. Single-unit recording during fear conditioning has indicated that some auditory cortex neurons develop late-conditioned responses (i.e., the conditioned response does not develop until 500 to

1,500 ms after CS onset) that are resistant to extinction. These late-conditioned auditory cortical neurons take more trials to show a conditioned response and respond more slowly than LA neurons within trials. Furthermore, amygdala lesions prevent these late-developed conditioned responses.

By contrast, other auditory cortex neurons show early (i.e., less than 50 ms after CS onset) plasticity during fear conditioning. This short-latency plasticity involves the conditioning-based enhancement of pre-existing electrophysiological responses of auditory cortex neurons to the CS and appears to rely on input from the auditory thalamus. Furthermore, this early response is not affected by amygdala lesions; however, the amygdala appears to be involved in preventing the extinction of these early responses, as they are extinguished more quickly in animals with amygdala lesions.

Neural Circuitry Underlying Fear Expression

The amygdaloid output nuclei, particularly the CE, receive convergent input from multiple amygdala regions and organize behavioral responses in line with the sum of the neuronal activity produced by multiple amygdala nuclei. Through CE projections to nuclei in the medulla, midbrain, and hypothalamus, the CE serves as the interface between the amygdala and the motor, behavioral, autonomic, and neuroendocrine system responses involved in fear. For example, the amygdala facilitates the release of stress-related corticotropin-releasing hormone (CRH) through intrinsic CRH-containing neurons within the amygdala and bisynaptic (double GABAergic [GABA, γ-aminobutyric acid]) projections to the paraventricular nucleus of the hypothalamus (PVN; the location of the majority of CRH-synthesizing neurons in the hypothalamus). Stimulation of the CE results in responses similar to those elicited by fear-conditioned stimuli, and lesions of the CE prevent the expression of several types of fear responses. In contrast, lesioning of specific structures efferent to the CE (e.g., the lateral hypothalamus or PAG) results in selective deficits in behavioral fear responses (e.g., cardiovascular or somatobehavioral, respectively). The amygdala also projects to regions involved in the organization of motor responses to threatening stimuli, such as the thalamus, nucleus accumbens, ventromedial caudate, and ventral putamen. Moreover, the amygdala may further impact motor behavior via projections to the hypothalamus and PAG.

Both the CE and BNST can directly activate structures in the hypothalamus and brainstem that mediate the expression of emotional behavior. In particular, the BNST has been implicated in sustained states of anxiety, and anxiety-like responses elicited by exposure to a threatening environment for several minutes or by intraventricular administration of CRH are specifically mediated via the BNST rather than the CE. Given these data, this system is hypothesized to be involved in mediating anxiety during exposure to less explicit or less-well-defined sensory cues and/or contexts that occur over a longer duration.

Fear Regulation Circuitry

Multiple areas of the medial and orbital PFC are involved in modulating anxiety and other emotional responses. These areas are posited to play a role in the interpretation of the higher-order significance of experiential stimuli, the modification of behavioral responses based on reinforcement contingencies, and the prediction of social outcomes of behavioral responses to emotional events. The amygdala modulates PFC neuronal activity, and the PFC modulates amygdala-mediated responses to emotionally salient stimuli through extensive reciprocal projections. Through input to the BA and the intercalated cells (a group of GABAergic neurons that regulate input from the BA to the CE), the mPFC further regulates amygdala output.

Areas of the mPFC implicated in anxiety and fear-related behavior include the infralimbic cortex (IL), prelimbic cortex, anterior cingulate cortex (ACC), and an anterior region extending from the rostral ACC (BA 24, 32) toward the frontal pole. Current theory suggests that reciprocal projections between the amygdala and mPFC play a critical role in reducing fear responses and extinguishing behavioral fear-conditioned responses that are no longer reinforced. In rats, lesions of the ACC result in enhanced freezing behavior in response to a fear-conditioned tone, thus suggesting that this region is involved in fear reduction. Additionally, neurons in the rat prelimbic cortex show reduced spontaneous firing in the presence of a fear-conditioned, aversive tone. This reduction is inversely proportional to the magnitude of the rat's fear and negatively correlated with increases in amygdala neuronal activity. Projections from the prelimbic cortex (posited to correspond to the dorsal ACC in humans) to the amygdala have also been shown to increase the magnitude of fear responses to fear-conditioned stimuli (Fig. 14.5–2). Furthermore, lesions

of the IL (believed to correspond to the ventromedial PFC [vmPFC] in humans) specifically interfere with extinction recall following long delays between extinction learning and re-exposure to the original CS.

FIGURE 14.5–2. Neural circuitry of fear expression and extinction. **(A)** During acquisition and expression of conditioned fear, projections from PL and thalamic nuclei (mediating converging sensory information) excited LA neurons, while hippocampal projections (mediating contextual inputs) lead to extinction of BA neurons directly or indirectly via connections with PL. LA and BA neurons activate CE output neurons, which project to downstream brainstem and hypothalamic nuclei responsible for mediating physiologic responses, resulting in fear expression. **(B)** During extinction of conditioned fear, hippocampal projections (mediating contextual inputs) lead to divergent excitation of IL neurons and inhibition of BA neurons. IL projections directly activate GABAergic ITC cells within the amygdala. Integration of ITC, BA, and LA inputs during extinction results in a suppression of CE output neurons, resulting in a lack of physiologic response and suppression of fear expression. Arrowheads delineate pathway excitation; straight ends delineate pathway inhibition. *For simplicity, connection arrows are delineated as being unidirectional, although bidirectional projections exist. (Reproduced from Pattwell SS, Lee FS, Casey BJ: Fear learning and memory across adolescent development: Hormones and Behavior Special Issue: Puberty and Adolescence. *Horm Behav.* 2013;64(2):380–389. Copyright © 2013, with permission from Elsevier. doi:10.1016/j.yhbeh.2013.01.016.)

In humans, the areas of the ACC located anterior to the genu of the corpus callosum (i.e., the pregenual ACC [pgACC]) show elevated hemodynamic activity during elicited anxiety states, both in healthy participants and in participants with anxiety disorders. Electrical stimulation of this area is associated with vocalization in animals and a sense of fear, panic, or foreboding in humans. The subgenual ACC (sgACC) has been implicated in adaptive sadness, major depressive

disorder (MDD), bipolar disorder, PTSD, and GAD. Specifically, patients with GAD show reduced gray matter volume compared to healthy controls.

Both the sgACC and pgACC have reciprocal projections with areas involved in emotional behavior, including the amygdala, hypothalamus, nucleus accumbens, posterior orbitofrontal cortex (OFC), PAG, VTA, raphe, locus coeruleus (LC), and nucleus tractus solitarius. In humans, lesions of the mPFC that include the pgACC and sgACC are associated with atypical automatic responses to emotionally provocative stimuli, inability to experience emotion related to concepts, and failure to use probabilistic information regarding possible aversive or rewarding social consequences to direct social behavior. In rats, lesions of the vmPFC (including IL, prelimbic, and ACC cortices) affect corticosterone secretion, sympathetic autonomic responses, and gastric stress pathology during restraint stress or exposure to fear-conditioned stimuli. Furthermore, stimulation of GC receptors in the rat ACC inhibits the release of stress-induced corticosterone.

In addition to these regions, more anterior mPFC areas are also implicated in emotional responses and evaluations in healthy humans. When anticipating an electrical shock, healthy humans show cerebral blood flow (CBF) increases in the rostral mPFC (near anterior BA 24, BA 32, and rostral BA 9). The magnitude of the change in CBF is inversely correlated with changes in anxiety ratings and heart rate. In addition, rats show exaggerated heart rate responses to fear-conditioned stimuli following lesions of the rostral mPFC, and stimulation of this region in rats reduces defensive behavior and cardiovascular responses induced by amygdala stimulation. In primates, the amygdala shares extensive reciprocal connections with BA 24 and 32; however, it shares only sparse connections with BA 9 cortex. Nevertheless, all three areas send extensive efferent projections to the PAG and hypothalamus, and these projections may modulate cardiovascular responses implicated in emotional behavior.

Role of the Hippocampus and Other Structures in Contextual Fear

The development of emotional responses to the environment involves interactions of the amygdala with the hippocampus, perirhinal cortex, ventrolateral PFC (vlPFC), and anterior insula. Projections from the hippocampal formation to the amygdala via the fornix are involved in

spatial contextual conditioning. For instance, lesions affecting these projections specifically inhibit fear conditioning to the context (i.e., particular chamber or location within a maze) in which fear conditioning previously occurred. By supplying contextual information about the degree of threat or safety in the environment, the hippocampus modulates frontoamygdala function and influences whether the original fear memory or extinction memory is expressed. This modulation of frontoamygdala function relies on projections from the ventral hippocampus to the BA, which can further modulate subsequent fear responses via projections to the CE. Moreover, connections between the ventral hippocampus and the vmPFC (or IL in rodents) modulate extinction learning using contextual cues in the surrounding environment. For example, inactivation of the hippocampus prior to extinction training results in impaired retrieval of cued extinction memories. In these ways, hippocampally mediated control of frontoamygdala connections enhances an organism's flexibility to respond to potentially dangerous stimuli in a manner appropriate to the current environment. Building off this foundation, recent work has suggested an increasingly central role of the hippocampus in the consolidation of contextual fear memories. Recent evidence suggests that contextual fear memories may be consolidated and maintained by both the amygdala and hippocampus, in contrast to the previous model of single contextual representations from the hippocampus unidirectionally influencing the associative contextual memory in the amygdala. While this model requires future investigation, it speaks to the important role of the hippocampus in contextual fear learning.

The perirhinal cortex shares reciprocal projections with the amygdala and is theoretically implicated in conveying information about complex visual stimuli to the amygdala during the presentation of fear-conditioned visual stimuli. Lesions of the anterior perirhinal cortex, basolateral nucleus of the amygdala, or CE can completely eradicate the behavioral fear response (e.g., FPS) during exposure to some conditioned visual stimuli. Conversely, removal of the visual cortex, insular cortex, mPFC, and posterior perirhinal cortex does not affect the magnitude of FPS, and lesions of the frontal lobe only partially diminish FPS. Lesions of the lateral geniculate nucleus, which sends input regarding conditioned visual stimuli to the perirhinal cortex, can also inhibit FPS. Finally, the anterior perirhinal cortex receives afferent projections from structures implicated in modulating behavioral responses to fear-conditioned stimuli, such as the

visual cortices and the ACC, infralimbic cortex, and parietal cortex. Lesions placed in the anterior perirhinal cortex following fear conditioning impede the expression of conditioned fear responses elicited by visual and auditory stimuli in contexts that differ from the original conditioning contexts. In contrast, lesions of the vlPFC and anterior insula do not affect conditioned learning or response extinction but do reduce fear reactivity to contextual stimuli.

The temporopolar cortex is theorized to play a role in modulating autonomic aspects of emotional responses and in processing emotionally provocative visual stimuli. Electrical stimulation of sites within the temporopolar cortex can affect a range of autonomic nervous system functions. In humans, exposure to emotionally provocative stimuli (whether sad, disgusting, or happy) is associated with increased neurophysiological activity in the anterior temporopolar cortex compared to exposure to neutral visual stimuli or to elicitation of emotional states via recall of autobiographical information. In this manner, areas within the temporopolar cortex may function as sensory association areas involved in evaluating the emotional salience of actual or anticipated stimuli and in modulating autonomic responses to such stimuli.

Emotion Processing and Other Related Circuitry

In both humans and nonhuman primates, other areas implicated in fear and anxiety include the posterior and lateral OFC, anterior insula, and vlPFC. Experimentally induced anxiety is associated with increased physiological activity in these regions in healthy human participants and participants with specific phobia or panic disorder (PD). The relation of physiological activity in the OFC and vlPFC with anxiety symptoms is complex. Specifically, CBF increases in the posterior OFC are observed in participants with animal phobias during exposure to phobic stimuli and in healthy participants with induced sadness; however, this change in CBF is inversely correlated with changes in anxiety.

Consistent with these findings, electrophysiological and lesion studies have demonstrated the role of the OFC in modulating fearful, defensive, and reward-directed behavioral and visceral responses in line with changing reinforcement contingencies. During the delay between stimulus and response, nearly one-half of OFC pyramidal neurons alter their firing rates in relation to the presence or absence of reinforcement. These cells are posited to be involved in extinguishing unreinforced responses to

appetitive or aversive stimuli. Furthermore, the posterior and lateral OFC and amygdala modulate each other's neural transmission through projections with each other and with overlapping areas within the striatum, hypothalamus, and PAG. For example, concurrent stimulation of OFC sites and the amygdala reduce or eliminate the behavioral and cardiovascular responses associated with stimulation of the amygdala; however, stimulation of OFC sites on their own does not produce these effects.

In humans, OFC lesions are associated with impaired performance on tasks that require the use of reward- or punishment-related information, continued use of unreinforced behavioral strategies, and difficulty switching intellectual strategies in response to changing task demands. Similarly, in monkeys, surgical lateral OFC/vlPFC lesions are associated with difficulty learning to inhibit prepotent responses to nonreinforced stimuli in response to changing reinforcement contingencies, a phenomenon known as "perseverative interference." These lesion data suggest that the OFC activation seen during normative anxiety or obsessional states may reflect endogenous attempts to attenuate emotional expression or to interrupt unreinforced aversive thoughts or emotions. In contrast, dysfunction of the OFC may impair one's ability to inhibit nonreinforced or maladaptive emotional, cognitive, and behavioral responses to social interactions and sensory or visceral stimuli and thus contribute to pathological anxiety and obsessional states.

Areas within the posterior cingulate cortex, including the retrosplenial cortex, show increased CBF in response to various types of aversive stimuli. The retrosplenial cortex, in particular, is believed to play a role in both cue-specific and contextual learning and memory. The posterior cingulate cortex is believed to function as a sensory association cortex that processes the affective salience of experiential stimuli. The posterior cingulate cortex then relays information to limbic circuitry through a major projection to the ACC.

Medial cerebellar activity shows increased activation in both healthy participants undergoing experimental anxiety or sadness inductions and in participants with anxiety disorders. A meta-analysis investigating the anatomical correlates of multiple types of anxiety across positron emission tomography (PET) studies identified the medial cerebellum and midbrain (near the PAG) as regions in which CBF increased across all normal and pathologic anxiety states studied. The medial cerebellum contains nuclei

that functionally complement the hypothalamus in the modulation of autonomic responses. In addition, most or all regions within the cerebral cortex form closed, multisynaptic circuits through the cerebellum, although the functional significance of these anatomical loops remains unclear.

Anxiety- and fear-related changes in regional physiological activity in other structures have been less reliably replicated. Several studies have reported anxiety-related CBF changes in the ventral striatum or the lateral temporal and inferior parietal cortical areas. These areas serve as sensory association cortices, and anxiety-related physiological activity in these regions may reflect sensory processing of anxiety-provoking stimuli or feedback to these regions from the amygdala or other subcortical regions.

Role of the Amygdala in Biologically Relevant Learning and Emotional Memory

In addition to its role in fear conditioning, evidence suggests the amygdala more broadly facilitates biologically relevant learning, including responding to aversive and appetitive CS, uncertainty, associability, violations of expectations, innate fear, processing affective elements of social interactions, and nonspecific attention and arousal that facilitates learning. In the context of social dominance hierarchies, monkeys with amygdala lesions tend to become more submissive to dominant conspecifics and to show attenuated aggression and fear. These amygdala-lesioned monkeys also appear not to recognize socially significant signals in the behavior or facial expressions of other monkeys and, ostensibly as a consequence, are generally killed by other monkeys in natural setting primate colonies. In humans, the amygdala has been found to play a role in evaluating social behavior (specifically, the emotional information conveyed by human facial expression or voice intonation). Humans with amygdala lesions show impaired ability to recognize fear in facial expressions and both fear and anger in voice intonation. In humans without amygdala lesions, viewing faces showing emotional expressions of varying types is associated with increased amygdala activity in PET and fMRI studies. This response is automatic, with the amygdala responding even when face stimuli are presented for so little time that the participants are not explicitly aware of seeing them.

The amygdala is also involved in the recall of emotional or arousing memories. In humans, the recollection of specific emotional events has

been associated with bursts of electroencephalographic (EEG) activity in the amygdala. Furthermore, electrical stimulation of the human amygdala can evoke experiences of fear or anxiety and the recollection of emotionally arousing life events from distant memory. Amygdala activation also enhances the strength of long-term memory for emotional stimuli or contexts represented in other cortical memory circuits. These circuits are posited to involve the medial temporal lobe memory system, which shares extensive projections with the amygdala that support interactions between storage and explicit recall of emotionally salient memories. Moreover, acquisition of fear-conditioned responses requires an intact central noradrenergic system, as memory consolidation is critically dependent on noradrenergic stimulation of β- and α-1-adrenoreceptors in the basolateral nucleus of the amygdala for at least some form of emotional learning. Notably, glucocorticoid (GC) hormone effects on noradrenergic neurons facilitate the activation of norepinephrine release during emotional learning.

Structures Mediating Endocrine and Autonomic Responses of Fear or Stress

The generation of adaptive responses to threat or stress is facilitated by the peripheral hormonal and autonomic responses to threat mediated by the hypothalamic–pituitary–adrenal (HPA) axis and the sympathetic and parasympathetic autonomic nervous systems. Cardiovascular and endocrine responses to threat and stress are modulated by projections from the ACC, anterior insula, and posterior OFC to the hypothalamus. Stimulation of the lateral nucleus of the hypothalamus via afferent projections from the CE, BNST, or ventral striatum activates the sympathetic nervous system, thereby producing increases in blood pressure and heart rate, sweating, piloerection, and pupillary dilation. During stress, the secretion of CRH from the PVN of the hypothalamus results in increased peripheral adrenocorticotropic hormone (ACTH) levels, which in turn stimulates the adrenal glands to secrete cortisol, the so-called “stress hormone.”

Regional differences in the regulation of CRH function by GC-receptor stimulation and stress appear to play important roles in the mediation of fear and anxiety. Feedback inhibition of CRH release by GC-receptor stimulation (i.e., suppressing HPA-axis activity) occurs at the level of the PVN and anterior pituitary. Specifically, systematically administered GC

hormones reduce CRH release in the PVN and CRH-receptor expression in the anterior pituitary. Conversely, administered GC hormones can increase CRH mRNA expression within the CE and BNST. Ultimately, this positive feedback of GC hormones on extrahypothalamic CRH function in the amygdala and the BNST may amplify stress responses.

The innervation of the parasympathetic nervous system through afferent projections from limbic structures is thought to mediate visceral symptoms associated with anxiety, such as alterations in cardiovascular, gastrointestinal, and genitourinary function. The major efferent projections of the parasympathetic nervous system to the viscera include the vagus and splanchnic nerves. The vagal nuclei receive afferent projections from the lateral hypothalamus, PVN, LC, amygdala, and infralimbic cortex, whereas the splanchnic nerves receive afferent connections from the LC.

Regions within the orbital and medial PFC are also implicated in the modulation of peripheral responses to stress, including heart rate, blood pressure, and secretion of GC hormones. In turn, neuronal activity within these areas of the PFC is modulated by an array of neurotransmitter systems that are activated in response to threats and stressors. For instance, by modulating neuronal activity in the PFC, the noradrenergic, dopaminergic, and serotonergic systems are involved in enhancing vigilance, regulating goal-directed behavior, and facilitating decision-making involving probabilities of rewarding versus aversive outcomes.

OVERVIEW OF NEUROIMAGING TECHNOLOGY

Structural Neuroimaging Techniques

Using structural imaging techniques, experimenters have examined regional size, shape, and tissue composition of brain regions and have investigated how these features relate to clinical symptoms in individuals with anxiety and stress-related disorders. Volumetric magnetic resonance imaging (vMRI) enables investigators to obtain indices of size or features of shape from high-resolution structural MRI data using automated or semiautomated segmentation of brain regions of interest. This approach capitalizes on techniques for parcellating cortical sub-regions, automated procedures for measuring cortical thickness, and voxel-based morphometry (VBM), which is an automated method for identifying voxels where structural differences can be inferred based on signal intensity differences in structural MRI scans. Furthermore, diffusion tensor imaging

(DTI) enables experimenters to index regularity and myelination of white matter tracts based on the degree of anisotropic diffusion (fractional anisotropy; FA).

Functional Neuroimaging Techniques and Paradigms

A variety of functional neuroimaging techniques and experimental paradigms have been developed to delineate the neurophysiological correlates of normal brain functions and the pathophysiological correlates of psychiatric disorders. One such technique is PET scans, which can be conducted with tracers to measure regional cerebral blood flow (rCBF) or glucose metabolism. Another popular method is fMRI, which is used to measure blood oxygenation level–dependent (BOLD) signal changes. Furthermore, EEG and magnetoencephalography (MEG) measure changes in electrical potentials and the external magnetic field, respectively, generated by brain activity. Importantly, these profiles of brain activity are sensitive to the cognitive-behavioral state of the individual at the time of tracer distribution or image acquisition.

Experimental paradigms capitalize on this sensitivity through a variety of state manipulations, and they may rely on an array of possible principal statistical comparisons to probe specific questions. In *neutral state* paradigms, participants are scanned while performing a nonspecific continuous task or during a nominal “resting” state. These paradigms thus support testing of hypotheses regarding between-group differences that do not particularly consider momentary state variables.

In *symptom provocation* paradigms, participants are scanned during both a symptomatic state (i.e., following the induction or exacerbation of symptoms) and during a control condition. Symptoms may be provoked using either behavioral or pharmacological challenges, or experiments may be designed to capture spontaneously occurring symptomatic states without additional provocation. These paradigms support testing of within-group hypotheses regarding the mediating anatomy of the symptomatic state, as well as group-by-condition interactions probing differential responses in patient versus control groups.

In *cognitive/behavioral activation* paradigms, participants are scanned while performing specially designed cognitive/behavioral tasks that activate particular brain systems of interest, thus increasing sensitivity and specificity. As in symptom provocation paradigms, both within-group analyses and group-by-condition interactions may be used to establish the

mediating anatomy of functional domains of interest and to compare the functional responsivity or integrity of target brain systems in patient versus control groups, respectively.

Each of these types of paradigms may be used in longitudinal studies. In *developmental* studies, longitudinal designs are used to examine brain measures across childhood and adolescence in individuals with or at risk for a disorder of interest. In *treatment* studies, participants are scanned before and after receiving treatment. Within-group analyses are then used to examine changes in brain activity profiles that are associated with symptom improvement. Such analyses may inform the mechanisms underlying effective treatment. Additional analyses of pre-treatment data may further identify pretreatment brain activity characteristics that predict response to treatment.

HUMAN NEUROIMAGING STUDIES OF FEAR CONDITIONING AND EXTINCTION

In line with findings from experimental animals, a growing body of neuroimaging studies in healthy humans has investigated the functional anatomy associated with conditioned fear learning, extinction, and extinction retention. In addition to neuroimaging techniques, these studies often use peripheral physiological endpoints (e.g., skin conductance) as indices of conditioned fear in the pursuit of identifying patterns of functional activation and connectivity associated with fear conditioning.

Many studies have demonstrated increased amygdala activation to the CS+ compared to the CS− during fear conditioning and have shown that amygdala activation during acquisition correlates with the conditioned fear response. Studies have also found activation of the vmPFC (particularly the pgACC) and vmPFC-amygdala connectivity, especially during extinction. For example, during testing of extinction following a 24-hour delay, vmPFC activation predicted extinction learning retention and correlated with amygdala activation. This finding is consistent with preclinical work indicating that the IL inhibits amygdala response during extinction recall. In a separate study, cortical thickness at a specific prefrontal location within medial OFC directly correlated with the magnitude of extinction recall in humans. In contrast, human neuroimaging studies have suggested that memory reconsolidation is

primarily mediated by the amygdala and may not rely on prefrontal engagement.

Human neuroimaging studies and lesion studies have supported the role of the hippocampus in contextual learning. Neuroimaging techniques have demonstrated activation of the hippocampus during contextual conditioning and in context-dependent extinction retention. Furthermore, consistent with work in experimental animals, humans with hippocampal lesions show impairment in contextually mediated reinstatement of extinguished fear.

In summary, these data implicate the amygdala, vmPFC, and hippocampus in human fear conditioning and extinction. By demonstrating the neural substrates of these functions in healthy humans, this research provides important tools for examining the functional anatomy underlying anxiety- and stress-related disorders.

COGNITIVE AND EMOTIONAL ACTIVATION PROBES

Human neuroimaging paradigms have employed cognitive and emotional components to study emotion processing, anxiety, and the neural circuitry hypothesized to underly anxiety and stress-related disorders. Most commonly, these paradigms employ pictures of emotionally valenced visual stimuli, such as emotionally expressive human faces. Given humans' vast experience with emotional facial expressions and the reinforcement provided by the information obtained about the environment through emotionally expressive faces, facial expressions of emotions can be conceptualized as conditioned stimuli.

Passive viewing of human face stimuli has been found to reliably evoke amygdala activation. The amygdala responds to fearful, happy, neutral, and angry faces; however, it appears to have a greater response to fearful faces. Some studies have suggested that the amygdala may "preferentially" respond to fearful faces in part because fearful faces predict uncertainty (i.e., increased probability of threat of unknown nature or location, as opposed to the direct threat entailed by angry faces). In line with its reactivity to uncertainty, the amygdala also shows robust activation to surprised faces, which are inherently ambiguous (i.e., they could predict either a positive or negative event). Of note, both fearful and surprised faces predict a salient but unknown event, and they share common features (e.g., widened eyes).

In addition to the amygdala, numerous other brain areas (e.g., visuotemporal cortices, PFC) are implicated in the processing of face stimuli. Thus, studying the neural circuitry underlying the processing of emotional faces allows for the assessment of the extended functional anatomical networks that are recruited in the evaluation of emotional stimuli. In particular, presenting face stimuli using backward-masking techniques (i.e., the subject is not explicitly aware of seeing the masked face) provides an opportunity to dissociate automatic amygdala responses to stimuli from top-down influences related to cognitive processes. Moreover, repeated presentation of face stimuli can be used to examine profiles of amygdala response habituation. These principles have been found to extend to viewing emotionally valenced visual stimuli other than emotional faces (such as those included in the International Affective Picture System), as studies have reported robust and reliable amygdala activation to emotionally valenced versus “neutral” visual stimuli.

Given that anxiety disorders are characterized by emotional interference and negative attentional biases (i.e., difficulty suppressing attention to and redirecting attention away from threat-related stimuli), functional neuroimaging paradigms that measure these processes play a large role in the literature on anxiety disorders. The ACC is critically involved in signaling the presence of conflict. Specifically, the dorsal ACC tends to signal cognitive interference (e.g., as probed by the Counting Stroop Task), whereas the ventral ACC tends to signal emotional interference (e.g., as probed by the Emotional Counting Stroop Task). The lateral PFC, on the other hand, is more directly involved in augmenting cognitive control and mediating attentional biases.

Another domain studied using functional neuroimaging is the enhancement of long-term memory for an emotional event associated with brain activation during the event. In healthy humans, the magnitude of amygdala activation when reading stories of differing emotional valence correlated with both the negative emotional intensity and the subsequent ability to recall the content of the story. Furthermore, activation in the amygdala and hippocampus during memory encoding correlated with enhanced episodic memory for both pleasant and aversive visual stimuli. These data suggest that the role of the amygdala in modulating emotional memory may more generally depend on the degree of arousal or the behavioral salience associated with target information and not exclusively on the negative emotional intensity, as was previously believed.

Finally, given that interoceptive sensitivity can be heightened in anxiety disorders (e.g., in PD), interoceptive functioning has been explored in functional neuroimaging studies. Using tasks such as perceiving one's own heartbeat, viewing faces expressing disgust, viewing disgusting pictures, and generating internal images of disgust, neuroimaging work has implicated the insular cortex in interoceptive function.

NEUROIMAGING STUDIES OF ANXIETY DISORDERS

Extrapolating from the previously described data in experimental animal models of fear and stress, theorists have posed hypotheses regarding dysfunction in homologous structures in humans with anxiety disorders. Specifically, individuals with anxiety disorders are hypothesized to show atypical functional connectivity of the amygdala with the mPFC and/or the hippocampus that contributes to intrinsically exaggerated amygdala hyperresponsivity and/or deficient top-down modulation of the amygdala response. Fear conditioning and extinction studies have found both behavioral and neuroimaging data supporting these hypotheses for some anxiety disorders. The following sections discuss the current theories and associated evidence base within specific anxiety disorders.

Panic Disorder

Models of PD must explain both the behavioral sequelae of panic attacks (e.g., agoraphobic avoidance) and the occurrence of spontaneous panic episodes. The behavioral sequelae can putatively be explained as a product of fear learning and operant conditioning processes. Several hypotheses have emerged regarding the occurrence of spontaneous panic episodes. One hypothesis suggests that typical physiological anxiety responses mediated by anxiety/fear circuitry may be spontaneously recruited as an aberrant event due to homeostatic deficits. This hypothesis is exemplified by the "false suffocation alarm" model and theories regarding monoaminergic dysregulation. Another hypothesis holds that failures in the systems responsible for modulating normal anxiety responses lead to the escalation of what would be minor anxiety responses into excessive, maladaptive responses. Such a process might involve deficits in the hippocampus or other regions within the temporal cortex. Finally, a third hypothesis proposes that panic attacks that are described as spontaneous may, in fact, reflect fear responses to stimuli

that are implicitly processed without conscious awareness. According to this model, panic attacks might involve amygdala hyperresponsivity to subtle environmental cues, such that implicit cues can trigger full-scale fear responses. Moreover, dysfunction in hippocampal or parahippocampal regions may underlie the absence of conscious awareness, as dysfunction in these regions may allow for abnormal escalation in response to contextual stimuli that are not explicitly recognized as inherently threatening.

In general, a broad range of disparate components of neurocircuitry has been implicated in PD. Notable elements include dysregulated ascending noradrenergic and/or serotonergic systems, aberrant responsivity to panicogenic substances (e.g., CO_2) at the level of the brainstem, global cerebral abnormalities in lactate metabolism, and abnormal interactions among hippocampus, parahippocampal cortex, and amygdala.

Functional Imaging Findings in Panic Disorder. In PD, the baseline state is characterized by mild to moderate levels of chronic anxiety (i.e., “anticipatory anxiety”). The neural correlates of this clinical observation have been examined using resting-state neuroimaging, which measures brain activity in the absence of a task (i.e., while the participant is at rest). Patients with PD show altered resting-state rCBF and functional connectivity in both PET and fMRI studies. Specifically, patients show altered activation in the parahippocampal gyrus, hippocampus, and superior temporal gyrus, as well as increased ACC-precuneus functional connectivity. These findings point to distinct patterns of alterations in brain function in PD, even in the absence of symptom provocation. However, the extent to which these alterations create versus reflect patients’ chronic anxious states remains unclear.

Symptom provocation studies of PD have relied on both pharmacologic challenges and cognitive/emotional challenges to induce symptoms. SPECT and PET studies using pharmacologic challenges have had mixed results. Following pharmacologic challenge, patients who experienced induced panic attacks have been found to have global reductions in CBF, reduced rCBF in the frontal cortex, and increased rCBF in both the putamen and ACC, compared to both healthy controls and patients who did not experience induced panic attacks. Findings regarding the insula activity during panic attacks have been inconsistent, with some studies reporting reduced rCBF and others reporting increased rCBF. In addition

to pharmacologic challenges, some studies have examined patterns of rCBF in the midst of spontaneous panic attacks that have occurred during imaging. These results have been based on a small number of participants and have been mixed, with recorded responses including decreased rCBF in the right OFC, subgenual PFC, ACC, and anterior temporal cortex in one case; increased amygdala, insula, and PFC activation in another; and increased PFC activation in a third case.

Cognitive/emotional challenges (such as script-driven panic-related imagery, agoraphobic-specific pictures, and panic-related visual stimuli) have also been used to probe the neural correlates of anxiety in PD. Patients have been found to show exaggerated activation in the inferior frontal cortex, cingulate cortex, OFC, hippocampus, insula, and striatum in response to such panic-related stimuli. Other studies have used emotional stimuli that are not disorder-specific, such as emotional faces, to probe neural changes associated with PD. In general, patients have been found to show increased activation in the amygdala and insula and reduced activation in the vmPFC and ACC in response to emotional faces; however, findings have been mixed, particularly for the amygdala and ACC. Consistent with the general pattern of intolerance of uncertainty that is characteristic of anxiety disorders, patterns of increased insula activation have been found in response to unpredictable, but not predictable, aversive stimuli.

Treatment studies have begun to identify potential mechanisms and predictors of treatment response in PD. Compared to nonmedicated patients, patients undergoing pharmacologic treatment have been found to demonstrate distinct patterns of brain function and structure following symptom remission, such as increased FA in the uncinate fasciculus. Furthermore, symptom remission following cognitive behavioral therapy (CBT) has been associated with reduced IFG activation and greater functional connectivity of the IFG with the amygdala, hippocampus, mPFC, and lateral PFC. In addition to these efforts to identify mechanisms underlying effective treatment, other studies have aimed to identify predictors of treatment response. Stronger negative functional connectivity between the ACC and the amygdala at baseline has been found to predict future response to both pharmacotherapy and CBT. Taken together, these studies suggest that alterations in frontolimbic connections may underlie effective treatments for PD.

Structural Imaging Findings in Panic Disorder. Compared to healthy controls, patients with PD have been found to exhibit smaller OFC, putamen, and overall temporal lobe volumes; increased insula and brainstem volumes; and lower gray matter density in parahippocampal cortex. Furthermore, some evidence suggests that smaller amygdala volume may be negatively associated with anxiety severity in PD; however, other studies have not detected abnormal amygdala volumes in this population.

Summary. In summary, the neuroimaging data implicate abnormalities in several brain regions in PD. Data suggest that PD is associated with abnormal hippocampal/parahippocampal activity at rest, as well as reduced activity in widespread cortical regions, such as the PFC. Morphometric MRI studies have also detected abnormalities in the gray matter volume of the parahippocampal/temporal cortex. Finally, regional abnormalities within the temporal lobes provide support for theories of dysfunctional top-down influence over the amygdala via the temporal cortex and/or the hippocampus. Such abnormalities may play a role in the liability for developing PD following an initial panic attack.

Specific Phobias

Prominent models suggest that specific phobias represent the product of dysregulation in systems related to assessing potentially threatening, anxiety-provoking, or disgusting stimuli or situations. To date, neuroimaging data has begun to provide an empirical model for such neurocircuitry-based models of specific phobias. These theories initially focused on the amygdala due to its crucial role in mediating both innate and conditioned fear. However, human neuroimaging data has more directly implicated anterior paralimbic regions and sensory cortical regions known to interact with the amygdala. In light of these data, these regions have taken an increasingly central role in theories of neurocircuitry underlying specific phobias.

Functional Imaging Findings in Specific Phobias. Meta-analyses have detected consistent findings of increased insula and amygdala activation to phobic stimuli in patients with specific phobias. Furthermore, meta-analyses have reported preliminary evidence for increased activation in the ACC, OFC, thalamus, and cerebellum. The majority of

such studies of neural activation in specific phobias have relied on fMRI and PET symptom-provocation studies using phobia-related stimuli. For example, one study exposed patients with spider phobia to pictures of spiders or neutral pictures under predictable (phasic) or unpredictable (sustained) conditions. Phasic fear of phobic stimuli was associated with elevated amygdala activation, whereas sustained fear of phobic stimuli was associated with elevated BNST and ACC activation. Patients with spider phobia also showed stronger BNST-amygdala functional connectivity compared to healthy controls. These findings demonstrate the dissociation between the role of the amygdala in acute fear and the role of the BNST in sustained anxiety.

Studies using nonphobic stimuli (e.g., emotional faces) have not detected heightened amygdala activity. Thus, amygdala hyperreactivity in participants with specific phobias appears to be unique to phobic stimuli. Notably, disruptions in cortical control regions or their connectivity with limbic and paralimbic regions may underlie this hypersensitivity to fear-related cues. For instance, a study of cognitive reappraisal in spider phobia instructed participants to use specific, effortful regulation strategies (i.e., up-regulate or down-regulate) or to automatically regulate (i.e., simply look) while presented with pictures of spiders and non–spider-related aversive pictures. Compared to controls, patients with spider phobia showed reduced vmPFC activation during automatic regulation of spider versus non–spider-related aversive pictures, as well as reduced dACC/dmPFC activation during effortful regulation (down-regulate versus simply look) to spider versus non–spider-related aversive pictures.

Several studies have attempted to identify neural substrates that may be common to all specific phobias or distinct to subtypes (e.g., spider vs. blood-injection-injury). For example, patients with spider phobia and those with blood-injection-injury phobia both show faster time-to-peak in amygdala reactivity compared to healthy controls. However, spider phobia may be more related to alterations in the dACC and insula, whereas blood-injection-injury may be more related to alterations in the PFC, thalamus, and occipito–temporo–parietal regions. Furthermore, evidence suggests that increased activation in sensory association cortices corresponds to the sensory modality associated with the symptomatic state in subtypes of specific phobias. In this context, it is noteworthy to recall that the amygdala sends anatomical projections to sensory cortices, and stimulation of these projections “tunes” (i.e., facilitates) responsivity in

those areas during amygdala activity (e.g., in response to threatening stimuli).

In addition to elucidating the neurocircuitry underlying specific phobia, neuroimaging has also been used to examine potential mechanisms involved in effective treatment. A meta-analysis reported that exposure therapy for specific phobias was associated with reduced activation in the frontal cortex, limbic regions, and cerebellum. Moreover, findings from a longitudinal study of patients with spider phobia who engaged in a single exposure therapy session (3 hour or less) indicate that successful exposure therapy leads to lasting reorganization of brain responses to previously feared stimuli, such that limbic activation is normalized without the need for active prefrontal down-regulation. Prior to treatment, patients showed increased amygdala, insula, and ACC activation to phobic versus neutral stimuli. Shortly following exposure therapy, effective treatment was associated with reduced amygdala activation and increased prefrontal engagement. Six months later, participants continued to show reduced amygdala activation but in the absence of increased prefrontal engagement. Moreover, lower activation in the visual cortex shortly following the exposure therapy session predicted better treatment outcomes 6 months later.

Structural Imaging Findings in Specific Phobias. Structural MRI studies have identified several volumetric differences associated with specific phobias in general and with particular subtypes. Participants with animal phobias have been found to show increased cortical thickness in the pgACC, insular cortex, and posterior cingulate cortex. Participants with dental phobia (a subtype of blood-injury-injection phobia) have been found to show increased gray matter volume in the sgACC, insula, OFC, and PFC. Finally, participants with spider phobia have been found to show cortical thinning in the ACC, as well as reduced amygdala volume that correlates negatively with symptom severity. The specificity exhibited by these subtype-specific findings may relate to the complex neurocircuitry underlying the representation of these multifaceted categories of stimuli.

Summary. Current evidence implicates activation of anterior paralimbic regions (i.e., anterior insula) and sensory association cortices corresponding to the sensory modality associated with the symptomatic state in specific phobia. These results are consistent with a model of hypersensitivity in the system responsible for evaluation of and response

to specific threat-related cues—a system that crucially involves the amygdala. The amygdala hyperresponsivity detected in specific phobia appears to selectively occur in response to phobic-related stimuli and may relate to disrupted interactions with cortical control regions that are typically involved in emotion regulation.

Social Anxiety Disorder

Similar to specific phobia, models of social anxiety disorder (SAD) center around increased sensitivity to the potential threat of a specific type of stimuli—in this case, socially relevant stimuli. Some possibilities for this increased sensitivity involve enhanced sensitivity to social threat or scrutiny. Other hypotheses suggest that SAD may involve heightened responses to novel social stimuli compounded by a decreased reward value of positive social stimuli. The majority of research paradigms in this area have examined primary responses to social stimuli (e.g., faces) of varying valence, arousal, and novelty. In addition, in line with hypothesized models of SAD, research paradigms have probed self- versus other-focused attention.

Functional Imaging Findings in Social Anxiety Disorder. A variety of symptom provocation paradigms, including public speaking challenges and exposure to contemptuous faces, have been used to examine neural mechanisms of SAD. Such symptom provocation studies using both PET and fMRI consistently demonstrate heightened amygdala activity in patients with SAD compared to healthy controls. This elevated amygdala activity has been found to persist across conditions, such as presentation of facial expressions of both low and high intensity. Such findings suggest that the amygdala may be activated at a relatively low threshold of social stimulus in SAD. Furthermore, several studies have reported correlations between patients' amygdala activation and the severity of their social anxiety. In addition to these findings of altered amygdala function, heightened insula activation to emotional stimuli, and lower striatal activation during implicit learning have also been implicated in SAD. Preliminary evidence further suggests altered function of the OFC, ACC, mPFC, and parahippocampal gyrus. Functional connectivity analyses suggest that weaker frontolimbic connections may underlie this heightened emotional reactivity (e.g., in the amygdala and insula).

Several studies have demonstrated that patients with SAD selectively show altered neural responses to social stimuli (and not to nonsocial stimuli). For instance, hyperresponsivity of the amygdala in SAD was detected in response to exposure to human face stimuli and not to aversive odors. Moreover, patients have been found to exhibit exaggerated amygdala and mPFC activation to self-referential critical comments but not to critical comments of others or to neutral or positive comments about the self or others. This suggests that processing of self-focused criticism or judgment may be particularly altered in SAD.

Treatment studies have identified possible neural mechanisms underlying effective treatments for SAD. As compared to patients in a wait-list control condition, patients who received CBT showed a greater reduction in negative emotion and corresponding greater dlPFC and dmPFC activation and stronger negative dmPFC-amygdala connectivity during cognitive reappraisal. Patients who received CBT also exhibited earlier onset of dmPFC activation. Several studies have also examined neural predictors of treatment response in SAD. CBT response has been shown to be predicted by pretreatment activation of the PFC and amygdala, as well as amygdala-ACC functional connectivity. Specifically, patients with greater regulatory capacity over emotional reactivity to faces at baseline have been found to be more likely to benefit from treatment. Thus, highlighting the potential contributions of neuroimaging for personalized medicine, studies have found that neural measures enhance the prediction of treatment response in SAD over and above clinical measures alone.

Structural Imaging Findings in Social Anxiety Disorder. Consistent with fMRI findings of weaker amygdala-OFC functional connectivity, structural neuroimaging studies have detected lower FA in the uncinate fasciculus in SAD. Furthermore, patients with SAD have been found to show greater cortical thickness in regions including the ACC, insula, dlPFC, and parietal cortex. Other studies have found lower gray matter volume in areas such as the lateral OFC, parahippocampus, and cerebellum.

Summary. Functional neuroimaging data implicates exaggerated responsivity to social stimuli in medial temporal lobe structures, particularly the amygdala, in SAD. Furthermore, patients with SAD may show weaker frontolimbic connectivity, and changes in frontolimbic

connectivity may underlie effective treatment. These data are consistent with the theoretical model of SAD stemming from a face evaluation system that is hypersensitive to social threat or salience, perhaps in part due to weakened cortical control.

Generalized Anxiety Disorder

Models of neural mechanisms underlying generalized anxiety disorder (GAD) have emerged more recently and received relatively less attention than those of other anxiety disorders. Similar to other anxiety disorders, models of GAD include a focus on fear learning. However, satisfactory models of GAD must also account for the overgeneralization of fear that characterizes this disorder. Thus, neuroimaging studies have focused on core features of emotion dysregulation and excessive worry, as well as the overgeneralization of conditioned fear. Of note, efforts to examine neurocircuitry underlying GAD have been complicated by high rates of comorbidity with MDD and other anxiety disorders. To address this challenge, the studies presented in this section have attempted to recruit samples of “pure” GAD or to control for comorbidities by comparing patients with only GAD to those with comorbidities.

Functional Imaging Findings in Generalized Anxiety Disorder. Inconsistent findings on amygdala function in GAD suggest a more complex picture than the classic pattern of amygdala hyperreactivity seen across most other anxiety and stress-related disorders. Whereas some fMRI studies have found no differences or even reductions in amygdala reactivity to fearful faces in GAD, evidence suggests that patients with GAD may exhibit nonspecific amygdala hyperreactivity. For instance, patients with GAD have been found to show heightened amygdala activation to both negative and neutral stimuli, as well as to both incongruent and congruent trials during emotional interference.

Patients with GAD may also display altered BNST function, given the role of BNST in sustained anxiety. Compared to controls, patients with GAD show lower amygdala activation but higher BNST activation and higher sustained arousal to a gambling task designed to induce high uncertainty and anxiety about monetary loss. Furthermore, a recent study provided evidence for this temporal dissociation of BNST and amygdala function during the anticipation of threat, reporting that patients with GAD showed elevated phasic amygdala activity to threat anticipation, followed

at a delay by heightened, sustained BNST activity (Fig. 14.5–3). Together, these findings may reflect earlier disengagement of the amygdala response to acute stress or anticipatory threat coupled with increased BNST activation that maintains a more sustained state of anxiety.

Consistent with clinical observations of sustained worry and anxiety, patients with GAD appear to show impaired prefrontal function. During a worry induction procedure, both patients with GAD and healthy controls activated the dACC and dmPFC, part of the "aversive amplification circuit"; however, while this activation normalized in healthy controls in resting-state scans following the worry induction, these regions showed persistent activation in participants with GAD. Moreover, activation in the dACC/dmPFC correlated with patients' self-reported worry symptoms. Another line of work has investigated prefrontal alterations that may relate to the overgeneralization of conditioned fear in GAD. Building off classical fear conditioning paradigms, fear generalization paradigms examine participants' responses to nonthreatening target stimuli that are increasingly dissimilar from the trained CS+ (e.g., the same shape as the CS+ but of increasingly smaller size). Patients with GAD show more overgeneralization (i.e., greater fear of the generalized stimuli), as well as less recruitment of the vmPFC. This reduced vmPFC recruitment is associated with poorer discrimination between a CS+ and a generalized stimulus. These findings point to potential neural substrates of fear overgeneralization and the failure to discriminate between threat and safety in GAD.

Connectivity analyses have provided critical information regarding the neural bases of emotion dysregulation in GAD. Several independent studies have provided evidence of altered corticolimbic connectivity in GAD. For example, an implicit emotion regulation task tested adaptation to emotional conflict through regulatory processes by asking participants to identify a target facial expression (fearful or happy). These facial expressions were overlayed with emotional words ("fear" or "happy") that either matched or conflicted with the expressions. Healthy participants showed strong negative pgACC-amygdala coupling during this task, consistent with the downregulation of emotional reactivity; however, patients did not activate the pgACC or show this negative pgACC-amygdala connectivity. Moreover, patients with GAD have also been found to exhibit disrupted functional connectivity of amygdala subregions at rest, thus providing additional support for altered amygdala connectivity.

Together, these findings suggest that GAD may be characterized by impaired interactions between cortical regions that are important for exerting control (e.g., the ACC) and subcortical limbic structures that may underlie deficits in emotion regulation (e.g., the amygdala).

Finally, several studies have begun to examine possible predictors or mechanisms of effective treatment for GAD. Better response to venlafaxine has been found to be associated with higher anticipatory ACC activation and with higher rostral ACC and lower amygdala activation to fearful faces pretreatment. Furthermore, treatment with citalopram resulted in lower activation in prefrontal and limbic regions to worry-related stimuli post-treatment. Finally, patients who received CBT showed less amygdala and sgACC activation to fearful and angry faces, as well as increased activation to happy faces.

Structural Imaging Findings in Generalized Anxiety Disorder. Consistent with findings of altered corticolimbic functional connectivity, reduced FA has been observed in the bilateral uncinate fasciculus in patients with GAD. Moreover, lower FA in the uncinate fasciculus was associated with weaker negative pregenual cingulate-amygdala functional connectivity during anticipation of aversive stimuli. Both structural and functional connectivity changes have been associated with poorer discrimination between threat and safety in GAD. Taken together, these combined structural and functional results suggest potential neural bases for the emotion dysregulation and fear generalization that are key features of GAD.

FIGURE 14.5–3. Elevated bed nucleus of the stria terminalis activity to threat minus neutral anticipation in patients relative to healthy controls. **(A)** Generalized anxiety disorder (GAD) patients relative to healthy controls (HC) responded with elevated sustained, but delayed bed nucleus of the stria terminalis (BNST) activity to threat minus neutral anticipation for all Sustained Response General Linear Models (GLM) with a delayed onset of at least 4 s in a highly overlapping cluster. **(B)** Time courses of the blood oxygen level-dependent (BOLD) signal change, extracted from the overlapping BNST cluster (of the 4, 6, 8, and 10 s Sustained Response GLMs) and averaged across time points and participants per group, are displayed for the anticipatory epoch (threat minus neutral anticipation) starting 4 s before cue onset. **(C)** Quadratic regression analyses on the average *t*-values for the contrast threat minus neutral anticipation in GAD patients as compared to HC extracted from the overlapping cluster of all significant Sustained Response GLMs, revealed a significant quadratic relationship. The vertex of the function was at 6.69 s, suggesting a delayed onset of about 6 to 7 s of the differential sustained BNST effect. The lower graph displays all Sustained Response Models. *$P < .05$. Activity alterations in the bed nucleus of the stria terminalis and amygdala during threat anticipation in generalized anxiety disorder. *Soc Cogn Affect Neurosci.* 2017;12(11):1766–1774, by permission of Oxford University Press. doi:10.1093/scan/nsx103.)

Summary. Unlike the clear pattern of amygdala hyperreactivity seen in other anxiety disorders, the BNST appears to play a critical role in the sustained state of anxiety characteristic of GAD. Furthermore, disruptions in functional (ACC-amygdala) and structural (uncinate fasciculus) connectivity appear to underlie key clinical features of GAD, including emotion dysregulation, which appears to relate to weaker frontoamygdala connectivity, and fear generalization, which may be associated with alterations in vmPFC function and connectivity. Finally, initial evidence suggests that both pharmacologic interventions and CBT may reduce symptoms by altering frontoamygdala circuitry.

Commonalities and Specificity Across Anxiety Disorders

The current neuroimaging literature suggests several commonalities among disorders. The amygdala has received the most attention and has been implicated across these disorders. Patients with PD exhibit amygdala hyperreactivity to both disorder-specific and general threat-related stimuli. Nonspecific amygdala hyperreactivity may also be seen in GAD, although more consistent results implicate the BNST. Conversely, amygdala hyperreactivity in specific phobias and SAD appears to be selective for disorder-specific stimuli. Notably, heightened activity in the anterior insula has also been observed across all of these disorders.

Data implicate the abnormalities in the hippocampus in PD. Temporal lobe volumetric abnormalities are reported in extrahippocampal regions, and most resting-state data suggest a rightward shift in laterality of function. Less compelling evidence implicates the hippocampus in specific phobias, SAD, or GAD.

With respect to the PFC, PD is associated with deficient recruitment of the pgACC. In specific phobias, pgACC cortical thickness appears to be increased, although evidence of PFC dysfunction during emotional processing in specific phobias is lacking. Findings are mixed for SAD, with some studies reporting diminished neurophysiological responses in the pgACC but others failing to detect this finding. The vmPFC has also been implicated in overgeneralization of fear in GAD.

These profiles of similarities and differences among anxiety and stress-related disorders are consistent with the nosologic categorization of these disorders as distinct from one another but with sufficient similarities to merit inclusion as anxiety disorders. There has been considerably less neuroimaging work on other anxiety disorders (e.g., separation anxiety,

selective mutism, adjustment disorder); thus, the extent to which these disorders have shared versus unique neural substrates will require further investigation.

The Developmental Perspective and Markers of Risk, Resilience, and Treatment

Anxiety disorders are the most common group of psychiatric disorders in childhood and adolescence, with estimated prevalence rates in adolescence as high as 32%. Moreover, anxiety disorders across the lifespan peak during adolescence. Understanding neurodevelopmental changes and the role these changes play in both illness onset and treatment efficacy is crucial to reducing the burden of anxiety and stress-related disorders. Developmental neuroimaging studies can thus have a major impact on understanding risk, resilience, and treatment for pediatric anxiety disorders.

Converging evidence from humans and experimental animals highlights dynamic changes in the neural circuitry supporting fear learning and extinction across development. The amygdala undergoes rapid structural and functional development early in life, followed by continuous change across development. Likewise, the hippocampus appears to develop earlier in life; however, the PFC shows protracted development and does not reach a mature functional architecture until early adulthood. Although the basic structure of the amygdala is present at birth, the fine-tuning of its connections with PFC and hippocampus continues throughout childhood and adolescence.

This earlier maturation of subcortical regions supporting fear reactivity, in conjunction with the protracted maturation of PFC, may result in altered fear regulation during adolescence. These developmental changes in neural function and connectivity are consistent with the changes observed in the processes of fear learning that are mediated by these structures. Evidence suggests that simple discrimination between a CS+ and a CS- improves linearly with age; however, the capacity to express and extinguish fear appears to undergo nonlinear changes across normative development. Translational evidence points to a period of diminished extinction of cued fear during adolescence, relative to childhood and adulthood, which may relate to protracted maturational changes in the PFC and its connections with the amygdala.

In addition to studies examining patterns of fear conditioning across normative development, a growing line of work has investigated fear conditioning in youth with anxiety disorders. A recent meta-analysis found that, although youth with and without anxiety disorders exhibited similar patterns of fear acquisition and extinction, fear responses to individual stimuli were of greater magnitude in youth with anxiety disorders. Several other studies have examined extinction recall across development in the context of anxiety disorders. In a recent study, 200 participants with and without anxiety disorders across a broad range of ages (8- to 50-years-old) viewed morphed stimuli of varying similarity to previously extinguished threat cues while in the scanner. Age was found to moderate anxiety-related differences in amygdala-vmPFC connectivity while processing threat-related cues. Specifically, adults with anxiety disorders showed lower amygdala-vmPFC connectivity to morphed stimuli that were increasingly more dissimilar to the originally conditioned CS+ (i.e., contained increasingly more safety-related information); however, this anxiety-related effect was reversed in youths (Fig. 14.5–4). Although based on the relatively small number of initial studies conducted to date, these findings highlight the importance of examining fear conditioning in youth versus adults with anxiety disorders.

Developmental changes in behavior and neurocircuitry have important implications for the effect of stress and anxiety on the brain. During developmental periods of heightened neuroplasticity (i.e., *sensitive periods*), environmental influences may have a particularly potent effect on neurodevelopment and may lead to a series of cascades that ultimately influence behavior (in a positive or negative manner). In other words, the brain may be more capable of remodeling itself during sensitive periods compared to windows of reduced plasticity; however, this remodeling is not inherently positive or negative. Sensitive periods may render the developing brain more vulnerable to the effects of later stress, but they could also serve as windows of opportunity, during which there is increased potential for positive adaptation or effective intervention. Dynamic neural and behavioral changes likely influence the effect of stress on the brain and the manner in which youth cope with stressors at unique developmental time periods. Ultimately, the risk for anxiety disorders may be increased by stressors that exacerbate transient imbalances in brain circuitry. Neuroimaging studies across childhood and

adolescence can inform the timing and nature of sensitive periods with direct relevance for the risk and treatment of anxiety disorders.

Particularly given the potential early age of onset and chronic course of anxiety disorders (when not effectively treated), developmental neuroimaging studies offer great promise for informing risk factors for anxiety disorders across the lifespan. Even in adulthood, individual differences often stem from early-life environments/influences (e.g., parental modeling, stressful events), genetic factors, or temperament. Elucidating risk conferred by such early individual differences is critical for informing prevention and early intervention. However, distinguishing markers of risk from markers of disease remains challenging. Both the promise and challenges of this work are highlighted by the example of behavioral inhibition (BI), a behavioral phenotype characterized by reactivity to novel stimuli and withdrawal/avoidance. This temperament is evident in early childhood but confers increased risk for pediatric anxiety disorders, which in turn confers increased risk for adult anxiety disorders. BI has been associated with exaggerated amygdala responses to novel versus neutral faces, a finding that has also been observed in adult anxiety. This underscores the potential danger of interpreting between-group differences in cross-sectional studies of adults with versus without a given disorder with respect to interpreting between-group differences; although investigators may be inclined to attribute such differences to the pathophysiology of disease, such experiments cannot rule out the possibility that observed differences instead represent markers of risk. To fully address these confounding influences, investigators must study comparison groups of participants who have the risk factor but not the full disease. Moreover, brain-based indicators of risk must account for age, sex, medication effects, and other pertinent temporal variables (e.g., menstrual phase, diurnal variation).

Overall, developmental neuroimaging studies have provided critical insight into the neural substrates of fear and anxiety in children and adolescents, with initial evidence of how developmental processes may relate to risk for anxiety disorders. However, developmental neuroimaging efforts must also contend with unique challenges, such as the need to dissociate disorder effects from developmental processes. Furthermore, methods must be adapted to be developmentally appropriate. Fear conditioning paradigms used with children and adolescents have traditionally employed UCSs that have been adapted to be appropriate for

children and adolescents, such as appropriately aversive noises, air puffs, or images. Moreover, neuroimaging research in children and adolescents has primarily relied on fMRI paradigms to avoid exposing children to the limited radiation inherent to PET studies.

Due to high rates of comorbidities among anxiety disorders in youth, a large proportion of studies have examined pediatric anxiety disorders as a unit rather than distinguishing among specific disorders. For example, across a sample of youth with GAD, SAD, and/or separation anxiety, increased activation in the inferior and superior frontal gyri (including the dlPFC and vlPFC) was associated with improved responses to either CBT or pharmacologic treatment. The bulk of research on specific types of anxiety disorders has primarily focused on SAD and GAD, whereas PD, specific phobias, selective mutism, and separation anxiety disorder remain less explored. Future work will be necessary to elucidate the neural substrates of these disorders during development and to understand predictors of treatment response in children and adolescents with specific anxiety disorders.

FIGURE 14.5–4. Left amygdala connectivity with the ventromedial prefrontal cortex (vmPFC) among youths and adults with anxiety disorders and healthy subjects. Whole-brain generalized psychophysiologic interaction (gPPI) analysis revealed a significant interaction of anxiety diagnosis, age, and linear trend in the task-related functional connectivity between the left amygdala seed and the vmPFC (panel **A**). Images are shown in neurologic convention (i.e., left is left) and thresholded at F > 10.76, df = 1, 4180, $P < .001$, cluster size > 57 voxels (890.625 mm^3). To decompose the complex interaction effects, mean extracted values for the vmPFC cluster are plotted separately by group, based on anxiety diagnosis (healthy, anxiety) and age (median split: adults, youths). In the graph (panel **B**), the y-axis shows the linear trend of the gPPI coefficient averaged across participants in each group. Error bars indicate standard deviation. (See eBook for color images.) Age differences in the neural correlates of anxiety disorders: an fMRI study of response to learned threat. *Am J Psychiatry*. 2020;177(5):460.)

Social Anxiety Disorder in Children and Adolescents. Social stimuli become increasingly salient in normative development in adolescence.

Thus, it is perhaps unsurprising that the incidence of SAD peaks during this developmental period. Using increasingly naturalistic paradigms, findings suggest important changes in brain responses to social stimuli in adolescents with SAD. For example, during a paradigm mimicking an online chatroom, adolescents with SAD showed increased amygdala activation when anticipating evaluation from peers they rated as undesirable for social interaction ("rejected peers"). These adolescents also displayed increased positive vmPFC-amygdala connectivity, which correlated with symptom severity. Other work with this task revealed that socially anxious adolescents show reduced activation in the nucleus accumbens when anticipating feedback from peers they rated as desirable ("selected peers"). Moreover, anxiety interacted with age. Among socially anxious participants, age and rACC activation were positively associated with rejected peers but negatively associated with selected peers; however, the opposite pattern was observed for controls. Interpreting these findings, the authors proposed that increased regulatory resources may be devoted to potentially adverse social outcomes as individuals with SAD mature. An age-by-anxiety interaction was also observed in striatal activation and connectivity in an fMRI paradigm in which participants received feedback from peers. Adolescents with SAD showed increased striatal activation and negative frontostriatal functional connectivity during unexpected positive feedback from highly valued peers, but this pattern was not detected for adults with SAD or for nonanxious adults or adolescents. Finally, a longitudinal study using both EEG and MRI reported that N400 amplitudes (the event-related potential that occurs at 400 ms after stimulus presentation believed to relate to processing of information in human faces) at ages 8 to 9 in healthy participants predicted social anxiety symptoms at age 14 to 15. Although preliminary, this suggests that limbic reactivity may predate or index risk for SAD. While much remains unknown about the interaction between anxiety and developmental processes, these findings emphasize the importance of investigating potential differences in the mechanisms underlying SAD across development.

Generalized Anxiety Disorder in Children and Adolescents. In line with findings in adults, studies of youth with GAD have reported inconsistent findings regarding amygdala reactivity. In one study, youth with GAD showed elevated amygdala, vPFC, and ACC activation to

fearful faces than happy faces when attending to their own fear, whereas this pattern of elevated activation was not seen in control youth. In contrast, another study did not detect differences in amygdala reactivity to angry faces in youth with GAD versus controls. However, this may be a function of the design of this second study, as subsequent studies have shown heightened amygdala activity to masked angry faces. Youth with GAD's amygdala reactivity has been found to positively correlate with the severity of their anxiety, and they also exhibit weaker vlPFC-amygdala functional connectivity. Furthermore, youth with GAD show elevated vlPFC activation, and vlPFC activation is inversely correlated with the severity of anxiety. Together, these findings suggest that the vlPFC may play a compensatory role in pediatric GAD. Though less is known about resting-state functional connectivity in pediatric GAD, evidence suggests that, as in adults, adolescents with GAD also display altered amygdala-mPFC functional connectivity at rest. In addition to these findings of functional alterations, several preliminary studies point to potential alterations in brain structure underlying pediatric GAD. To date, existing data suggest that youth with GAD have larger amygdala volumes and increased cortical thickness in regions including the vmPFC, inferior and middle temporal cortex, and lateral occipital cortex.

Initial evidence points to possible neural predictors and mechanisms of effective treatment for pediatric GAD. Higher amygdala reactivity pretreatment has been associated with greater symptom improvement in youth with GAD following CBT or psychopharmacologic treatment. Furthermore, these treatments appear to be associated with higher post-treatment vlPFC activation. Across these characterization and treatment findings, additional studies will be necessary to evaluate the extent to which these developmental findings are similar to or distinct from adults with GAD.

Summary of Neuroimaging Findings in Pediatric Samples. Children and adolescents are highly vulnerable to anxiety disorders. The growing literature on pediatric anxiety has begun to identify common neural mechanisms that are known to underlie anxiety disorders in adults, such as alterations in the amygdala and PFC. However, further research is necessary to elucidate the dynamic longitudinal developmental changes that occur across childhood and adolescence in youth with anxiety disorders. Samples that span across developmental periods to include

children, adolescents, and adults will contribute to our understanding of anxiety- and stress-related changes to neurodevelopmental trajectories. Finally, identifying sensitive periods and risk/resilience factors will ultimately be essential for early identification and intervention efforts and for optimizing treatments for youth.

FUTURE DIRECTIONS

Using neuroimaging techniques to investigate the neurobiological bases of anxiety disorders continues to yield seminal information regarding the functional anatomical and neurochemical correlates of both normal and pathologic anxiety and fear states. Converging evidence from the systems neuroscience data obtained from human neuroimaging studies and the physiological and anatomical data obtained from preclinical studies with experimental animals has facilitated the development of general neurocircuitry models of anxiety disorders. Moreover, studies of specific disorders (PD, specific phobias, SAD, and GAD) have supported disease models that involve altered function of and interactions among the amygdala, hippocampus, and medial and orbital PFC.

Investigating the neurodevelopmental processes associated with pediatric anxiety disorders will be crucial to support the early identification of risk and optimization of treatment for youth with anxiety disorders. Innovative study designs, including developmental studies, are also needed to disentangle core substrates of pathophysiology from confounding neural substrates of risk, compensatory processes, and epiphenomena. Moreover, the neurobiological heterogeneity encompassed within criteria-based psychiatric diagnoses presents an additional challenge, which may be reflected in the mixed findings observed across some studies. Research that integrates neuroimaging with genetic and neurochemical data may help to characterize this heterogeneity. Ultimately, such integrative work is optimally poised to contribute to the refinement of phenotypes of anxiety disorders, the elucidation of their pathogenesis, and the development of personalized medicine approaches that tailor treatments based on individual differences and developmental stages.

14.6 Anxiety Disorders: Cognitive-Behavioral Therapy

Jonathan D. Huppert, Ph.D., and Edna B. Foa, Ph.D.

This section focuses on cognitive-behavioral therapy (CBT) for *pathological anxiety* that may lead to significant impairment in functioning or substantial distress. The fifth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) specifies five primary anxiety disorders: phobias, panic disorder, agoraphobia, social anxiety disorder, and generalized anxiety disorder (GAD). Common to the anxiety disorders are intense anxiety related to exaggerated and/or unrealistic cognitions about future threats of harm (either physical or psychological), physiologic responses when confronted with anxiety-relevant stimuli, and behavioral tendencies to escape from or avoid anxiety triggers and to prevent anticipated harm. Whereas the DSM-5 includes obsessive-compulsive disorder (OCD), post-traumatic distress disorder (PTSD), and illness anxiety disorder (hypochondria) in separate categories from the anxiety disorders, most of the principles that will be discussed here also apply to both OCD and PTSD. With the exception of panic disorder, in all anxiety disorders, the focus is on the harm related to the specific source of fear rather than on the panic itself.

ASPECTS OF THE ANXIETY DISORDERS PARTICULARLY RELEVANT TO CBT

Each anxiety disorder is distinguished by specific symptoms and specific negative cognitions. Panic attacks in panic disorder, for example, are discrete episodes of intense anxiety associated with cognitive symptoms (e.g., thoughts that one is going to die, go crazy, or lose control), along with a fear that the attacks will recur. The central feature of panic disorder, according to CBT theories, therefore, is the fear of one's own anxiety reactions because they are perceived as harmful (also known as "fear of fear"). Conceptualizations similar to the fear of fear for panic disorder can be made for social anxiety disorder, in which the focus is on the fear of embarrassment and rejection; OCD, in which the fear is of an idiosyncratic concern (contamination, fire, being an evil or harmful person, etc., often related to one's values and being responsible for negative outcomes); generalized anxiety, in which the worry is about the uncertainty of future negative outcomes; PTSD, in which the fear is about the consequences of thinking about the trauma or approaching situations that are similar to the trauma with the expectation that of another traumatic event occurring in these situations, or inability to tolerate distress while thinking about the trauma; and specific phobia, in which the fear is circumscribed to a specific situation or object.

Fortunately, effective psychological and pharmacologic treatments have been developed for the anxiety disorders. In fact, CBT has been endorsed as a first-line treatment for anxiety disorders by the United Kingdom's National Institute of Health and Clinical Excellence, the American Psychiatric Association Treatment Guidelines, and many other healthcare and government agencies around the world. These guidelines have been influenced by research suggesting that CBT for anxiety disorders is more cost-effective than medication or other treatments in the long term, and patient preferences tend to be 3:1 for psychosocial interventions over medical ones. We now discuss the theory and practice of CBT for anxiety disorders and review evidence of its efficacy.

EMOTIONAL PROCESSING THEORY: A PSYCHOLOGICAL MODEL OF ANXIETY DISORDERS AND THEIR TREATMENT

Before describing the components of CBT and its efficacy in treating various anxiety disorders, a general psychological theory of anxiety disorders and the hypothesized conditions necessary for successful treatment are presented. Emotional processing theory, developed by Edna Foa and Michael Kozak, is based on the idea that a cognitive *fear structure* that includes representations of stimulus, response, and meaning serves as a blueprint for avoiding or escaping from danger. The theory integrates information processing concepts and recent learning theories of acquisition and extinction. It posits that environmental stimuli activate matching information in the fear structure, resulting in the spreading of activation throughout the rest of the structure via associative connections, thereby activating the fear structure. A fear structure is adaptive if the stimuli represented in it are objectively harmful and the responses represented in it lead to effectively avoiding, escaping, or coping with the threat. A fear structure is pathologic, as is the case in anxiety disorders when the associations among stimulus, response, and meaning representations do not accurately reflect reality, such that harmless stimuli or responses are erroneously interpreted as being dangerous. For example, the fear structure for an individual with a dog phobia would include associations among representations of dogs; meaning representations of dogs as being dangerous and uncontrollable; and responses such as physiologic arousal and various defensive behaviors (e.g., calling for help, running away). The fear structure in panic disorder is characterized by fear of physical sensations associated with panic symptoms (e.g., rapid breathing, heart palpitations) and interpretation of these sensations as indications of danger, such as a heart attack or going crazy. As a result of the erroneous meaning associated with these sensations, people with panic disorder avoid situations that they anticipated to give rise to panic or cause similar sensations, such as intense physical activity. The fear structure of social anxiety disorder represents an erroneous association between social interactions and negative consequences, such as being perceived as boring or stupid, which will lead to rejection. The fear structure in GAD is much more diffuse, as there is often no central or “core fear.”

Emotional Processing

Emotional processing refers to the changes in pathologic elements of fear (emotional) structure (e.g., most dogs are not dangerous) that result in

long-term fear reduction and recovery of the anxiety disorder. According to emotional processing theory, two conditions are necessary for emotional processing to take place. First, the fear structure must be activated either through a match with stimuli in the environment (e.g., confronting the feared stimulus) or through symbolic means (e.g., imagining or thinking about the feared stimuli). Second, new information that is *incompatible* with the pathologic aspects of the fear structure must be available and incorporated into the structure, thereby altering the structure and creating a realistic or "nonfear" structure via the new, competing associations. These two conditions have been supported via research in animal and human studies, the latter of which includes both basic research and treatment process research. Indeed, this theory is consistent with current models of neuroscience, suggesting that the brain is constantly scanning, processing the environment, and making predictions. When surprising information counter to predictions occurs, this leads to a prediction error (a signal that something needs to be processed), and oftentimes error correction, or updating one's predictive model.

Emotional processing theory explicitly aimed to explain the phenomenology and mechanisms of anxiety disorders and the efficacy of exposure therapy in treating pathologic anxiety. Exposure therapy involves helping patients systematically confront feared but otherwise safe stimuli in a manner that promotes eventual fear reduction. The efficacy of exposure therapy in reducing anxiety has been widely demonstrated, and exposure procedures (i.e., confrontation with feared stimuli and responses followed by changes in their meaning) are a basic component of nearly every CBT program that has been shown to be effective in the treatment of the various anxiety disorders. The relevance of emotional processing theory to other treatments for anxiety, specifically anxiety management training and cognitive therapy, is addressed later.

Recent elaborations of emotional processing theory specify two indicators of emotional processing that can be measured separately from treatment outcome. Following from the proposal that activation of the fear structure is necessary for change in the structure to occur, one indicator of emotional processing is sufficient emotional activation of the fear structure (emotional engagement), as reflected in the assessment of fear and distress such as facial reactions, self-reports of fear and anxiety, or physiologic reactions such as increased skin conductance or heart rate when the person confronts or thinks about the feared stimulus or

response. The second indicator of emotional processing is a reduction in the levels of fear or distress across repeated sessions, or *between-session habituation (extinction or learning)*. Fear reduction obtained in one session that does not at least partially transfer to a subsequent session (i.e., the lack of between-session learning) indicates that the fear structure was not altered and suggests that any previously observed fear reduction may have been brought about by some kind of compulsion, safety behavior, or other form of defensive tactic. By contrast, fear reduction that does transfer across sessions strongly suggests that the exposure experiences have led to some enduring change in the fear structure (typically of the meaning of the stimuli and or responses). Other indicators of between-session emotional processing may include reductions in fear-related cognitions or changes in biased cognitive processes, such as reductions in the investment of attentional resources to threat stimuli or decreased negative and/or increased positive interpretations of ambiguous situations.

Earlier formulations of emotional processing theory included a third indicator of emotional processing: Gradual reduction in these indices of emotional reactivity to the feared situation over the course of an exposure exercise. In the context of exposure therapy, this is called *within-session habituation*. However, acute fear reduction can occur for reasons other than habituation, such as distraction or engaging in compulsions or other safety behaviors. Such measures limit emotional engagement and prevent the encoding of disconfirming information, thereby preventing therapeutic changes from taking place in the fear structure. For example, if a person with panic disorder fears dying from a panic attack experiences an attack, thus activating the fear structure, but then immediately sits down and drinks water to prevent dying, they will not learn that the panic attack is not dangerous and attribute the lack of anticipated harm to drinking water. Given the potential unreliability of this indicator and many null findings, revisions of emotional processing theory suggest that within-session habituation, although a possible indicator, is neither necessary nor sufficient.

Several studies conducted across a range of disorders, including specific phobias, social anxiety disorder, panic disorder, OCD, and PTSD, investigated the relationship between indicators of emotional processing and treatment outcomes of exposure therapy. Many of these studies showed a relationship between initial activation and long-term outcome

and between changes in either cognition or fear between sessions and outcome. The relationship between within-session changes in fear or cognitions and outcome was less consistent, though some recent studies using more fine-grained analyses have found positive results.

Sources of Corrective Information and Conditions That Interfere With Emotional Processing

It is relatively easy to see how exposure therapy promotes emotional engagement as patients are encouraged to think and talk about feared thoughts, images, and memories; confront feared objects and situations; and engage in feared activities. It may not be as easy to see what sources of corrective or fear-disconfirming information are contained in an exposure exercise.

One important source of corrective information is within-session fear reduction, which provides new response and meaning information embedded in the experience of the *reduction* of physiologic responding in the presence of feared stimuli that is incompatible with prior response information and the incorporation of nonthreat meaning related to this response. Take, for example, a patient with panic disorder; the experience of habituation disconfirms their belief that anxiety will persist unless the person escapes the situation, and it corrects misperceptions that physiologic responses associated with fear and anxiety lead to heart attack or to going crazy. In-session activation also frequently teaches the patient that the magnitude of the anxiety is not as great as initially expected. Experiencing the anxiety also frequently teaches the patient that they can tolerate the anxiety and that it does not last indefinitely.

Repeated and prolonged exposure may also provide corrective information regarding the actual likelihood or significance of feared consequences. Anxious people frequently overestimate the probability of feared events and the significance of those consequences, should they happen. For example, a person with social anxiety may make an unrealistically high estimate of the probability of being rejected in social interactions. Repeated exposure allows the person to test whether the feared consequence happens. Moreover, even if it does happen—for example, the person says something embarrassing—the person could learn that these consequences, although unpleasant, are not catastrophic.

Exposure to intrusive and unwanted thoughts can help a person distinguish between unpleasant thoughts that occur in their mind and

reality or separate thoughts from overt actions. Exposure therapy allows these individuals to learn that they can think of upsetting thoughts without acting on them and that thinking about upsetting consequences does not make them happen.

Explicit provision of corrective information can also be extremely important and facilitate new associations within a fear structure. For example, psychoeducation about the causes and consequences of panic attacks can substantially reduce anxiety and panic attacks in approximately 30% of patients with panic disorder. This education includes corrective information regarding the likelihood of fainting because of panic attacks (which is close to zero in individuals other than those with blood-injection phobias) and distinguishing heart attacks and strokes from panic attacks, and a description of the biopsychosocial model of panic. On the other hand, many individuals require more experiential exercises to incorporate such corrective information. For example, individuals with social anxiety disorder can benefit significantly from the provision of video and confederate feedback after an exposure to make explicit some of the corrective information that would otherwise not be observed. At times, within-session habituation does not occur in these circumstances, but between-session habituation does, making the latter a more reliable indicator of emotional processing than the former.

Failures of Emotional Processing

If repeated exposure to feared stimuli contains corrective or fear-disconfirming information, then why do most anxiety disorders have a chronic course? An important feature of all anxiety disorders, in addition to the experience of intense distress on exposure to the presence of the feared stimuli, is a strong tendency to escape from feared situations or avoid them altogether. To the extent that such escape and avoidance strategies are effective at reducing anxiety, they are strengthened through the principle of negative reinforcement, making it even more likely that the person will engage in escape or avoidance in the future. Moreover, successful escape or avoidance limits the person's exposure to fear-disconfirming information. For example, a person who is afraid of dogs and successfully avoids even friendly dogs will not have the opportunity to learn that dogs can be not only safe but also fun to play with, and thus they will maintain the belief that avoiding dogs has prevented harm from occurring to them.

One intervention studied in the context of exposure therapy that has been found to promote acute reductions in distress while in the presence of feared stimuli but that interferes with between-session habituation is the use of benzodiazepine medications. When taken shortly before exposure to a feared stimulus, benzodiazepines can significantly reduce anxiety. As with distraction, however, the fear reduction that occurs with the medication does not transfer to subsequent tests in a nonmedicated condition and, indeed, appears to interfere with the normal process of cognitive changes and between-session habituation. Researchers demonstrated this among a group of patients undergoing treatment for fear of flying that involved taking two flights scheduled one week apart. Ninety minutes before taking the first flight, half of the patients took the high-potency benzodiazepine alprazolam, and the remaining patients took a placebo. Patients taking the active medication reported significantly less anxiety during the first trip than patients who took the placebo. Before the second flight, all patients were given a placebo pill. Patients who had taken the placebo before the first flight showed a reduction in their anxiety on the second flight, whereas those who had taken the active medication showed an increase in anxiety on the second flight, showing lack of extinction without fear activation. Similar findings were found in animal studies of extinction.

Another intervention that has led to more mixed findings is distraction during exposure. Studies have differed substantially in how distraction was manipulated, the population that was studied, and the duration of the exposure sessions, which may account for some of the variability in results across studies. Overall, a recent meta-analysis showed that, under some circumstances, distraction can produce acute reductions in anxiety that are equivalent to focused exposures. Results suggest that these effects are found more when multiple sessions are studied, and distraction is more interpersonal/interactive in nature. It is possible that engagement of others during exposure recruits interpersonal emotion regulatory systems or that implicit learning via modeling or subtle verbal or nonverbal cues facilitates processing. Alternatively, such interactions may help facilitate engagement of approach/reward systems and deactivation of threat/fear systems. A more recent theory suggests that distraction is an effective emotion regulation process when emotions are too intense and resources are viewed as too limited to cope. Distraction in such cases may moderate anxiety to a point that it is manageable to process. At

times, uninstructed exposure seems to be superior to either focused or distracted exposure, suggesting that distraction may not be effective in some circumstances. It should be noted that the degree of distraction (e.g., complete engagement of cognitive resources on another task versus divided attention, splitting one's resources between the exposure and another task) may have different outcomes and that most of the studies conducted to date used analog participants or patients with specific phobia. Therefore, more research is needed for more complex anxiety and related disorders.

Other Approaches to Understanding the Mechanisms of Exposure and CBT for Anxiety Disorders

It is beyond the scope of this chapter to describe in detail all the theories attempting to explain the mechanisms of exposure and CBT for anxiety disorders. However, two additional approaches should be noted, given their prominence in the literature. First, the belief disconfirmation approach was developed first by Aaron T. Beck and colleagues. The main aspect of this model is that thoughts and beliefs lead to emotions and behaviors. This approach was initially called cognitive therapy to contrast it with behavior therapy and exposure approaches. The belief disconfirmation model suggests that explicit discussions, contrived "experiments," and experiential exercises are used to dispel maladaptive beliefs the patient holds that are not realistic. Typically, such models do not attempt to explain implicit learning or concepts such as conditioning, habituation, or extinction. Ultimately, cognitive theories have become integrated with behavioral theories, including emotional processing theory, and their theoretical and practical distinctions are at most subtle. Indeed, in practice, most researchers and clinicians today call their treatments cognitive behavioral therapy rather than pure behavioral or pure cognitive therapy.

A second approach that has been used recently by Michelle Craske and colleagues to contrast with emotional processing theory is the inhibitory learning approach. The basis of inhibitory learning is that exposure leads to fear reduction due to inhibition of fear associations. This model is based predominantly on modern, neo-classical learning theory. Accordingly, fear is thought to occur due to pairing of neutral stimuli with an aversive stimulus (classical conditioning). Fear is then "unlearned" through both habituation and extinction, leading to an inhibition of the association. The

primary issue suggested here is that associations are not replaced but only inhibited. Thus, they can be reactivated when the inhibitory processes weaken or fail, leading to relapse. There are competing models with the idea of inhibitory processes, such as retrieval competition (suggesting that new and old memories both exist and compete to be expressed) and memory reconsolidation (suggesting that memory is constantly being reconstructed and not static). Some suggested implications of the inhibitory model are that it is essential to design exposures to maximize expectancy violation (or prediction errors; common in many CBT models today, including cognitive therapy and emotional processing), remove safety signals, vary exposures, and change contexts of exposures. Most of these implications are not unique to inhibitory theory and are included in most current CBT models, including those of belief disconfirmation and emotional processing, as well as models that are not readily integrated into those models. Thus, many of the models proposed to explain the mechanisms of exposure and CBT for anxiety use different language to ultimately describe very similar processes. It is likely that the best explanatory model integrates all of these models, thereby incorporating their large overlap and adopting the subtle unique differences.

COGNITIVE-BEHAVIORAL THERAPY PROCEDURES FOR ANXIETY DISORDERS

Most CBT programs for anxiety disorders begin with an assessment, patient education, and specific treatment planning. The actual treatment procedures involve at least one of four components: (1) exposure to thoughts, objects, situations, and physiologic sensations that are not dangerous but are nonetheless feared, avoided, or endured with great distress; (2) training in general anxiety or stress management techniques (including acceptance or mindfulness); (3) use of cognitive therapy techniques; and (4) training in specific skills, such as dating skills, assertiveness, and so forth.

Assessment, Psychoeducation, and Treatment Planning

CBT begins with a thorough assessment of the patient's presenting complaints using empirically validated assessment procedures. Self-report and interviewer rating measures have been developed for the diagnosis

and assessment of severity of each anxiety disorder. The assessment may also include measures of related psychopathology, such as depression and general anxiety, and specific theoretically relevant variables associated with the disorder of interest, such as worry-related metacognitions in GAD and anxiety sensitivity in panic disorder. Typically, assessments are repeated over the course and at the end of treatment for the purpose of establishing a diagnosis, selecting treatment procedures, monitoring the process of treatment, and evaluating treatment outcomes.

The next step of CBT is psychoeducation. Patients are typically provided with a cognitive-behavioral formulation of their specific diagnosis and a related treatment rationale that serves as a guiding framework for future treatment sessions. In addition, alternative treatments shown to have similar efficacy are discussed to allow the patient to make an informed choice about treatment.

As part of the initial assessment and patient education, the therapist and patient work together to identify specific targets for treatment and to work out the details of the treatment plan. An example of this is the development of a hierarchy for conducting in vivo exposure exercises or determining the patient's core beliefs and core fears to determine the proper exposures and their course. In addition, expectations are set that the patient will engage in homework between sessions to increase mastery of the therapy skills and self-monitoring procedures for symptoms.

Exposure Therapy

Exposure therapy involves intentionally confronting feared but otherwise not dangerous objects, situations, thoughts, memories, and physical sensations for the purpose of reducing fear reactions and avoidance associated with the same or similar stimuli. Systematic desensitization, where gradual imaginal and in vivo exposure was combined with relaxation, was the first exposure therapy technique to undergo scientific investigation. Although an effective treatment for some anxiety disorders, it has generally fallen out of use among researchers and cognitive-behavioral therapists due to the finding that concurrent relaxation was deemed unnecessary and possibly contraindicated. In addition, it does not seem necessary to progress systematically up the hierarchy (though it can be helpful at times). Finally, systematic desensitization did not appear helpful for OCD or agoraphobia, while more intense in vivo exposures

were helpful for these as well as specific phobias. The contemporary use of exposure therapy may be usefully divided into three classes of procedures: In vivo exposure, imaginal exposure, and interoceptive exposure. These are typically conducted while encouraging the patient to prevent safety behaviors, or strategies used to prevent negative outcomes but prevent learning.

In Vivo Exposure. In vivo exposure involves helping patients directly confront feared objects, activities, and situations. It is usually conducted in a graduated fashion according to a mutually agreed-on (between patient and therapist) hierarchy. For example, a hierarchy for a specific animal phobia, such as snakes or spiders, may begin with looking at pictures and other representations of the feared animal, followed by looking at the actual animal kept in a cage, first at a distance and then gradually moving closer. Depending on the animal, subsequent steps may involve touching and handling the animal, perhaps first while wearing a glove and then without the glove. These steps may be repeated across several different examples of the animal, differing in such dimensions as size and activity level.

In the case of social anxiety disorder, individuals are asked to engage in conversations and other interpersonal situations. Recent evidence suggests that such exposures maximize the incorporation of corrective information by ensuring that patients with social anxiety make explicit, specific predictions prior to their exposures, focus their attention outward and drop safety behaviors during the exposure, and receive feedback from those they interacted with and by carefully planned postexposure review of videotapes of the exposure. In the case of panic disorder, individuals expose themselves to situations in which they fear having panic attacks, such as riding in elevators, waiting in line at a store, and so on. GAD does not have standard in vivo exposure as part of its treatment because there is not usually a specific source of fear.

Imaginal Exposure. Imaginal exposure typically involves having the patient close their eyes and imagine feared stimuli as vividly as possible. One common form of imaginal exposure is imaginal flooding, in which the patient imagines the worst possible scenario repeatedly in order to help them imagine the full stream of occurrences that would need to happen in order for the feared outcomes to occur. Such imaginal exposure helps the patient process the fear, which is often avoided both behaviorally (by

avoiding contact with feared objects) and cognitively and emotionally (i.e., by avoiding thinking thoroughly about the feared consequences or avoiding how they would feel in the feared situations). Imaginal exposure has two general uses. The primary use is to help patients confront feared thoughts, images, and memories in order to process them. For example, individuals with social anxiety may experience extreme distress over thoughts of being rejected. Imaginal exposure to feared thoughts and consequences is used to promote reduction of emotional reactivity to the scenarios, to decrease the belief in the likelihood that the event will occur, to learn that the consequences are less severe than imagined, and to help the patient distinguish between thoughts and reality. In the case of phobias where there is a clear traumatic cause (e.g., fear of driving after a car accident), imaginal exposure is used to help the patient confront their memory of the traumatic event. Here again, the procedure promotes habituation to the memory and helps the patient to distinguish between the actual traumatic event, which was dangerous, and the current memory of the event, which, although distressing, is not harmful. With patients who have PTSD, imaginal exposure to traumatic memories is also used to help the patient get a new perspective of the trauma and how they behaved during the trauma. For example, a patient who was raped and blamed herself for not fighting during the rape might realize during imaginal exposure that she fought vigorously during the rape; a soldier who blamed himself for not saving his friend during the battle might realize during imaginal exposure that he was too far away from his friend to be able to save him. In these cases, imaginal exposure also creates or organizes a coherent narrative, which may help the patient to cope with their fears.

A second use of imaginal exposure is in lieu of in vivo exposure when arranging direct contact with the feared situation is not safe or feasible or as a preparatory exercise to facilitate subsequent in vivo exposures. In these cases, the patient imagines confronting the feared object or engaging in the feared task. When the patient's level of anticipatory anxiety is reduced, in vivo exposure may be conducted with the actual feared object or task, assuming that it is both safe and available.

Recently, another imaginal procedure that builds from imaginal exposure has started to enter the repertoire of CBT: imagery rescripting. In imagery rescripting, after eliciting a past memory, one retells the memory from the perspective of the current self or another individual, helping the patient in the past cope better, get their needs fulfilled, and

ultimately distinguish the past event from their current life. They then retell the experience of the original memory, now incorporating the new information. This intervention has been shown effective for PTSD, and preliminary studies have suggested potential use in GAD, OCD, and more.

Interoceptive Exposure. Interoceptive exposure is the most recent form of exposure therapy to be introduced. This procedure is designed to induce feared physiologic sensations under controlled circumstances. Interoceptive exposure exercises are most commonly used in the treatment of panic disorder and certain specific phobias, for example, the fear of vomiting, in which internal cues such as those associated with physiologic arousal (e.g., rapid heart rate, dizziness, tingling in the fingertips) or gastric upset (e.g., after eating a spicy meal) elicit fear, anxiety, and further arousal.

Several specific exercises have been developed by David Barlow and colleagues to induce specific panic-like sensations. For example, hyperventilating produces shortness of breath, dizziness, and tingling in the fingers and around the mouth and can produce a sense of unreality. Breathing through a thin straw produces the sensation of not getting enough air. Spinning in a chair or spinning in place produces dizziness and, in some people, mild nausea. Other possible activities include aerobic exercise to induce rapid heart rate and shortness of breath, consuming mild stimulants (e.g., eating chocolate-covered espresso beans), or eating spicy foods. The goal is to find an activity that produces similar sensations to the ones that patients find unduly distressing and attempt to avoid (e.g., the core panic symptoms in panic disorder). As with other forms of exposure, the purpose of inducing these sensations is to learn that these sensations are not dangerous. By intentionally inducing these feared sensations, the patients can learn to dissociate the sensations from danger per se by learning that these sensations do not cause harm and also gain a sense of control and mastery over their anxiety by accepting it. These exercises also promote habituation of fear in response to them (i.e., the fear of fear or anxiety sensitivity) and distinguish these sensations, which are normal responses to the various exercises, from physiologic sensations that may actually signal a significant health problem. More recently, there have been suggestions and research supporting the use of interoceptive exposure as an exercise

that assists patients in tolerating negative activating emotions (arousal), even outside the context of panic disorder. This is consistent with the notion that exposures (all types) in the context of acceptance of negative emotions (as opposed to attempts to suppress them) facilitate improvement during exposure.

Cognitive Therapy

The basic assumption of cognitive therapy is that people's beliefs and appraisals of events and situations are at least as important in determining their emotional reactions as the actual events and situations. Problematic emotions such as anxiety are frequently the result of unrealistic and unhelpful beliefs about the world, the self, and others. The goal of cognitive therapy is to help patients to identify unhelpful cognitions and cognitive distortions (e.g., probability overestimation, catastrophic thinking, all-or-nothing thinking, overgeneralization, and only considering evidence that is consistent with existing beliefs) and to modify them. Three of the most common traditional cognitive therapy procedures are (1) the use of Socratic dialogue, in which the therapist uses a series of questions to help the patient identify and challenge unhelpful beliefs or to uncover evidence disconfirming fear-related beliefs; (2) the downward-arrow technique, in which the therapist helps to uncover deeper beliefs and meanings by repeatedly asking for greater clarification; and (3) the use of thought records, in which patients record automatic beliefs, list evidence for and against those beliefs, review potential cognitive errors that may be reflected in those beliefs, and then generate more realistic and helpful beliefs. All these procedures can be conducted formally as traditionally intended or in a more integrated fashion with exposures, as is more typically done in contemporary CBT. Indeed, behavioral experiments epitomize this integration. The goal of a behavioral experiment is to test beliefs about the nature and probability of feared consequences under conditions that will optimize exposure to, and the encoding of, disconfirming information. Accordingly, before conducting a behavioral experiment, the patient makes detailed predictions about what they believe will happen under a particular set of circumstances and then conducts the relevant experiment to see what happens. For example, consider a person with panic disorder who fears they will go crazy if they feel dizzy. A behavioral experiment to test predictions about the likelihood of going crazy might be to spin in a chair slowly at first, then work up to

spinning quickly, and see what the consequences of feeling intense dizziness are. Each time patient feels dizzy without going crazy (operationalized idiosyncratically for the given patient), the patient is confronted with evidence that disconfirms their beliefs about the probability of going crazy. The conceptual emphasis in cognitive therapy on changing beliefs through exposure to disconfirming evidence is consistent with the tenets of emotional processing theory. The practical and empirical issues involve determining the best ways to accomplish this goal.

Anxiety Management and Stress Inoculation Training

Anxiety management training is a general approach to treating anxiety, of which Meichenbaum's stress inoculation training is one specific example. Emotions in general, and stress and anxiety, reflect the activity of three loosely coupled and interacting "channels," or modes, of responding: Cognitive-phenomenologic, physiologic, and behavioral. Stress inoculation training involves training patients in applying specific skills and techniques designed to address each of these response modes in a flexible manner tailored to the individual's needs. The assumption underlying anxiety management training is that some people lack the skill of managing their anxiety and need to learn these skills. For example, spiraling negative cognitions that often occur during times of stress may be interrupted by the use of thought stopping, in which the patient thinks the word "stop" in their mind while vividly imagining the word "stop" and then replaces it with positive or coping self-statements. The physiologic manifestations of anxiety and stress (e.g., hyperventilation and its consequences, muscle tension, and gastric symptoms) may be addressed through training in diaphragmatic breathing and progressive muscle relaxation (e.g., Jacobson "tense and relax" method). Changes in overt behavior are promoted through role-playing and covert rehearsal, in which patients practice new behaviors while executing other coping skills either with another person or in their mind. Exposure to feared situations either in vivo or in the imagination is frequently a part of stress inoculation training but is usually for the purpose of practicing new skills and is accompanied by the use of other coping skills. From the perspective of emotional processing theory, stress inoculation training brings about successful coping with fear and anxiety, which provides new meaningful

information related to personal competence that counters typical fear-related perception of oneself as incompetent.

Acceptance and Mindfulness-Based Training

Over the past two decades, there has been an increase in interest in combining exposure and other forms of procedures that aim at coping with anxiety via mindfulness, meditation, and a related concept frequently associated with mindfulness called “acceptance.” The interest is due to several CBT treatments that have their roots in Buddhism and have been integrated with humanism and CBT. Three of the most popular treatments are acceptance and commitment therapy (ACT), mindfulness-based stress reduction (MBSR), and mindfulness-based cognitive therapy. All of these and other versions have in common the idea that fighting one’s anxiety (in the case of anxiety disorders) leads to a vicious cycle of attempting to suppress or otherwise force the downregulation of anxiety, which typically backfires. Therefore, acceptance-based techniques emphasize the need to first acknowledge that the anxiety exists and to try to objectively and nonjudgmentally observe it. Importantly, much of this concept was part of earlier versions of exposure therapies, but the aspect of radical acceptance was not emphasized. While some argue that acceptance-based techniques are in direct contrast with habituation models, anxiety reduction models, and cognitive therapy, we believe that all these techniques likely facilitate one another and that such techniques are easily integrated into exposure. Indeed, acceptance techniques and their integration with the other procedures may facilitate emotional processing.

Interpersonal Skills Training

Research has suggested that some individuals with social anxiety disorder, as well as those with other anxiety disorders, sometimes have interpersonal deficits that contribute to the maintenance of their anxiety and potentially negatively affect treatment. Thus, some people with anxiety lack important skills needed to interact effectively with others. Consequently, they experience fewer interpersonal rewards and more punishments, leading them to avoid social interactions when possible, thereby further limiting their ability to acquire effective social skills and decreasing their social support. Accordingly, comprehensive treatment for anxiety provides explicit training to help patients acquire and use

appropriate social skills and thereby reverse the negative cycle when necessary. These skills include assertiveness training and training in initiating, maintaining, and ending conversations. At times, it may be that training in such skills helps individuals have more confidence in their own skills and stop engaging in avoidance or safety behaviors. In addition, some research groups have suggested adding more interpersonal components to CBT to further help patients learn that the goals of interpersonal interactions are not to pass a test but rather to seek intimacy or simply to be in a relationship.

Efficacy of Cognitive-Behavior Therapy

Phobias and Agoraphobia. A large body of research, beginning in the mid-1960s, has clearly demonstrated the efficacy of several exposure therapy protocols in reducing simple phobias and fear of public speaking. This research establishes exposure therapy as the treatment of choice for these disorders. The earliest studies focused on systematic desensitization. In the first controlled study, systematic desensitization was compared with a waitlist control condition in the treatment of students with a fear of snakes. In the first phase of the study, participants in the desensitization group separately practiced relaxation and created a hierarchy. In the second phase, participants in the desensitization group paired the feared images from the hierarchy with relaxation. Neither group showed any changes during the first phase, but the desensitization group showed significant improvement across the second phase, whereas the control group showed no change.

In a follow-up study, desensitization was found to be superior to a pseudotherapy that, like desensitization, included training in relaxation and hierarchy construction. After the initial preparation, participants in the desensitization group paired the feared images with relaxation, whereas the pseudotherapy group engaged in positive imagery during relaxation. Another study compared the efficacy of five sessions of systematic desensitization for public speaking fears and other forms of social anxiety with waitlist and two alternative treatment conditions (insight-oriented psychotherapy and an attention-placebo condition in which subjects were given a placebo pill but told that it was a drug that reduced anxiety in stressful situations and then conducted a task that was said to be stressful but actually induced drowsiness). Results revealed that all three treatments were superior to the waitlist and that systematic

desensitization was superior to the alternative treatments, which did not differ from one another. This pattern of outcome was maintained for up to 2 years after the completion of treatment.

Research in the 1970s began to investigate the “flooding” approach to imaginal and in vivo procedures, which involved repeated and prolonged exposure to fear cues of high intensity without relaxation. Results from the earliest of these studies provided evidence for the efficacy of all three approaches (systematic desensitization, imaginal exposure, and in vivo exposure), but the results were mixed regarding the relative efficacy of the treatments. One group found that both systematic desensitization and imaginal exposure were more effective than a nonspecific treatment control condition among a mixed sample of patients with specific phobias and patients with agoraphobia. However, they did not replicate the finding of superiority of imaginal exposure over desensitization for agoraphobia.

A more consistent pattern of outcome in favor of a particular form of in vivo exposure, called *participant modeling* or *guided mastery*, over other forms of exposure therapy in the treatment of phobias and agoraphobia has been reported in a series of studies by Albert Bandura and colleagues. In participant modeling, the therapist actively models handling the feared object for the patient and may use various “response induction aids” to help the patient successfully to handle the feared object. For example, in treating a patient with a spider phobia, the therapist may first demonstrate how to touch, handle, and control a tarantula. The therapist would then coach the patient in performing the same behaviors, first while wearing protective gloves and then without gloves. This active approach to in vivo exposure may be contrasted with more-passive approaches in which the patient may be instructed to sit and observe a snake in a cage and attempt contact with the object when their fear at the earlier step has decreased.

Systematic desensitization, prolonged imaginal exposure, and prolonged in vivo exposure have all been found to be effective in the treatment of phobias, but in vivo exposure was generally more effective than imaginal exposure, both with phobias and agoraphobia. Prolonged in vivo exposure is at least as effective as, and often more effective than, desensitization and prolonged imaginal exposure. The participant modeling variation of in vivo exposure is particularly effective in treating a range of phobias, including small-animal phobias, acrophobia, and agoraphobia. Some recent studies have suggested that in vivo exposure

plus a mildly distracting social interaction is more effective and tolerable than full focus on the feared stimulus. Studies have also found virtual reality-based exposure therapy to be effective.

Panic Disorder. According to the cognitive-behavioral model of panic disorder, a consequence of experiencing unexpected panic attacks for some individuals is the development of a vicious cycle. The cycle begins with hypervigilance for somatic cues indicative of a panic attack that, if detected, are interpreted negatively (e.g., as an indicator of having a heart attack or going crazy). The negative interpretation of somatic sensations results in increased anxiety and arousal, spiraling into a panic attack. Agoraphobic avoidance may also develop as an attempt to avoid experiencing panic attacks in situations in which help may not be available. Cognitive-behavioral treatments based on this model contain several components: (1) psychoeducation regarding the cognitive-behavioral model of panic disorder, (2) cognitive restructuring to challenge catastrophic cognitions about the likelihood and significance of panic attacks, (3) interoceptive exposure to feared somatic sensations to reduce the “fear of fear,” and (4) in vivo exposure to avoided cues, particularly in cases in which agoraphobic avoidance has developed. Oftentimes, later phases of treatment include combinations of phases 3 and 4 to help the patient learn to deal with physical sensations in the context of formerly avoided situations. Relaxation and breathing retraining were early components of CBT protocols, but research has suggested that they are at best unnecessary and possibly lead to greater dropout or interference with treatment gains.

The efficacy of CBT programs based on this model has been demonstrated in a series of well-controlled studies and meta-analyses. Between 41% and 87% of patients receiving CBT are panic free after treatment, compared to 36% receiving relaxation only, 50% receiving alprazolam, 20% receiving imipramine (Tofranil), 13% to 36% receiving placebo, and 30% to 33% undergoing waitlist. In the one study that combined imipramine with CBT (Barlow et al., 2000), the combination treatment was found to be slightly more effective than CBT alone but not CBT combined with placebo. In this study, 6 months after treatment discontinuation, CBT alone and CBT plus placebo were superior to CBT plus imipramine, suggesting that medication may interfere with the maintenance of CBT gains after medication discontinuation. Several other

research groups investigated variations of CBT, with similar results, replicating the superiority of CBT over relaxation, supportive counseling, and waitlist. Another large, multicenter study examined CBT as a first-line treatment for panic with agoraphobia. Individuals who did not respond to 10 to 12 sessions of CBT for panic and agoraphobia were randomized to either more sessions of CBT or paroxetine. Individuals who received paroxetine responded more quickly to treatment than continued CBT, though individuals who received CBT had caught up by 9-month follow-up. Individuals who responded to treatment were randomized to maintenance CBT or no maintenance treatment. Maintenance sessions decreased relapse significantly (5%) in comparison to those not randomized to maintenance treatment (18%; White et al., 2010).

Several studies attempted to identify which components add to treatment outcomes. Two studies found that adding cognitive restructuring to in vivo exposure substantially improved outcomes, although other researchers have not been able to replicate this. Another study compared CBT consisting of education, cognitive restructuring, and interoceptive exposure with the same program plus relaxation and found that adding relaxation did not improve outcomes. A 1997 study compared two treatments that incorporated cognitive restructuring and in vivo exposure. In addition, one included interoceptive exposure, and the other group substituted breathing retraining. Both treatments were associated with improvement, but the group receiving interoceptive exposure had superior outcome on panic frequency at post-treatment and follow-up assessments. In a study using a crossover design, patients were assigned to receive four sessions of cognitive therapy followed by four sessions of interoceptive exposure or the reverse. Both treatments were associated with improvement, and more improvement was observed for the first intervention administered, but there was no difference in the efficacy of the two components. An additional study compared cognitive therapy without interoceptive exposure to interoceptive exposure without cognitive therapy and found similar positive outcomes in both groups that were equivalent to other studies examining combined packages. Another study compared education, cognitive restructuring, and in vivo exposure with or without the inclusion of breathing retraining and found no reduction in treatment efficacy. Three variations of self-conducted exposure therapy—in vivo exposure, interoceptive exposure, and the combination of in vivo plus interoceptive exposure—were compared with a waitlist control in

another study. All three treatments were superior to the waitlist condition, but there were no significant differences among treatment conditions.

Treatment for panic disorder has largely consisted of multicomponent packages consisting of education about the cognitive-behavioral model of panic along with one or more of the following: Diaphragmatic breathing, relaxation, cognitive therapy, in vivo exposure, and interoceptive exposure. Dismantling studies have been partially successful in identifying the active ingredients, which seem to be cognitive restructuring combined with in vivo or interoceptive exposure. Indeed, the addition of interoceptive exposure may be particularly helpful. In a meta-analysis of 43 controlled studies of treatment for panic disorder, the largest mean effect size was obtained for the combination of cognitive therapy plus interoceptive exposure (.88), followed by CBT without interoceptive exposure (.68), CBT plus medication (.56), and medication alone (.47). Moreover, dropout rates from CBT were lower than dropout rates from medication conditions (alone or in combination with therapy). Another review by the Cochrane Collaboration found 21 trials comparing CBT to medications and their combination. Results suggested that combination treatment is superior to medication alone. Combination treatment also had superior symptom reduction to CBT alone in the acute phase but also had more dropouts. After treatment discontinuation, no difference between CBT and combined treatment was found. Some trials showed that CBT for panic can also be helpful for treating medication-resistant patients, as well as for helping patients discontinue medications, including benzodiazepines and selective serotonin reuptake inhibitors (SSRIs). Recent trials also showed the ability to disseminate treatment for panic in community mental health clinics in addition to primary care. Other studies showed that CBT is effective for nocturnal panic and that focused CBT on panic also significantly reduces comorbid conditions. In addition, several trials suggested the efficacy of group CBT treatment for panic disorder. More recently, numerous studies have demonstrated the efficacy of online or internet-based, therapist-guided interventions for panic disorder. Finally, some studies showed promising results for early intervention with CBT in individuals at risk for developing panic disorder.

Social Anxiety Disorder

Individuals with social anxiety disorder experience marked and persistent fear and avoidance of one or more social or performance situations. The

person may fear doing or saying something embarrassing or manifesting signs of anxiety (e.g., blushing, sweating, trembling) in such situations. Thus, social anxiety disorder can be conceptualized as a fear of embarrassment or social rejection. Most individuals with social anxiety disorders fear and avoid multiple situations, falling within the generalized subtype of social anxiety disorder. Recent research has suggested that individuals who suffer from social anxiety disorder have a fear of positive evaluation as well as a fear of negative evaluation. They also tend to have diminished positive affect, particularly due to a lack of pride (more than joy), which has been theorized to reflect some underlying low self-esteem.

Treatments for social phobia have generally consisted of exposure therapy, cognitive therapy, and the combination of exposure plus cognitive therapy (sometimes also including social skills training). A network meta-analysis summarized the outcome of 101 studies of 41 different treatments or control conditions for social anxiety. Most active treatments were superior to waitlist. However, individual CBT had the largest effect size (greater than group CBT and other treatments) and was significantly more effective than psychodynamic therapy, supportive therapy, or mindfulness. The results of individual dismantling studies yield an ambiguous picture. In the first such study, exposure alone was compared with exposure plus cognitive therapy. Although both groups improved, the outcome was somewhat better for the combined treatment, particularly at the 3-month follow-up assessment. In a second study by the same group, the efficacy of each component alone, as well as the combination of the two, was compared with a waitlist control group. Compared to the waitlist control group, all three treatments were found to be effective in reducing social anxiety. Again, however, outcome was best among subjects who received the combined treatment. By contrast, another study did not find evidence for superiority of combined treatment over exposure alone. On some measures, patients who received exposure only had numerically better outcome than those who received the combined program.

One treatment program that has received considerable research attention is Richard Heimberg's cognitive-behavioral group therapy (CBGT), consisting of in-session exposure to feared social situations, cognitive restructuring, and corresponding homework. The group format not only serves to make treatment more affordable, but it is also believed that group treatment provides a great resource for conducting exposures, obtaining feedback, and learning vicariously. One study found CBGT to be

superior to waitlist, and three studies found CBGT to be superior to a group attention control condition, in which patients received education about social anxiety and nondirective group therapy. Heimberg and colleagues also compared CBGT with phenelzine (Nardil) and placebo. Although there were no differences between CBGT and phenelzine immediately after treatment, there were more instances of relapse for patients receiving phenelzine during the 6-month follow-up. Another study also compared CBGT with the same treatment components administered individually and found the two methods to be comparable. However, more recent studies have suggested that individual treatment is superior to group treatment. One of the largest randomized trials found that group CBT including social skills training yielded similar outcomes to fluoxetine and the combination of fluoxetine plus CBT, and all these treatments were superior to placebo.

The most promising results have come from a version of CBT developed by David M. Clark and colleagues. Several randomized studies have been published, showing large effects compared to fluoxetine, exposure alone, psychodynamic therapy, and group CBT (although not CBGT). Recent data support the efficacy of this treatment in a fee-for-service clinic. Some differences between the newer program and other CBT for social anxiety include a stronger emphasis on identifying and eliminating safety behaviors and shifting attention outward from the self. In addition, exposures are integrated carefully with cognitive challenging in the context of making specific predictions and evaluating these predictions post hoc with feedback from multiple sources, including videotape and those with whom the patient interacted during the exposure. Much of this is consistent with modern theories of CBT discussed above. One of the latest advances in this treatment is an online internet administration of much of the program, using videos, chats, and other interactive activities. Results seem to suggest excellent outcomes with less time spent by the therapist (most of which is online), though considerable patient investment in time on their own. Indeed, multiple studies of internet-based CBT have been conducted and reviewed in meta-analyses, suggesting good efficacy.

Generalized Anxiety Disorder (GAD)

The key feature of GAD is the presence of excessive worry accompanied by anxiety and physiologic symptoms of tension, irritability, and sleep

disturbance. Pathologic worry, as occurs in GAD, is distinguished from normal worry in that the frequency, intensity, and duration of the worry, in addition to the attendant anxiety, greatly exceed the actual probability or impact of the feared event and that the worry is experienced as difficult to control. GAD is the least focused of anxiety disorders and has the greatest overlap with depressive disorders. GAD is one of the only psychiatric disorders with a specific cognitive criterion A variable in the DSM-5: excessive, uncontrollable worry. Individuals with GAD tend to worry about minor matters (a sometimes-distinguishing feature of GAD) as well as major ones (health, children's future, etc.). In addition to worry, individuals with GAD tend to have physiologic responses that are less autonomic and more related to stress (e.g., sleep disturbance, muscle tension, irritability).

CBT packages for GAD have typically included training in relaxation and cognitive therapy. In addition, some packages have included some form of exposure therapy to the worry content and problem-solving. Relaxation alone, cognitive therapy alone, and their combination (with and without the further addition of exposure) have all been found to be effective in reducing worry and anxiety compared to waitlist. In addition, CBT has been shown to be more effective than supportive control conditions. One meta-analysis found that CBT and relaxation did not yield different results for GAD. Several meta-analyses and reviews have found CBT superior to waitlist and placebo conditions. One meta-analysis found that CBT effects were somewhat smaller than those for medications; another more recent review found CBT to be superior. The general results of these trials have been positive, but there is a consensus that improvements in treatment efficacy are necessary, perhaps more than in CBT for other anxiety disorders. Several attempts have been made to improve treatment outcomes for GAD. One study added more treatment sessions for individuals predicted to have poorer outcome, with nonsignificant improvement in outcome compared to standard treatment. Others attempted to modify or add to existing models of CBT. Refinement of the CBT model includes a greater focus on meta-worry (worry about worry) or a greater focus on the intolerance of uncertainty and the separation of worry into worry about current problems (addressed by problem-solving) and worry about future unknown events (addressed by increasing skills in tolerating uncertainty, including imaginal exposure). Additional areas and techniques to integrate with current CBT models

include interpersonal treatment strategies, emotion regulation strategies, mindfulness, and experiential avoidance strategies, additional focus on achieving positive well-being, and schema-focused treatments. Most data to date have not shown that these techniques provide improved outcomes compared to standard CBT packages, though one study focusing on emotion regulation found larger effect sizes. As with the other disorders, internet-based treatments for GAD are also showing efficacy and great promise.

Future Directions

The current literature review demonstrates the efficacy of CBT programs in the treatment of anxiety disorders. These treatments appear to be effective in children, adolescents, adults, and geriatric populations and are typically more effective than treatment as usual in the short and long term. Exposure in vivo to feared but otherwise safe stimuli and imaginal exposure to unwanted and upsetting thoughts are essential components of most CBT programs for anxiety. The cessation of safety behaviors or other subtle avoidance behaviors is essential for the anxiety disorders in order to disconfirm the patients' erroneous perceptions. The addition of interoceptive exposure appears to make a significant contribution to the treatment of panic disorder. In addition, exposure is typically conducted in the presence of cognitive challenges or discussions, helping the patient to attend to the corrective information. Anxiety management training and cognitive therapy have also been shown to be effective in the treatment of GAD. Cognitive therapy that includes behavioral experiments, which inherently involves in vivo exposure, is also an effective treatment for panic disorder and social anxiety disorder.

Several researchers have demonstrated the efficacy of multicomponent CBT packages that include components of anxiety management, cognitive therapy, and exposure. However, few of the relevant dismantling studies showed significantly improved outcome for these combined treatments as compared to the individual components. This may, to some extent, reflect low statistical power to detect the additive effects of treatments that individually are effective. Consistent with this hypothesis, meta-analyses have sometimes detected evidence for the superiority of combined treatments (typically of cognitive therapy plus exposure) that were not as evident in individual studies. Overall, it seems that the integration of exposure therapy with discussions that increase patients' attention to the

disconfirmation of their expectations of negative outcomes to exposures to the feared stimuli is the best method for optimizing treatment outcome. Perhaps the addition of cognitive therapy to exposure enhances outcome because it serves to enhance attention to disconfirming information. It is important to note that, as was hypothesized by emotional processing theory, exposure should match the fear of the patient. It follows that exposures that maximize opportunities for correction of erroneous associations by matching the patient's fears carefully and providing corrective information via these experiences are likely to lead to the best outcomes. The need for relaxation or similar coping or management strategies seems questionable.

Regarding the execution of these specific techniques, it is important to note that some studies suggested that outcomes can differ across therapists using the same techniques, and some studies showed that expert sites are more effective in delivering the same techniques than nonexpert sites (although this literature also includes data to suggest that some nonexpert sites can obtain similar effects for some treatments). When therapist or site differences occur, it is due to two aspects of treatment delivery that likely interact. First, execution of these techniques typically requires experience and competence in formulating and articulating the treatment rationale (i.e., creating a flexible hierarchy that targets core fears, determining the proper focus of imaginal exposures, etc.), addressing the many overt and covert avoidance behaviors effectively, and knowing how to push exposures to their optimal level. In addition, although formation of the therapeutic alliance, warmth, empathy, and other nonspecific therapeutic skills are not the central focus of CBT, they are still important components that likely interact with the focused treatment techniques, facilitating compliance and thus better outcome. However, having nonspecific characteristics without the expertise in technique is insufficient for provision of optimal treatment. Therefore, when experts are not available, it is essential to monitor patient progress carefully (also true when experts are available), and if there is no progress after 10 sessions of treatment, referral to an expert out of one's locale may be warranted. Alternatively, there is increasing data to suggest that therapist-supported internet-based programs can be effective treatments, which yield promising results that often are similar to face-to-face treatments.

Despite the success of CBT in the treatment of anxiety disorders, it is important to acknowledge two limitations. First, not every patient is responsive to treatment, and many people judged to have responded to treatment continue to experience significant residual symptoms. Thus, one avenue for future research is to identify ways to enhance existing treatments or to develop new treatments that are more effective. As noted, however, attempts to augment one psychological component with another treatment have not generally been very successful in significantly enhancing treatment outcome. Some of the recent improvements in outcome appear to be due to techniques that are developed based on specific maintenance mechanisms identified in studies on experimental psychopathology. Hopefully, continued study and improvement in understanding the psychological mechanisms involved in each of the anxiety disorders will help to improve outcome.

Another approach to potentially improving outcome is to combine psychotherapy with standard types of pharmacotherapy. This section did not provide coverage of the many studies that have investigated the efficacy of combining medication and CBT. The data tend to show that combining medication for anxiety disorders, such as SSRIs, with CBT either provides a small advantage or does not enhance outcome beyond those achieved by CBT alone, whereas adding CBT to medication enhances medication outcome. Most studies of combined treatments, whether combining two forms of CBT or combining CBT with medication, implemented both treatments simultaneously. This strategy may actually serve to minimize the ability to detect the effects of combined treatments when the individual treatments are generally effective. An alternative strategy would be to use an augmentation strategy, in which partial responders to one active treatment are then randomized to continue with the original treatment alone or to add a second treatment, as was done in the panic study described above.

The second limitation of CBT is its relative inaccessibility to people who do not live in large cities or near a university-based medical school or graduate program in clinical psychology. Greater research is needed to determine the factors that limit the use of CBT among community-based clinicians and the development of models for the dissemination of these treatments to make them more widely available. Some advancements in this area include using self-help and stepped-care approaches to treatment and using internet-based interventions.

14.7 Somatic Therapies for Anxiety Disorders

LAKSHMI N. RAVINDRAN, M.D., F.R.C.P.C., AND MURRAY B. STEIN, M.D., M.P.H.

Anxiety disorders are associated with a high-burden of illness with significant personal and societal consequences. However, not all patients with anxiety symptoms require somatic treatments. In a significant proportion of anxious patients, symptoms are transient and subsyndromal. There have also been concerns that the “medicalization” of certain symptoms, such as normal worries and shyness, may lead to unnecessary pharmacologic interventions. However, studies confirm that “overdiagnosis” is relatively low and that anxiety disorders are frequently under-recognized and untreated, particularly in primary care settings. This is attributed to factors including lack of awareness of symptom significance and stigma associated with receiving psychiatric help. Unfortunately, a proportion of patients that do seek help do not always receive optimal care. This is due to a myriad of reasons, including: the tendency of anxious patients to present with physical rather than psychological symptoms, their reluctance to report emotional symptoms, and clinicians’ failure to inquire about psychological issues. Thus, unsurprisingly, detection rates of anxiety and depression in primary care are estimated to be less than half, and among them, only a quarter receive appropriate evidence-based care. However, detection rates increase substantially with increased symptom severity and repeated clinic attendance. The diagnosis of anxiety disorders, and provision of appropriate care, are enhanced through systematic screening using questionnaires such as the Generalized Anxiety Disorder Scale (GAD-7), which has been validated for use in primary care settings. Education of clinicians, in particular general practitioners, about subgroups vulnerable to anxiety disorders, including those with chronic physical illness and adverse social determinants, would enhance early recognition and intervention. If detected and correctly diagnosed, most patients with anxiety disorders can be effectively managed in primary care.

Table 14.7–1.
Pharmacotherapy of Anxiety Disorders: Key Principles

- Diagnostic assessment
  - Determine primary diagnosis
  - Assess medical or psychiatric comorbidity
  - Document contributions of psychosocial stressors
  - Determine baseline symptom severity/frequency
- Physical examination and laboratory investigation
- Psychoeducation
- Choice of pharmacologic agent
  - Based on evidence
  - Family history
  - Past response
  - Drug interactions
  - Cost and access
- Monitor treatment program with validated tools

In many patients, the lack of confidence in the efficacy of medication leads to poor treatment adherence, specifically in those with somatic symptoms of anxiety. Psychoeducation for patients on the side effects of psychotropic treatment is also particularly relevant, as patients suffering from anxiety disorders are more prone to experience adverse events.

PRINCIPLES OF MANAGEMENT

As with all psychological illnesses, the management of anxiety disorders should follow recognized principles (see Table 14.7–1). This includes determining the primary diagnosis using standard diagnostic criteria as well as the presence of comorbid psychiatric and medical conditions, including the use of medications. Assessing the contribution of life stressors and familial-genetic factors, a screening physical examination and laboratory tests contribute to a comprehensive evaluation.

FIGURE 14.7–1. Factors influencing choice of treatment.

After assessment, the recommended initial interventions for anxiety disorders include pharmacotherapy, empirically supported psychotherapy (such as cognitive-behavioral therapy [CBT]), or a combination of the two. These interventions are supplemented by psychoeducation and systematic monitoring of progress. The specific choice of interventions is informed by several factors (see Fig. 14.7–1) based on a holistic understanding of personal and family history, in conjunction with knowledge of the evidence based as well as factors such as access and cost. Medications and psychological therapies are reported to have similar benefits in the acute phase, but their comparative efficacy over the long term has not been well evaluated. While it would be intuitive to assume that the combination would be superior to either intervention, the evidence remains inconclusive due to lack of long-term data.

PHARMACOLOGIC OPTIONS FOR TREATING ANXIETY DISORDERS

Several classes of agents have been evaluated in the treatment of anxiety and related disorders. These include antidepressants, benzodiazepines (BZDs), anticonvulsants, and antipsychotics, among others. There are significant differences in efficacy and tolerability between classes as well as among agents within the same class. There is also significant variability in the degree of symptom alleviation and the time points of optimal benefit in the illness trajectory.

Antidepressants

Selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) are considered first-line

agents for the treatment of anxiety disorders. Several novel agents, as well as tricyclic antidepressants (TCAs), monoamine oxidase inhibitors (MAOIs), and reversible inhibitors of monoamine oxidase type A (RIMAs), are used as second-line agents for specific subgroups of patients.

Selective Serotonin Reuptake Inhibitors (SSRIs) and Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs). SSRIs are effective in treating a broad spectrum of anxiety disorders and are often considered the first medication treatment option. SSRIs include fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram, and escitalopram. There are several SNRIs available, including venlafaxine, desvenlafaxine, duloxetine, and levomilnacipran. Most guidelines recommend SSRIs or venlafaxine as the initial antidepressant treatment for anxiety disorders.

Treatment is usually initiated at low doses to minimize an initial anxiogenic effect (which is almost always short-lived) and a slow up-titration to an optimal dose range. Although an initial response may be seen as early as 2 to 4 weeks, a trial of up to 8 to 12 weeks at a therapeutic dose is necessary to assess efficacy. In some patients, time to response and remission may be prolonged even up to 6 months after initial dosing. The aim of treatment should always be remission, as patients exhibiting a partial response and residual symptoms continue to have functional impairment and carry a greater likelihood of relapse. Even after achievement of remission, relapse or recurrence is not uncommon when medications are discontinued. As such, the use of SSRIs and SNRIs long-term for patients with anxiety disorders is not uncommon. The practice of gradual tapering before discontinuation and the adjunctive use of CBT may mitigate the likelihood of relapse.

The significant advantages of SSRIs and SNRIs over the older TCAs and MAOIs are their tolerability and low likelihood of abuse and overdose. Although there are individual differences between SSRI/SNRI agents, they are generally well tolerated. Potential troublesome adverse effects include initial nervousness, insomnia, gastrointestinal issues, agitation, tremors, headache, and dizziness, many of which improve with continued use. If these side effects persist for more than a few weeks, it may be necessary to switch to a different agent or reduce the dose and introduce augmenting agents. Although rare, it is also worth noting the more dangerous and potentially life-threatening side effects of these agents, including seizures and induction of mania. Treatment-emergent sexual

dysfunction across various domains (desire, arousal, erectile, ejaculatory, and orgasmic dysfunction) are also commonly reported side effects of SSRIs, though their frequency varies to some extent within the SSRI class (slightly less with SNRIs) and to a significant extent between antidepressant classes (see Table 14.7–2). Since there is usually little or no likelihood of tolerance development for SSRI-induced sexual dysfunction, a switch to another class of agents, dose reduction, or the adjunctive use of sildenafil or similar agents may be needed. Agents with less propensity for sexual side effects include agomelatine (not available in the United States), bupropion, mirtazapine, or moclobemide (not available in the United States). Long-term use of SSRIs has been associated with several serious but uncommon adverse effects, including serotonin syndrome and neuroleptic malignant syndrome. Hyponatremia, agranulocytosis, osteoporosis, and fractures in older adults have been reported in a small subgroup of patients. Increased risk of gastrointestinal bleeding, specifically when prescribed with NSAIDs, is another well-documented serious adverse event.

Table 14.7–2.
Frequency of Sexual Dysfunction among Most Commonly Prescribed Agents for Anxiety Disorders

Class	Drug	Frequency of Sexual Dysfunction
SSRI	Desvenlafaxine	<10%
	Citalopram	10–30%
	Escitalopram	10–30%
	Fluoxetine	>30%
	Fluvoxamine	>30%
	Paroxetine	>30%
	Sertraline	>30%
SNRI	Reboxetine	<10%
	Duloxetine	10–30%
	Levomilnacipram	10–30%
	Venlafaxine	10–30%
RIMA	Moclobemide	<10%
Other Psychotropics	Agomelatine	<10%
	Buspirone	<10%
	Mirtazapine	<10%
Atypical Antipsychotics	Quetiapine	10–30%
Anticonvulsant	Pregabalin	10–30%

With a similar adverse effect profile to SSRIs, SNRIs are generally well tolerated; among them, venlafaxine extended-release is the most prescribed globally. Its common adverse effects include dry mouth, increased sweating, and constipation. Other notable side effects include headache, insomnia, diarrhea, and sexual dysfunction; the severity of most side effects increases with higher doses. At the upper end of the therapeutic range (e.g., venlafaxine 225 mg or higher), routine blood pressure monitoring is also warranted because some patients (fewer than

5%) experience dose-related hypertension. Venlafaxine at lower doses (i.e., <150 mg) is said to have mainly serotonergic effects. Thus, it should be prescribed at higher doses to obtain the dual reuptake inhibition. A newer SNRI, duloxetine, has a similar efficacy and tolerability profile to venlafaxine, including discontinuation syndrome, and is not recommended for individuals with liver dysfunction. More recently, desvenlafaxine, the major metabolite of venlafaxine, was released as a standalone compound. It has primarily been investigated as a treatment for major depression, although it is often used off-label for other conditions, including anxiety disorders (GAD, SAD, and PD in particular). It is thought to offer the advantage of dual uptake inhibition even at lower doses, unlike venlafaxine, where it occurs only in the upper dose range. To date, reports of tolerability relative to its parent compound are quite favorable.

Levomilnacipran is an antidepressant recently introduced into the North American market. Similar to other SNRIs, levomilnacipran is safe to use and generally well tolerated among patients who may report mild side effects such as nausea, sweating, and agitation following use. There is also a need to monitor an increase in blood pressure following initiation of use. The advantage of levomilnacipran is that the degree of norepinephrine reuptake inhibition is said to be proportionally the highest (compared to the serotonin effect) among all SNRIs. Published evidence of levomilnacipran's use in pure anxiety conditions is lacking, but the literature suggests individuals with anxiety conditions comorbid with depression are known to benefit.

Both with SSRIs and SNRIs, abrupt stopping can lead to discontinuation syndrome. Commonly reported symptoms of this condition, which tend to occur 2 to 4 days after medication cessation, include increased anxiety, irritability, tearfulness, dizziness, lightheadedness, malaise, sleep disturbance, and concentration difficulties. Although discontinuation symptoms can occur with all SSRIs and SNRIs, they are more common with agents with shorter half-lives (e.g., paroxetine and venlafaxine). Patients should discontinue SSRIs or SNRIs only under the supervision of their physician, with gradual taper; if discontinuation symptoms emerge while tapering, the dose should be increased to stop symptoms, followed by a restart of the discontinuation at a slower rate. An alternate option is the use of fluoxetine as a transition agent because of its long plasma half-life.

Ongoing controversy concerning antidepressant use and increased suicidality in the initial few months of treatment prompted the FDA to issue a black box warning on all antidepressant medication, cautioning against their use in children and young adults. This led to more systematic evaluations of the risk of such occurrence, which found no clear evidence to support an increase in risk of suicidality in individuals aged 24 and above over the short-term. Their use may, in fact, confer a degree of protection in the adult and older populations. With child and young adult samples, independent and more recent meta-analyses show a 1.5- to 2-fold risk of increasing suicidal thoughts and behaviors with newer antidepressants, but not in the number of completed suicides and with only a very small increase of absolute risk. Given the low-absolute risk and the significant impact of anxiety disorders in children and adolescents (the known age of onset), the use of pharmacotherapy in these populations is warranted, particularly in the more severely affected.

Tricyclic and Heterocyclic Antidepressants (TCAs and HCAs). TCAs were the earliest proven agents in the treatment of anxiety disorders until SSRIs were invented. TCAs and related HCAs used for treatment of anxiety disorders include desipramine, nortriptyline, clomipramine, amitriptyline, and doxepin. TCAs and HCAs work by inhibiting the reuptake of multiple monoamines, including norepinephrine and serotonin, in the synaptic cleft. They also block cholinergic, histaminic, and alpha-1 adrenergic receptors, which contributes to their significant side-effect profile. These include sedation, weight gain, hypotension, dry mouth, blurred vision, and constipation, among others. Subgroups of patients often report an initial “jitteriness” when treatment is initiated with TCAs, which can often be mitigated with low doses and a gradual up-titration to a therapeutic level. TCAs are suggested to be less efficacious than the SSRIs/SNRIs for anxiety disorders and also carry a greater risk of serious adverse effects, including a lowered seizure threshold and cardiotoxicity, specifically from overdose. In addition, drug–drug interactions and discontinuation syndrome are not insignificant issues with TCAs.

Monoamine Oxidase Inhibitors (MAOIs). MAOIs are effective antidepressants whose use has been superseded by equally effective but significantly safer SSRIs and SNRIs, relegating them to second-line use. The two most commonly used MAOIs in North America are phenelzine

and tranylcypromine. The benefit of phenelzine is well documented in panic disorder and social anxiety disorder. MAOIs irreversibly inactivate both isoforms of the enzyme monoamine oxidase (MAO-A and MAO-B), leading to a relative increase in monoamines serotonin, norepinephrine, and dopamine in the synaptic cleft. The irreversibility of the inhibition requires patients to have a minimum 2-week “washout” period when switching from an MAOI to any other antidepressant class or even from one MAOI to another. The enzymatic inhibition is generic for monoamines and reduces the ability of the body to break down tyramine, leading to the risk of a hypertensive crisis after consumption of food rich in this monoamine. Though this reaction is rare, patients on MAOIs need to follow a low-tyramine diet during treatment and for an additional 2 weeks after discontinuation. The more common and more benign side effects of MAOIs include postural hypotension, insomnia, and weight gain. Similar to TCAs, patients taking MAOIs should be monitored closely for drug–drug interactions and the possibility of overdose.

Reversible Inhibitor of Monoamine Oxidase Type A (RIMAs). RIMAs are unavailable in the United States, although one member of this class, moclobemide, is available in Canada and several other countries globally. Randomized clinical trials (RCTs) have shown that moclobemide is effective in reducing symptoms of depression and several anxiety disorders (SAD in particular); however, anecdotal reports suggest that it may be less efficacious than MAOIs. Clinicians have also noted the gradual development of tolerance in a proportion of patients, leading to the need for an incremental increase in dose. Close monitoring is advised when used in patients with hypertension. The key advantage of RIMAs over MAOIs is that dietary restrictions can be less stringent but are still recommended when RIMAs are used in higher doses. More common and more benign adverse effects include insomnia, dizziness, agitation, and dry mouth; most are transient and self-limiting. RIMAs, when available, represent an alternative to SSRIs or SNRIs for patients with SAD who have experienced significant side effects with those agents.

Novel Antidepressants. Mirtazapine is a noradrenergic and specific serotonergic antidepressant (NaSSA). It has not been extensively studied in anxiety disorders but is claimed to be a useful agent for treating symptoms of panic disorder and GAD, as well as anxiety symptoms in older adult patients. Adverse effects are generally immediate and short-

term and include sedation, dry mouth, and dizziness. Mirtazapine is relatively free of sexual side effects but has a propensity to increase appetite and cause weight gain. Additionally, its favorable effect on sleep often makes it a useful adjunctive agent for patients with insomnia.

Buproprion is a dual norepinephrine dopamine reuptake inhibitor that is not often used as a first-line agent for the treatment of anxiety disorders. This is in part due to a clinical impression that it may trigger agitation and worsen anxiety, at least in initial therapy. It is more often used as an adjunctive agent to address residual symptoms and improve sexual dysfunction.

Vortioxetine is a newer agent with a multimodal mechanism of action on the serotonergic system. It acts as an agonist and partial agonist at 5-HT_{1A} and 5-HT_{1B} receptors, respectively, and as an antagonist at 5-HT_3, 5-HT_7, and 5-HT_{1B} receptors. To date, the limited clinical trials of its use in anxiety have primarily focused on GAD, where results remain preliminary. However, its neurochemical profile and the reported reduction of anxiety symptoms in patients with MDD would suggest benefit.

Agomelatine is a novel agent, not available in the United States. Its action is said to occur through agonism of melatonin receptors MT1 and MT2 and antagonism of 5-HT_{2C} receptors, leading to increased monoamine neurotransmission. The evidence for its benefit in treating the symptoms of anxiety disorders is still preliminary, but there is promising evidence for its use in GAD and its prophylaxis. It has the advantage of a low likelihood of sexual dysfunction and weight gain and does not cause discontinuation symptoms. Adverse effects, mostly gastrointestinal symptoms and fatigue, are mild and self-limiting. Regular monitoring of liver function is advised in the early period of treatment.

Vilazodone, recently introduced in North America, works by combining selective serotonin reuptake inhibition with partial agonism of the 5-HT_{1A} receptor. Approved for use in depression, a recent trial found that a flexible dose (20 to 40 mg/day) of vilazodone incurred a statistically significant reduction of symptoms in patients with GAD when compared to placebo. However, more studies are needed to provide a more robust understanding of its use in anxiety disorders as well as its long-term effects. Finally, milnacipran is an SNRI available in several countries worldwide but not currently approved in North America. Two small open trials have suggested potential utility in GAD and PD, but controlled trials are needed to confirm benefit.

Benzodiazepines (BZDs)

BZDs have been used for several decades for the treatment of anxiety disorders. Their therapeutic effect is mediated through augmentation of GABAergic neurotransmission, specifically in “fear circuits” mediated by the amygdala. In addition to anxiolytic effects, they also possess sedative, anticonvulsant, and muscle relaxant properties. Most BZDs (e.g., clonazepam) are metabolized by the liver, primarily through CYP-mediated oxidation, but others (e.g., lorazepam, oxazepam, and temazepam) are metabolized via a conjugation process, and thus are the preferred choice for individuals with impaired liver function. Common adverse effects of BZDs include mild dizziness and sedation, both of which are generally attenuated by time or dose reduction. Patients should be cautioned about using heavy or dangerous machinery and driving, especially at initiation and after a dose increase. Consumption of alcohol should be avoided as it can intensify the effects of BZDs. Although potential for abuse and development of tolerance to therapeutic effects are of some concern, when used appropriately under medical supervision, BZDs are efficacious (even when used chronically), have a rapid onset of action, and are generally well tolerated. They are particularly useful for as-needed (PRN) use for symptomatic relief of those with occasional panic attacks or performance anxiety. However, PRN use of BZDs is generally discouraged in individuals with frequent panic attacks, where regular use of medication to prevent panic (rather than try to abort an attack once it has started) is recommended.

BZDs are classified based on their half-life as short-, intermediate-, and long-acting. Agents with a short or intermediate half-life (e.g., alprazolam or lorazepam) are the most commonly prescribed agents for as-needed use but are also prescribed for regular use, although long-acting agents (e.g., clonazepam) are often preferred for regular use. BZDs are often prescribed for a brief period (3 to 4 weeks) when antidepressant treatment is initiated to improve delayed or partial response or to help relieve adverse effects from the antidepressant, such as insomnia or jitteriness. At other times, BZD monotherapy can be justified when other treatments have failed or are not tolerated and when anxiety is persistent, severe, and disabling. BZDs are also often used as an adjunct to antidepressant therapy in instances where the antidepressant provides some, but not optimal, anxiety reduction.

Some patients have been noted to remain stable on BZDs for many years with continued therapeutic response and no evidence of tolerance or abuse. However, BZD use is best avoided in individuals with histories of alcohol or substance abuse unless there are compelling clinical reasons (i.e., nonresponse to other agents); under such circumstances, care should be under the supervision of a psychiatrist.

Anticonvulsants

Antiepileptic drugs have long been used in the treatment of mood disorders, but their use in anxiety disorders is still mostly anecdotal. Controlled studies support the benefit of pregabalin in these conditions, particularly in GAD, panic disorder, and social anxiety disorder. Pregabalin, a structural analog of GABA, has evidence from several good-quality RCTs supporting its use as a monotherapy as well as an adjunctive agent therapy in acute treatment and prophylaxis of anxiety disorders. It may be of specific benefit when there are comorbid pain conditions and when insomnia is prominent. Dizziness and drowsiness are common side effects, and weight gain occurs in a minority of patients. It can be used safely in patients with hepatic dysfunction but is best avoided in patients with renal impairment. Other anticonvulsant medications, often used as adjunctive therapies to antidepressants, can be considered on a case-by-case basis in the treatment of patients with refractory anxiety disorders. These medications include gabapentin, levetiracetam, topiramate, tiagabine, and lamotrigine; however, evidence of efficacy from RCTs for most of these agents is lacking or inconclusive.

Antipsychotics

The use of typical antipsychotics for the treatment of anxiety disorders is limited by their significant adverse effects, including risk of tardive dyskinesia (TD) and extrapyramidal symptoms (EPS). The “atypical” antipsychotics (AAPs) include olanzapine, risperidone, quetiapine, ziprasidone, aripiprazole, and lurasidone, among others. AAPs are distinguished from the older generation of antipsychotics in part by their therapeutic effect being mostly mediated by the serotonergic system and, thus, lower propensity for extrapyramidal adverse events. Several AAPs have been shown to be effective augmentation agents to antidepressants for treatment of depression. Evidence for their benefit in anxiety disorders is less robust, with the possible exception of quetiapine, which has been

shown to be an effective agent for the treatment of GAD. Use of AAPs is limited by their propensity to cause weight gain and metabolic syndrome.

Other Antianxiety Medications

Beta-adrenergic antagonists, also called beta-blockers, are primarily useful as needed for performance anxiety. They block the peripheral effects of adrenaline and noradrenaline and thus reduce symptoms such as tachycardia and tremors, which patients with performance anxiety often tend to experience. Propranolol and atenolol are the commonly prescribed agents with some variability in the dosing. The dose range for propranolol is usually between 20 and 40 mg, and that for atenolol is between 25 and 50 mg. It has been suggested that targeting a heart rate reduction by 10 beats/minute and evaluating the patient's subjective feedback on performance is a useful strategy to determine the optimum dose. While published literature indicates a marked reduction of somatic anxiety symptoms, clinical impression suggests a less robust benefit. Beta-blockers used short-term as needed are generally well tolerated, but occasional side effects include dizziness, vertigo, or sleep disturbance. Their use in patients with certain cardiac or pulmonary diseases, angle-closure glaucoma, or diabetes is usually contraindicated.

Buspirone, an azapirone, is effective in the treatment of chronic anxiety states, primarily GAD. Buspirone is usually prescribed in two or three divided doses at a dose range of 20 to 60 mg. The time course of response to buspirone is similar to that of antidepressants, and it may take time to reach full therapeutic benefit. Hydroxyzine is an antihistamine with preliminary evidence of benefit in the treatment of GAD. While initial symptom relief can be experienced within the first 15 to 20 minutes of administration, it can take up to several weeks to achieve an optimal therapeutic effect. Hydroxyzine can be used for both short-term and long-term anxiety symptoms but may lead to mild side effects, including dry mouth, sedation, and tremors. It may be a good alternative to BZDs for some patients, although tolerance to the anxiolytic effects of hydroxyzine may occur rather quickly.

Treatment Resistant Anxiety Disorders

Partial or nonresponse to pharmacotherapy is not uncommon with anxiety disorders. In such cases, confirmation of the diagnosis (including ruling out potentially contributing medical conditions, such as thyroid disorders),

evaluating the impact of potential comorbidities (e.g., substance use), and pharmacokinetic interactions, as well as validating adequate trials (i.e., adequate dose and duration) are prudent first steps. In many patients, treatment resistance occurs even when pharmacotherapy is used in combination with CBT. Literature on treatment-resistant anxiety remains sparse, with few well-conducted clinical trials. Augmentation agents commonly used include anticonvulsants, AAPs, and BDZ. A common strategy in practice for addressing treatment-resistant GAD is the augmentation of SSRIs with pregabalin or BZDs. Despite lack of controlled trials and mixed evidence, in clinical practice, gabapentin is often used as an adjunct for refractory anxiety disorders (GAD and PD), particularly in cases of comorbid alcohol use disorder. The literature on the benefit of AAPs is mixed. Several small case series/open trials of olanzapine and aripiprazole indicate their utility of use as augmentation while data with quetiapine augmentation is mixed. With all AAPs, the risk of adverse metabolic effects needs evaluation and long-term monitoring. For treatment-resistant PD, there is evidence for adding clonazepam to an SSRI if a patient is not amenable to or suitable for CBT.

Novel Therapeutics for Anxiety

Despite the relative wealth of pharmacologic options for the treatment of anxiety disorders, clinicians continue to struggle with a subset of patients who are refractory to conventional treatments. There is an increasing interest in several novel strategies, including the use of neurostimulation therapy as well as several unique pharmacologic compounds, complementary and alternative (CAM) therapies, and NMDA receptor agents for this population.

Repetitive transcranial magnetic stimulation (rTMS) has shown promise as a treatment for depression or depression comorbid with anxiety disorder; however, evidence for rTMS applied for pure anxiety disorders is sparse. Case reports have suggested utility for rTMS in SAD and PD, but a double-blind trial failed to show benefit over placebo for rTMS treatment for PD. More promisingly, a small trial of fMRI-guided rTMS for GAD showed positive results following acute treatment, with gains generally maintained at 6-month follow-up; however, more controlled studies are needed to confirm these findings.

Transcranial direct current stimulation (tDCS), which involves application of a low-intensity direct electrical current to specific brain areas

to modulate cortical activity, has preliminarily demonstrated benefit in treatment-resistant depression. There are reports of its efficacy in GAD and PD, but it needs more systematic evaluation. Cranial electrotherapy stimulation, another novel, noninvasive technique using low-intensity alternating current, has shown early signals of benefit but needs further study.

There is emerging evidence regarding the use of neurosteroids for the treatment of anxiety disorders. Due to their ability to rapidly impact the central nervous system, there is some indication that their use can relieve anxiety symptoms. In particular, three good-quality trials have shown a nasally administered neurosteroid (compound PH94B) to be superior to placebo in treating symptoms of social anxiety disorder; this drug is still under investigation.

Ketamine and its analogs are seen as promising new interventions for treatment-resistant depression. Significant relief of anxiety symptoms in these patients suggests its benefit for depression comorbid with anxiety disorders and potentially even refractory anxiety conditions. While high-quality data for the latter is lacking, smaller studies have shown intravenous ketamine to produce a marked improvement in anxiety symptoms in patients with SAD and GAD. Results with intranasal esketamine are pending.

With the recent legalization of cannabis in many countries worldwide, as well as its increasing use for multiple medical conditions, use of cannabis for psychiatric conditions has become commonplace. However, to date, systematic trials of cannabinoids for anxiety disorders are few. The only meta-analysis to date on the topic suggests some utility for cannabinoids in SAD and GAD. However, methodologic issues, including heterogeneity in study design, preparation differences, duration of treatment, absence of studies of long-term efficacy, and publication bias, mitigate making any clear conclusions.

Consumers, particularly those with mood and anxiety disorders, are increasingly turning to CAM to either self-treat or augment their more conventional medications. These therapies include herbal medications, acupuncture, biofeedback, and yoga, among others. However, many herbal preparations have the potential to cause drug–drug interactions, so it is imperative that clinicians routinely check for the use of these substances. Two meta-analyses noted that kava, one of the most common herbs taken for anxiety, does demonstrate benefit for mild to

moderate anxiety, but its utility in specific anxiety disorders is still unclear, and there is also possible risk of hepatotoxicity and documented interactions with medications metabolized through the cytochrome P450 enzyme system. Other herbal remedies with purported antianxiety properties but insufficient clinical data to support their use include valerian root, passiflora (passion flower), inositol, St. John wort, gotu kola (*Centella asiatica*), California poppy, hawthorn, Ginkgo biloba, lemon balm, and sour date seed. Aerobic exercise has some data for utility in anxiety conditions and, given its myriad health benefits, should be routinely recommended. Preliminary evidence suggests benefits of yoga for performance and some other forms of anxiety.

TREATMENT RESPONSE AND COURSE OF ILLNESS ACROSS ANXIETY DISORDERS

In general, all first-line agents are thought to be equally effective, but in practice, SSRIs are often chosen as first-line options since they are often better tolerated than SNRIs. Starting with lower doses and increasing them gradually, as well as adding short-term concomitant BZDs, may improve their efficacy and tolerability. Partial or nonresponse to the initial trial of a first-line antidepressant may necessitate a switch to another first- or second-line agent from a different class. Augmentation with BZDs or pregabalin also has evidence for benefit. Guidelines recommend combining pharmacotherapy with psychological treatment as a first-line option for patients showing partial or nonresponse to medications.

Although individually, either pharmacotherapy or psychotherapy (e.g., CBT) show efficacy in the treatment of anxiety disorders, their combination has not been extensively studied. Available data shows inconsistent benefits for the combination; this may be because one treatment modality alone is sufficiently good that showing an additive (or better) effect is difficult without large sample sizes or because superiority of the combination to individual therapies in acute treatment fails to be sustained long-term. Access to CBT is often limited or expensive in many settings. If available, it is sometimes recommended that pharmacotherapy and CBT be started simultaneously. However, for many patients with partial or nonresponse to pharmacotherapy, sequential provision of CBT is a pragmatic option.

Empirical data on the optimal duration of pharmacotherapy are not extensive for most anxiety disorders. For many patients, at least 8 to 12 weeks of medications at therapeutic doses may be needed to evaluate the efficacy of acute treatment. Systematic data on long-term maintenance is limited for anxiety disorders. However, several RCTs do show that 20% to 50% of patients with chronic anxiety disorders relapse within several months of antidepressant discontinuation. It is thus recommended that such patients be maintained on treatment for at least 1 to 2 years before considering dose reduction or discontinuation and that any discontinuation be done by gradual decrements of 10% to 25% every 1 to 2 months while observing for recurrence.

The degree of response to pharmacotherapy differs among the anxiety disorders. Panic disorder is among the most responsive, with efficacy seen in 60% to 70% of treated subjects. However, for patients with comorbid agoraphobia, the response rates may be lower, and some patients may require higher doses of medication or concomitant CBT. Response rates for effective pharmacotherapy in GAD and SAD are slightly lower, with 50% to 60% of patients having a good clinical outcome.

Table 14.7–3.
Evidence-Based Recommendations for Monotherapy of Anxiety Disorders

Classes and Agents	Anxiety Disorders		
	SAD	**GAD**	**PD**
SSRIs	First-line	First-line	First-line
SNRIs	First-line	First-line	First-line
TCAs	Not recommended	Second-line	Second-line
MAOIs	Second-line	Insufficient evidence	Second-line
RIMA	Second-line	Insufficient evidence	Insufficient evidence
Buspirone (serotonergic agent)	Second-line	Second-line	Second-line
Novel Antidepressants			
Agomelatine	Needs further evaluation	Preliminary evidence	Needs further evaluation
Buproprion	Needs further evaluation	Needs further evaluation	Needs further evaluation
Mirtazapine	Needs further evaluation	Preliminary evidence	Preliminary evidence
Vortioxetine	Needs further evaluation	Preliminary evidence	Needs further evaluation
Vilazodone	Needs further evaluation	Preliminary evidence	Needs further evaluation
Milnacipran	Needs further evaluation	Preliminary evidence	Preliminary evidence
Benzodiazepines	Second-line	Second-line	Second-line
Quetiapine (AAPs)	Not recommended	Second-line	Insufficient evidence
Pregabalin (anticonvulsant)	First-line	Second-line	Insufficient evidence

SSRI, selective serotonin reuptake inhibitor; SNRI, serotonin norepinephrine reuptake inhibitor; TCA, tricyclic antidepressants; MAOIs, monoamine oxidase inhibitors; RIMA, reversible inhibitors of monoamine oxidase A; AAPs, atypical antipsychotics.

Note: SSRIs may be useful as second line for specific phobia nonresponsive to psychotherapy, and beta-blockers are recommended only for performance anxiety.

MANAGEMENT OF INDIVIDUAL ANXIETY CONDITIONS

The following sections review the literature for the treatment of individual anxiety conditions and make medication recommendations based on the strength of evidence available for different classes of drugs. See Table 14.7–3 for a summary of recommendations and Table 14.7–4 for general pointers.

Generalized Anxiety Disorder

GAD, which is characterized by excessive and frequent worries in multiple domains accompanied by psychic and somatic symptoms of anxiety, often presents with physical symptoms (e.g., fatigue, muscle tension, sleep disturbance) and usually in primary care settings. Comorbidities include depression, other anxiety disorders, or substance use are common. GAD often follows a chronic, fluctuating course, but periods of remission may occur.

Large RCTs, as well as systematic reviews and meta-analyses, confirm the benefit of SSRIs (fluoxetine, citalopram, escitalopram, paroxetine, sertraline) and SNRIs (venlafaxine and duloxetine) as first-line choices for the treatment of GAD. Novel agents agomelatine, mirtazapine, pregabalin, buspirone, quetiapine, and vortioxetine are suggested as alternative options. Two double-blind trials and one prevention trial of agomelatine for GAD indicated that agomelatine treatment improved clinical response and remission of anxiety symptoms and reduced the rate of relapse. The TCA imipramine has also been shown to be beneficial, but it is often used as a second-line option due to adverse effects. SSRIs are usually the initial choice, followed by pregabalin. Another highly prescribed class of agents for GAD are BZDs, which include alprazolam, lorazepam, diazepam, and bromazepam. Evidence for their benefit is strong, but they are often used only short term due to risk of tolerance and dependence. While the AAP quetiapine has significant efficacy in GAD, guidelines designate it as a

second-line intervention due to adverse metabolic effects and low acceptability and tolerability. Buspirone is often used similarly due to lack of comparative data with antidepressants. Other AAPs (olanzapine, risperidone, and aripiprazole) and bupropion, which have lower evidence of efficacy, may also be useful as adjunctive therapies. Among the newer antidepressants, vilazodone has shown promise for the acute treatment of GAD, but the two published meta-analyses reported contradictory findings, and there are no comparator data. Similarly, studies of another newer antidepressant, vortioxetine, yielded inconsistent results. Beta-blocker propranolol, anticonvulsant tiagabine, and AAP ziprasidone have not been shown to be effective in GAD.

Table 14.7–4.
Optimizing Pharmacotherapy

- Remission as goal of treatment
- Use first-line agent
- Adjunctive benzodiazepines short-term for selected subgroups
- Avoid quick dose escalation and high-dose use
- Patient education regarding adverse effects
- Trial of 8–12 weeks of pharmacotherapy at optimum dose
- Maintenance treatment recommended for a year

For relapse prevention, there is good evidence to support the use of SSRIs and SNRIs as maintenance therapy. A similar benefit has also been demonstrated with pregabalin and quetiapine. The benefit of continued maintenance medications may last at least 6 months, and cognitive behavior therapy (CBT) may be similarly effective.

Panic Disorder

Panic disorder is characterized by the presence of recurring, unexpected panic attacks. While periods between panic attacks are relatively symptom-free, persistent concern about future attacks and avoidance behavior is common. Meta-analyses and RCTs have confirmed the benefit of several classes of antidepressants for panic disorder. SSRIs (citalopram, fluoxetine, paroxetine, sertraline, fluoxetine, and escitalopram) and the SNRI venlafaxine are often recommended as initial therapy (though SSRIs tend to be the preferred choice). TCAs (in

particular, clomipramine and imipramine), as well as MAOIs (phenelzine and tranylcypromine), have equal efficacy but are often used as second- or third-line treatment because of their adverse event profiles. Other second-line agents include mirtazapine, bupropion, and reboxetine (not currently available in North America). Several BZDs (alprazolam, lorazepam, diazepam, and clonazepam) have also been proven effective in reducing panic symptoms, particularly in short-term treatment. Although classified as second-line interventions due to the risk of dependence and withdrawal, they are useful as concomitant short-term treatment to reduce or prevent the panic attacks and reduce anticipatory anxiety. BZDs also have the added benefit of a rapid onset of action. In contrast, AAPs have only preliminary evidence of benefit and are restricted to adjunctive third-line options for cases of partial or nonresponse to first- or second-line agents. Studies with the beta-blocker propranolol and anticonvulsants tiagabine, gabapentin, and carbamazepine have reported negative findings, while there are only preliminary reports evaluating pregabalin.

Maintenance studies in panic disorder have reported that many treatment responders show further improvement over time with antidepressant therapy effective in preventing relapse, with data up to 3 years. In addition to most first-line agents, which are effective in maintenance therapy, there is evidence that BZDs (alprazolam and clonazepam) may provide effective treatment for maintenance without the development of tolerance. In general, maintenance treatment for at least a year is recommended for most patients. Once a decision is made to stop medication, gradual tapering and slow discontinuation are recommended, particularly with BZDs.

Agoraphobia

Agoraphobia is **characterized by anxiety or fear of being in a situation from which escape or obtaining aid would be difficult.** Most presentations of agoraphobia are accompanied by panic attacks or PD, and agoraphobic symptoms improve in parallel with panic symptoms upon appropriate pharmacotherapy for PD. In other cases, agoraphobic symptoms often overlap with those of social anxiety disorder, GAD, and avoidant personality disorder. The efficacy of pharmacotherapy in “pure” agoraphobia has not been well evaluated; early studies with BZDs (alprazolam and diazepam), the TCA imipramine, and the MAOI phenelzine had negative findings, but little research has been done since.

Published literature confirms that pharmacologic treatment of common comorbidities, including depression and other anxiety disorders, often results in reduction of agoraphobia. Psychotherapeutic interventions, in particular, CBT with a focus on exposure therapy, appear to be effective interventions. It has also been suggested that patients with “pure” agoraphobia are often housebound and avoid seeking help, leading to an underestimation of its true prevalence and limited research on its treatment.

Social Anxiety Disorder

With an estimated lifetime prevalence of 8% to 12%, social anxiety disorder is a common condition. Its key symptom is excessive discomfort in social situations for fear of embarrassment or negative evaluation, which often leads to avoidant behavior. Evidence from meta-analyses, systematic reviews, and large RCTS suggest that all SSRIs, SNRIs (venlafaxine and duloxetine), pregabalin, and clonazepam, have strong evidence for benefit and are recommended as first-line treatments for SAD. The MAOI phenelzine is also very efficacious for SAD, but because of a poor adverse effect profile, it is used as a second-line agent for refractory illness. Other second-line options include the novel antidepressant mirtazapine and RIMA moclobemide, as well as BZDs bromazepam and alprazolam, and gabapentin. Due to negative findings, TCAs, the novel agent buspirone, and the AAP quetiapine are not recommended. While beta-blockers propranolol and atenolol can be beneficial in performance anxiety, they do not appear to help in the generalized subtype of SAD. There is also very limited positive evidence regarding the use of ketamine as a treatment for SAD.

While routine use of high doses of antidepressants is not recommended for SAD, it may benefit a subgroup to attain and maintain remission. However, lack of remission, even with optimum treatment, is not uncommon. Unfortunately, there are few systematic studies of strategies to treat refractory SAD. Switching to an alternative first-line agent or phenelzine, augmentation with pregabalin or clonazepam, or combination with CBT are among the common strategies employed to treat refractory SAD.

Longer-term studies have noted that following acute treatment, a significant proportion of patients continue to show incremental benefit, increasing the overall rate of response. Relapse prevention RCTs

confirms the benefit of several agents, including SSRIs, pregabalin, and clonazepam, over a 6-month period. As with acute treatment, psychological interventions, including CBT and mindfulness-based stress reduction, have been documented as efficacious in reducing SAD symptoms.

Specific Phobia

The key feature of specific phobia is an intense fear or anxiety of a specific object or situation, leading to its avoidance. Examples of common specific phobias include fear of airplanes, insects, and heights. Subsyndromal presentations are common, and lifetime prevalence is estimated at 10% to 13%, with many affected reporting multiple fears. Clinical presentations are rarely for the phobia itself but more often for comorbid depression and other anxiety disorders.

Psychological interventions, particularly exposure-based therapies, are considered to have the most evidence for efficacy in treating specific phobias. The benefit of pharmacotherapy has not been well studied, but very limited evidence suggests that SSRIs (escitalopram and paroxetine) may be useful as second-line treatments if patients do not respond to psychotherapy. So far, BZDs have not been found to be beneficial even as adjuncts to exposure therapy and may even reduce the efficacy of exposure-based psychological treatments. Thus, in general, there is little evidence to support the benefit of pharmacotherapy in the management of specific phobias. Of note, the presence of comorbid depression and other anxiety disorders, which are common, would lead to a recommendation of treatment with appropriate first-line pharmacologic agents.

Separation Anxiety Disorder

Separation anxiety disorder is characterized by an extreme fear or anxiety of being away from attachment figures, often accompanied by worry of harm befalling them. This often leads to avoidance of being away from home or loved ones. Historically recognized primarily as a disorder of childhood and adolescence, DSM-5 classified SpAD as an anxiety disorder. Its lifetime prevalence rates are estimated to be between 4% and 8%, and it is reported to be more common in those with a family history of agoraphobia and panic disorder. Comorbidity with a wide variety of psychiatric conditions is common.

Pharmacotherapy of SpAD has been primarily derived from research in children and adolescents, as SpAD has been historically under-recognized in adults. In studies looking at mixed populations of youth with GAD, SAD, and SpAD, SSRIs have shown good evidence of benefit. However, trials for TCAs (imipramine) and BDZ (clonazepam) reported negative findings. Most recently, a small RCT did not find vilazodone to be superior to placebo for Adult SpAD after 12 weeks of treatment.

Selective Mutism

Selective mutism is a disorder typically seen in childhood whereby individuals who are physically able to speak and understand speech fail to do so in selective situations (e.g., school). Children with selective mutism will readily speak in other more comfortable situations (e.g., home). Selective mutism is relatively rare, with prevalence rates reported to be between 0.02% and 1.9%; it is increasingly recognized as a forerunner of social anxiety disorder.

While psychosocial interventions are preferentially used in treatment of selective mutism, case reports and open trial studies suggest that SSRIs (e.g., fluoxetine and fluvoxamine) may be helpful, especially in more severe cases. The black box warnings issued by the FDA regarding increased risks of suicidality with SSRI use in children and adolescents means these medications are now generally reserved for young people who do not respond to psychological interventions. Nevertheless, the findings of meta-analyses that the increase in absolute risk of suicide is very small, and recognition of the serious functional morbidity associated with chronic anxiety and avoidance in children and adolescents, would suggest that the use of pharmacotherapy with appropriate monitoring should not be unduly withheld in these situations.

TREATMENT OF ANXIETY DISORDERS IN CHILDREN AND ADOLESCENTS

Anxiety disorders are the most prevalent mental health conditions in young people and, if left untreated, can result in long-term psychological impairment, poor treatment outcomes, and increased risk of psychiatric comorbidities later in life. Several RCTs have provided conclusive evidence that SSRIs and SNRIs are useful in the treatment of certain anxiety disorders in children and adolescents, particularly GAD, SAD, and

separation anxiety disorder in youth. Preliminary data also suggests that the combination of medication and CBT is better than either intervention alone for separation anxiety in children. Similarly, while psychosocial interventions are preferentially used in treatment of selective mutism, early case reports and pilot studies suggest that SSRIs (particularly fluoxetine and fluvoxamine) may be helpful, especially in more severe cases. The black box warnings issued by the FDA regarding increased risks of suicidality with SSRI use in children and adolescents means these medications are now generally reserved for young people who do not respond to psychological interventions. However, meta-analyses suggest that the increase in absolute risk of suicide is very small. Together with observed recognition of the serious functional morbidity associated with chronic anxiety and avoidance in children and adolescents, it is suggested that use of pharmacotherapy should be considered whenever it might be beneficial and safe.

SUMMARY

Pharmacotherapy is a key treatment option for anxiety disorders. Among them, SSRIs and SNRIs remain the first-line option, with novel agents, pregabalin, and other psychotropic medications relegated to second-line use. When considering psychopharmacologic options for treatment of anxiety disorders, clinicians are encouraged to take a holistic approach that considers a patient's personal and family history, published literature on the subject, as well as the accessibility and cost of the intervention. Mild to moderate side effects are not uncommon following initiation of medical intervention, and thus it is recommended that physicians provide adequate psychoeducation (about side effects and overall setting expectations about the anticipated time course of response, etc.), start patients on a low dose and up-titrate to the optimal therapeutic dose. Similarly, discontinuation of treatment must be done gradually with vigilant monitoring for signs of withdrawal or relapse. Given the increasing burden of disease due to anxiety disorders, it is of utmost importance that practitioners, especially those in primary care settings, inquire about psychological symptoms and that patients receive appropriate psychoeducation to increase help-seeking behavior and treatment adherence. Whereas physicians will often be in the role of medication prescribers for anxiety disorders, they can and should also play an

important role in making patients aware of and referring them to evidence-based psychological therapies, such as CBT.

A large majority of pharmacologic clinical trials to date have focused on pure anxiety disorders, often excluding common comorbidities such as major depression. This has been helpful in ascertaining the effects of medications on individual anxiety disorders but does not reflect real-world anxiety populations. It would be helpful for future research to systematically include common comorbid populations (e.g., SAD and PD) and pharmacologic combinations in treatment-resistant anxiety disorders. As noted above, there is also a need to further develop alternative biologic therapies for treatment-refractory patients, particularly as we continue to further understand the underlying pathophysiology of these illnesses as well as to take into account patient preference for more complementary types of treatments.

Obsessive-Compulsive and Related Disorders

Dan J. Stein, M.D., Ph.D., and Christine Lochner, Ph.D.

Obsessive-compulsive and related disorders (OCRDs) constitute a new chapter in both the DSM-5 and the ICD-11. In DSM-5, and its text revision (DSM-5-TR) this grouping of disorders includes obsessive-compulsive disorder (OCD), body dysmorphic disorder (BDD), hoarding disorder (HD), trichotillomania (TTM) (hair-pulling disorder), and excoriation (skin-picking) disorder, while ICD-11 additionally includes olfactory reference disorder, hypochondriasis, and Tourette syndrome. Both nomenclatures include the OCRDs in a separate chapter, given the evidence that these share some phenomenologic and psychobiological features, and to improve the recognition and management of these underdiagnosed and undertreated conditions. Here, each of the DSM-5-TR OCRDs will be covered in turn.

OBSESSIVE-COMPULSIVE DISORDER

Introduction

OCD is the paradigmatic OCRD and the one on which most research has been done. Like several other OCRDs, it is characterized by repetitive, intrusive thoughts and repeated mental acts or behaviors in response to those thoughts. OCD was once central to psychodynamic thinking, but it is now an exemplar par excellence of a neuropsychiatric disorder with a specific neurocircuitry proposed. Furthermore, whereas OCD was once

considered rare, it is now known to be quite prevalent—patients are often embarrassed by and ashamed of their symptoms, and careful screening is needed to ensure case-finding. Finally, whereas OCD was once considered very refractory to treatment, the introduction of specific pharmacotherapeutic and psychotherapeutic interventions has led to more favorable outcomes for many.

Definition

The presence of obsessions or compulsions characterizes OCD. Obsessions are intrusive and unwanted repetitive thoughts, urges, or impulses that often lead to a marked increase in anxiety or distress. Compulsions are repetitive behaviors or mental acts in response to obsessions or performed in a rigid rule-bound way. Some patients may have only obsessions or only compulsions, but both obsessions and compulsions are present in most cases.

History

Although there are earlier descriptions of OCD symptoms in the medical literature, the English term derives from Westphal's description of *zwangsvorstellung* in the late 19th century, translated as "obsession" or "compulsion." Janet subsequently made an important contribution to the literature, describing the role of "incompleteness" in OCD patients, as well as symptoms such as tics. Freud's theories on the role of the unconscious in obsessive-compulsive symptoms were particularly influential on clinical practice in the early part of the 20th century, as was his description of a spectrum of symptoms ranging from obsessive-compulsive personality traits through obsessive-compulsive neurosis and on to obsessive-compulsive psychosis.

In the middle of the 20th century, case reports indicated that the serotonergic tricyclic antidepressant, clomipramine, was useful in OCD. Randomized controlled trials confirmed the efficacy of clomipramine and gave impetus to a serotonin hypothesis of OCD. The introduction of behavior therapy and selective serotonin reuptake inhibitors (SSRIs) to treat OCD were additional significant steps forward. The finding that unique patterns of activation accompanied OCD on brain imaging and that both of these interventions helped normalize the altered functional neuroanatomy of OCD gave significant impetus to further research on this condition. Over time, other interventions, including dopaminergic and

glutamatergic agents and neurosurgical interventions, were also developed for treatment-refractory OCD.

The finding that clomipramine was more effective than desipramine, a noradrenergic tricyclic, in OCD and a range of other conditions characterized by intrusive thoughts or repetitive behaviors helped consolidate the notion of an obsessive-compulsive spectrum of disorders. SSRIs proved to be helpful for several of these conditions, but not all. Overlapping, but somewhat different behavioral approaches, have also proven helpful for these conditions. At the start of the 21st century, cutting-edge research methods, including neurogenetics, have been used to help delineate the relationship between OCRDs, particularly OCD and tic disorders.

Comparative Nosology

DSM-III provided operational criteria for OCD, defining obsessions and compulsions along the lines of the definition above. DSM-IV introduced the notion that compulsions can be mental acts. DSM-5 made relatively subtle adjustments to the DSM-IV criteria to further clarify the symptoms, for example, replacing the term “impulse” with “urge” (to avoid confusion with impulse-control disorders) and noting that obsessions cause anxiety in most individuals (given that this is not the case in all individuals). However, in DSM-5, OCD was shifted into a new chapter on OCRDs, a more substantial change. Another significant change from DSM-IV was the extension of the insight specifier to include absent insight; this emphasizes to clinicians that some patients with OCD (around 4%) may have delusional thoughts, yet they should be diagnosed with OCD rather than with a psychotic disorder.

Table 15–1.
Obsessive-Compulsive and Related Disorders

DSM-5-TR		ICD-11	
Disorder	**Diagnostic Criteria**	**Disorder**	**Diagnostic Guidelines**
Obsessive-compulsive disorder	Intrusive and unwanted recurrent and persistent thoughts, urges, or impulses (obsessions) or repetitive behaviors or mental acts that the individual feels driven to perform in response to an obsession or according to rules that must be applied rigidly (compulsions).	Olfactory reference disorder	Persistent preoccupation with the belief that one is emitting a perceived foul or offensive body odor or breath. The individual engages in repetitive and excessive behaviors in response to the odor concerns.
Body dysmorphic disorder	Preoccupation with one or more perceived defects or flaws in physical appearance that are not observable or appear slight to others. The	Hypochondriasis (health anxiety disorder)	Persistent preoccupation or fear about having serious, progressive, or life-threatening illness. Preoccupation is accompanied

	individual has performed repetitive behaviors or mental acts in response to the appearance concerns.		by repetitive and excessive health-related behaviors or maladaptive avoidance behavior related to health.
Hoarding disorder	Persistent difficulty discarding or parting with possessions, regardless of their actual value, accumulates possessions that congest and clutter living areas compromising their intended use.	Tourette Syndrome	Presence of chronic motor tics and vocal tics, beginning during childhood. Tics are rapid, nonrhythmic, and recurrent movements or vocalizations.
Trichotillomania (hair-pulling disorder)	Recurrent pulling of hair, resulting in hair loss, with repeated unsuccessful attempts to reduce or stop pulling.		
Excoriation (skin-picking) disorder	Recurrent picking of skin, resulting in		

	lesions, with repeated unsuccessful attempts to reduce or stop pulling.

The ICD-10 description of OCD does not include the notion that obsessions give rise to compulsions. There is certainly support in the literature for the idea that compulsions may precede obsessions, and indeed some have even suggested that the disorder be termed compulsive-obsessive disorder. At the same time, from a treatment planning perspective, it may be useful for clinicians to understand the cycle of obsessions and compulsions, and ICD-11 emphasizes that in many patients with OCD, obsessions lead to anxiety or distress, and compulsions are undertaken to reduce these negative emotions. ICD-11 also has a new chapter on OCRDs and emphasizes that some patients with OCD have absent insight.

The DSM-5-TR chapter on OCRDs includes OCD, BDD, HD, TTM (hair-pulling disorder), and excoriation (skin-picking) disorder. ICD-11 lists both TTM and excoriation disorder as body-focused repetitive behavioral disorders (BFRBDs) and includes olfactory reference disorder, hypochondriasis, and Tourette syndrome (Table 15–1). ICD-11 emphasizes that whereas patients with BDD are preoccupied with flawed appearance, those with olfactory reference disorder are preoccupied with smelling bad, with both groups displaying repetitive mental acts and behaviors in response to these concerns. DSM-5-TR includes illness anxiety disorder in the somatoform disorders, whereas ICD-11 emphasizes that this condition is characterized by intrusive, repetitive thoughts and repetitive behaviors in response and lists it under both OCRDs and anxiety or fear-related disorders. Both DSM and ICD-11 recognize the relationship between OCD and tics; DSM-5-TR classifies Tourette disorder as a neurodevelopmental disorder and includes a tic-related specifier for OCD, whereas ICD-11 lists Tourette syndrome in three places: neurodevelopmental disorders, OCRDs, and disorders of the nervous system.

Epidemiology

Individuals with OCD are characteristically aware that their compulsions are excessive. In the past, they may have been too embarrassed to seek professional help and unlikely to have received efficacious intervention—factors that may have led to early authors describing OCD as a rare condition. The Epidemiological Catchment Area study found that OCD was, in fact, one of the most prevalent of all psychiatric disorders, and follow-up cross-national surveys confirmed its presence across several different countries. The National Comorbidity Survey Replication (NCS-R) was able to delineate clinical from subclinical obsessive-compulsive symptoms in a rigorous way, and findings were that OCD had a lifetime prevalence of 2.3%, but that subclinical OCD was much more prevalent.

Several additional findings with public health relevance emerge from community and clinical studies. First, although the exact prevalence of OCD differs from study to study, OCD is a relatively common disorder in most countries surveyed, and subclinical OCD is even more prevalent. Second, OCD is accompanied by significant comorbidity, with particularly high rates of OCRDs, mood and anxiety disorders, as well as suicide ideation. Third, OCD is accompanied by significant morbidity, including impairment in social, academic, and occupational functioning and reduced quality of life comparable to that seen in other severe medical and mental disorders. Early Global Burden of Disease data indicated that OCD was one of the most disabling of all medical disorders, with more recent iterations emphasizing the crucial contributions of anxiety disorders (including OCD) as a whole. Fourth, there is significant underdiagnosis and undertreatment of OCD even in high-income countries. Fifth, partly because of this underdiagnosis and undertreatment, OCD is associated with high economic costs, both for the individual and society.

OCD has a median age of onset of 19 in the NCS-R. Approximately one-quarter of cases have onset by age 10, with early onset more common in males. In other cases, OCD may have a later onset; in females, onset is often during adolescence, with some developing OCD during pregnancy or the puerperium. Onset after 30 is unusual. OCD has surprisingly similar features in children and adults, but compulsions are typically more central to the presentation earlier in life, with some children either not experiencing obsessions or being unable to articulate them. Community studies indicate a higher prevalence of OCD in females, but there may be roughly equal numbers of male and female patients in clinical contexts. Males and females have similar symptoms, but males

are more likely than females to have comorbid tics. Individuals with OCD have an increased family history of OCD and OCRDs, including tic disorders.

Etiology

OCD is increasingly viewed as a neuropsychiatric disorder mediated by specific neurocircuits. From a cognitive-affective neuroscience perspective, OCD appears to be characterized by deficits in cognitive control, with a shift from goal-directed to habit-driven behavior. Aspects of cognitive dyscontrol may include alterations in inhibitory control (e.g., inability to withhold task-irrelevant responses), task shifting (e.g., increased cognitive inflexibility), and error-monitoring (e.g., altered detection of response errors); such alterations may contribute to repetitive, habitual behavior. Early clinical work established that OCD could be precipitated by damage to striatal circuitry, as seen in the global influenza epidemic in the early 20th century. More recent advances in structural and functional brain imaging have delineated the role of these and related circuits in mediating OCD, and translational work in animal models has allowed further delineation of the neuroanatomy of cognitive dyscontrol and habit-driven behavior. In recent decades, a range of laboratory and clinical work has focused on the neurotransmitters and other molecules found in these circuits and potentially involved in the pathogenesis of OCD.

Cognitive and neuropsychological studies of OCD have found a range of alterations, including impaired executive function, with evidence for cognitive inflexibility and excessive habit formation. Such work is consistent with the hypothesis that OCD is characterized by cognitive dyscontrol, with a shift to habit-driven behavior. A second group of studies has emphasized alterations in affective and reward processing in OCD, with perhaps the most specific findings related to perceptions of disgust. Patients with OCD appear to show increased recognition of disgust compared to other emotions. This finding is consistent with the view that OCD differs fundamentally from anxiety disorders, which are characterized by alterations in fear processing. These cognitive-affective findings, as well as work on temperamental risk for OCD (such as increased behavioral inhibition), are consistent with a view that emphasizes that OCD symptoms, particularly in subclinical form, can be understood through the lens of evolutionary theory; they have an adaptive

role in protecting individuals from harmful stimuli, whether by grooming to ensure the removal of harmful organisms or via the avoidance of disgust cues.

Several brain regions, including the anterior cingulate, orbitofrontal cortex, and striatum, have consistently been implicated in OCD, although there is also evidence that a wide range of other regions play a role. One hypothesis has been that cortico–striatal–thalamic–cortical (CSTC) circuitry plays a critical role in mediating the cognitive-affective impairments seen in OCD, with activation or inhibition of different components of this circuitry driving the compulsive and impulsive features of OCRDs. Laboratory research has indicated that these circuits control automated behaviors such as habits and grooming. Clinical research has indicated that there are gray matter volumetric changes in components of this circuitry and alterations in frontostriatal connectivity and a range of white matter tracts in OCD. A growing database of functional imaging studies has found increased activity in these circuits both at rest and exposed to feared stimuli. Early imaging work was seminal in showing that both pharmacotherapy and cognitive-behavioral therapy (CBT) could normalize functional alterations in CSTC circuitry in OCD, and the relevant evidence base has continued to grow.

Magnetic resonance spectroscopy and molecular imaging studies have begun to delineate the specific neurochemical alterations found in CSTC and other circuitry implicated in OCD. Such work has been complemented by work on blood and cerebrospinal fluid (CSF) metabolites and studies of pharmacologic “challenges” in OCD, pharmacotherapeutic dissection, and neurogenetics. This work has indicated that many neurotransmitter systems contribute to OCD, including serotonergic, dopaminergic, glutamatergic, and GABAergic systems. A serotonin hypothesis of OCD has been influential; a range of evidence points to the involvement of this system in OCD, and patients respond to treatment with serotonin reuptake inhibitors (SRIs) but not to treatment with noradrenergic reuptake inhibitors. At the same time, there is relatively little evidence that altered serotonergic function plays a causal role in OCD. Furthermore, a range of evidence points to the involvement of the dopaminergic system in OCD, and, notably, augmentation of serotonin reuptake blockers with dopamine receptor antagonists is considered a first-line intervention for treatment-refractory OCD. There has been recent interest in additional systems, including the glutamatergic system in OCD, with evidence that some

glutamatergic agents, such as memantine, may be helpful in this condition.

Genetic findings may increasingly influence future work on the cognitive-affective neuroscience of OCD. Twin and family studies indicate that genetic susceptibility plays a role in OCD, and more so in childhood-onset OCD. To date, OCD has been associated with serotonin-related polymorphisms and variants involved in catecholamine modulation; taken together, meta-analyses of candidate gene studies suggest that OCD may be associated with multiple genes of relatively small effect. Growing data from genome-wide association studies support this hypothesis, and, notably, the most significant findings have included genes that contribute to glutamatergic function. It is also noteworthy that gene variants in OCD may be associated with some specific brain imaging findings. The future hope is that a better understanding of the relevant intermediate phenotypes involved in OCD and their underlying molecular neurobiology will help development of a personalized medicine approach.

Diagnosis and Clinical Features

OCD can readily be diagnosed based on a thorough psychiatric history and examination. While patients often attempt to neutralize obsessions with compulsions, these behaviors or mental acts are not realistic in terms of what they are designed to prevent or are excessive. The DSM-5-TR diagnostic criteria for OCD address the presence of obsessions and compulsions and emphasize that these symptoms are time-consuming or distressing, impairing, are not due to substances, medications, or other medical conditions, and are not due to other psychiatric disorders (Table 15–2). Repetitive thoughts and behaviors can be seen in a range of other mental disorders, as is discussed in more detail below. When assessing the negative impact of OCD symptoms, it is also essential to assess avoidance of triggers of obsessions and compulsions. In addition, key features to ascertain during the history and examination of an individual with OCD include the age of onset and course of the symptoms and any possible precipitants, the type and severity of symptoms, the extent of insight and impairment, and the presence of comorbid disorders and symptoms.

As noted above, OCD may have an early age of onset; while there is often no specific precipitant, OCD onset has been linked to various infections, certain substances, and traumatic or stressful life events. In

factor analytic studies of OCD, symptoms fall on several limited dimensions, including contamination/cleansing, forbidden thoughts/checking, symmetry/ordering, and hoarding symptoms. While patients with OCD typically have good insight into the fact that their OCD beliefs are not true, some patients have poor insight, and a small percentage have absent insight—their thoughts are, in fact, delusional. As these patients may be misdiagnosed with a psychotic disorder and treated with inappropriately high doses of antipsychotic medication, DSM-5 and DSM-5-TR extend the insight specifier to include absent insight/delusional OCD.

Table 15–2.
DSM-5-TR Diagnostic Criteria for OCD

A. Presence of obsessions, compulsions, or both:

Obsessions are defined by (1) and (2):

1. Recurrent and persistent thoughts, urges, or images that are experienced, at some point during the disturbance, as intrusive and unwanted, and that in most individuals cause marked anxiety or distress.
2. The individual attempts to ignore or suppress such thoughts, urges, or images, or to neutralize them with some other thought or action (i.e., by performing a compulsion).

Compulsions as defined by (1) and (2):

1. Repetitive behaviors (e.g., handwashing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) that the person feels driven to perform in response to an obsession or according to rules that must be applied rigidly.
2. The behaviors or mental acts are aimed at preventing or reducing distress, or preventing some dreaded event or situation; however, these behaviors or mental acts either are not connected in a realistic way with what they are designed to neutralize or prevent, or are clearly excessive.

Note: Young children may not be able to articulate the aims of these behaviors or mental acts.

B. The obsessions or compulsions are time-consuming (e.g., take more than 1 hour per day) or cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The obsessive-compulsive symptoms are not attributable to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

D. The disturbance is not better explained by the symptoms of another mental disorder (e.g., excessive worries, as in generalized anxiety disorder; preoccupation with appearance, as in body dysmorphic disorder; difficulty discarding or parting with possessions, as in hoarding disorder; hair pulling, as in trichotillomania [hair-pulling disorder]; skin picking, as in excoriation [skin-picking] disorder; stereotypies, as in stereotypic movement disorder; ritualized eating behavior, as in an eating disorder; preoccupation with having an illness, as in illness anxiety disorder; sexual urges or fantasies, as in a paraphilic disorder; impulses, as in disruptive behavior disorders;

guilty ruminations, as in major depressive disorder; thought insertion or delusional preoccupations, as in a psychotic disorder; or repetitive patterns of behavior, as in autism spectrum disorder).

***Specify* if:**

With good or fair insight: The individual recognizes that obsessive-compulsive disorder beliefs are definitely or probably not true or that they may not be true.

With poor insight: The individual thinks obsessive-compulsive disorder beliefs are probably true.

With absent insight/delusional: The individual is completely convinced that obsessive-compulsive disorder beliefs are true.

***Specify* if:**

Tic-related: The individual has a current or past history of a tic disorder.

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:265, 266.

DSM-5-TR also includes a tic-related specifier for OCD, as many patients with OCD have current or past tics. OCD with tics is more commonly seen in males, has an earlier age of onset, is more likely to be accompanied by specific OCD symptom dimensions (e.g., symmetry/ordering), and may be less likely to respond to SSRIs. Sensory phenomena or premonitory urges can precede both OCD symptoms and tics, and in the case of complex tics, it may be quite challenging to differentiate tics from compulsions. Given their comorbidity and the close familial relationship between OCD and tic disorders, there is a strong argument that Tourette disorder (TD, characterized by motor and vocal tics) is the OCRD par excellence. Nevertheless, DSM-5-TR retains TD as a neurodevelopmental disorder. In contrast, ICD-11 lists Tourette syndrome under neurodevelopmental disorders, OCRDs, and movement disorders.

Individuals with OCD are more likely to suffer from other OCRDs than those without OCD, and they are also more likely to provide a family history of such conditions. However, the most common comorbid disorder in OCD patients presenting to the clinic is depression. From a clinical perspective, it is crucially important to assess for suicidal symptoms, which are quite prevalent in OCD. Comorbid anxiety disorders are also common in OCD. Notably, substance use disorders are more common in

community studies than in clinical studies of OCD. Individuals with OCD may also have several personality disorders, including schizotypal and obsessive-compulsive personality disorder (OCPD). There is an argument that OCPD—although not characterized by obsessions and compulsions, but rather by a pattern of excessive perfectionism and need for control—is best conceptualized as an OCD spectrum condition; OCPD may share neuropsychological impairments with OCD and may perhaps respond to treatment with SSRIs.

There is a growing literature on diagnostic interviews for screening for OCD and ensuring accurate differential diagnosis, and symptom measures for assessing the severity of OCD symptoms. DSM-5-TR includes a Self-Rated Level 1 Cross-Cutting Symptom Measure with two items for OCRDs, and this can be followed up by a Level 2 Repetitive Thoughts and Behaviors Scale. The Level 1 items focus on “unpleasant thoughts, urges, or images that repeatedly enter your mind” and about “feeling driven to perform certain behaviors or mental acts over and over again.” The Level 2 questions are adapted from the Florida Obsessive-Compulsive Inventory (FOCI) Severity Scale and assess the time occupied by symptoms, distress caused by the symptoms, difficulty in controlling the symptoms, avoidance caused by the symptoms, and interference associated with the symptoms. The Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) is a clinician-rated instrument that assesses similar items and is commonly used as a primary outcome measure in clinical trials. Adaptations of this scale include a version that provides a score for each major OCD symptom dimension. The Structured Interview for OCRDs provides questions that target DSM criteria for each OCRD and key issues critical in different diagnoses (e.g., are symptoms exacerbated by substance use), allowing a comprehensive assessment of each of these conditions.

Diagnosis and assessment should also cover several other key issues. First, it is crucial to ascertain the patient’s explanatory model of OCD. Many patients are quite comfortable with a biomedical explanation of OCD. However, others may have entirely different models, and it is then imperative to provide psychoeducation and negotiate a joint approach to management. In occasional cases, obsessions and compulsions may themselves interfere with management (e.g., patients may view medications as contaminating). Second, it is essential to ascertain how family members are impacted by or accommodate symptoms. This is

particularly important when planning CBT, which demands increased exposure to feared stimuli and refraining from compulsions. Third, it is vital to take a meticulous medical history. There is a growing literature indicating that OCD may be precipitated by Streptococcal infection or a range of other insults, so a comprehensive medical history is warranted.

In children with OCD, the aim of compulsions may not be easily articulated. It is also relevant to differentiate normal developmental rituals from OCD in this age group. In children and adolescents with OCD, it is vital to assess the impact of OCD on developmental outcomes, ask about a family history of OCD, and assess how symptoms impact or are accommodated by the family. Males and females have similar presentations, although males are more likely to have earlier-onset, certain OCD symptoms, and comorbid tics, and females may have onset during pregnancy and the puerperium, and perhaps exacerbation of symptoms during the premenstrual period. OCD symptoms appear largely independent of culture and geography, although the local context may influence the specific content of symptoms.

Pathology and Laboratory Examination

At the current time, there are no biomarkers for OCD. Brain imaging may ultimately be clinically helpful in predicting response to treatment, but presently it remains a research tool. Similarly, while neurogenetic investigations have been valuable in the research context, they do not have sufficient clinical utility for more widespread use, except for obsessive-compulsive symptoms secondary to conditions such as autistic spectrum disorders, where such investigations may be helpful.

Differential Diagnosis

The psychiatric disorder hierarchy criterion in DSM-5-TR lists a large set of psychiatric conditions that should be differentiated from OCD: generalized anxiety disorder, BDD, HD, TTM, excoriation disorder, stereotypic movement disorder, eating disorders, substance-related and addictive disorders, illness anxiety disorder, paraphilic disorders, disruptive, impulsive-control and conduct disorders, major depressive disorder, schizophrenia spectrum and other psychotic disorders, and autism spectrum disorders. Worries in generalized anxiety disorder are about real-life concerns. They tend to be less irrational and egodystonic than OCD. Similarly, the ruminations of depression and the

preoccupations of mania are typically mood-congruent and egosyntonic; in neither case are symptoms neutralized by compulsions. In BDD, illness anxiety disorder, TTM, excoriation disorder, stereotypic movement disorder, anxiety disorders, and eating disorders, the focus of preoccupations and repetitive behaviors is distinct from that typically seen in OCD.

Hoarding behaviors can be seen in OCD; for example, patients may hoard newspaper articles to prevent harm should they forget an important matter. However, in most cases of HD, there is no specific obsession. Patients with OCD may experience a “just right” feeling on completion of compulsions, but in paraphilic disorders, substance-related and addictive disorders such as gambling disorder and disruptive, impulse-control, and conduct disorders, repetitive behaviors are typically gratifying. Thus, although terms such as compulsive gambling or compulsive stealing are used, these conditions should not be conflated with OCD. While some patients with OCD have absent insight into their symptoms, the delusional beliefs are related to OCD, and they do not have other features of schizophrenia spectrum disorders. A subgroup of OCD patients suffers from comorbid schizophrenia spectrum disorders, including schizotypal personality disorder. Similarly, while patients with autistic disorder often have repetitive symptoms, they also have a broad array of other characteristic symptoms.

Course and Prognosis

OCD is generally chronic, and symptoms may persist for decades without intervention. Nevertheless, growing data emphasize that long-term outcomes can be positive. Thus, patients should be encouraged to remain hopeful, reminded of the availability of a range of different evidence-based interventions, and strongly encouraged to persist with treatment.

Treatment

Psychoeducation is a crucial component of the treatment of OCD. Exploring the patient’s explanatory model of OCD is a useful first step in key elements of treatment, such as understanding the patient’s suffering, building a collaborative approach to care, and instilling hope. Many patients and families are relieved to learn basic facts about OCD, including its high prevalence, the fact that many others with this condition are embarrassed by or ashamed of symptoms, that it is not due to

commonly voiced factors (e.g., bad mothering), and that treatments are efficacious for many. Consumer advocacy organizations, such as the Obsessive-Compulsive Foundation, may play a crucial role in conveying such information.

Pharmacotherapy. Seminal early work reported that patients with OCD responded to clomipramine, a relatively serotonergic tricyclic antidepressant. Subsequent randomized controlled trials showed that clomipramine was efficacious in children, adolescents, and adults with OCD. Furthermore, this agent was more effective than the relatively noradrenergic tricyclic antidepressant, desipramine. Clomipramine became the first registered agent for the treatment of OCD, and a "serotonin hypothesis" of OCD influenced a good deal of subsequent research on both OCD and OCRDs.

The subsequent introduction of the SSRIs was significant in that these provided a set of efficacious and well-tolerated agents. In meta-analyses of SRIs in OCD, clomipramine has the largest effect size, but this may reflect that these were simply the earliest trials. There is equal efficacy in head-to-head comparisons of clomipramine and SSRIs, but SSRIs are better tolerated. Several of the SSRIs are Food and Drug Administration (FDA) or European Medicines Agency (EMA) approved for OCD, including childhood OCD, and these agents are therefore considered first-line for OCD pharmacotherapy.

Critical clinical questions include the optimal dose and duration of SRIs in the pharmacotherapy of OCD. Although there is not a very steep dose–response curve, meta-analysis indicates that higher doses of SRIs are associated with better outcomes in OCD. Therefore, clinical guidelines suggest increasing the dosage of SRIs over time in OCD to relatively high ranges (e.g., escitalopram 30 mg, fluoxetine 80 mg, sertraline 200 mg), with some patients responding to even higher doses. However, exceeding the recommended doses is not advisable for clomipramine or citalopram due to safety concerns. There is also some evidence that response to SRIs is slower in OCD than in depression; clinicians are therefore encouraged to prescribe an SRI for at least 12 weeks before deciding to switch agents or augment with another psychotropic. A general rule of thumb is that the dose required for a response should be continued for at least 1 to 2 years. There is a real risk of relapse when discontinuing

medication, so this should be done very gradually, with small adjustments every few months.

Patients who fail to respond to one SRI may respond to another. In patients who fail to respond to an SRI, reasonable options include augmentation with additional medications. A range of medications has also been used to augment SRIs, with the most extensive evidence base comprising studies of low-dose dopamine receptor antagonists (e.g., risperidone) or partial agonists (e.g., aripiprazole) in adult OCD. Some studies have indicated that these are particularly useful in patients with tics, but not all data are consistent. From a clinical perspective, it is notable that when a response to these agents is seen, it typically occurs within a relatively short time (i.e., 4 weeks). Despite the relatively low doses used in this setting, it is important to monitor adverse events. There is some indication that agents with increased D2 and D3 binding (e.g., aripiprazole) are more effective in treatment-refractory OCD, but this hypothesis requires further investigation.

Outcomes have been negative, inconsistent, or modest for other potential SSRI augmentation agents. Perhaps most promising are small studies that have indicated that certain glutamatergic agents, such as memantine, riluzole, ketamine, lamotrigine, and topiramate, may be helpful in this condition. However, these remain proof-of-principle investigations. Sometimes low doses of clomipramine are used to augment SSRIs, but careful electrocardiographic monitoring is required. D-cycloserine is a partial glutamatergic agonist that has been used to augment CBT in OCD and anxiety disorders, but efficacy data in OCD are currently inconsistent. Choice of medication in refractory patients is guided by a range of clinical considerations, including the presence of comorbid disorders. Monotherapy with irreversible monoamine oxidase inhibitors remains a potentially useful option in refractory cases.

Psychotherapy. There is a long history of understanding obsessive-compulsive symptoms from a psychodynamic perspective. However, there is no rigorous evidence that a psychodynamic approach is useful in treating OCD. Instead, empirical research on the psychotherapy of OCD has emerged from behavioral and cognitive perspectives. Exposure and response prevention (ERP) has proven to be a particularly effective component of treatment, with more recent work also focusing on the potential role of cognitive and mindfulness approaches.

To some extent, most clinicians, including primary care physicians involved in diagnosing and treating OCD, can apply the principles of exposure and response prevention. The essential principle is minimizing avoidance of distressing cues and encouraging in vivo exposure to feared situations and imaginal exposure to feared consequences. After such exposures, it is important not to engage in the usual compulsive response. A hierarchy of gradual exposure to more distressing cues is then developed and followed. Self-help volumes and internet programs have been developed to assist with the process. There may, however, be significant resistance to undertaking exposure and responsive prevention, in which case a skilled cognitive-behavioral therapist is needed. As in the case of pharmacotherapy, it is essential to ensure that the dose and duration of exposure and response prevention treatment are sufficient.

More cognitive approaches to the psychotherapy of OCD have also been developed. These focus on thought distortions, for example, those related to inflated responsibility. The therapist and patient collaborate to test such distortions and replace them with more adaptive thinking patterns. Although the evidence base is not as well developed, mindfulness techniques may help supplement these approaches. Family sessions may also be a beneficial component of psychotherapy, particularly in younger patients; families are likely to benefit from a better understanding of OCD and exposure and response prevention principles.

Combined Treatment. Clinical guidelines indicate that either pharmacotherapy or psychotherapy is a reasonable first-line intervention for the management of OCD. In younger patients, it seems reasonable to begin CBT first. It seems reasonable to begin pharmacotherapy in patients with more severe symptoms or comorbid depression. There is some evidence from rigorous comparisons of CBT and pharmacotherapy and their combination that combined behavior therapy and SRIs are particularly useful, including in children and adolescents. Further, one careful study in adults indicated that ERP augmentation of SSRIs was more efficacious than risperidone augmentation. In very refractory cases, partial hospitalization for combined treatment may also be helpful. In everyday clinical practice, judicious sequencing of interventions may be used; for example, patients on pharmacotherapy may be encouraged to decrease avoidance and increase exposure while gradually tapering dosage.

Somatic Therapies. Targeted neurosurgical lesions to CSTC tracts have been shown efficacious in a proportion of highly treatment-refractory patients. Initial work focused on stereotactic neurosurgical lesions, with subsequent work using radiosurgical techniques without craniotomy. The more recent focus of neurosurgical work has been on deep brain stimulation (DBS) by implanting electrodes to stimulate specific brain regions. As a reversible, nonablative alternative to cingulotomy/capsulotomy, DBS has shown some promise for treatment-resistant OCD. A small number of centers worldwide have the skills to do such work, and the FDA has approved targeting of the ventral striatum/ventral capsule. Transcranial magnetic stimulation (TMS) has also been studied for OCD, and deep TMS provided in tandem with CBT is FDA approved for treatment-resistant OCD. Electroconvulsive therapy is not thought to be efficacious for OCD.

Figure 15–1 summarizes the epidemiology, pathology, diagnosis, treatment, and prognosis for OCD.

BODY DYSMORPHIC DISORDER

Introduction

Although long described in the medical literature, BDD was rarely recognized by clinicians or studied by researchers. It was only introduced into the official nomenclature in DSM-III-R and was only recognized for the first time as an independent disorder in the ICD system in ICD-11. Since its introduction to the nomenclature, there has been a substantial increase in the literature on this underrecognized condition. Recent decades have witnessed a growing awareness of its prevalence and morbidity—embarrassment and shame about symptoms mean that careful screening is needed to ensure case-finding. Fortunately, approaches to evaluation and treatment developed for OCD and appropriately modified for BDD have led to improved outcomes.

Definition

BDD is characterized by persistent preoccupations about one or more perceived defects or flaws in one’s appearance. The defects or flaws appear slight or are not observable to others. In response to their appearance concerns, individuals with BDD demonstrate a range of

mental acts or behaviors, including comparing themselves with others, checking in the mirror, or camouflaging their perceived flaws.

FIGURE 15–1. Key points about OCD. (Reprinted with permisison from Springer Nature. Obsessive–compulsive disorder. *Nat Rev Dis Primers.* 2019;5:53. doi:10.1038/s41572-019-0112-1.)

History

The term dysmorphophobia was introduced more than a century ago by an Italian psychiatrist, Enrico Morselli (1852–1929). It is derived from "dysmorphia," meaning misshapenness or ugliness. Subsequently, both Janet and Freud described cases with BDD symptoms, conceptualizing them as obsessive-compulsive conditions. The introduction of BDD into the official nomenclature in 1987 helped increase clinical awareness of this condition as an independent entity and of how similar BDD was to OCD—which had been found to respond to selective pharmacotherapies and psychotherapies—gave impetus to ongoing research.

Comparative Nosology

DSM-5 made several changes from DSM-IV. The wording was altered to be clearer and perhaps less pejorative to patients. An additional diagnostic criterion was added to address BDD's repetitive mental acts or behaviors. Significantly, an insight specifier was added, including absent insight, so that patients with delusional BDD are now classified as having an OCRD rather than a psychotic disorder. In ICD-10, BDD was collapsed together with hypochondriacal disorder. ICD-11 follows DSM-5 in recognizing BDD as a separate disorder in the chapter on OCRDs.

Epidemiology

BDD has rarely been included in major nationwide community surveys of the prevalence of mental disorders. However, point prevalence estimates in the United States and elsewhere have ranged from 1.7% to 2.4%, indicating that this is one of the more common OCRDs. Furthermore, clinical studies have found high rates of BDD in general adult psychiatric inpatients, cosmetic surgery clinics, and dermatology clinics.

Community and clinical studies confirm that BDD is associated with significant morbidity and comorbidity. Patients are often highly impaired, with very poor quality of life. Compared with OCD, there are high rates of depression and suicidality, further contributing to the burden of disease associated with this condition. The mean age of onset is in adolescence, and as in the case of OCD, community studies indicate a higher prevalence of females with BDD, while clinical reports indicate a roughly even male-to-female ratio.

Etiology

There is evidence that specific cognitive-affective impairments characterize BDD; for example, neuropsychological studies have suggested deficits in executive functioning, including cognitive inflexibility and visual processing. Brain imaging and neurogenetic studies have provided insights into the potential mechanisms that underlie such deficits and potential overlaps with other OCRDs. At the same time, the current evidence base remains relatively thin, and the etiology of BDD is still far from clear.

The few structural and functional brain imaging studies in BDD have tentatively suggested some involvement of the CSTC circuits that appear to play a role in OCD. At the same time, other neurocircuitry may also be relevant, for example, that involved in visual processing. Family and twin

data provide preliminary evidence for genetic susceptibility and a relationship to OCD. However, there is a paucity of data on specific genetic variants underlying susceptibility to BDD. While childhood adversity, including a history of teasing, has been associated with BDD, it is not clear if this association is a specific one.

Diagnosis and Clinical Features

As in the case of OCD, the diagnosis of BDD is based on a rigorous psychiatric history and examination. The DSM-5-TR diagnostic criteria for BDD address the presence of appearance preoccupations, repetitive behaviors, or mental acts in response to these preoccupations, the consequent distress and impairment, and emphasize that such symptoms are not due to other medical conditions or other psychiatric disorders. It is crucial for clinicians to also assess avoidance due to being BDD symptoms; this can range from minor social avoidance to housebound. Again, key features to ascertain during the history and examination include the age of onset and course of the symptoms, the type and severity of symptoms, the extent of insight and impairment, and the presence of comorbid disorders and symptoms. Table 15–3 lists the DSM-5-TR criteria for BDD.

Patients incorrectly perceive themselves as ugly or grotesque when they look normal or attractive. Symptoms may focus on any body area, but they most commonly focus on the face and head, with concerns most often involving the skin, nose shape and size, and hair. Individuals may be concerned with one feature or many; throughout their illness, patients are preoccupied with about five to seven different body areas. More than a quarter of patients are concerned with the symmetry of their appearance.

Table 15–3.
Body Dysmorphic Disorder

Diagnostic Criteria

A. Preoccupation with one or more perceived defects or flaws in physical appearance that are not observable or appear slight to others.
B. At some point during the course of the disorder, the individual has performed repetitive behaviors (e.g., mirror checking, excessive grooming, skin picking, reassurance seeking) or mental acts (e.g., comparing his or her appearance with that of others) in response to the appearance concerns.
C. The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The appearance preoccupation is not better explained by concerns with body fat or weight in an individual whose symptoms meet diagnostic criteria for an eating disorder.

Specify if:

- With muscle dysmorphia: The individual is preoccupied with the idea that his or her body build is too small or insufficiently muscular. This specifier is used even if the individual is preoccupied with other body areas, which is often the case.

Specify if:

- Indicate degree of insight regarding body dysmorphic disorder beliefs (e.g., “I look ugly” or “I look deformed”).
- With good or fair insight: The individual recognizes that the body dysmorphic disorder beliefs are definitely or probably not true or that they may or may not be true.
- With poor insight: The individual thinks that the body dysmorphic disorder beliefs are probably true.
- With absent insight/delusional beliefs: The individual is completely convinced that the body dysmorphic disorder beliefs are true.

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:271, 272.

Most individuals with BDD have ideas of reference, falsely believing that people are staring at or talking about their deformities. BDD by proxy is

rarely described in the literature, that is, preoccupation with the appearance of others, such as a family member.

Most patients attempt to camouflage their perceived flaws. Common repetitive behaviors in BDD include comparing body parts with the same areas in others, checking body parts in the mirror or other reflective surfaces, grooming (including applying make-up, hair-pulling, and skin-picking), seeking reassurance, touching body parts to check them, changing clothes, dieting, tanning, exercising, lifting weights, and undergoing cosmetic procedures. Such symptoms can involve serious harm to self (e.g., skin-picking can lead to significant medical complications) and others.

On one survey, 40% of cosmetic surgeons reported that a dissatisfied BDD patient had threatened them legally or physically, and there are occasional reports of homicide.

Individuals with BDD generally have less insight into the excessiveness and irrationality of their beliefs than those with OCD. The section on BDD in DSM-5-TR includes a specifier for level of insight. Only a quarter of BDD patients have fair or good insight, and around one-third have absent insight. Patients with delusional BDD have greater symptom severity and more significant morbidity. Individuals with BDD sometimes focus on whether their body build is too small or not sufficiently muscular; such so-called muscle dysmorphia is also available as a DSM-5-TR BDD specifier. Patients with muscle dysmorphia mostly look normal, though some may be unusually muscular due to body-building. They are more likely to be male and are more likely to have abnormal eating behavior (e.g., eating high-protein meals) and abuse substances (e.g., anabolic steroids) related to their appearance concerns. Compared to other patients with BDD, they may also be more suicidal.

Of the various OCRDs, it appears that BDD is the one most associated with comorbid depression with a lifetime rate of 75%, and suicidality with 80% having experienced suicidal ideation. About one-third of BDD patients have a lifetime history of OCD, and around 30% of BDD patients experience panic attacks triggered by appearance concerns. BDD is also associated with high levels of rejection sensitivity and low self-esteem. Many patients with BDD use substances to self-medicate social anxiety or emotional pain symptoms. Several measures are now available to assess BDD symptoms and their severity. The Y-BOCS has been adapted for use in BDD, and the Brown Assessment of Beliefs Scale can be used to

assess insight. Practical screening questions for BDD include “Are you very worried about your appearance in any way?” and “Are you unhappy with how you look?”

A majority of BDD cases have onset before 18; in children and adolescents, it is essential to assess the impact of BDD symptoms on developmental trajectories and family functioning. Males and females have similar presentations, although males are more likely to be preoccupied with thinning hair, small penis size, and small body build, while females are more likely to be preoccupied with weight, breasts, hips, legs, and excessive body hair. Women are more likely to camouflage their bodies, check mirrors, and pick their skin. BDD symptoms appear universal, although local contexts may influence the precise range of appearance concerns. In the East, a variant of taijin kyofusho, termed *shubo-kyofu*, is characterized by a fear that one’s ugliness will offend others.

Pathology and Laboratory Features

At the current time, there are no biomarkers for BDD. Brain imaging may ultimately be clinically helpful in predicting response to treatment, but presently it remains a research tool. Similarly, while neurogenetic investigations have been employed in the research context, they do not have sufficient clinical utility for more widespread use.

Differential Diagnosis

The specific focus of BDD on appearance concerns serves to differentiate it from other conditions characterized by repetitive behaviors (e.g., OCD, TTM, excoriation disorder), anxiety or social avoidance (e.g., generalized anxiety disorder, panic disorder, social anxiety disorder, agoraphobia), depression (e.g., major depressive disorder), or delusional beliefs (e.g., psychotic disorder). For example, some patients with BDD have hair-pulling, and many have skin-picking, but in BDD, such behaviors are in response to concerns about body flaws, while in TTM and excoriation disorder this is not the case.

Differentiating BDD from eating disorders may require care; if the patient’s appearance concerns focus only on body fat or weight, and symptoms meet the criteria for an eating disorder, then an eating disorder should be diagnosed. That said, BDD and eating disorders are often comorbid. BDD should not be diagnosed when an individual is only

concerned with their genitals or secondary sex characteristics and when symptoms meet the criteria for gender dysphoria.

Olfactory reference disorder is characterized by repetitive concerns about emitting a foul odor from the body or mouth (i.e., halitosis), which leads to a range of repetitive behaviors such as repetitive washing, changing clothing, or toothbrushing. Compared to OCD and BDD, those with olfactory reference disorder are even more likely to demonstrate poor or no insight. Nevertheless, it may be helpful to classify olfactory reference disorder as an OCRD, given that some patients with this presentation appear to respond to treatment with SSRIs.

Illness anxiety disorder (in DSM-5-TR) and hypochondriasis (in ICD-11) are repetitive thoughts about being ill rather than about body flaws. As in the case of BDD, however, there are compulsive responses to the somatic preoccupations (e.g., checking, visiting physicians), and treatment approaches overlap to some extent with those used for OCD.

Course and Prognosis

The course of BDD is generally chronic, and in the absence of intervention, symptoms may persist for decades. Earlier age of onset and more severe symptoms at intake may predict a worse course.

Treatment

Psychoeducation is a critical component of the treatment of BDD. Exploring the patient's explanatory model is a practical first step to understanding the patient's suffering, building a shared decision-making approach to care, and instilling hope. Basic facts, such as the frequent response of symptoms to treatment, may bring some relief. While patients cannot simply be talked out of their symptoms, key facts, such as that cosmetic procedures may exacerbate symptoms, may need to be presented. Engaging patients at the start of treatment is critical and challenging when there are low levels of insight. Given high rates of suicidality in BDD, evaluating and monitoring such symptoms is essential throughout treatment.

Pharmacotherapy. Clomipramine is more effective than desipramine in BDD, and limited but rigorous data from randomized controlled trials indicate that SSRIs are efficacious in treating BDD, including delusional BDD. Thus SSRIs are first-line agents for the pharmacotherapy of BDD,

including delusional BDD. There is also some limited evidence for the efficacy of these agents in children and adolescents with BDD. Unfortunately, the pharmaceutical industry has not undertaken registration trials.

There is some evidence that, as in the case of OCD, doses higher than those ordinarily used in the treatment of depression are beneficial in BDD and that a longer treatment duration is needed to see the full effects of treatment. Again, the duration of treatment should be longer rather than shorter, with gradual tapering of dosage and close monitoring of emergent symptoms.

Patients who do not respond to one SRI may respond to another. There is anecdotal evidence that buspirone augmentation of SRIs is useful in partial responders. The very limited controlled data on the augmentation of SRIs with low-dose dopamine receptor antagonists are not favorable. However, in clinical practice, strategies used for treatment-resistant BDD include adding antipsychotics such as aripiprazole and monotherapy with irreversible monoamine oxidase inhibitors.

Psychotherapy. CBT for OCD has been modified for BDD, and studies have indicated efficacy, including for individuals with delusional BDD. Core elements of such treatments include exposure, response prevention, and cognitive restructuring. As in the case of OCD, the dose and duration of treatment should be sufficient; some have suggested weekly CBT sessions for at least 6 months, with daily homework.

Modifications of OCD manuals are necessary to address the substantial social avoidance often present in BDD (e.g., use of behavioral experiments to test the accuracy of beliefs about others) and to target visual processing abnormalities (e.g., use of perceptual retraining to develop a more holistic view of appearance). Further, given that BDD is accompanied by ideas of reference and often by poor or absent insight, motivational interviewing may be needed when ambivalence about treatment is expressed, and cognitive interventions may need to be more complex and more intensive than in OCD. Habit reversal may be needed for BDD-related skin-picking, hair-pulling, and body touching.

Combined Treatment. There are no data from rigorous trials comparing pharmacotherapy and psychotherapy in BDD. Nevertheless, it would seem sensible to make judicious use of both in the clinical setting. Thus, pharmacotherapy may be helpful at the start of treatment if patients

are too depressed to undergo CBT for BDD. Psychotherapy may be helpful while gradually tapering medication dosage over the long term. A judicious combination or sequencing of modalities may be needed in clinical practice.

HOARDING DISORDER

Introduction

Hoarding symptoms have long been described in the medical and psychiatric literature, but HD is a recent entry into the official nomenclature, appearing first in DSM-5. This will hopefully give further impetus to research on this condition. Like so many other OCRDs, it is prevalent and impairing but underdiagnosed and undertreated.

Definition

HD involves accumulating possessions due to persistent and profound difficulty discarding or giving away possessions. This leads to significant congestion, clutter, and substantive distress or impairment, differentiating normal collecting from the clinical disorder.

History

Freud described hoarding symptoms as a component of OCPD. In the DSM-III era, clinicians interested in OCD typically viewed hoarding as a subtype of OCD. During work on DSM-5, a review of the growing literature on hoarding symptoms emphasized that many patients with clinical hoarding did not meet diagnostic criteria for either OCPD or OCD and noted important differences between OCD and hoarding in phenomenology and psychobiology, and so concluded that HD should be included in the nomenclature as a separate diagnostic entity. Hoarding symptoms are a predictor of a worse response to treatment for OCD, and one hope is that more specific diagnostic categories will help lead to better outcomes for patients.

Comparative Nosology

Hoarding is mentioned in DSM-IV in the section on OCPD but is not described in the equivalent ICD-10 category of anankastic personality disorder. DSM-IV also noted that when differentiating OCD from OCPD, a

diagnosis of OCD should be considered when hoarding is extreme. DSM-5, and its text revision (DSM-5-TR) for the first time, provides diagnostic criteria for HD and includes this condition in the OCRD section. Similarly, ICD-11 includes HD as a separate entity. There are distinctions between DSM-5-TR and the ICD-11 HD; for example, ICD-11 emphasizes that excessive acquisition is seen in most patients with this condition, whereas DSM-5-TR includes excessive acquisition as a specifier.

Epidemiology

DSM-5 and DSM-5-TR diagnostic criteria for HD have not yet been widely employed in epidemiologic studies. However, preliminary data indicate that HD is remarkably prevalent in Western countries, with one study employing DSM-5 criteria yielding a point prevalence of 1.5%. Epidemiologic data indicate that HD is associated with significant comorbidity and morbidity. In a study using DSM-5 criteria, the male-to-female ratio was about 1. In contrast, females are more common in clinics than males, perhaps indicating greater insight. Unlike the picture seen in most OCRDs, the prevalence of hoarding increases with age, and in clinical settings, the average age of first treatment is around 50. As in the case of other OCRDs, most studies have been done in high-income countries, and much further work is needed in low- and middle-income countries.

Etiology

Patients with HD may demonstrate impairment in various neuropsychological domains, including spatial planning, working memory, response inhibition, and set-shifting. Structural and functional brain imaging studies have indicated that the relevant neurocircuitry overlaps partially with that involved in OCD. Research on patients with neurologic disorders has suggested that ventromedial prefrontal-anterior cingulate cortices and medial temporal regions are involved in hoarding.

Animal studies have pointed to a possible role for the dopaminergic system in hoarding. Twin studies indicate genetic susceptibility for developing pathologic hoarding. While there is a relative dearth of neurogenetic studies, GWAS data from OCD studies provide a preliminary indication that a range of genetic variants are involved in mediating hoarding symptoms.

Diagnosis and Clinical Features

The diagnosis of HD is made based on a rigorous psychiatric history and examination. DSM-5-TR diagnostic criteria for HD emphasize that individuals have difficulty discarding or parting with possessions, regardless of their actual value. This difficulty is due to a perceived need to save the items and the associated distress from discarding them. It results in congestion and clutter so that the use of living areas for their intended use is severely compromised. If living areas are uncluttered, it is likely that others assisted the individual. For example, friends or family members may agree to store items in their own homes. Hoarding is associated with clinically significant distress or impairment and is not attributable to another medical condition or mental disorder. Table 15–4 lists the DSM-5-TR diagnostic criteria for HD.

Key features to ascertain during the history and examination include the age of onset and course of the symptoms, the type and severity of symptoms, the extent of insight and impairment, and the presence of comorbid disorders and symptoms. Many objects may be hoarded, but they are usually everyday items (e.g., newspapers, books, clothing), and the resulting clutter is usually highly disorganized. There is literature on animal hoarding, which some conceptualize as a subtype of HD. Patients cite various reasons for hoarding, including utilitarian value, sentimental attachment, concerns about losing information, and not being wasteful. In some cases, exposure to traumatic or stressful events may precede the onset or exacerbation of hoarding.

Table 15–4.
Hoarding Disorder

Diagnostic Criteria

A. Persistent difficulty discarding or parting with possessions, regardless of their actual value.
B. This difficulty is due to a perceived need to save the items and to distress associated with discarding them.
C. The difficulty discarding possessions results in the accumulation of possessions that congest and clutter active living areas and substantially compromises their intended use. If living areas are uncluttered, it is only because of the interventions of third parties (e.g., family members, cleaners, authorities).
D. The hoarding causes clinically significant distress or impairment in social, occupational, or other important areas of functioning (including maintaining a safe environment for self and others).
E. The hoarding is not attributable to another medical condition (e.g., brain injury, cerebrovascular disease, Prader–Willi syndrome).
F. The hoarding is not better explained by the symptoms of another mental disorder (e.g., obsessions in obsessive-compulsive disorder, decreased energy in major depressive disorder, delusions in schizophrenia or another psychotic disorder, cognitive deficits in major neurocognitive disorder, restricted interests in autism spectrum disorder).

Specify if:

- With excessive acquisition: If difficulty discarding possessions is accompanied by excessive acquisition of items that are not needed or for which there is no available space.

Specify if:

- With good or fair insight: The individual recognizes that hoarding-related beliefs and behaviors (pertaining to difficulty discarding items, clutter, or excessive acquisition) are problematic.
- With poor insight: The individual is mostly convinced that hoarding-related beliefs and behaviors (pertaining to difficulty discarding items, clutter, or excessive acquisition) are not problematic despite evidence to the contrary.
- With absent insight/delusional beliefs: The individual is completely convinced that hoarding-related beliefs and behaviors (pertaining to difficulty discarding items, clutter, or excessive acquisition) are not problematic despite evidence to the contrary.

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:277.

Hoarding may be associated with a broad range of sequelae, including health and safety problems (e.g., patients may not have sufficient space to cook or keep clean and may be at increased risk for a broad range of illnesses). “Clutter avalanches” may lead to falls and even mortality. In some individuals, conditions become entirely unsanitary; this is termed “domestic squalor.” Family relationships can be negatively impacted, and in some cases, dependents may need to be removed. Threats of eviction or forced clearing of possessions may lead to substantial distress and even suicide.

DSM-5-TR provides two specifiers for HD. The excessive acquisition is specified if difficulty discarding possessions is accompanied by excessive acquisition of items that are not needed or for which there is no available space. As in OCD and BDD, insight can be specified as good or fair, poor, or absent/delusional. However, the definition is framed somewhat differently from that in OCD and BDD; in absent/delusional insight, the individual is wholly convinced that hoarding-related beliefs and behaviors are not problematic despite evidence to the contrary. History from other informants may be critical for accurately evaluating symptoms when insight is absent.

Commonly associated features of HD include indecisiveness and procrastination, difficulty planning and organizing tasks, and distractibility and avoidance. Comorbid OCD is elevated in HD compared with the general population. Prevalent comorbid disorders in HD include generalized anxiety disorder and major depressive disorder. Clinical evidence suggests that other OCRDs may also be more commonly comorbid than expected by chance. In older adult patients with HD, there may be medical complications of HD. Several different measures, including the Saving Inventory-Revised and the Hoarding Rating Scale, can be used to assess the severity of hoarding symptoms. Home visits, or home photographs, are helpful for the accurate assessment of symptoms.

Pathology and Laboratory Examination

There are no biomarkers for HD.

Differential Diagnosis

Differentiating normal collecting from HD is not typically problematic. In normal collecting, accumulation is confined to a narrow range of objects, acquired in a structured way, and then well organized. Furthermore, collecting is a pleasurable activity that does not lead to impairment. In contrast, pathologic hoarding is characterized by the accumulation of a range of objects, unstructured or impulsive acquisition, haphazard clutter, as well as consequent distress and impairment.

One key differential diagnosis to consider is that of OCD. In OCD, hoarding is undertaken in response to an unwanted obsession, most commonly due to symmetry obsessions, feelings of incompleteness, or fears of harm or contamination (e.g., an object may be kept in case discarding that object leads to harm). In contrast, in HD, there is no associated obsession; instead, the individual wishes to retain saved items and is distressed by the thought of discarding them. In some cases, both OCD and comorbid HD may be diagnosed.

Although the DSM-5 proposal was for OCPD to remove the hoarding criterion, no changes were made to the DSM-IV diagnostic criteria for personality disorders. Hoarding symptoms may also be seen in a range of other psychiatric disorders, including autism spectrum disorders (where collections may reflect a particular interest) and psychotic disorders. HD should only be diagnosed if the hoarding symptoms are independent of these other conditions; that is when they have a different onset and course.

Several neurodevelopmental and neurodegenerative conditions are associated with hoarding, for example, Prader–Willi Syndrome (where individuals are characterized by hoarding of food, obesity, and skin-picking) and Alzheimer disease. Damage to particular brain regions, including the anterior ventromedial prefrontal and cingulate cortices, has been associated with excessive and indiscriminate hoarding activity. Saving “bizarre” items (e.g., feces, rotten food) or severe squalor may point to a diagnosis other than HD.

Course and Prognosis

HD has a somewhat later onset than most OCRDs. Without intervention, its course appears to be often chronic and progressive. Hoarding symptoms often begin in childhood and adolescence, with diagnostic criteria met only in the 30s and worsening symptoms in each subsequent decade.

Treatment

Pharmacotherapy. The literature on pharmacotherapy of OCD has indicated that hoarding symptoms predict less favorable outcomes to treatment with SSRIs. Nevertheless, these agents remain the first-line intervention for HD in clinical practice, and uncontrolled data indicate that these agents, as well as the serotonin–norepinephrine reuptake inhibitor venlafaxine, may be efficacious for this indication. The number of studies on the pharmacotherapy of HD is relatively small, but, interestingly, some case reports have noted a response to glutamate modulators.

Psychotherapy. CBT has been adapted for HD, and research to date indicates that this manualized treatment is superior to a wait-list. Components include psychoeducation and goal setting, organization skills training, practice with resisting acquisition, and cognitive restructuring. Many patients have limited insight, so motivational interview techniques may be needed to engage patients in treatment. Group therapy is considered a cost-effective alternative to individual CBT. Involving family members and social services may be critical, particularly when insight is absent.

Combined Treatment. There are no rigorous studies of combined treatment in HD, and clinical judgment is used to determine the optimal combination and sequencing of different modalities.

TRICHOTILLOMANIA (HAIR-PULLING DISORDER)

Introduction

The term TTM was coined by a French dermatologist, François Hallopeau (1842–1919), in the 19th century. In the early part of the 20th century, a large case series of patients was described by two surgeons, who operated on individuals with trichobezoars (due to swallowing of hair after hair-pulling). Attention was directed to TTM when researchers discovered that, like OCD, TTM responded selectively to clomipramine. Interest in the disorder increased when consumer advocacy organizations rose in response to the demand for appropriate recognition and efficacious interventions for this underrecognized and undertreated condition.

Definition

TTM is characterized by pulling out of one's hair. This is not done for cosmetic reasons, but instead, individuals often describe an irresistible urge to pull out their hair.

History

Pulling out of one's hair has long been described in the medical literature as a symptom of psychopathology, with descriptions dating at least as far back as Hippocrates. Hallopeau's term derives from the Greek for hair (trich) and pull (till). However, TTM is a relatively late entrant to the nomenclature; it was included for the first time in DSM-III-R. In DSM-5, TTM was first characterized as an OCRD given its overlapping features with OCD. In ICD-11, TTM and excoriation (skin-picking) disorders are classified as BFRBDs, appropriately recognizing this overlooked set of conditions.

Comparative Nosology

In DSM-IV, TTM was classified as an impulse control disorder not otherwise classified. Accordingly, diagnostic criteria include a description of rising tension prior to hair-pulling, followed by gratification during hair-pulling. DSM-5 reviews noted that many patients with TTM did not meet diagnostic criteria for these two phenomena. Patients who did not meet these diagnostic criteria did not demonstrate clinically meaningful differences, so they suggested replacing this with a criterion referring to unsuccessful attempts to stop hair-pulling.

Epidemiology

Studies of select populations, such as college students, indicate that noncosmetic hair-pulling has a prevalence of 10% or higher, with 1% to 3% meeting DSM-5 diagnostic criteria for TTM. Age of onset is typically at menarche, and female to male ratio is about 9:1. Pediatric samples include more girls but with a less skewed gender ratio. There is also growing evidence of the comorbidity and morbidity associated with TTM; this includes comorbid psychiatric disorders, various medical sequelae (e.g., trichobezoars), and decreased quality of life.

Etiology

From a cognitive-affective neuroscience perspective, neuropsychological investigations of TTM have demonstrated some evidence of impairments, including deficits in working memory and visual–spatial learning. Structural and functional brain imaging studies have suggested some involvement of CSTC circuits relevant to habit learning, although the database of studies is sparse. There is also evidence of the involvement of other regions, such as those involved in reward processing and affect regulation, which may well be relevant to TTM.

Animal models of TTM include “barbering” and have investigated the role of various molecular systems in this behavior. Family and twin studies provide evidence for genetic susceptibility and a relationship to OCD and other BFRBDs. Several interesting candidate genes have preliminarily been associated with TTM, including SAPAP3 and SLITRK1, but unbiased genome-wide association studies have not yet described the genetic architecture of this disorder. There is evidence of increased childhood trauma in TTM, but this association is likely not specific to this particular OCRD.

Diagnosis and Clinical Features

The diagnosis of TTM is made based on a rigorous psychiatric history and examination. DSM-5-TR criteria refer to hair-pulling resulting in hair loss, repeated attempts to decrease or stop hair-pulling, clinically significant distress or impairment, with the hair-pulling or loss not attributable to another medical condition, nor better explained by the symptoms of another medical disorder. Key features to ascertain during the history and examination include the age of onset and course of the symptoms, the type of symptoms, the extent of impairment, and the presence of comorbid disorders and symptoms. Table 15–5 lists the diagnostic criteria for TTM.

Hair-pulling may be from any body area but is most commonly from the scalp, eyebrows, and eyelashes. It is worth inquiring about hair-pulling from the pubic area as this may be more embarrassing for patients to volunteer. Patients often pull hair daily, either more continuously or in fewer isolated episodes. Most patients pull with their fingers, but some use tweezers or other instruments. Patients may have a range of habits associated with hair-pulling, for example, stroking or playing with hair, choosing a particular kind of hair to pull, and mouthing the hair once it is pulled. It is also important to inquire about trichophagy (compulsive eating

of hair), partly because of associated shame and partly because it may have serious medical sequelae. Some individuals pull hair from dolls or other objects, pets, or other people.

States of both hyperarousal (e.g., stress) and hypoarousal (e.g., boredom) may trigger hair-pulling. It has been suggested that there are two significant kinds of hair-pulling; focused and automatic. In focused hair-pulling, the person is aware of an urge to pull, tries to resist this, and then gives in. In automatic hair-pulling, the person has less awareness of the hair-pulling, and before they realize it, has pulled out several hairs. Most people with TTM report both kinds of hair-pulling, but individuals differ in the extent to which they employ focused or automatic hair-pulling. Hair-pulling may occasionally be seen in infants and toddlers; this is not well studied but may be self-soothing and self-limited.

TTM is associated with substantial morbidity and comorbidity. First, TTM is associated with significant emotional distress. Repeated failures to control hair-pulling may lead to shame, frustration, and decreased self-esteem. Time-consuming camouflage and avoidance of situations or activities where hair loss may be discovered may further contribute to impairment. Comorbid conditions in TTM include other BFRBDs, with excoriation (skin-picking) disorder the most common. OCD is also more prevalent in TTM than in the general population. More than half of treatment-seeking individuals with TTM have a comorbid psychiatric disorder, with mood and anxiety disorders the most common. A range of measures is now available to assess hair-pulling severity and type, including the Massachusetts General Hospital Hairpulling Scale and the Milwaukee Inventory for Subtypes of TTM. Photographs of pulled areas may also be helpful to assess progress during treatment.

Table 15–5.
Trichotillomania (Hair-Pulling Disorder)

Diagnostic Criteria

A. Recurrent pulling out of one's hair, resulting in hair loss.
B. Repeated attempts to decrease or stop hair pulling.
C. The hair pulling causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The hair pulling or hair loss is not attributable to another medical condition (e.g., a dermatological condition).
E. The hair pulling is not better explained by the symptoms of another mental disorder (e.g., attempts to improve a perceived defect or flaw in appearance in body dysmorphic disorder).

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:281.

Hair-pulling symptoms are somewhat similar across the life course, although younger patients may be less likely to report urges or arousal prior to pulling or gratification and relief after pulling. Females and males also have similar symptoms, but there is some evidence that males have slight differences in hair-pulling patterns (e.g., pulling more commonly from face and chest) and are more likely to have comorbid tics. While there are limited data on TTM from different countries and cultures symptoms seem relatively similar across the world.

Pathology and Laboratory Examination

The majority of patients with TTM can describe their symptoms. In cases of alopecia, where hair-pulling is denied and the diagnosis is unclear, trichoscopy may be helpful.

Differential Diagnosis

TTM should be differentiated from hair-pulling for cosmetic or cultural reasons and from other repetitive hair behaviors that do not lead to pulling. In TTM, there is no associated intrusive obsession or appearance concern, differentiating it from hair-pulling due to OCD (with symmetry concerns) or BDD (with body appearance concerns). Similarly, on the rare occasion that hair-pulling is in response to a psychotic symptom or a

substance, TTM should not be diagnosed. Alopecia may occur for a range of reasons other than TTM.

Course and Prognosis

There are relatively few data on the long-term course of TTM. In the absence of intervention, its course is likely often chronic. However, some data indicate that remission does occur in a proportion of cases.

Treatment

Psychoeducation is a critical component of the treatment of TTM. As in other OCRDs, exploring the patient's explanatory model is a useful first step in progressing key elements of treatment such as understanding the patient's suffering, building a collaborative approach to care, and instilling hope. Many patients and families are relieved to learn basic facts about TTM, including its high prevalence, the fact that many others with TTM are embarrassed by or ashamed of symptoms, that it is not due to commonly voiced factors (e.g., bad mothering), and that treatments are efficacious for many. Consumer advocacy organizations, such as the Trichotillomania Learning Centre (TLC) Foundation for Body-Focused Repetitive Behaviors, may aid in conveying such information.

Pharmacotherapy. Early data indicated that TTM, like OCD and BDD, responded more robustly to clomipramine than desipramine. Unfortunately, subsequent SSRI trials in TTM have not consistently demonstrated efficacy. The most significant positive clinical trial in adults with TTM to date is with N-acetylcysteine (NAC) (1,200 to 2,400 mg/day), a nutraceutical that acts on the glutamatergic system. However, a trial of NAC in pediatric TTM was negative. Small controlled trials indicate that dopamine receptor blockers may also be helpful in these conditions. Given its favorable side-effect profile, it may be reasonable to use NAC as a first-line agent in adults with TTM, use SSRIs when patients have comorbid conditions for which these agents are efficacious, and consider low-dose dopamine receptor antagonists in more treatment-refractory cases.

Psychotherapy. Habit reversal therapy (HRT) is a set of cognitive-behavioral techniques that have been shown efficacious in treating childhood and adult TTM. Components of HRT include awareness

training, competing response training, and social support. Awareness training includes elements such as self-monitoring and collecting pulled hair. In competing response training, the patient substitutes hair-pulling with an incompatible action (e.g., fist-clenching). Social support involves using another individual to reinforce the competing response and may be particularly useful in pediatric TTM. In addition, stimulus control (SC) is used to change the patient's environment so that hair-pulling is more effortful and less reinforcing. There is also preliminary evidence that web-based administration of HRT/SC may be efficacious. Finally, controlled trials of augmentation of HRC/SC with acceptance and commitment therapy, dialectical behavior therapy, or cognitive therapy, which focus on strategies such as affect regulation, enhanced motivation, relapse prevention, or cognitive restructuring, have also suggested efficacy in TTM.

Combined Treatment. There is preliminary evidence that SSRIs in combination with psychotherapy are more beneficial than either treatment alone in some individuals. From a clinical perspective, judicious combination and sequencing of different treatment modalities may be helpful.

EXCORIATION (SKIN-PICKING) DISORDER

Introduction

Cases of "neurotic excoriation" or "psychogenic excoriation" have long been described in the medical literature. However, excoriation (skin-picking) disorder is new to DSM-5. This debut reflects a gradually accumulating research literature, and hopefully, the inclusion of skin-picking disorder (SPD) in the nomenclature will give impetus to even more investigation and bring this often overlooked condition to the attention of clinicians. In ICD-11, TTM and excoriation disorder are listed together under the umbrella of BFRBDs, given their many similarities.

Definition

SPD is characterized by recurrent skin-picking, resulting in skin lesions. Individuals with skin-picking attempt to decrease or stop skin-picking but cannot do so. While some picking of scabs is likely universal, there is associated clinically significant distress or impairment in the case of SPD.

History

This disorder was first described in detail by a French dermatologist, Louis-Anne-Jean Brocq (1856–1928), who noted the development of skin-picking in young women with acne ("acne excoriee"). The field of psychodermatology was influenced by psychodynamic constructs, as evidenced by the subsequent term "neurotic excoriation." In 1978, Robert D. Griesemer reported that 2% of dermatology patients had SPD. Early work with the SSRIs suggested that these agents were helpful in SPD, and productive questions arose about the relationship between OCD, TTM, and SPD. Consumer advocacy associations have further raised awareness of TTM, SPD, and their frequent co-occurrence.

Comparative Nosology

In DSM-IV, SPD is mentioned briefly as an "impulse control disorder not otherwise specified" in the chapter on "impulse control disorders not elsewhere classified." SPD is classified in the nomenclature for the first time in DSM-5. This inclusion recognized the increasing scientific evidence for the diagnostic validity and clinical utility of this entity, as well as the voice of patients and patient advocates. Diagnostic criteria in DSM-5 and DSM-5-TR closely reflect TTM, consistent with the many phenomenologic similarities between these conditions. Diagnostic guidelines in ICD-11 are also similar, but both TTM and SPD fall under the umbrella of BFRBDs. The most common of these conditions are TTM and SPD, but they include a range of other conditions with repetitive behaviors that damage the integument, including, for example, severe nail-biting, lip-chewing, and cheek chewing.

Epidemiology

Community-based prevalence studies of SPD have found a point prevalence of 1.4% to 5.4%. Age of onset is somewhat more variable than TTM, although the mean age is 12 years, typically coinciding with the onset of puberty. Although many more females than males have SPD, the ratio is more even than in the case of TTM. There is also growing evidence of the morbidity and comorbidity associated with SPD; this includes comorbid psychiatric disorders, various medical sequelae (e.g., infection), and decreased quality of life.

Etiology

From a cognitive-affective neuroscience perspective, neuropsychological investigations of SPD have demonstrated some overlap with OCD in that there is evidence of motor impulsivity. Brain imaging studies have similarly suggested some involvement of CSTC circuitry, although the database of investigations is sparse, and other regions also appear to be implicated.

Animal data, the finding that skin-picking is precipitated by dopaminergic stimulants, and respond to dopamine receptor antagonists suggests that the dopaminergic system plays a role in SPD. Family and twin studies provide evidence for genetic susceptibility and a relationship with OCD and other BFRBDs. Several interesting candidate genes have preliminarily been associated with SPD, including SAPAP3, but unbiased whole-genome association studies have not been undertaken.

Diagnosis and Clinical Features

The diagnosis of SPD is based on a rigorous psychiatric history and examination. DSM-5-TR diagnostic criteria for SPD refer to skin-picking resulting in skin lesions, repeated attempts to decrease or stop skin-picking, clinically significant distress or impairment, with the skin-picking not attributable to another medical condition, nor better explained by the symptoms of another medical disorder. Key features to ascertain during the history and examination include the age of onset and course of the symptoms, the type of symptoms, the extent of impairment, and the presence of comorbid disorders and symptoms. Table 15–6 lists the diagnostic criteria for Excoriation (Skin-Picking) Disorder.

Table 15–6.
Excoriation (Skin-Picking) Disorder

Diagnostic Criteria

A. Recurrent skin picking resulting in skin lesions.
B. Repeated attempts to decrease or stop skin picking.
C. The skin picking causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The skin picking is not attributable to the physiological effects of a substance (e.g., cocaine) or another medical condition (e.g., scabies).
E. The skin picking is not better explained by symptoms of another mental disorder (e.g., delusions or tactile hallucinations in a psychotic disorder, attempts to improve a perceived defect or flaw in appearance in body dysmorphic disorder, stereotypies in stereotypic movement disorder, or intention to harm oneself in nonsuicidal self-injury).

Skin-picking may be from any body area but is most commonly from the face, followed by the hands, fingers, arms, and legs. Patients may pick from multiple sites; one study found that patients picked from an average of 4.5 sites. Most patients pick with their fingernails, but some use tweezers or other instruments. Patients often skin pick daily, either more continuously or in fewer isolated episodes. Individuals may have a range of habits associated with skin-picking, for example, stroking or playing with the skin, choosing a particular scab to pick, and mouthing or swallowing the scab once it is picked. Some individuals pick the skin from other people.

Patients may report that skin-picking began after a dermatologic condition such as acne but continued even with the resolution of that condition. States of both hyperarousal (e.g., stress) and hypoarousal (e.g., boredom) may trigger skin-picking. As with hair-pulling, it has been suggested that there are two major kinds of skin-picking: focused and automatic. In focused skin-picking, the person is aware of an urge to pick, attempts to resist, and then gives in. In automatic skin-picking, the person has less awareness of the skin-picking, and before they realize it, has picked again. Most people with SPD report both kinds of skin-picking, but

individuals differ in the extent to which they employ focused or automatic skin-picking.

SPD is associated with substantial morbidity and comorbidity. First, SPD is associated with significant emotional distress. Repeated failures to control skin-picking may lead to shame, depression, and self-medication. Time-consuming camouflage and avoidance of situations or activities where skin lesions may be discovered may further contribute to impairment. Comorbid conditions in SPD include other BFRBDs, with TTM being the most common. OCD and BDD are also more prevalent in SPD than in the general population. Other common comorbid psychiatric disorders in SPD include mood and anxiety disorders. A range of measures are available to assess skin-picking severity and type, including the Skin Picking Impact Scale. A thorough physical examination may be helpful to assess the extent and severity of skin-picking, and photographs of skin lesions may help assess progress.

Skin-picking symptoms are somewhat similar across the life course, although further work is needed in this area. In one study, males had a later age of onset, more severe symptoms, and greater impairment than females with SPD. While there are limited data on SPD from different countries and cultures, symptoms seem relatively similar across the world.

Pathology and Laboratory Examination

Most patients with SPD can describe their symptoms, and dermatologic examination reveals classical features. Thus, for example, lesions often have linear or circular shapes, are often grouped at easily accessible sites, and may be at various stages (from small superficial erosions to deep ulcerations to scars).

Differential Diagnosis

Skin-picking is quite common in BDD, but it is done in response to concerns about body appearance in these individuals, and SPD should not be diagnosed. Similarly, skin-picking may also occur in response to obsessions about contamination, delusions, or tactile hallucinations related to infestation (parasitosis) or may be induced by dopaminergic psychostimulants (e.g., cocaine). Skin picking may also be due to a factitious disorder (dermatitis artefacta). Finally, skin-picking may be seen in response to a broad range of dermatologic conditions associated with

itching (such as scabies), as well as in several medical conditions (such as Prader–Willi syndrome).

Course and Prognosis

Available data on the long-term course of SPD suggest that this is often chronic, albeit with fluctuations in severity over time in the absence of intervention. As is the case in other OCRDs, individuals often report that they have not sought medical attention because they are embarrassed by their symptoms, feel they should stop the symptoms themselves, or are unaware that the symptoms may be part of a known condition with efficacious treatments.

Treatment

Psychoeducation is a key component of the treatment of SPD. As in other OCRDs, exploring the patient's explanatory model is a useful first step in understanding the patient's suffering, building a collaborative approach to care, and instilling hope. Many patients and families are relieved to learn basic facts about SPD, including its high prevalence, the fact that many others with SPD are embarrassed by/ashamed of symptoms, that it is not due to commonly voiced factors (e.g., bad mothering), and that treatments are efficacious for many. Consumer advocacy organizations, such as the TLC Foundation for Body-Focused Repetitive Behaviors, may aid in conveying such information.

Pharmacotherapy. There is some evidence from randomized controlled trials that SPD responds to SSRIs, although there are few studies with small samples. The largest positive clinical trial in adults with SPD to date is once again with NAC, a nutraceutical that acts on the glutamatergic system. Preliminary data show that low-dose dopamine receptor antagonists may also be helpful in SPD, but the cost–benefit ratio should be carefully weighed. Data on the efficacy of lamotrigine in SPD are inconsistent.

Psychotherapy. There is a good deal of overlap in psychotherapy for TTM and SPD. HRT has been shown efficacious in treating childhood and adult SPD compared to wait-list controls. Components of HRT for SPD have included awareness training, competing response training, and social support. Awareness training includes elements such as self-

monitoring. In competing response training, the patient substitutes skin-picking with an incompatible action (e.g., fist-clenching). Web-based HRT may be helpful. Social support involves using another individual to help reinforce the competing response. Manualized CBT treatment for SPD includes cognitive restructuring and relapse prevention. There is interest in acceptance-enhanced augmentation of HRT for SPD, but this has not been rigorously studied.

Combined Treatment. There are no rigorous studies comparing pharmacotherapy and psychotherapy in SPD. From a clinical perspective, judicious combination and sequencing of modalities may be helpful.

OCRD DUE TO ANOTHER MEDICAL DISORDER

This category is new to DSM-5-TR and ICD-11, reflecting that in a new chapter on OCRDs, it is relevant to exclude conditions due to another medical disorder. To determine whether OCRD symptoms are etiologically linked to another medical disorder, consideration should be given to the presence of a clear temporal relationship between such symptoms and the medical disorder. As noted earlier, obsessive-compulsive symptoms have long been described in the context of various neurologic lesions, most notable in the aftermath of the influenza epidemic in the early 20th century. At postmortem, patients had striatal lesions. More recent work has documented the occurrence of OCD due to several other striatal pathologies, including stroke and infection. For example, it is notable that a significant proportion of cases of Sydenham chorea have obsessive-compulsive symptoms.

Pediatric neuropsychiatric disorders associated with Streptococcus (PANDAS) is a condition thought similar to Sydenham chorea, in that a Streptococcal infection is hypothesized to trigger an autoimmune reaction, resulting in sudden onset of obsessive-compulsive and other symptoms. Rigorous research has demonstrated that cases of PANDAS respond to immunotherapeutic interventions. At the same time, this is a relatively new area of research, and some have argued that sudden-onset obsessive-compulsive symptoms can be seen after a broad range of insults.

SUBSTANCE/MEDICATION-INDUCED OCRD

There is evidence that particular substances or medications can trigger or exacerbate obsessive-compulsive symptoms. For example, skin-picking may be seen in patients with cocaine intoxication. Such work is theoretically interesting as it points to the potential role of the dopaminergic system in OCRDs. However, there is less evidence that chronic symptoms of OCRDs are due to substances or medications.

OTHER SPECIFIED AND UNSPECIFIED OCRDS

DSM-5-TR notes a range of other specified and unspecified OCRDs. Other specified OCRDs include obsessional jealousy and cultural variants such as *shubo-kyofu*, which involves repeated concerns about body appearance, and *koro*, which is a concern that the penis will recede into the body. Other specified OCRDs are also diagnosed when the presentation differs fundamentally from those outlined in the chapter; for example, BDD symptoms in patients who have visible body flaws or do not have repetitive behaviors.

CONCLUSION

The DSM-5-TR chapter on OCRDs aims to improve the assessment and management of these underrecognized and undertreated conditions, which are highly prevalent and associated with a great deal of comorbidity and morbidity. ICD-11 has a similar chapter but includes a broader spectrum of conditions. Both DSM-5-TR and ICD-11 list OCRDs adjacent to anxiety disorders to emphasize the overlap between these groups of conditions. Any particular approach to the meta-structure of the nomenclature arguably has pros and cons; on the one hand, the OCRD chapter highlights significant phenomenologic and psychobiologic similarities across these conditions, but there is the risk that naïve clinicians may overlook important differences required in their evaluation and treatment. Certainly, when assessing an individual with any one OCRD, it may well be helpful to ask about the presence of other OCRDs in the individual and family members. There are some similarities in pharmacotherapy and psychotherapy approaches across these conditions. At the same time, as in other DSM-5-TR and ICD-11 chapters, it is important to emphasize that there are also important distinctions that

must be made between these conditions and consequent differences in treatment approaches.

Pathological and Problem Gambling: Gambling Disorder

Harvey Roy Greenberg, M.D.

Pathological gambling has always been a characteristic of humans, a scourge in the shadows. Because of an unprecedented worldwide increase in gambling opportunities over decades, the illness can no longer be condemned nor ignored. It is a universal public health problem, often as crippling as schizophrenia, major affective illness, and anxiety disorders.

Mental health professionals have become more adept at diagnosing pathologic gambling. Unfortunately, efforts at increasing the public awareness of its ravages lag significantly behind the attention paid to other psychiatric problems which do not bear the unwarranted attainder of sinfulness.

One cannot precisely gauge the take from legitimate gambling in the United States. A reasonable guesstimate is approximately 150 billion dollars. The annual profit from American licit and illicit gambling enterprises is at least several hundred billion dollars, as much as 1% of the U.S. gross national product. Worldwide gambling profit is estimated at one-quarter to one-half trillion dollars.

The so-called brick-and-mortar gambling locales, casinos, bingo and videogame halls, etc., have spread from Biloxi to Buffalo, London to Las Vegas, and Moscow to Montreal.

Macao, Singapore, and Hong Kong are the Xanadus of today. Their pleasure domes dwarf Las Vegas' gaudy palaces.

A "whale" is casino slang for a multizillionaire gambler. Casinos make much of their money from whales, many of whom come from abroad. (Most high-end casinos have a private mini-casino for a "whale.") At sumptuous casinos within casinos, multibillionaire whales bet a developing nation's wealth on the turn of a card. Workaday employees are more enthralled by the weekly football pool than their jobs. The weekly church bingo night seems infinitely more exciting to some than the humdrum of their daily lives. Impoverished individuals may wager their last few dollars on ubiquitous state lotteries.

Recreational gamblers are more eager than ever to toss away dollars or euros, pounds or yen. Casino resort vacationers routinely figure acceptable losses into their holidays. But as surely as the house percentage destroys an ordinary roulette player's stake, the lives of a predictable percentage of gamblers will be ground down; careers ruined and family lives devastated, as they sink ever deeper into the idiosyncratic world of the pathologic gambler.

HISTORICAL BACKGROUND

David Schwartz's *Roll the Bones: The History of Gambling (Casino Edition)* comprises an engrossing account of the archeology, anthropology, and history of gambling. Schwartz describes the ubiquity of gambling in virtually every place and era from West to East, primeval to postmodern. One envisions Cro-Magnons wagering flints on how far Og or Magog could chuck his spear, or whether Og would beat Magog in a prehistoric wrestling match.

Some forms of gambling originally had a religious basis, evolving from divination pitched at sussing out the future intentions of the gods. One of the oldest of these is sortilege, interpreting the patterns in a random throw of sticks, stones, or bones. It was only a matter of time before a punter of yore conceived it would be entertaining and profitable to bet on the immediate outcome of rolling the bones, rather than the outcome of a war next year.

Astragali, the knucklebones of goats and sheep, often figured in the divination of antiquity. Shaved into cubes, marked with numbers or letters, they became forerunners of dice. Early examples have been exhumed from the tombs of Mesopotamia Ur and the palaces of Babylon.

The ancient Greeks and Romans were devotees of divining as well as extravagant gambling. Rolling the bones, once used to predict the future, now determined who went home broke at the end of the evening. Romans of every class—emperors and plebes—were ardent dicers. (Lest torture and execution follow, tyrants like Nero and Caligula were allowed to win large night after night.) Rabid fans also handicapped gladiatorial combats.

In the ancient East, punters wagered on combat between men or beasts, birds, and insects. Cockfighting was popular in India several millennia ago. In the gambling houses of dynastic Chinese towns, enthusiasts bet on matches between quails, fish, and crickets.

Board and tile games were popular in antiquity, played for pleasure or serious coin. Chinese gambling houses featured “mahjong-like games.” Pharaonic Egyptians enjoyed early versions of checkers and backgammon. Modern chess derives partly from the ancient Indian game of chaturanga, in which moves of the pieces were dictated by the throw of a die.

Gambling flourished in Europe throughout the medieval period and Renaissance. Crusaders played at hazard to pass tedious hours while laying siege to Arab castles, or staked fortune, limb, and life in savage jousting tournaments. Dicing was the most common gambling activity for the gentry and commoner of the early renaissance.

“Contests between humans, animals, and both were denounced by authority, but nevertheless drew crowds.” Bear baiting, forbidden in Elizabethan London, flourished just outside the city proper. It pleasured people of the better or lesser sort as much as the dramas staged in nearby theaters like Shakespeare’s Globe. Audiences of bloody tragedies like “Hamlet” could smell genuine blood in the air from the nearby bear pits.

In the first half of the 15th century, a new gambling craze swept across Asia and Europe—card playing. With more variations possible, card games quickly became dicing's chief rival. Cards also figured prominently in divination—and still are. The Tarot deck used for fortune-telling derives from the deck employed several hundred years ago in Italian card play.

Gambling historians believe that playing cards originated in China and Korea, then were brought to Europe by travelers, traders, sailors, and mountebanks. Florence became a major center for the manufacture and export of cards. The deck of the common player was crude and cheap. The nobility commissioned exquisitely crafted decks at extravagant cost.

Venice figured significantly in the history of Renaissance wagering. The first legitimate European casinos were founded there: a stiff percentage of their earnings went to the Doge and his cronies, one of the first examples in early modernity of a government-gambling connection.

Lotteries were even more likely to be joined to the political fortunes of the Italian city-states that sponsored them. Venetians, Genoese, and Romans were notable devotees (the Papacy-sanctioned lotteries in 1732). The fiscal debacles that helped precipitate the French revolution were in part stoked by the diversion of state wealth into the pockets of lottery profiteers (Voltaire included).

Probability theory was arguably first applied to gaming by Gerolamo Cardano, a 15th-century physician and pathologic gambler. Before Cardano, wins or losses were chalked up to the whims of fortune. With a mathematical grasp of odds, shrewder bets could be laid. Claudius' elaborate wager in the duel between Laertes and Hamlet is based on the assumption that Laertes is the better swordsman. "Hence have we odds," says the wily king, even though he has already plotted a lethal payoff for his nephew.

Blaise Pascal, the 17th-century philosopher, mathematician, and theologian, also studied probability theory. Pascal's wager famously proved that belief in God was the safest bet in the Heavenly House. Pascal is also credited with crafting a precursor of the modern

roulette wheel, supposedly while trying to build a perpetual motion machine.

Roman soldiers allegedly had already invented a crude version of roulette by upending a chariot and wagering on the spin of its wheel. Although the attribution may be apocryphal, soldiers have always been ardent gamblers, a function of the perennial boredom of hurry up and wait military life.

During the Age of Enlightenment, gamblers throughout Europe continued to wager heavily against all reason. English gentlemen of the Enlightenment and Regency periods bet hugely on cards and dice as well as horse races, dog/rat fights, and savage bare-knuckle boxing contests.

Many a Lord lost his estate at the tables, then looked to marrying an heiress to mend his fortunes. Groundlings mostly wagered at dice. They also subscribed farthings to lotteries sponsored by the Crown to establish hospitals and charitable institutions. These honorable and occasionally rigged enterprises were the antecedents of the numbers racket and legitimate lottery play of today.

At least since the Renaissance, gambling condemned by authority morphed into respectable and powerful businesses. Once more, Venice, hub of international trade, became a singularly auspicious locale for gambling on or against the arrival of rich cargo ships from distant climes.

The venerable Lloyds of London was a coffeehouse-cum-bourse before it became a respectable insurance firm. Like the first casinos, early stock markets stood on equivocal moral and legal footing enormously lucrative for owners and the state, yet at the same time harshly condemned from the pulpit, by the press, and the courts for promoting gambling, as it were, by others means.

During the 18th and 19th centuries, elegant gambling halls were erected in spas frequented by the idle, where the pursuit of health served as a convenient pretext for wooing Lady Luck. The watering holes of Baden-Baden, Monte Carlo, Nice, and Bath were notorious for high-stakes play. Roulette was the most popular table game across the social spectrum; faro and variants of baccarat and

blackjack were also played in the public halls. Separate private rooms were set aside for high-stake card games of whist and piquet.

The fortunes of the great spas eventually waned, although their vestiges still can be found in Nice and Monte Carlo. European public gambling severely declined after World War II because of postwar social and economic devastation. However, renewed prosperity quickly led to the return and profitability of gambling. As always, the authorities took their cut from the proceeds, even as they intermittently denounced wagering. With the rise of powerful international gaming corporations, legitimate gambling has achieved undreamed-of profit in Europe as well as Asia (*vide infra*).

Gambling in America

Long before Europeans set foot on the American continent, indigenous tribes were eagerly betting on games and sports. *Roll the Bones* contains an excellent discussion of early Indian gambling. Despite the Puritan ethic of the early New World settlers, gambling quickly became an omnipresent and predictably ambivalent presence in precolonial America.

The pervasive double standard perennially applied to gambling is piquantly illustrated by the gaming behavior of the Founding Fathers. George Washington played cards almost nightly during the darkest years of the American Revolution. He also issued an edict strictly forbidding wagering among his officers and troops, proclaiming that:

> . . . at this time of public distress, men must find enough to do in service to their God and their country without abandoning themselves to vice and immorality . . .

Luckily for the nation, Washington was a better general than gambler. His meticulous expense accounts reveal he was consistently down a few pounds every year, predominantly at whist.

During the 18th century, American gentry imitated the gambling habits of their English counterparts, wagering on card games, horse racing, boxing, and wrestling matches. Everyday Americans diced as busily as their English brethren. Bearbaiting and similar blood sports were not as popular as abroad, except for cockfighting.

American variations of European rummy- and bridge-like games emerged during the first half of the 19th century. The game known today as poker derived from European models. Craps, which had once been the rage of well-heeled Parisians after the French revolution, became hugely popular among average Americans. By the Civil War, it was the favorite dice game among soldiers on both sides of the conflict.

As the borders of the nation expanded, the gambler followed close upon the heels of the prospector, the homesteader, and the entrepreneur. Gambling flourished everywhere—in the marginal milieus of mining camps and cattle towns; on Mississippi riverboats; in bustling New Orleans (where Bourbon Street was rechristened the Rue De Craps); in the slums and salons of major cities; and in posh summer resorts where political and financial makers and shakers congregated.

American gambling legends spread. During a draw poker session, a known cheater declares he has beaten Wild Bill Hickock with a flush. But Bill calls a full house, turns over a pair of sixes and one ace. He draws his gun, says “Here’s my six …,” then plunges his knife into the table—“and here’s my spike! (gambling lingo of that time for an ace).” The cheater turns pale and folds.

The professional gambler’s persona acquired an ineluctable shimmer compounded out of a yeasty, penny-dreadful blend of romance and danger. Gambling idioms entered the vernacular, for example, passing the buck, from the practice of denoting the dealer in a poker game by sticking a buckhorn knife in the table before him.

By mid-19th century, gambling in the United States figured prominently in coalitions between criminal elements and political machines. In the 20th century, widespread corruption of police, judicial, and other government officials accompanied the consolidation of powerful empires built around gambling, prostitution, loan-sharking, and bootlegging after the Volstead Act was passed. The mob/government symbiosis especially flourished in Chicago, New York, Atlantic City, New Orleans, Little Rock, Phoenix, and Las Vegas.

Vegas was the brainchild of the notorious Bugsy Siegal, gunned down in the 1950s at the order of Mafia capos unhappy about his managerial skills. As the city grew, mob muscle power controlled casinos as well as illicit gambling, loan-sharking, and related criminal enterprises throughout the 1950s and early 1960s.

Eventually, the mob's iron control yielded to legitimate business interests. With the bad old Ratpack days gone, casinos on the Las Vegas Strip and elsewhere reinvented themselves into family entertainment centers. Middle- and working-class patrons with relatively modest budgets became prime targets of opportunity. Conventioneers replaced the high-rolling "whales" of the past. Major money began to be reaped from slot machines rather than table games.

At this writing, family fun still exists in Las Vegas. But one also encounters a sanitized version of the mobbed-up 50s, catering to a younger clientele with money to burn. In garish, theme-based resort/gambling complexes like the Venetian and Caesar's Palace, tourists of every stripe enjoy carefully marketed wretched excess; ever more elaborate slot-gaming technology, celebrity/Cirque de Soleil megashows, and dancing clubs. Five-star restaurants rub elbows with cheap noodle bars and Burger Kings. The heady promise of unzipped sexuality pervades the scene.

The Las Vegas model has spread to casino/resort complexes elsewhere in America, Asia, and throughout the world. The multinational gaming corporations which run them have branched out into running film and record companies.

Since the 1990s, brick-and-mortar casinos have been challenged by the internet's virtual casino, with its ever-expanding cornucopia of gaming websites. Internet poker garnered the greatest attention in America until it was banned several years ago. It is now being slowly relegalized, probably because of its potential for generating tax income for states in straightened circumstances. Meanwhile, internet sport and poker gambling continue to thrive worldwide, available at the tap of a computer key.

NOSOLOGIC CONSIDERATIONS

Pathologic gambling was designated as a separate diagnostic entity in the third edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III). Parameters of the disorder were altered in the revision of the DSM-III, reformulated yet again for the fourth edition (DSM-IV), and were retained essentially unchanged in the revision of that edition (DSM-IV-TR). The illness continued to be subsumed in the category of impulse control disorders: not otherwise specified (which also included pyromania, kleptomania, trichotillomania, etc.).

The DSM-5 and DSM-5-TR

Substantive laboratory and clinical research over the past decade have definitively shown that pathologic gambling should be considered an addiction, rather than an impulse control disorder or obsessional variant. Accordingly, the DSM-5 removed it from the group of impulse control disorders, not otherwise specified, and situated it in a new category of non–substance-related disorders. This was retained in the DSM-5-TR.

The DSM-5 also replaced pathologic/problem gambling with gambling disorder. The renamed diagnosis has a tame, homogenized ring. It does not intimate at first glance the devastating nature of the illness, as it should for the unknowledgeable reader. Pathologic gambling disorder or problem/pathologic gambling disorder would have been more appropriate if there must be a disorder at all. Problem gambling is also not mentioned as such in the DSM-5-TR's gambling disorder.

Most of the criteria for gambling disorder essentially replicate earlier criteria for pathologic gambling with various emendations. Some of these seem rather notional, and there are a few significant omissions.

To meet the diagnosis of any subcategory of gambling disorder, four of the following nine criteria must exist for 12 months:

1. Wagering increasing amounts of money in order to achieve the peculiar excitement of the illness.
2. Restlessness and irritability accompanying efforts to decrease wagering, or abstain from it altogether.
3. Repeated unsuccessful efforts to control, diminish, or stop gambling.
4. An overwhelming preoccupation with past and future actual gambling activities and gambling-related endeavors such as handicapping a horse race.
5. Gambling in the context of dysphoric affect, anxiety, depression, etc. (One submits that the causes of dysphoria are not cited at sufficient length, nor is it sufficiently emphasized that dysphoria may be a product of pathologic gambling itself.)
6. Attempts to get even by repeatedly returning to gamble (chasing losses).
7. Lying to significant others in order to conceal the extent of gambling activity.
8. Gambling-related jeopardizing or loss of significant family and social relationships, jobs, and educational/career opportunities.
9. Escalation of the search for sources of money to pay off gambling debts. Loan-sharking is not specifically mentioned.

The DSM-5-TR indicates that a diagnosis of gambling disorder cannot be made if excessive wagering is better explained by a manic episode. (Other disorders and conditions which can precipitate pathologic gambling are not cited, e.g., delusional schizophrenia, or the administration of dopamine agonists in the treatment of Parkinson disease.)

The DSM-5-TR distinguishes between episodic and persistent forms of gambling disorder. (The factors which precipitate relapse are not cited.) The time necessary for achieving early or sustained remission is notionally set at 3 and 12 months, respectively. The distinction between mild, moderate, and severe types of gambling disorder is based on how many of the nine essential criteria are met at any given time in a patient's course.

Reflecting one's position on appropriate diagnosis, pathologic gambling is used below instead of gambling disorder in discussing the illness' severest presentation. (The majority of clinical studies at this time still employ pathologic gambling [PG].) The abbreviation is frequently used in clinical practice and research. Problem gambling is also employed rather than the mild subset of the DSM-5-TR gambling disorder which is characterized by presenting fewer of the criteria.

EPIDEMIOLOGY

Evidence-based research across the world consistently indicates that approximately 2% to 3% of any population are problem gamblers who do not meet diagnostic criteria for full-fledged pathologic gambling; 0.5% to 1% of any population do meet those criteria. Some problem gamblers remain stable although compromised throughout their lives; others shift back and forth between problem and pathologic gambling or slide permanently into pathologic gambling.

A definite connection has been established between new casino construction and the rise of problem/pathologic gambling in the surrounding area, which did not exist before. Over 3 to 5 years' postconstruction, the prevalence rate then increases to approximately 3%.

The escalation of casino and internet gambling over the past several decades has been paralleled by an increase in nonpathologic and problem/pathologic gambling. In this context, it is inevitable that many individuals with no previous history of problem/pathologic gambling will have their latent disorder activated. (Quite possibly, these subjects were involved in some other form of addictive activity before gambling became available.)

The typical patient in earlier studies was a middle-aged White male from a comfortable economic background. However, reliable comprehensive surveys of treatment as well as nontreatment populations indicate that problem/pathologic gambling now cuts across every ethnic, class, age, and occupational divide. (According

to anonymous sources within the casino world, physicians are among their most consistent heavy players and losers.)

The prevalence of pathologic gambling has especially increased in the following groups over the past two decades:

1. The poor: Particularly poor minorities dwelling in urban ghettos.
2. Adolescents and young adults: This group notably includes teenage internet poker players, who can gain access to the virtual tables without identification. In general, peer pressure to “get with it and join the game” plays a major role in adolescent gambling of any sort. Male teenage gamblers predominate significantly over females. Adolescent gamblers are particularly likely to have parents, grandparents, and other relatives with serious gambling pathology. Many preadolescent gamblers also bet on internet poker, Magic Cards, fantasy sports contests, and videogames without a cash payoff. These young gamers are thought to be at risk for developing gambling difficulties later on.
3. The elderly: Particularly retirees with an inadequate social network, who live alone, have limited recreational or educational interests, or are homebound because of health problems. Problem drinking or frank alcoholism frequently accompanies gambling problems in this cohort, often with no prior history of alcohol abuse or gambling difficulties. “Day Trip” gambling by seniors in assisted living and nursing home facilities is often encouraged by nearby casinos and slot parlors. Inevitably, some day trippers become pathologic gamblers.
4. Women: Several decades ago, male pathological gamblers were said to outnumber females by 5 to 1. Recent studies indicate a shift toward gender equality. Although evidence-based study is limited, it is postulated that more women gamble today because of their increased presence in the workplace, with more ready cash at hand.

   Women formerly favored bingo, lotto, and slot machine play, but now participate in every wagering activity. Most women begin intemperate wagering later than men but are quicker to become full-fledged pathological gamblers. Gambling-related suicidality is higher in this group.

5. Prisoners: Studies indicate that approximately one-third of American prison inmates have formidable gambling issues. Many bring a previous gambling problem to incarceration. But some gambling begins in prison as an endemic solution to the tedium of prison life. Offenders with no previous difficulties often become pathologically involved with card games like poker, hearts, backgammon, or chess. Cigarettes, drugs, privileges, and cash comprise the common currency of prison gambling. Loan-sharking is common. Failure to pay debts can exact brutal punishment, even death.

   Prisoners with gambling problems frequently suffer from cross-addiction to alcohol and other substances, as well as other serious psychiatric disorders. Unfortunately, prison systems rarely have treatment programs for pathological gamblers, compared with programs for substance and alcohol addiction.

FAMILY HISTORY

The family histories of pathologic gamblers reveal that one or more parents, grandparents, or significant relatives are heavy or frankly pathologic gamblers. Family members also have increased rates of affective illness—notably major depressive and bipolar disorder; substance abuse, particularly of alcohol, cocaine, and nicotine; and also experienced verbal and sexual abuse in childhood. Attention deficit hyperactivity disorder (ADHD) is supposedly found more often in family members with pathological gambling, but to date, there is no hard research on this score.

One conceives pathologic gambling as the dark underbelly of the American dream, for the patholoogical gambler's family of origin typically prizes competition, is highly materialistic, and has little inclination to save or budget. Intense admiration for wealth and its signatures is common. Frequently a parent or grandparent has become well-to-do through hard work. Sadly, the same individual may have gambled away his business.

CLINICAL FEATURES

Lesieur's description of the pathologic gambler's signs, symptoms, and life trajectory in 1977 is as relevant today. His typical subject was a middle-class married male in his 30s or 40s. This type is still quite common, but the clinician will encounter many similarities, differences, and variations of the model as a function of age, gender, ethnicity, and social class.

The pathological gambler's intense preoccupation with betting usually begins in adolescence but can emerge even in the preteen years. In his youth, he acquires considerable gambling skills, often in a number of activities. A patholoogical gambler often experiences exhilarating big wins early in his career, which augments an ineffable sense of specialness.

Because of his desire to make it big, he commonly drops out of high school or college and moves away from home. Frequent gambling continues into adulthood but is reasonably well integrated into his life. Most pathological gamblers marry, raise children, work hard, often achieve considerable success, and live large. Contrary to a popular image of the pathological gambler as a callous, entitled narcissist, he is usually deeply committed to family life and takes great pride in being a good provider and parent.

At some point, the pathological gambler becomes embroiled in an ever-escalating, ever-tightening spiral of gambling involvements and options. He may start losing in the context of life stress; by wagering in new locales such as casinos and the internet; or for no discernible reason whatsoever. Instead of stopping and cutting losses, which he has often been able to do before, he begins to chase, calling on more and more options to recoup mounting losses.

The pathological gambler taps into sources of cash for gambling such as family checking and savings accounts; piggy bank and rainy-day stashes; his personal or workplace business; legal and illegal lending institutions; credit cards; and fellow gamblers.

As ever more options are used, they are also used up. The spiral tightens, until fewer and fewer options remain. The pathological gambler becomes trapped in a formidably powerful, self-enclosed system which ensures his inevitable downfall. He bets ever-larger sums and becomes embroiled in more types of gambling for longer

periods of time. Greater losses occur because of the grinding down of natural and house odds, as well as uncharacteristic, impulsive, foolish play.

Most pathologic gamblers are highly knowledgeable. But their expertise steadily crumbles as loss accrues. Indebtedness is compounded by the exorbitant interest rates (vigorish or the vig) on loans floated by sharks and credit card advances. When every option is exhausted, and every source is dried up, the pathological gambler reaches the disastrous moment of closure.

Crimes such as embezzlement, passing bad checks, and other types of fraud may be undertaken to get even. Female pathological gamblers may become prostitutes. Such offenses were once believed to be hallmarks of end-stage pathologic gambling. Recent studies indicate that petty criminality often begins earlier and continues throughout the patient's career. However, pathologic gamblers without genuine antisocial or sociopathic traits rarely become involved in major criminal enterprises.

The revelation of the pathological gambler's transgressions is excruciatingly humiliating, and the consequences are often catastrophic. Exposure may precipitate imprisonment, professional disgrace, divorce, escape to another state or country, or the ultimate deliverance—suicide.

But it is more likely for exposure to be followed by a favorable outcome with restitution of debts undertaken by family or friends; remission of debts by a bookmaker, bank, or loan shark; an employer's forgiveness; a kind judge who orders probation rather than incarceration. Typically, the pardoner is deeply moved by one of the innumerable "sad tales" every pathological gambler always has at their beck and call.

The craving for action is central to the pathological gambler's modus vivendi. A pathological gambler frequently rationalizes this overwhelming desire by convincing himself that one simply must be wherever the action takes in order to catch up and stop chasing. But it is the pull of action itself that draws the pathologic gambler ever deeper into the gambling vortex. It matters little whether he is losing

or catches up. The ineluctable lure of action is captured by Dostoyevsky's mot "le jeu pour le jeur" ("the game for its own sake").

Trippett observes that:

> Supposedly . . . action speaks to the process of betting. I suspect it speaks more deeply to what happens within the gambler. He places the bet, juices flow, he really feels . . . alive. Action: when the bet is on, his existence is confirmed . . .

The idiosyncratic action rush is inflected by the peculiar ambiance of each gambling locale; the racetrack's steamy milieu, polluted by rumor and false report; the clockless eternal present of the casino, with its idiosyncratic symphony of sounds—the click of a roulette wheel, the mellow warbling of slot machines, the joyful uproar around a craps table when a winner on a roll makes his number again.

The action high can be obtained in so-called action systems: a pool hall; bowling alley; the backroom of a candy store; and a diner—where bookmakers, pros, and recreational and pathologic gamblers congregate. Here every kind of play is found or can be arranged.

Some PGs stay wedded to the game they have always played as they become enmeshed. However, a chasing pathological gambler usually finds that one kind of gambling is insufficient to satisfy his craving. So he branches out into other gambling activities. A lack of expertise in a new game often compounds losses, accelerating the chase.

As the spiral deepens, the trajectory of action inevitably extends beyond the time consumed in betting to embrace longer time before and after wagering—planning action; setting up a poker game; handicapping races at several tracks during a single day; getting to action as in leaving work prematurely to get to a racetrack in time for the daily double; dealing with the consequences of action—collecting winnings or, more often, dashing madly about to cover losses; making interminable excuses to a bookie for coming up short; to an employer for lateness and absences; to his wife for coming home at 4 AM only to leave a few hours later.

The pathologic gambler is a master at manipulating cash flow—moving money. His previous business skills are now directed at the business of enabling play. He shuffles loans, bank accounts, and cash, from one source to another in dazzling displays of financial legerdemain which would do a Ponzi proud. His hectic strategies in moving money actually become an integral ingredient of the ominous, raw excitement of the action-seeking lifestyle.

The pathological gambler in serious chase mode is like a juggler, desperately fielding an ever-increasing number of plates, oranges, and bowling clubs tossed at him from offstage. Like his psychological twin, the adolescent, he is supremely engaged in an eternal present. A central cause of mounting losses is his utter incapacity to envision a future more than a few days away, a time when he won't be able to secure the cash to forestall closure and exposure.

The pathological gambler's trajectory over years is consistently marked by repeated cycles of spiraling, closure, exposure, bailout, and relapse. Relapse is often precipitated by the prompting of fellow pathological gamblers who cannot abide the presence of an abstainer; by the intense boredom accompanying abstinence; or by the very fact that the problems precipitated by closure have been resolved. As the horror of indebtedness fades from memory—the memory for gambling disasters is notably short—the pursuit of action is all too easily resumed.

Pathologic gambling occurs in companionable social circumstances at a blackjack or craps or poker table, at a horse or dog track, or football game. Most pathological gamblers are outwardly gregarious, with an apparently wide network of relationships including other gamblers. These often have a curious ephemeral quality. For several hours of poker play, the man beside you is your best friend before he gets up and vanishes forever into the night. The decision to gamble with fellow pathological gamblers at the expense of the sufferer's family and social life is an especially significant choice in the course of the illness.

A lone-wolf pathological gambler is rare. In aid of rationalizing schizoid tendencies, he will often assert that he shuns fellow gamblers to avoid bad advice or loaning hard-won cash. Most

internet gamblers are not lone wolves. Computer play commonly alternates with social gambling. However, when internet waging creates the pathologic spiral in one so predisposed, outside wagering activities along with other social outlets fall away.

The induction of a gambling spiral has been ascribed *inter alia* to marital problems, death of a loved one, the birth of a child, and business reverses or successes. However, on closer examination, these may not really be the actual causes of chasing but *post hoc propter hoc* events. Marital problems may be the consequence, not the precipitant of pathologic gambling.

Whatever stressor precipitates the chase, the pathological gambler becomes an extraordinary source of stress for others, at home and at work. For many, the hallmark of the illness' increasing severity is not simply the time devoted to gambling, or the preoccupation with gambling, or mounting indebtedness—all wrenching enough. It is rather the devastating impact of pathologic gambling upon every relationship outside gambling.

As the chase escalates, the pathological gambler's quality of life progressively deteriorates. For years, spouse and family may have been totally unaware of the extent and severity of gambling, until indebtedness drives the patient to invade family funds. Exposure is especially calamitous for the pathological gambler's spouse, shaking confidence in the pathological gambler's successful image and evoking angry feelings of betrayal.

Exposure regularly is followed by impassioned promises to cease gambling, leading to tearful reconciliation. But as the pathological gambler continues repeated chasing cycles and deceitful tactics to avoid the spouse's complaints, an atmosphere of pervasive mistrust comes to pervade the marriage. It degenerates into squalid ploys and counterploys revolving around the pathological gambler's concealment strategies, and the spouse's maneuvers to protect themself and the children.

Despite suffering, the pathological gambler's spouse does not easily oppose the pathological gambler. Once forged, the dysfunctional marital bind may continue for years before the spouse issues a final ultimatum to cease or face divorce. Research does not

support the common belief that spouses of pathological gamblers are inherently masochistic. Nor do they subtly encourage the pathological gambler's illness.

It is rather that a wife, husband, or lover becomes locked into a uniquely compelling interpersonal system that eventually justifies its own existence. The spouse genuinely cares for the pathological gambler and tends to deny or excuse gambling behavior, especially with the pathological gambler's convincing expressions of guilt. Even when a spouse winds up loathing the pathological gambler, they may be unable to break free of the system because they fear being unable to support themself, or realistically cannot do so (one notes the similarity to the battered spouse's plight).

The pathologic gambler's children are tragic victims of the illness. They bear the burden of neglectfulness, of parental disharmony, and of actual abuse. Predictably they have a high rate of psychiatric symptoms and behavioral problems. By that poignant process through which one identifies with a traumatizing parent, they also stand at considerable risk of becoming pathological gamblers themselves.

The crumbling of the pathological gambler's value system is as traumatic to themself as others. The pathological gambler has always treasured honor; loathes themself for abrogating it. Like addicts in the throes of their illness, the pathological gambler becomes demoralized and exhibits ego-alien and indeed abhorrent behavior, which would never exist were they not caught up in the chase. In end-stage gambling, the pathologic gambler's entire existence revolves around play. At this point, the Pathological gambler may paradoxically derive little real pleasure from gambling. Winning has long since ceased to be an end, rather the means of securing further action.

Some Pathological gamblers cease serious gambling in later life. Cessation does not appear related to treatment of any sort. Akin to the burn out of drug addicts, the craving for action seems to simply wither away for obscure reasons. Mutatis mutandis, a Pathological gambler may escalate chasing in old age, as gambling becomes life's raison d'être.

Personality Characteristics

Pathologic gamblers display a strikingly similar cluster of personality traits. Depending on age, gender, and social class, some may be exaggerated or absent.

In pure culture, pathologic gamblers are competitive, going back as far back as latency or early adolescence. They are intelligent, although usually not deeply intellectual.

They consider themselves rugged individualists; they are highly independent and overconfident to the point of abrasive. A keen interest in sports participation and viewing parallels their interest in gambling. They are perennial optimists and deniers, and they possess a distinctive gallows humor:

Joe: Which fighter are you betting on tonight?
Jim: Both.
Joe: But you'll only come out even.
Jim: I need the money!!!

Pathological gamblers are by turns touchingly loyal, or gaggingly insensitive, notably when chasing. Despite their apparent sociability, they are often beset by profound feelings of loneliness. They do not easily express feelings, indeed may be so unable to get in touch with their emotions as to be alexithymic.

Pathological gamblers as well as successful professional gamblers often project an air of grandiose elitism. They believe they always know the score at gambling and life in general, for which they hold gambling as a Hobbesian dog-eat-dog metaphor. The pride of pathologic gamblers in their idiosyncratic vocation, even at its disastrous end-stage, is poignant.

COMORBIDITY

Extensive research indicates that impressive comorbidity exists between gambling and affective disorders, notably major depression

and bipolarity, and addictive disorders, notably to alcohol and cocaine, nicotine, and caffeine.

There is significant comorbidity between pathologic gambling and ADHD in adolescent as well as adult problem/pathologic gamblers. One has the sense that many pathological gamblers have a forme fruste of full-blown ADHD.

Various personality disorders have been described in PGs, especially narcissistic, borderline, and antisocial disorders. Although many pathologic gamblers have obsessive personality traits, full-blown obsessive-compulsive disorder (OCD) is rare.

Mutatis mutandis, a higher rate of pathologic gambling has been discovered in patients with a primary diagnosis of affective illness (particularly bipolar) and schizophrenia. One's clinical impression is that patients with generalized anxiety disorder, panic disorder; narcissistic, borderline, and antisocial personality disorders are more likely to have gambling problems. However, the relationship has yet to be proven.

The pathologic gambler's course is often worsened by serious comorbid conditions, particularly alcohol and drug addiction. The easy accessibility of these substances in or near gambling milieus further disinhibits the Pathological gambler, resulting in wilder play and greater losses.

Exacerbation of an affective disorder may be a primary precipitant of a gambling binge. Heavy indebtedness may precipitate a dysthymic state or frank major depression, which then triggers off more betting binges.

Pathologic gamblers paradoxically are often both hypochondriacal and dreadfully neglectful of their physical well-being. Pathological gamblers eat poorly and excessively; are chronically sleep deprived and underexercised. They are more vulnerable to hypercholesterolemia, arteriosclerotic cardiovascular disease, diabetes, peptic/gastric ulcer, and hepatic and pulmonary disorders (often a function of nicotine abuse).

DIFFERENTIAL DIAGNOSIS

Making a diagnosis of pathologic gambling is often problematic because pathological gamblers so often minimize, rationalize, or absolutely deny their difficulties. Should doubts arise, the clinical interview may be supplemented by reasonably reliable tests such as the South Oaks Gambling Screen (SOGS) and the National Opinion Research Center DSM Screen for Gambling Problems (NODS). SOGS is better known and frequently used in pathological gambler research. NODS is a population-based telephone interview that identifies gambling problems according to DSM criteria. Although initially useful, an extensive clinical interview obviously provides the most accurate information for the diagnosis to be made.

A problem gambler is most likely to be seen first by a clergyperson or general physician. Referral to a psychiatrist or other mental health practitioner usually occurs further down the line. Because of the patient's intense denial, both laypeople and practitioners need to recognize the symptoms and behavior that will differentiate problem/pathologic gambling from the recreational betting practiced by at least 85% of Americans.

Ordinary recreational wagering is based on a mix of conscious and unconscious factors unique to each unproblematic bettor, for example:

1. A desire for relaxation in a companionable social setting, away from the everyday grind. Recreational gamblers usually play on designated occasions such as a weekly poker game. They have a firm grip on acceptable losses.
2. The profit motive. One often hears players proclaim they don't care if they win or lose, it is the fun that counts. If pressed, however, most recreational gamblers will admit that they would rather win than lose.
3. The inherent pleasure of exercising a variety of skills and ego functions depending on the nature of the game or sport.
4. The satisfaction of nonpathologic competitive drives.
5. The attraction of risk taking in a betting situation where a negative outcome produces minimal if any psychic trauma. In a quixotic world where mortality is the only certainty, yet the time of

its coming ever in doubt, gambling allows one to indulge in the illusions of omnipotent control over destiny.

6. The impression of control is fostered by games in which the chance element can be reduced by studying the parameters of play and doping out the odds, for example, racetrack handicapping. When loss does occur, one is gently reacquainted with the limitation of one's powers.
7. The gratification of other obscure, possibly conflict-based drives and motives stemming from early stages of psychological development, etc.

For the professional gambler, wagering is a business, plain and simple. Contrary to the myth of the glamorous high roller, most pros avoid the limelight if only to avoid taxes. Their expertise is impressive. They are summarily prepared to take requisite risks; coolly acknowledge the losing streaks which come with the territory; and are able to weather losses on any given day without losing control. However, given the inherent nature of the work and personality factors, a pro is much more likely to slip into pathological gambler chase mode than the ordinary gambler.

Acute substance abuse accompanied by temporary disinhibition may precipitate a gambling bout without other symptoms of pathologic gambling. Alcohol and cocaine are particular offenders in this regard.

Gambling binges are occasionally seen in the setting of an acute or chronic schizophrenic delusional system, for example, a patient who believed God had ordered him to stake his life savings at the dog track so as to hasten the end of days foretold in Revelations.

Excessive wagering may occur during the manic stage of a bipolar disorder in patients who have been unproblematic gamblers before or have never gambled at all. The correlation between gambling episodes and mood swings in pathologic gamblers with significant comorbid affective illness is a vexed question—obvious in some pathological gamblers, either nonexistent or obscure in others.

Bipolar pathological gamblers with mania in remission nevertheless can appear as wired to the universe as a patient in a

full-blown manic state; crackling with tension as they pursue their dizzy dance over the abyss. However, in the former case, the pathological gambler quickly returns to a more temperate mood once play has ceased. He may be reactively and temporarily elated after a win, or just as appropriately depressed after a loss. In any case, a mood-disordered problem/pathologic gambler will generally wager excessively whether clinically manic, depressed, or euthymic.

Individuals with antisocial personality disorder frequently gamble, but the nature of their behavior reflects their essential criminality and utter lack of empathy. They will do anything possible to win and are chronic cheaters. They are often poor players and blame others for their losses rather than recognize their own inadequate play. An antisocial individual may retaliate violently after a loss; indeed, may subsequently rob an individual to whom he lost, or hold up a game where he lost.

Unlike antisocial gamblers, the majority of pathologic gamblers have a better work record, a more stable family life, and a reasonably scrupulous moral set before their illness catches up with them. They are ashamed when driven to crime—usually petty—out of profound desperation, to cover losses and keep gambling.

Although gambling may seem to have an obsessive element, it is rare for an individual with obsessive-compulsive illness to become a pathologic gambler. Unlike the tormenting ego-alien symptoms of an OCD patient, the pathologic gambler's overwhelming preoccupation with play is usually quite ego-syntonic, even persisting when the patient has reached a terminal, end stage of gambling.

Bouts of pathologic gambling are rarely due to compromise of cerebral function by injury, infection, or neoplasm. Intemperate wagering in patients with Parkinson disease treated with dopamine agonists is further discussed below.

ETIOLOGY

For centuries, pathologic gambling was chiefly viewed as a moral stain rather than a medical problem. Gamblers were said to suffer from an engrained weakness of character that rendered them

susceptible to temptation from the dark side. The evils of gambling were associated with the evils of drink, sexual depravity, and low companions.

Pseudopsychological theories surfaced in the 19th century, ridden with sanctimonious moralizing. The advent of psychoanalysis spurred awareness that pathologic gambling might have a scientific, rather than a “weak-brain” or theologic basis. During the last two decades, exploration of the pathological gambler’s psyche has been joined by impressive research into the illness’ genetics and neuroscience.

Psychoanalytic Theories

The literature on pathologic gambling was sparse at the advent of psychoanalysis. Theories chiefly addressed the gambler’s childhood trauma and psychic complexes.

Early analytic investigators drew analogies between pathologic gambling and sexual excitement. It was commonly supposed that compulsive wagering comprised some sort of neurotic substitute for mature erotic fulfillment.

However, players state, and researchers have affirmed, that the unique thrill of gambling action is utterly divorced from Eros. Nell Kimball, a madam of the frontier days whose establishment provided prostitutes and a gambling house declared that “if you give a man a choice between gambling and sex, he will take gambling any time.” The majority of pathologic gamblers are fully capable of enjoying sex. All in all, the displacement of libido from bedroom to bookie must be rated a very vexed question.

The first psychoanalytic theories now appear simplistic or simply wrongheaded, but the findings of depth psychology over a century should not be dismissed out of hand. While analytically oriented therapy without other adjuvants will not benefit most pathological gamblers, it does yield helpful insights into the gambler’s inner life and motivation, his vertiginous fluctuations between exhilaration and despair.

Simmel published the first account of a pathologic gambler's analysis in 1920. He thought that pregenital and Oedipal conflicts were implicated in the illness. Stekel described the gambler's frequent mood swings, preoccupation with superstition and rituals, and fantasies of omnipotence. He classified the pathological gambler as a compulsive neurotic with latent homosexual tendencies.

In his famous 1928 monograph, "Dostoevsky and Parricide," Freud likened pathologic gambling to other obsessive-compulsive behaviors. He argued that the great writer's gambling addiction stemmed from a displacement of childhood masturbatory urges. The frenetic drivenness, escalating tension, and use of the hands in roulette and other games were autoerotic equivalents.

Fenischel astutely compared the gambler's cycles of triumphant wins and desolating losses with manic-depressive cycling between giddy elation and devastating despair. He speculated that pathologic gamblers believe they are entitled to special protections and gratifications, based on grandiose infantile expectations of parental bounty. Gambling is the magical means by which fate is compelled to act on the patient's behalf. In a variation of the *Schicksalneurosis,* the destiny neurosis, the pathologic gambler surrenders autonomy and responsibility for his actions, perceiving himself either as destiny's favorite or victim, depending upon whether he is winning or losing.

Kris theorized that the pleasure of the pathological gambler's wagering articulates with guilt-ridden Oedipal sexual tensions so that the heady joy of action becomes ineluctably fused with dread. The patient's ego is unable to control what it has initiated. He becomes trapped in a vicious cycle of anxiety: the need for reassurance of his survival through winning; more play; mounting losses; and the ominous escalation of tension. Gambling evolves from an innocent pastime into a literal matter of life and death.

Edmund Bergler's theories about pathologic gambling were immensely influential for decades. His signal assumption was that the pathologic gambler is driven by a desire to lose. Bergler asserts that the pathological gambler bears profound grudges, first against parents, then later authority figures who are resented for imposing

the reality principle on his infantile narcissism and omnipotent fantasies.

According to Bergler, aggressive impulses unconsciously directed against the misperceived deprivers of nursery days cause inordinate guilt and an intense need for punishment. Gambling recapitulates the cycle of childhood rage, aggression, and remorse. Pleasure in wagering reflects the exhilaration of grandiose rebellion; pain arises from the morbid certainty of punishment.

As the pathologic gambler's anguish about losses becomes erotized, he develops psychic masochism: savoring his victimhood, relishing injustice collecting, reveling in self-pity, and spurious righteous indignation. Lady Luck at base is his Bad Mother. He hopes his suffering will compel her to restore the blissful infantile nurturing she snatched from him.

While Bergler's ideas are now viewed as at least questionable, they nevertheless have provided grounds for more sophisticated psychoanalytic study.

Whatever the pathologic gambler's other key conflicts, one speculates that the pathological gambler's devotion to wagering constitutes an uncanny spilt religion. His plethora of superstitions and rituals seem pitched at winning Fate over to his side, in aid of dealing with a devastating fear of death which has largely gone unappreciated in the literature. One wonders if the pathological gambler may court the erratic favors of Lady Luck in aid of making the ultimate score—a triumph over death itself.

MATERIALIST RESEARCH AND HYPOTHESES

Imaging Studies

More questions have been raised than answered about the neurobiology of the pathologic gambler. Nevertheless, researchers are beginning to make progress in mapping cerebral centers and pathways that mediate judgment, mood regulation, decision making, and impulse control. These are compromised in pathologic gambling, as they so often are in substance addictions.

Patients with cerebral trauma, tumors, or infectious processes that damage the ventromedial prefrontal cortex and amygdala *inter alia* may exhibit denial or unawareness of situations that require common sense judgments. Actions with immediate rewards are favored, while long-term negative consequences are ignored. Experts speculate that pathological gamblers may have some sort of analogous cerebral compromise which facilitates immoderate betting activity.

Many imaging studies have focused on the ventral and ventrolateral striatal prefrontal cortex and connections with other brain loci mediating prudent judgment. Experts speculate that suppression of activity within these pathways may cause a blunted neurophysiologic response to rewards and losses, in turn eroding the ability to make appropriate decisions. Pathological gamblers, like substance abusers, regularly seek short-term gratification without regard for later consequence.

The role of visual cueing in pathologic gambling has been studied with various imaging techniques. Pathological gamblers viewing videos of gaming scenarios demonstrate heightened activity in pathways between *inter alia* the right dorsolateral prefrontal cortex, right parahippocampal gyrus, and the left occipital cortex. Corollary conscious cravings to gamble were experienced by subjects after exposure to the gambling videos.

The impact of risk taking upon the pathological gambler's brain has been demonstrated in PET research, in which subjects playing for real rather than simulated money showed an increased metabolic rate in the primary visual cortex, cingulate gyrus, putamen, and various prefrontal areas.

These findings are intriguing, but only scratch the surface. Any episode of recreational as well as pathologic gambling involves many other activities than betting. A bout includes arousal of the urge to gamble; planning the time, place, and choice of gambling activity; experiencing the ebb and flow of action, for example, at the racetrack or card table; dealing with the outcome of winning or losing (e.g., moving money to cover losses). Investigators are still far from being able to monitor what precisely the pathological gambler's brain

is doing, which cerebral loci and pathways drive the doing, over the entire trajectory of a gambling episode.

Neurotransmitter Research

Many recent studies indicate that pathological gamblers suffer from complex neurotransmitter dysregulation similar to the abnormalities found in substance abusers and patients with other behavioral/impulsive problems. Imbalances across the entire neurotransmitter spectrum—serotonergic, noradrenergic, dopaminergic, GABA, etc.—have been variously postulated as significant factors in the dysfunction of cerebral sites and pathways mediating behavioral arousal, inhibition/disinhibition, reward/reinforcement, and psychophysiological stress.

The particular focus on the role of increased dopaminergic activity in pathologic gambling arose from the serendipitous discovery that approximately one-third of patients being treated for Parkinson disease with dopamine agonists develop the illness without any previous history. The gambling excesses of these patients usually disappear upon withdrawal of the offending drug.

Pathologic gambling in the Parkinsonian group treated with dopamine agonists has been ascribed *inter alia* to disproportionate stimulation of dopamine receptors localized in mesolimbic pathways, which are thought to be involved in reward seeking.

However, one notes that two-thirds of the Parkinsonian patients studied do not develop pathologic gambling, indicating that other factors must play a role in the afflicted third: pre-existing cerebral damage due to Parkinson disease itself, genetic, family, and sociocultural influences, etc.

Other Predisposing Materialist Factors

Adolescents, particularly male teenagers, have a higher incidence of impulsivity and stimulus seeking than other age groups, as well as a higher incidence of recreational gambling, arguably attributable to the cerebral and hormonal changes of that period. While it has not been established that average teenagers are more predisposed to

pathologic gambling than adults, adolescents with ADHD are significantly comorbid for pathologic gambling and vice versa.

A small study of adult nongambling subjects exposed to high- and low-risk gambling experiments showed that those preferring stimulus-rich environments consistently sought long shots, wagering more to win more. One wonders if such subjects have some sort of inborn predisposition toward stimulus seeking, which given other factors, might lead them to become more attracted to social, and even problematic, gambling.

Twin studies suggest that pathological gamblers, beyond identifying with a gambling relative, may have an inherited genetic potential to develop the illness.

Variations in several alleles have been discovered in pathological gamblers, but more research is needed to establish whether a predisposition for problem/pathologic gambling exists at a chromosomal level.

Behavioral/cognitive research focuses on pathologic gambling as a learned, disastrous habit. Based on the available research as well as one's own clinical work, it appears more likely that the pathological gambler's habit is driven by neurobiologic factors, rather than simple introjection of a gambling relative's addiction. Hence the discussion of behavioral/cognitive factors has been placed in the category of materialist hypotheses.

Many pathologic gamblers exhibit sensitivity to a gamut of reinforcers directly or indirectly related to wagering. An example of direct or primary reinforcement is the slot machines' lure of high return for a repetitious low-response small investment.

An example of indirect or secondary reinforcement is the "comp" offered by casinos, depending on hours of play, player's wealth, etc. The comp can include a special room rate or no charge at all, free food, drinks, etc.

Contemporary casino design, technology, and management practices demonstrate an elegantly sinister deployment of virtually every behavioral stimulus for a vulnerable problem or pathologic gambler to bet over his head, not with it.

Pathologic gamblers are exceptionally prone to betting-related cognitive biases and distortions. These include discounting the large sum of money owed as a result of making small bets toward achieving the big score; magnifying one's own skills while minimizing the real talents of other players; losing sight of the amount of gambling time needed to recover losses; selectively remembering memories of wins over losses; the abiding conviction that a chain of losses must herald an impending win, especially after a near miss (the so-called gambler's fallacy, but actually one of many).

A Darwinian Sidebar

At first glance, gambling would seem to have little if any evolutionary value. If the impulse to gamble is inherently unhelpful for survival today, why has it not simply mutated away?

There is obvious survival value in prudently choosing to stay inside the cave while outside the winds rage and the beasts howl. *Arguendo* the chance of group survival was improved when some Og or Magog proposed a better, if more dangerous, plan to kill a mammoth in aid of providing better sustenance.

But what if the daring caveman subsequently began to wonder if a life better than bone-chilling subsistence lay over the next mountain, or beyond? It is not unreasonable to suppose that he, his children, or grandchildren would eventually decide to defy the prevailing belief that monstrous creatures or molten pits of fire lay over that mountain and seek a land where the weather was mild and food plentiful.

One conjectures that certain individuals have always been more genetically/neurobiologically hardwired, as well as characterologically predisposed, to appropriate risk taking, whether in geographical exploration, warfare, scientific research, finance, athletics, etc. Not only would these risk takers enjoy the prospect of their perilous venture's success, but they might also savor the peril *sui generis* to an appropriate extent.

Now, entertain the possibility that viable risk-taking turns pathologic for a small subset of the daring ones. In such cases, the risk inherent in a dangerous enterprise may become the sole end,

rather than merely one aspect of attaining whatever achievement is being sought. Throughout history, perilous enterprises have suffered or even failed because a pathologic risk taker courted greater danger than warranted for its own sweet sake. (One would expect to find a wide range of behavior between appropriate and absolutely pathologic risk taking.)

Whyte acutely speculates that the appropriate risk taker is able to see a useful, albeit perilous pattern of opportunity in the environment, and takes prudent advantage of it, but an inappropriate risk taker may play down the pattern's inherent danger, indeed misperceive that one risk or another should never be taken, no matter how auspicious the intended outcome.

From this perspective, one conceptualizes gambling of any sort, recreational to pathologic, as a spin-off of the Cro-Magnon's hard-wired risk-taking behavior. With no mammoth to slaughter, with no journeying into frightening terra incognita, wagering at best provides a pleasurable anticipation in the moment, joined to the hope of a successful outcome; at the very worst, the pathologic gambler savors pleasure even when he knows the odds are stacked against him. Research cited above indicates that the pathological gambler's pleasure might actually be heightened by the heady promise of ultimate success, after heavy initial losses.

TREATMENT

Psychotherapy

Virtually every modality has been used to treat the pathologic gambler. For decades, results were ungratifying and relapse rates high. Better understanding of the disorder's psychology and neurobiology have improved outcome somewhat—this in the context that only 10% to 20% of pathological gamblers actually seek or are compelled to seek professional help. Success hinges upon carefully individualizing treatment, case by case. Combined approaches are frequently required. It is not unusual for a patient to need psychotherapy; cognitive/behavioral work; medication; couple and

family therapy, and membership in a Gamblers Anonymous (GA) group. Recent data provide the most support for cognitive behavioral therapy (CBT) and motivational interviewing.

Pathological gamblers make extremely difficult patients. They rarely want help, persistently deny flagrant problems, and can charm the pants off an unwary therapist. The average pathologic gambler is often forced into treatment only after disclosure precipitates an ultimatum to get help or suffer divorce, prosecution, etc.

The pathological gambler's enormous pride, formidable denial, alexithymic lack of introspection, chronic impatience, and incurable optimism, all militate against forming a viable working alliance, particularly in psychoanalytically oriented therapy. These patients usually present a host of dire symptoms and problems related to the chase—depersonalization, hypochondriasis, panic attacks, substance abuse (notably of alcohol, cocaine, and tobacco)—which do not readily yield to talking approaches. The patient is also likely to suffer from other physical illnesses that have gone untreated or poorly attended to because of his own neglect—obesity, peptic ulcer, etc.

Pathologic gamblers expect magical interventions and frequently quit treatment when miracles are not forthcoming. They often go through the motions of patienthood, while remaining inwardly convinced that a turn in luck and improved cash flow are all that is needed to resolve their problem. They are usually scornful of someone who doesn't gamble. However, the therapist who is a gambling novice can put his ignorance to work by having a client teach him the ropes, much as an adolescent therapist will ask a stony silent youngster to instruct him about rap music.

Psychoanalytically oriented therapy with a pathologic gambler is stormy indeed, akin to working with a resistant adolescent. One routinely expects missed sessions; relapses; and financial crises which cause disruption or cessation of treatment due to inability to pay.

Firm, but kind limit setting is crucial. In most cases, the patient is asked to pay for each session on the spot, regardless of the cost. Greater responsibility in handling fees is often a sign of

improvement. One has found that carrying a pathological gambler seriously undermines therapy, as does lowering a fee because of gambling losses unless serious physical illness supervenes, or the patient loses a job for reasons not related to gambling.

The therapist should be vigilant vis-à-vis the veracity of the patient's explanation about problematic treatment issues, as well as serious family and work difficulties. A pathological gambler in chase mode will minimize troubles or justify them with a "sad tale." Reality can be treated like toffee stretched here or there according to whatever will work. As in the treatment of seriously disturbed children and adolescents, it may be necessary to contact significant others to get a clearer picture of what is truly going on. The patient should be informed of this possibility at the beginning of treatment, with the understanding that the therapist would rather maintain confidentiality if the patient will hold up his end of the contract.

Cognitive and behavioral strategies appeal to the pathologic gambler's inherent pragmatism. These approaches aim at decreasing or redirecting the need for action, as well as demonstrating specifically how one or another gambling milieu incites or facilitates excessive gambling. Patients are instructed in relaxation exercises to decrease tension; taught to identify gambling triggers; substitute meaningful rewards for the imagined gain of gambling, etc.

Workbooks enable gamblers to impartially assess the time and cash spent gambling, as well as the time consumed by thinking about gambling. Other helpful CBT methods include stopping techniques, structured motivational sessions which encourage the pathological gambler to think ahead and explore future goals, and strategies that help the pathological gambler recognize the irrationality of his particular gambling fallacies.

Evidence-based research suggests that a cohort of pathologic gamblers will be more likely to accept therapy of some sort, or stay in therapy longer, when a therapist does not insist on total abstinence, at least early in the game. Indeed, some gamblers become abstinent once they get a clear understanding of their dysfunctional behavior.

Pathological gamblers require a tolerant, noncritical attitude regardless of the treatment modality employed. With their testy pride and razor-keen ability to sense disapproval, they will quickly reject help if they suss out even the smallest tincture of moralizing or criticizing.

The attractiveness of group techniques for pathologic gamblers is not surprising, given their extraversion. Group, family, and couple therapy can all be helpful. The distressing impact upon significant others often registers more compellingly in family sessions than in individual therapy alone.

A number of other treatment modalities are undoing investigation, with some promise. These include mindfullness-based therapy, neuromodulation with rapid transcranial magnetic stimulation (rTMS) and transcranial direct current stimulation (tDCS), and cognitive remediation. More research is needed in these areas.

Psychopharmacology

Psychopharmacologic treatment, once largely unsuccessful, now frequently plays a significant role in management. Success has been reported with antidepressants, notably the SSRIs and bupropion; mood stabilizers including lithium and lamotrigine; atypical antipsychotics; opioid antagonists such as naltrexone; and N-acetylcysteine. (The use of benzodiazepine drugs should be avoided or carefully monitored because of the potential for triggering, or increasing, comorbid substance addiction.)

In many patients, it is difficult to determine whether an antidepressant or mood stabilizer is alleviating gambling cravings directly or through treating the comorbid condition—especially affective/bipolar disorders. Many short-term outcome studies have demonstrated improvement. Unfortunately, there are much fewer studies of long-term effectiveness. The same problem exists with other treatment strategies. Pathologic gambling is not a monolithic entity. Different pathological gamblers may respond robustly to a medication that somehow addresses their specific neurophysiology.

Self-Help Interventions

GA is an international self-help organization administered by abstinent pathologic gamblers, with branches in many large cities and small towns, here and abroad. GA groups are found throughout the first world, but can be hard to come by in developing countries.

GA is run along traditional 12-step lines, analogous to Alcoholics Anonymous, with similar groups for relatives. These can be very worthwhile when the pathologic gambler himself refuses help. Cross-addicted pathologic gamblers often attend 12-step groups related to other forms of substance abuse (principally alcohol and cocaine) and indebtedness.

In a GA meeting, clients are encouraged to confront their problems in the company of others thoroughly acquainted with every turn and twist of chasing. Sponsors can be provided. Many new members eventually become sponsors themselves. Organizing financial restitution is a crucial aspect of GA work. Unfortunately, GA dropout rate is high, especially for clients facing exposure for the first time, and when GA is the only source of help. Many pathological gamblers quit GA groups after a bailout: under the rubric of “no debts, no problem.”

Other Interventions

A surprising number of pathologic gamblers, especially adolescents, are unknowledgeable about their illness. Education about substance abuse is common in elementary and high school, but education about problem/pathologic gambling remains sparse. Several studies show that pathological gamblers willing to learn more about their disorder from an instruction manual, structured telephone interviews, and GA interventions have a better likelihood of ceasing or at least reducing their wagering.

It may be necessary to halt a debilitating gambling cycle by hospitalization, taking the pathological gambler out of his terribly stressful milieu. With remission of more serious symptoms, an effective outpatient treatment plan can be organized. At this time, there are more outpatient programs for pathologic gamblers, but still

relatively few inpatient units devoted to working with pathologic gamblers.

A bingeing or end-stage pathological gambler will usually be placed in a standard medical hospital setting, or shoehorned into inpatient drug and alcohol programs. Intriguingly, a hospitalized pathologic gambler may suffer initially from physiologic as well as emotional distress analogous to a hospitalized drug addict undergoing detoxification.

Given the pathological gambler's poor health habits, many clients require a complete physical and neurologic examination, appropriate laboratory studies, and thorough evaluation of nutritional and exercise status beyond evaluating and treating their chief physical disorder(s).

GAMBLING AND THE LAW

Federal, state, and local legal systems have traditionally been oriented toward the punishment of pathologic gamblers, rather than their rehabilitation.

Approximately 60% of pathologic gamblers commit illegal acts over the course of their illness. As noted, the majority of pathological gambler crimes are nonviolent—bouncing checks, financial scams, and prostitution. Earlier in the course of his illness, a pathological gambler under arrest is unlikely to be incarcerated, but bailed out and quickly returned to the street where he is likely to relapse again. Incarceration itself can paradoxically become a disguised bailout, forestalling restitution or eliminating it altogether.

Experts in the field have repeatedly told legal authorities that rather than jailing most pathological gamblers—particularly the majority who do not demonstrate antisocial pathology—these offenders should be offered the option to discontinue gambling, make restitution, and undergo some form of treatment as a condition of strict probation. Several projects modeled after drug-related diversion programs have been set up across the United States, with promising results. Funding is a recurrent problem.

At this writing, most states have set up agencies and programs to deal with pathologic gambling. The sum set aside for counseling derived from lotteries, taxing race tracks, and casinos is still relatively small, compared to cash committed to drug and alcohol treatment programs.

Casinos that once refused to admit that pathologic wagering ever existed have begun to fund research into the prevention and treatment of the illness. Some casinos allow compulsive gamblers to set limits on their betting in advance, or even to bar entrance to a pathological gambler when so requested. Casino employees are also being taught to identify out-of-control gamblers and give information about sources of help. Unfortunately, some of these efforts turn out to be mere window dressing. It is exceedingly difficult to create programs to convince the clientele to bet with your head, not over it, while developing evermore creative methods of separating punters from their money.

Attempts to outlaw gambling by local, state, and federal authorities have proven no more successful than the prohibition against selling alcohol during the Roaring Twenties. Protests from antigambling groups often receive only token attention. Across America, straightened economic conditions and formidable lobbying by a flourishing gaming industry are chief causes of nullification of antigambling legislation as more casinos rise.

Internet poker was outlawed several years ago in the United States after cheating scandals and embezzlement schemes were uncovered. No such prohibitions have taken place elsewhere in the world. At this writing, online poker and sports wagering have been re-established in several states. Over the next several years, most states are expected to follow in re-establishing online casino and sports wagering.

THE FUTURE

The Future for the Gambling Industry

The business of gambling has always been fraught with risk *sui generis*. Sponsors of illegal gambling enterprises, from floating crap games to unlicensed casinos, traditionally face the possibility of prosecution by authority as well as criminal harassment for protection. Legal gambling business is exquisitely sensitive to the fickle winds of fashion and the fashionable; the pressure of antigambling forces; and the vicissitudes of socioeconomic circumstances. War is no friend to gambling, except among the warriors.

"Roll the Bones" tells a fascinating and often dispiriting tale of the rise and fall of gambling meccas over the past three centuries. During the past 70 years, Las Vegas casinos have undergone several boom-and-bust cycles.

The proliferation of brick-and-mortar casinos, notably tribal enterprises, poses a challenge to the gaming industry. Although there are more gamblers than ever, they have more places to gamble, diminishing the chances of small as well as large casinos to stay winners.

Today, the greatest gambling industry profit is scored in Asia, particularly in Hong Kong, Singapore, and Macau. The latter's megacasinos have generated higher yearly returns than Las Vegas since 2008. The Asian boom is linked to rising middle-class prosperity across the Pacific Rim, as well as the preference of regional whales to wager colossally closer to home. Japan's pachinko machine parlors continue to generate cascades of yen each year (the government, deriving much coin from the parlors, has gotten around its own gambling ban by declaring that pachinko is a painless pastime).

Punters will always seek out real gambling locales, but one predicts that the greatest future profit for the industry will be reaped from the internet virtual casino, especially with the return of the American poker and sports network to the scene.

The Future for Problem/Pathologic Gamblers

Ominously, millions of preteens and children visit internet sites which, intentionally or otherwise, teach them the rudiments of gambling in games where wagering wins prizes instead of cash. One wonders how many of these youngsters will become serious adult recreational gamblers, and for some tomorrow's problem/pathologic gamblers.

Even were gambling opportunities to escalate only modestly over the next decade (unlikely), and the world population increases modestly (also unlikely), one forecasts that the silent public health crisis caused by problem and pathologic gambling will grow even more dire, as more of the afflicted make their debut. Pathological gamblers have a higher mortality rate than ordinary citizens, but they won't perish fast enough to mitigate disaster.

The avalanche of future pathological gamblers certainly could be reduced by a combination of truly useful legal measures, for example, mandating more diversion and treatment programs for gamblers charged with minor criminal offenses; increased public and physician awareness; and the development of more effective treatments.

Educating the public and health professionals about pathologic gambling has increased substantively over the last 20 years. Film, broadcast, print, and internet media devote more time and space to the problem. One lauds the work of groups like the National Council on Problem Gambling (NCPG) (see next section). Nevertheless, it is disheartening to discover that many people, lay and professional, still denounce the sick gambler as a reprobate.

Research into the cause and treatment of gambling problems has increased dramatically and will continue. It is possible that neurobiologic study will yield more effective medications. Perhaps future science will engineer a better fit between the patient and medication.

One predicts there will be refinement of existing cognitive/behavioral strategies, as well as the development of new techniques, as discussed above. Marital, family, and group therapies including GA hopefully will flourish with heightened public awareness.

Brief talking therapies will continue, and perhaps new strategies will be developed. Prolonged psychoanalytically oriented individual treatment will diminish, if only because most insurance schemes do not support it in the United States and worldwide.

The chronic obstacle for treatment success, now and in the future, remains the afflicted gambler's formidable resistance to getting help. The number of pathological gamblers entering any form of therapy is still scant. A prospective patient frequently presents in the advanced stage of the disorder, which is extremely difficult to treat, a situation that one surmises won't change much in the near future. Early identification of fledgling pathological gamblers more likely to accept treatment would seem to be vital, but it is uncertain whether significant programs toward that end can be developed in this country and across the world, or whether the average pathological gambler-to-be would accept them.

THE NATIONAL COUNCIL ON PROBLEM GAMBLING

The NCPG is a nationwide advocacy organization for pathologic gamblers and their families. Membership includes former pathological gamblers, mental health practitioners, researchers, lawyers, and legislators. NCPG is an invaluable source of cutting-edge information about every aspect of gambling. It also maintains a hotline for pathological gamblers, relatives, and friends which offers immediate help and provides information about gambling treatment across the United States. Address: 730 11th Street NW, Suite 601, Washington, DC 20001. https://www.ncpgambling.org/. 1-800-GAMBLER.

CLINICAL VIGNETTES

INTERNET GAMBLING

Jim, a 19-year-old freshman, was introduced to internet poker by his roommate. Initially, he played free games. He quickly graduated to low-stake cash games. After winning several hundred dollars, he thought he was ready to take on big-league high-stakes play.

By midterm, Jim had lost several thousand dollars and was spending most days on his computer, playing several games simultaneously. He neglected studies, slept through examinations, and ate irregularly and poorly. He quickly exhausted the money his parents sent every month, maxed out several credit cards, and began borrowing heavily from friends. Eventually, he was placed on academic probation and contemplated suicide. Luckily, a friend succeeded in getting him to go to the student health center, and he was able to get straight through individual therapy and GA membership.

GAMBLING IN THE ELDERLY

Fred, a 79-year-old Air Force sergeant, moved to Las Vegas after retiring in his mid-40s. He and his wife were easily able to afford a small house 10 miles out of town. For the next 20 years, he worked as a casino security officer, then retired.

Fred lived comfortably for another decade until his wife died from breast cancer. He was inconsolable, hid his grief beneath a stoic façade, and became increasingly depressed. He had never gambled much and had only visited the Strip for the occasional dinner or show.

To alleviate grief and boredom, he began working again as a part-time guard at the casino. Its glitter and excitement made him feel better; he found the warbling of slot machines peculiarly soothing. He began playing a few coins before returning home. Within a month, he was spending every evening after work and during the weekend at the slots. He enjoyed the company of other devotees, swapping stories about hot machines and big cash-outs.

At first, Fred hardly noticed that his hobby was cutting into his finances. He told himself that he was only betting quarters and that his wife would want him to enjoy himself. But within 6 months, he had poured his entire savings into the machines. He could not meet bills and cut back on food and other essentials.

He realized how sick his gambling had become when he began thinking he might sell the home his wife loved so much to support his habit. He joined GA and subsequently exchanged his job for work at a supermarket near his house. “I never believed this could happen to me,” he says, “just as sure as I am it could happen tomorrow.”

A CLASSIC PATHOLOGIC GAMBLER

Gerry is a 35-year-old former auto dealership owner. Two of his uncles were compulsive gamblers, and his paternal grandfather had been hospitalized for bipolar illness. He began playing poker and going to the racetrack when he was 15. He dropped out of college after a few months and became a car salesman. Soon, he was promoted to showroom manager, then went out on his own. By 32, he was a multimillionaire owner of a dealership chain, happily married with two children.

Throughout his life, Gerry continued to gamble frequently. He was a successful weekend sports bettor, as well as a consistent winner in weekly gin rummy, poker games, and occasional jaunts to Las Vegas and Atlantic City.

Gerry had always wanted a third child. His wife developed eclampsia, and the baby was premature and died of respiratory failure. Gerry became depressed for the first time in his life. He visited casinos more often, and gradually increased his bets at blackjack and craps. His card games became boring—the action was zilch. He began frequenting a mob-backed local poker parlor which featured megastake action.

Over several years, Gerry slipped into a typical gambling spiral. He accumulated several million dollars in debts and invaded his personal bank accounts, including his children's college money. He maxed out all his credit cards and began borrowing from loan sharks at exorbitant rates. He thought of killing himself in a car crash so that insurance would take care of his family.

Gerry's illness was exposed when his Porsche was repossessed one Sunday morning. His wife threatened to divorce him when she learned the extent of his losses, but her wealthy father intervened and bailed him out. He swore never to gamble again, entered GA, and within 2 months resumed chasing. Over the next 10 years, Gerry endured four more episodes of recovery

and relapse. His wife left him, he lost his dealerships, and he was forced into bankruptcy.

He finally signed himself into a medical center with a pilot dual-diagnosis recovery program, where he was diagnosed with atypical bipolar disorder. His treatment included GA meetings, individual and family counseling, and pharmacotherapy with bupropion and lamotrigine.

Gerry eventually reconciled with his wife and family. He started selling cars again, now lives modestly, still attends meetings regularly, but thinks of himself as a gambler who could relapse on any given day.

A PATHOLOGIC LOTTERY GAMBLER

Nelly, a 35-year-old housewife, had been playing the State Lotto for a dollar every Saturday for many years. She rotated numbers based on her children's birthdays, her anniversary, home address, etc. Occasionally, she won a few dollars, which she always reinvested in more tickets.

Then Nelly missed a 5-million-dollar jackpot because she inadvertently had reversed the last two numbers of her license plate. She felt inexplicably cheated. Thoughts about her near triumph increasingly filled her mind, and she became obsessed with "finding my way back to the right combination—it's gotta happen."

Nelly began playing Lotto every day and soon was buying 20 tickets. She also went to church bingo games several times a week, then over weekends. She gradually distanced herself from her family and friends and became profoundly depressed.

In order to finance her wagering, Nelly spent the money she had carefully saved over a decade, then surreptitiously sold jewelry inherited from her mother. Overwhelmed with guilt, she finally revealed her problem to her husband as well as a sympathetic priest. She reluctantly agreed to enter treatment.

She responded well to family support, medication, and individual and family therapy, but shunned GA groups because she "doesn't want to hang around with a bunch of bums every day slurping coffee. Everyone thinks the lottery is harmless, but it nearly destroyed my life."

AN INCARCERATED PATHOLOGIC GAMBLER

Lonnie, an 18-year-old young man with ADHD, received a 3-year prison sentence for low-level drug dealing. On the outside, he dealt with the chronic boredom characteristic of that disorder by snorting cocaine and playing hearts. He considered himself a master at the game.

He dealt with the tedium of prison life by playing hearts at every chance. He knew, yet denied, that he was up against career criminals who had honed their skills over years of play. He began borrowing heavily from the loan shark of a feared gang. When he fell behind, he was repeatedly beaten and raped by gang members. Traumatized both physically and psychologically, he hung himself.

Post-Traumatic Stress Disorder

Arieh Y. Shalev, M.D., and Charles R. Marmar, M.D.

Post-traumatic stress disorder (PTSD) is classified in the Fifth Edition of the American Psychiatric Association (APA) Diagnostic and Statistical Manual (DSM-5) as a Trauma and Stressor-Related Disorder. Like other DSM-5 disorders, PTSD is defined by its clinical features and, specifically, by four groups of symptoms that develop following exposure to a traumatic event. PTSD diagnostic criteria allow clinicians to reliably identify and diagnose affected individuals and provide a framework for research. PTSD symptoms do not directly reflect the disorders' underlying neuropathologic processes. They are best understood *as varying behavioral expression of an underlying neurobehavioral systems' pathology, shaped by individual, environmental, and cultural factors*.

Individuals who suffer from PTSD relive distressing instances of the traumatic event with vivid emotional proximity and high, imperative intensity. They organize their lives trying to contain and mitigate the persistent effects of past traumatic experience. For those traumatized in a warzone, "*the war never ends.*" Victims of rape, assault, or torture describe difficulties engaging and trusting other humans. Repeatedly re-experiencing the trauma in the present, PTSD patients' lives are dominated by effortful attempts to avoid concrete and mental reminders including thoughts, images, and feelings associated with the traumatic event. They scan the environment for threat signals, which they fearfully expect and remain on guard, tense, restless, and exhausted.

PTSD has been diagnosed across continents and cultures. It is a common pathologic outcome of a wide variety of traumatic events, from wars and disasters to individual events such as road traffic or work

accidents. The concrete content of PTSD symptoms (e.g., specific situations avoided, nightmare themes) reflects aspects of the triggering events and thus may differ from one individual to another. Core symptom patterns however (e.g., insomnia, exaggerated startle response, or emotional numbing), are similar across traumatic events, nationalities, races, social classes, and cultures, suggesting a common underlying neurobehavioral foundation.

Symptom persistence despite threat termination and inability to regain a sense of safety are core features of the disorder and determine its "post-traumatic" or postexposure signature. Another core feature is the involuntary, uncontrollable, and intense nature of the symptoms. PTSD patients live under the shadow of past trauma. They are unable to distance themselves emotionally from their traumatic experiences, which are ever-present, powerful, and dominant. These features differentiate PTSD from an immediate reaction to traumatic events and from remote memories of trauma exposure. The latter are not forcefully "relived" but rather remembered. They are not ever-present, but rather occasional, such as on anniversaries or memorial days. They do not dominate behavior. Those with PTSD report frequent, intrusive, and distressing "flashbulb" recollections of the traumatic events during daytime or in nightmares. They respond to reminders of the event by involuntary and uncontrollable alarm, and defensively avoid external and internal stimuli reminiscent of the trauma. They are tense, anxiously aroused, expecting harm, and at the same time tired, emotionally numb, and unable to enjoy previously pleasurable activities. Many express these symptoms for years and even decades.

Understanding the bio-psycho-social mechanisms leading from trauma to PTSD is central to predicting and preventing the disorder. Chronologically, these mechanisms combine pretrauma vulnerability factors, trauma exposure impact, and postexposure "symptom maintaining" factors. Vertically, each of these categories comprises molecular, brain circuit, neurobehavioral, cognitive, emotional, interpersonal, and social dimensions. The etiology and the pathogenesis of PTSD are, therefore, complex and multifactorial, triggered but not fully explained by the traumatic event.

DEFINITION

PTSD is a trauma and stress-related disorder, defined by the co-occurrence of re-experiencing, avoidance, negative beliefs, and hyperarousal symptoms in survivors of significant adversity. PTSD is a common outcome of all types of traumatic events, from the most horrifying and protracted (e.g., captivity and torture) to shorter events or incidents (e.g., accidents). The construct of PTSD has, in fact, replaced several event-related "syndromes" that pre-existed its definition (e.g., "*concentration camp syndrome*," "*war neurosis*," or "*rape victim syndrome*"). Unlike most other mental disorders, the diagnosis of PTSD relies on associating current symptoms with a triggering traumatic event (e.g., a triggering life event is not a required diagnostic feature of depression or psychosis). The association of PTSD symptoms with the traumatic event can be chronologic (symptoms starting shortly after the event) or content-related (intrusive recollections of aspects of the traumatic event, or avoidance of specific reminders).

The essential features of PTSD are the development of characteristic symptoms and associated functioning difficulties following direct (i.e., being a victim of) or indirect exposure (witnessing, being told about) to one or more traumatic events (see Table 17–1).

Like other complex disorders, the clinical presentation of PTSD may vary among individuals. Fear-based re-experiencing, emotional, and behavioral symptoms may predominate in some individuals whereas others may primarily show anhedonia, dysphoria, negative cognitions, emotional numbing, social isolation, irritability, or insomnia.

Table 17–1.
DSM-5 Diagnostic Criteria for Post-Traumatic Stress Disorder

Post-Traumatic Stress Disorder DSM-5 Diagnostic Criteria

A. Exposure to actual or threatened death, serious injury, or sexual violence in one (or more) of the following ways:
   1. Directly experiencing the traumatic event(s).
   2. Witnessing, in person, the event(s) as it occurred to others.
   3. Learning that the traumatic event(s) occurred to a close family member or close friend. In cases of actual or threatened death of a family member or friend, the event(s) must have been violent or accidental.
   4. Experiencing repeated or extreme exposure to aversive details of the traumatic event(s) (e.g., first responders collecting human remains: police officers repeatedly exposed to details of child abuse).

   Note: Criterion A4 does not apply to exposure through electronic media, television, movies, or pictures unless this exposure is work related.

B. Presence of one (or more) of the following intrusion symptoms associated with the traumatic event(s), beginning after the traumatic event(s) occurred:
   1. Recurrent, involuntary, and intrusive distressing memories of the traumatic event(s). **Note:** In children older than 6 years, repetitive play may occur in which themes or aspects of the traumatic event(s) are expressed.
2. Recurrent distressing dreams in which the content and/or effect of the dream are related to the traumatic event(s).
3. Dissociative reactions (e.g., flashbacks) in which the individual feels or acts as if the traumatic event(s) were recurring. (Such reactions may occur on a continuum, with the most extreme expression being a complete loss of awareness of present surroundings.)
4. Intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).
5. Marked physiologic reactions to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).

C. Persistent avoidance of stimuli associated with the traumatic event(s), beginning after the traumatic event(s) occurred, as evidenced by one or both of the following:

1. Avoidance of or efforts to avoid distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).
2. Avoidance of or efforts to avoid external reminders (people, places, conversations, activities, objects, situations) that arouse distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).

D. Negative alterations in cognitions and mood associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:
1. Inability to remember an important aspect of the traumatic event(s) (typically due to dissociative amnesia and not to other factors such as head injury, alcohol, or drugs).
2. Persistent and exaggerated negative beliefs or expectations about oneself, others, or the world (e.g., “I am bad,” “No one can be trusted,” ‘The world is completely dangerous,” “My whole nervous system is permanently ruined”).
3. Persistent, distorted cognitions about the cause or consequences of the traumatic event(s) that lead the individual to blame him-/herself or others.
4. Persistent negative emotional state (e.g., fear, horror, anger, guilt, or shame).
5. Markedly diminished interest or participation in significant activities.
6. Feelings of detachment or estrangement from others.
7. Persistent inability to experience positive emotions (e.g., inability to experience happiness, satisfaction, or loving feelings).

E. Marked alterations in arousal and reactivity associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:
1. Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects.
2. Reckless or self-destructive behavior.
3. Hypervigilance.
4. Exaggerated startle response.
5. Problems with concentration.

6. Sleep disturbance (e.g., difficulty falling or staying asleep or restless sleep).

F. Duration of the disturbance (criteria B, C, D, and E) is more than 1 month.

G. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

H. The disturbance is not attributable to the physiologic effects of a substance (e.g., medication, alcohol) or another medical condition.

Specify whether:

With dissociative symptoms: The individual's symptoms meet the criteria for post-traumatic stress disorder, and in addition, in response to the stressor, the individual experiences persistent or recurrent symptoms of either of the following:

1. Depersonalization: Persistent or recurrent experiences of feeling detached from, and as if one were an outside observer of, one's mental processes or body (e.g., feeling as though one were in a dream; feeling a sense of unreality of self or body or of time moving slowly).
2. Derealization: Persistent or recurrent experiences of unreality of surroundings (e.g., the world around the individual is experienced as unreal, dreamlike, distant, or distorted).

Note: To use this subtype, the dissociative symptoms must not be attributable to the physiologic effects of a substance (e.g., blackouts, behavior during alcohol intoxication) or another medical condition (e.g., complex partial seizures).

Specify if:

With delayed expression: If the full diagnostic criteria are not met until at least 6 months after the event (although the onset and expression of some symptoms may be immediate).

DSM-5 parses PTSD symptoms into four subcategories or diagnostic criteria: re-experiencing, avoidance, negative cognitions, and hyperarousal. To qualify for a diagnosis of PTSD, a trauma-exposed individual must express a predefined minimum number of symptoms in

each category. The numerous combinations of qualifying symptoms allowed by DSM-5 can accommodate significant heterogeneity of individual presentations. Although such flexibility has been criticized as being too permissive and allowing different kinds of patients under the same diagnosis, such variety is in line with the multiple ways in which dysfunctions of specific molecular pathways and brain circuits are expressed by individuals who have different neurocognitive, emotional, and interpersonal resources, different life history, environmental pressures, beliefs, and understanding of causality. PTSD symptoms are best understood, therefore, as varying behavioral indicators of underlying neurobiology.

The *directly experienced traumatic* events (PTSD criterion A) include, but are not limited to, exposure to war as a combatant or civilian, threatened or actual physical assault, threatened or actual sexual violence, being kidnapped, being taken hostage, terrorist attack, torture, incarceration as a prisoner of war, natural or human-made disasters, and severe motor vehicle accidents. Medical disorders that qualify as traumatic events involve sudden, catastrophic illnesses. *Witnessed events* include, but are not limited to, observing threatened or serious injury, unnatural death, physical or sexual abuse of another person due to violent assault, domestic violence, accident, war or disaster, or a medical catastrophe. The latter has received ample demonstration among agony- and death-exposed health-care personnel, patients, and the public during the recent COVID-19 epidemic. *Indirect exposure* through learning about an event is limited to experiences affecting close relatives or friends and experiences that are violent or accidental (e.g., violent personal assault, suicide, serious accident, and serious injury).

Characteristic symptoms resulting from trauma exposure include persistent intrusion symptoms associated with the traumatic event (criterion B), persistent avoidance of stimuli associated with the traumatic event (criterion C), negative alterations in cognitions or mood associated with the event (criterion D), and marked alterations in arousal and reactivity associated with the traumatic event (criterion E). The full symptom picture must be present for more than 1 month (criterion F), and cause clinically significant distress or impairment in social, occupational, or other important areas of functioning (criterion G) and should not be attributable to the physiologic effects of a substance or another medical condition.

Symptoms of intrusion (five symptoms, one needed to meet PTSD diagnostic criterion) reflect the unrelenting, unavoidable, and uncontrollable presence of the traumatic event in the person's life. Symptoms must be recurrent, intense, and marked. They evoke significant distress and, often, physiologic alarm reactions (heart pounding, cold sweats). Most importantly, they are experienced and lived "here and now" and not as retrospective, distant recall of past events. PTSD intrusion symptoms differ, therefore, from other autobiographic or episodic memories in that they are not perceived as having occurred "there" and "then" but rather as recurring and current. Their emotional "here and now" presence coexists with the patient's clear understanding that the traumatic event occurred in the past. At their extreme expression (criterion B3; dissociative reactions), however, they literally transport the person back to the traumatic situation, overshadowing the sense of current reality.

Symptoms of avoidance (two symptoms, one needed) similarly reflect a direct linkage with the traumatic event. Criterion C2 (avoidance of reminders) reflects threat avoidance acquired during the traumatic event and reinforced thereafter, in line with the fear conditioning theory of PTSD. Studies have shown that the C2 criterion (avoidance of places and situations) tend to expand with time, such that new objects and situations are avoided (e.g., avoidance of combat situations may extend to avoiding weapons, uniforms, crowds, mail envelops reminding those used to call people to reserve duties, etc.). Such "inappropriate generalization" can progress to a point of confining severely affected PTSD patients to restricted environments with "no surprises." Criterion C1 is equally intriguing in that it reflects an effort to avoid inner (mental) representations of the traumatic event, as if these representations are analogous to external reminders. In that sense, trauma survivors with PTSD carry with them internalized representations of the trauma that, when accessed, evoke significant distress and are intensely avoided. Just being removed from a traumatic situation is not enough to reduce PTSD patients' avoidance: they avoid thoughts and memories. This clinical feature resembles the "obsession" component of obsessive-compulsive disorder (OCD), where ruminations and thoughts become as distressing as actual encounters with feared objects. Patients expressing C1 have been described as constantly trying to push thoughts and images out of their consciousness and thereby paradoxically reinforcing their presence and

never letting them fade away. Individuals who recover from traumatic experiences, in contrast, progressively forget and don't have to deliberately suppress their recollections.

The *negative alterations in cognitions and mood associated with the traumatic event* criteria (seven symptoms, two needed) is a new DSM-5 cluster, which did not exist in DSM-IV. It expands the scope of PTSD symptoms beyond reactions to the traumatic event into general dispositions toward life, other humans, and society. The "diminished interest" (D5), "detachment and estrangement" (D6), and "inability to experience positive emotions" (D6) criteria are remnants of one of the theoretical sources of PTSD, namely the loss and grief analogy, in which, during acute grief, unrelated aspects of life lose their appeal. Freudian theory suggested that the bereaved are not free to re-engage emotionally until they mourn their loss. Those symptoms mark a profound dysphoria and anhedonia and overlap with depression symptoms. The "inability to recall" criterion (D1) follows a long historical thread starting with the construct of "repression" (of traumatic memories), but also supported by a more modern construct of "failure to encode" traumatic experiences in memory at the height of their occurrence. Inability to recall is one of the most difficult symptoms to ascertain clinically. Other negative alterations criteria reflect changes in cognitive schemata and belief (e.g., sustained belief that the world is dangerous, other people untrustworthy, and oneself worthless). Indeed, what characterizes PTSD negative cognition is its permanence: the "world is *always* dangerous" (not sometimes); "I am irreversibly worthless" or unable to cope with another trauma (a construct known as "low self-efficacy"). Symptoms under criterion D are remarkably heterogeneous and not event specific. They nonetheless reflect the extent to which PTSD is associated with widespread modification of personal dispositions, mood, and beliefs—far beyond the direct effect of the traumatic event.

Finally, the *alteration in arousal (E criterion, five symptoms, two needed)* combines an unrelenting scanning of the environment for threat signals (hypervigilance) with irritability, insomnia, loss of concentration, exaggerated startle, and reckless behavior. As with the "negative alterations" criterion, symptoms may begin with the traumatic event or worsen after it but do not have a direct link with the content of the event or refer to content-specific aspects of the event. Frequently observed in PTSD patients, the resulting irritability, outburst of anger, restlessness,

and at times progression to violence are often directed at family members and close relationships and further enhance the patient's isolation and loneliness.

Clinicians using DSM-5 diagnostic criteria for PTSD should be aware of the syndrome's inherent heterogeneity, varying individual presentations, and co-occurrence with other mental disorders. They must rely on symptoms with a direct link to the traumatic event when making a diagnosis of PTSD. Relative to DSM-IV, DSM-5 raised the bar for identifying PTSD. Furthermore, it identifies slightly different subsets of trauma survivors as having PTSD, such that some individuals with DSM-IV PTSD may not meet DSM-5 strict diagnostic criteria and vice versa. A formal diagnosis of DSM-5 PTSD, therefore, clearly identifies subjects in need of help. However, it should not be used to exclude other, slightly different distressing responses to traumatic events from receiving assistance, help, and treatment.

HISTORY

Traumatic syndromes resembling PTSD have been described and sharply debated during the 18th, 19th, and 20th centuries. "Stragglers" in the American Civil War were described as "*trembling, staring into the middle distance and jumping at any loud noise.*" Survivors of ship explosions in Toulon in 1907 and 1911 exhibited *"recapitulation of the scene, terrifying dreams, diffuse anxiety, fatigue, and various minor phobias.*" World War I trench warfare survivors were labeled with "shell shock" and "war neurosis," the first suggesting an organic cause (traumatic brain injury) and the second a psychological origin. The term "combat fatigue," used by the U.S. army during World War II and "combat operational stress" used by the U.S. military in Iraq and Afghanistan, implies a normal reaction to extreme demands rather than a mental disorder. Resembling current PTSD symptoms, the manifestations of "operational fatigue" included, "*Irritability, fatigue, difficulties falling asleep, startle reaction, depression, tremor and evidence of sympathetic over-reactivity, difficulties in concentration and mental confusion, preoccupation with combat experiences, nightmares and battle dreams, phobias, personality changes, and increased alcoholism.*" Symptoms of "traumatic neurosis" similarly included, "*Fixation on the trauma, typical dream life, contraction*

of general level of functioning, irritability, and proclivity to explosive aggressive reactions."

Despite clinical observations during World War I and World War II, traumatic stress disorders were not included in the first two Diagnostic and Statistical Manuals of mental disorders, DSM-I (1952 to 1968) and DSM-II (1968 to 1980). DSM-I included a category of "Gross Stress Reaction" of a maximum 2-month duration, thereby implying that, unless there is other underlying psychopathology, reactions to major stressors are transient. Those who remain ill after a traumatic exposure were seen as having another disorder (e.g., neurosis, depressive illness). DSM-II eliminated the "Gross Stress Reaction" and did not have a diagnostic category for reactions to major stressors. Ironically, therefore, American psychiatrists did not have a diagnostic category to accommodate war-related disorders during one of the harshest U.S. military engagements, the Vietnam War.

The introduction of PTSD into DSM-III (1980) followed a delayed realization of psychopathologic sequelae of the Vietnam War. The APA Task Force on Nomenclature (the DSM-III Task Force) reviewed over 700 clinical observations of psychologically disabled veterans and rape victims. It coined the term PTSD and organized its symptoms into three diagnostic criteria (re-experiencing of the trauma, numbing of responsiveness, and other, mainly hyperarousal symptoms) following Kardiner's description of "traumatic neuroses" and UCSF researcher Mardi Horowitz's delineation of "stress response syndrome." Like other DSM-III disorders, PTSD diagnostic criteria were an optimized template, based on tradition and preliminary studies, and meant to be validated by empirical research: the APA *Committee on Reactive Disorders* included PTSD in DSM-III as a "*consensus*" rather than "*empirically validated*" disorder.

Empirical findings during the first decades after the publication of DSM-III refined PTSD diagnostic criteria, and these refinements were included in subsequent editions of the diagnostic and statistical manual: DSM-III-R (1987) and DSM-IV (1994). For example, survivor guilt, initially included in DSM-III, was found to be rare and excluded from subsequent DSM editions. Physiologic reactivity to reminders was moved from the arousal to the re-experiencing criterion. The most radical change, however, involved the definition of a "traumatic event" (PTSD criterion A). The disorder was originally seen as resulting from extreme events that were

"*out of the realm of normal life experience*." Based on evidence that PTSD also occurred in survivors of less dramatic occurrences (e.g., road traffic accidents, natural disasters), the array of traumatic events leading to PTSD was extended in DSM-IV and the "universally devastating" qualification was replaced by the "individually shattering" one. Traumatic events in DSM-IV also included instances of witnessing trauma to others (such as witnessing an execution or body handling). DSM-IV added a requirement of experiencing *intense fear, helplessness, or horror at the time of exposure* to its traumatic event criterion. DSM-IV also introduced a related syndrome, acute stress disorder, occurring during the first days and weeks following trauma exposure and characterized by re-experiencing, avoidance, arousal, and by prominent symptoms of dissociation.

DSM-5 (2013; Table 17–1) eliminated the requirement for strong emotional reaction at the time of the trauma, introduced a new symptom cluster, namely the *negative alterations in cognitions and mood,* removed PTSD from the group of anxiety disorders, and created a new category of trauma and stressor-related disorders. Underlying DSM-5 changes were studies showing limited emotional reactions at the time of the trauma among some combat-exposed military personnel and first responders who subsequently developed the full PTSD syndrome, as well as theoretical considerations regarding the importance of alterations in worldview and mood in individuals with prolonged PTSD.

Reliability and Validity of the Syndrome

Originally introduced as a disorder awaiting empirical validation, the nature and persistence of PTSD have been repeatedly validated. Early studies evaluating the construct validity of PTSD found it to be very good and to generally match DSM-III original symptom clusters (re-experiencing, avoidance, and hyperarousal). More recent work suggested that avoidance symptoms comprise two distinct subcategories: specific avoidance of trauma memories and reminders, and a broader restriction or alteration of social engagement and mood. DSM-5 criterion D reflects these new findings.

Originally referred to as a *normal reaction to abnormal circumstances*, PTSD is currently recognized as a psychopathologic consequence of trauma exposure, occurring in some individuals and sparing others. The traumatic event is seen as triggering rather than causing PTSD. *The*

etiology of PTSD is multicausal, involving pre-exposure vulnerability (risk) factors, exposure characteristics, and postexposure recovery environment at biologic, neurobehavioral, and psychosocial levels. Accordingly, PTSD observable diagnostic criteria are symptomatic expressions of underlying neuropathology, which current research is progressively evaluating.

PTSD symptoms and their communication by those with the disorder are influenced by self-awareness, social norms, belief systems, desirability of disclosure, stigma, and help-seeking behavior. Numerous survivors misinterpret their symptoms as reflecting a normal response, or delay communicating their symptoms or seeking help. In U.S. military personnel with PTSD, for example, the median time from the end of the last deployment to engagement in mental health care was over 2 years. Contrary to a prevalent late 20th-century criticism, PTSD is *not* a psychosocial construct. It is a major disturbance of the central nervous system's (CNS) threat sensitivity, threat detection, emotion regulation, and processing of reward, triggered or exacerbated by trauma exposure, usually present well before formal help-seeking.

Innovation in PTSD Classification and Subtyping

Recent years have seen a growing interest in parsing PTSD biologic heterogeneity and identifying clinically and biologically pertinent subtypes. Psychophysiological studies have identified a large subgroup of PTSD patients who did not respond to trauma reminders by hyperarousal and, instead, developed dissociative symptoms. A series of clinical, psychometric, and functional brain imaging studies subsequently laid the foundations for a dissociative subtype of PTSD, currently recognized by DSM-5, and characterized by symptoms of depersonalization and derealization, gaps in awareness and memory, and frequent reckless or self-destructive behavior, and characterized biologically by an overmodulation of the amygdala alarm signaling. Data from the World Mental Health Surveys, a large and demographically broad sample, estimated the prevalence of dissociative subtype at 14.4% of those with PTSD.

The 11th revision of the International Classification of Diseases (ICD-11) reduced the number of PTSD symptom criteria (intrusive and distressing re-experiencing of the traumatic event; avoidance of internal and external reminders of the traumatic event; hypervigilance and enhanced startle reaction to stimuli) and, at the same time, defined complex PTSD. The

new disorder describes the more complex reactions that are typical of individuals exposed to chronic trauma that include, in addition to PTSD symptoms, disturbances of emotion regulation, self-identity, and relational capacities. Studies of U.S. military personnel and large international samples have shown that numerous individuals diagnosed with PTSD using DSM-5 criteria do not meet ICD-11 PTSD criteria and vice versa, calling for caution in using either classification to exclude traumatized patients who are clinically distressed and functionally impaired.

COMPARATIVE NOSOLOGY

Previously classified among the anxiety disorders (DSM-III through DSM-IV-TR), research has shown that many PTSD patients do not show prominent anxiety symptoms, but rather anhedonia, dysphoria, irritability, or dissociation. These findings have justified the inclusion of PTSD in a new trauma and stress-related disorders category. The latter is defined by a linkage between current symptoms and past exposure to external stressors. Other disorders in that category include acute stress disorder, adjustment disorder, reactive attachment disorder, and disinhibited social engagement disorder.

PTSD often co-occurs with other mood and anxiety disorders: about 50% of adults with PTSD concurrently meet diagnostic criteria for major depression, and the lifetime comorbidity of the two disorders is about 90%. Military veterans and survivors of interpersonal trauma demonstrate higher rates of comorbid PTSD and major depressive disorder (MDD). PTSD and depression may co-occur shortly after trauma exposure or develop years later. These high co-occurrence rates emphasize the need to routinely assess MDD among individuals with PTSD.

Most trauma survivors do not develop PTSD. Contrasting with PTSD patients, trauma survivors who do not develop PTSD often express transient initial symptoms and may be occasionally reminded of past trauma (e.g., at “anniversary” dates), but their lives are not dominated by the imperative, uncontrollable, and inescapable presence of the traumatic experiences. PTSD, therefore, is a distinct pathologic consequence of trauma exposure and postexposure disorder-maintaining factors such as lack of social support and repeated exposure to stress. Traumatic events are better construed as a *necessary but not sufficient cause of PTSD*. Along with PTSD, traumatic events can accelerate or exacerbate other

DSM-5 disorders, such as major depression or substance misuse. When trauma survivors meet both PTSD and depression diagnostic criteria, both disorders can be diagnosed as comorbid, and clinicians have to prioritize their responses to address the most prominent, or life-threatening, condition.

EPIDEMIOLOGY

Prevalence of PTSD in the Community

Trauma exposure is common, with estimates of lifetime trauma exposure in the United States ranging from 50% to 89%. The most prevalent types of traumatic events in the United States are physical or sexual assault (52%) and being involved in an accident or fire (50%). Lifetime exposure to multiple events is common: in a worldwide study of 69,000 adults, 70% of the responders reported lifetime exposure to a traumatic event, and a striking 30.5% were exposed to four traumatic events or more.

The National Comorbidity Survey Replication (NCS-R) surveyed a nationally representative sample of 9,282 Americans aged 18 years and older. PTSD was assessed among 5,692 participants, using DSM-IV criteria. The NCS-R estimated the lifetime prevalence of PTSD among adult Americans to be 6.8%. Current past year PTSD prevalence was estimated at 3.5%. The lifetime prevalence of PTSD among men was 3.6% and among women was 9.7%. The 12-month prevalence was 1.8% among men and 5.2% among women.

Despite the high prevalence of trauma exposure, only a minority of those exposed develop PTSD. The *conditional prevalence* of developing PTSD upon trauma exposure varies by trauma types and gender: from 65% for men and 46% for women following sexual assault, to 2% for men and 22% for women following physical assault. The conditional prevalence of PTSD following gender-neutral accidents is similar in males and females. Approximately 17% to 33% of people with acute PTSD go on to develop chronic PTSD, with survivors of interpersonal violence taking longer to remit. A minority of trauma-exposed individuals experience delayed onset of PTSD. Importantly, most individuals with PTSD (>50%) do not seek treatment. Furthermore, only 58% of individuals with PTSD in treatment are seen by a psychiatrist, clinical psychologist, or other mental health professional. Importantly, more than a

third of individuals with PTSD have been found to have persistent PTSD (even for many years), regardless of treatment received.

Traumatic events among children trigger PTSD as well as a wide array of mental and developmental disorders. In a 2019 population-representative birth-cohort study of 2,232 children in England and Wales, 31.1% of the participants reported trauma exposure by age 18, and 7.8% had PTSD. Trauma-exposed children also reported major depressive episodes (29.2%), conduct disorders (22.9%), self-harm (25.0%), and suicide attempts (8.3%), and those with PTSD reported more frequent major depressive episodes (54.7%) and a staggering 20.1% experienced suicide attempts. Similarly, in a 2007 representative population sample study of 1,420 children in the United States, two-thirds of children had experienced at least one traumatic event by age 16, with 13.4% of these children developing some PTSD symptoms; fewer than 1% met DSM-IV PTSD diagnostic criteria. The 6-month prevalence of PTSD in a household probability sample of 4,023 *adolescents* between the ages of 12 and 17 was estimated to be 3.7% for boys and 6.3% for girls.

Prevalence of PTSD in Veterans

The National Vietnam Veterans Readjustment Study (NVVRS), conducted between 1986 and 1988, interviewed 3,016 American Vietnam Veterans and civilian controls selected to provide a representative sample of those who served in the armed forces during the Vietnam era. The estimated lifetime prevalence of PTSD among these veterans was 30.9% for men and 26.9% for women. Among Vietnam theater veterans, 15.2% of males and 8.1% of females were currently diagnosed with PTSD at the time the study was conducted. A 25-year follow-up of the NVVRS, the National Vietnam Veteran Longitudinal Study (NVVLS), was conducted between 2011 and 2013, assessing the course of PTSD 40 years after the war. The estimate for current DSM-5 warzone PTSD was 4.5%, 10.8% for current plus subthreshold warzone PTSD, and 17.0% for lifetime warzone PTSD.

Comorbid major depression occurred in a third of veterans with current and subthreshold warzone PTSD. Over the past 25 years, 16% of theater veterans reported a greater than 20-point increase, and 7.6% reported a greater than 20-point decrease in PTSD symptoms. The Health of Vietnam-Era Women's Study estimated that 15.9% of female veterans had current PTSD 40 years after the Vietnam War. In 2008, the RAND Corporation estimated the prevalence of PTSD to be 13.8% in a

household telephone survey of a representative sample of Iraq and Afghanistan veterans. These findings underscore the need for mental health services over many decades for Vietnam veterans with PTSD symptoms and the urgent need to provide care for a new generation of warfighters.

Prevalence Following Mass Trauma and Disasters

The population prevalence of PTSD among communities exposed to mass-trauma and disaster has been estimated by studies of the World Trade Center attacks of September 11, 2001, the 1995 Oklahoma City bombing, and the 2005 “Katrina” hurricane disaster in New Orleans. Shortly after trauma exposure, studies found that 4% to 7% of all residents had probable PTSD. These numbers declined from 1% to 2% after 9 to 12 months, showing both a general trend toward community recovery and a significant proportion of persistently affected individuals. Higher prevalence of PTSD was observed among rescuers, directly exposed survivors, and low-income minorities.

Contrasting with the formers’ limited impact phase, recent COVID epidemics (SARS, MERS, and COVID-19) are prolonged, deadly, and lingering events. In line with DSM-5 inclusion among potentially traumatic events of “*repeated or extreme exposure to aversive details of the traumatic event(s),*” COVID virus trauma concerns both afflicted individuals, first responders, frontline healthcare workers, and threatened communities and combine both strictly postexposure, residual symptoms, and peritraumatic responses to ongoing threat.

Estimates of COVID-19 PTSD prevalence vary by type of exposure. Stressful exposure among health-care personnel, for example, include managing critical medical situations, witnessing agony and death, operating in crowded settings, and daily exposure to life threat. PTSD symptoms of concern were found in over 20% of health care workers during COVID-19 infection waves. Among survivors of critical medical conditions and ICU admission, 30.2% reported severe PTSD symptoms 30 to 90 days after discharge, and 17% had major depression. Delirium during treatment and residual symptoms contributed to PTSD severity.

ETIOLOGY

Risk Factors for PTSD

In considering risk factors for PTSD, one should separate those informing PTSD risk in the general population, those specifically affecting trauma-exposed individuals (e.g., combat veterans, disaster survivors), and those affecting exposed individuals who develop early PTSD symptoms. Population risk factors encompass exposure risk, propensity to develop PTSD upon exposure, and postexposure PTSD memory consolidation and persistence factors. Risk factors among trauma survivors are more focused, and often of greater clinical relevance.

In a meta-analysis of clinical, biographical, and epidemiologic risk factors for PTSD in the community, it was reported that female gender, age at trauma, race, lower education, childhood abuse, greater severity of trauma exposure, lack of social support, and additional life stress increased risk for PTSD. A second meta-analysis identified seven predictors: prior trauma, prior psychological adjustment, family history of psychopathology, greater perceived life threat during the trauma, lower post-trauma social support, greater emotional distress during exposure, and greater dissociation during exposure. A large epidemiologic study found that exposure to interpersonal violence and have experienced four or more traumatic events carry a higher PTSD risk.

Among trauma-exposed survivors, a meta-analysis of risk factors for combat-related PTSD identified lower education, nonofficer ranks, army service, combat specialization, higher numbers of deployments, longer cumulative length of deployments, more adverse life events, prior trauma exposure, and prior psychological problems as PTSD risk factors. Aspects of deployment that increase the risk of PTSD include higher levels of combat exposure, discharging a weapon, witnessing someone being wounded or killed, and other deployment-related stressors. Another study reported that killing enemy combatants, prisoners of war, and civilians in the warzone increased the risk of PTSD.

Risk factors should be differentiated from risk indicators; the former being mechanistically related to PTSD pathogenesis and potentially informing PTSD prevention, whereas the latter informing PTSD likelihood but unrelated to its etiology (e.g., early symptoms). A longitudinal study of 2,473 civilian trauma survivors identified early PTSD symptom severity as a reliable risk indicator of chronic PTSD, and female gender, lifetime exposure to personal violence, and lower education as potent pre-exposure modifiers of the risk inferred from early symptoms.

Because the etiology of PTSD is complex and multifactorial, involving interacting biologic, personal, and psycho-social contributing factors, the contribution of a single risk factor (e.g., gender) hinges on the presence of other interacting factors (e.g., trauma type). A recent longitudinal machine learning study, for example, found that cortisol levels shortly after trauma exposure interact with lifetime history of child abuse to increase PTSD likelihood.

A few of the above-mentioned risk factors can be modified and are thereby amenable to preventive interventions. Interpersonal conflict, including disorganization and severance of attachment ties after trauma exposures are such “malleable” risk factors and should be addressed during a disaster’s aftermath. Several biologic risk factors, such as low cortisol levels after trauma exposure or high adrenergic drive, have been the subject of early prevention studies with limited success.

Genetics and Risk for PTSD

Individuals’ genetic propensity to develop PTSD has been intensely researched during the last decades. The initial hopes to uncover a single, major genetic PTSD vulnerability trait have been replaced by a polygenic minor effects approach, and more recently by emerging attempts to evaluate the cascading effects, leading from genetic endowment, environmental pressure, gene expression, protein synthesis, brain cellular, and connectivity effects, and, ultimately, clusters of PTSD symptoms. Consequently, while a portion of PTSD risk is inherited, the specific mechanisms linking genetic endowment to expressing PTSD remain one of biologic psychiatry’s greatest challenges.

Based on early twin studies of Vietnam Veterans, it is estimated that 30% of the variance in the risk for PTSD is determined by genes alone. Researchers who studied 222 monozygotic and 184 dizygotic twin pairs reported PTSD symptoms to be moderately heritable with the remaining variability accounted for by unique environmental experiences. A number of common genetic variants have been associated with PTSD, including polymorphisms in FKBP5, PACAP1, COMT, DRD2, GABA alpha-2 receptor, G protein signaling 2 (RSG2), an SNP in an intergenic region of the fourth chromosome, and an estrogen response element on ADCYAP R1. In addition, the s/s genotype of the serotonin transporter gene interacts with childhood adversity to increase PTSD risk.

A recent genome-wide association study (GWAS) of **over 2,50,000 participants of the Million Veteran Program** identified a tight coherence of a PTSD symptom factor that shares genetic variance with internalizing (mood-anxiety-neuroticism) symptom factor often observed in PTSD. The study further identified an enrichment in tissue-specific genetically regulated gene expression in several cortical and subcortical regions related to PTSD pathophysiology and pathogenesis. These results validate the biologic coherence of the PTSD syndrome, inform its relationship to comorbid anxiety and depressive disorders, and provide new brain tissue considerations for treatment.

The genetic vulnerability for PTSD is shared with other mental disorders: a study of **Vietnam veteran twin pairs reported that monozygotic** twins of veterans with combat-related PTSD had more mood disorder symptoms than monozygotic cotwins of combat controls or dizygotic cotwins of veterans with PTSD. Recent studies by **the Psychiatric Genetic Consortium PTSD (PGC-PTSD)** currently evaluate very large samples of trauma-exposed and PTSD patients. A 2020 PGC GWAS of 32,000 PTSD cases and 100,000 trauma-exposed controls found a significant shared genetic risk of PTSD with other psychiatric disorders. It also found higher heritability in females compared with male individuals. Extending beyond GWAS, the recent PGC studies address PTSD epigenetics, gene expression, imaging, and integrative systems biology with the ultimate goal of elucidating the molecular architecture of this complex disorder.

In a multiethnic cohort of over 30,000 PTSD cases and 170,000 controls, Nievergelt and colleagues, conducted a GWAS of PTSD. Three significant loci were identified, two in European, one in African ancestry, and elsewhere, with heritability estimates varying by sex, ranging from 5% to 20%. Five genes were associated with PTSD in those of European ancestry (CDHHC14, a Parkinson disease gene PARK2, KAZN, TMEM51-AS1, and ZNF813) and five distinct genes in those of African ancestry (LINC02335I, MIR5007, TUC338, LINC02571, and HLA-B). Two additional genes, SH3RF3 and PODXL, were identified from 18,222 protein-coding genes, associated with European but not African ancestry. The two gene sets identified in those of European ancestry suggest a role for the immune system in PTSD. Genetic signals associated with re-experiencing symptoms in this cohort were strongly correlated with

markers associated with re-experiencing symptoms in an independent cohort.

DIAGNOSIS AND CLINICAL FEATURES

As mentioned previously, the diagnosis of PTSD relies on identifying a traumatic event and confirming the presence of symptoms belonging to four diagnostic criteria: intrusion, avoidance, negative alteration in cognition, and hyperarousal.

To a degree, PTSD symptoms, despite their apparent heterogeneity, reflect an inner logic and theoretically meaningful functional interrelations. Traumatic events remain lively and ever-distressing, they are experienced as personal defeat, surrender to overwhelming stress, or failure to react properly, hence their endlessly distressing rumination and lack of emotional resolution. Because they remain extremely painful, utterly uncontrollable and persistent, individuals with PTSD avoid stimuli that can provoke this reliving of them, including inner states of mind, thoughts, emotions, and bodily experiences. Fending threat, either external or internal, becomes an imperative priority and leads to always remaining on guard, ever more vigilant, attending to and seeking signs of potential threat, and inability to allocate attentional resources needed to deal with real-life challenges. Ultimately, PTSD patients may feel defeated by the intensity, uncontrollability, and timelessness of their post-traumatic distress and flashbulb memories, and their Sisyphean attempts to escape their predicament or regulate their emotions, and thus are likely pessimistic, moody, and distant.

Importantly, post-traumatic psychopathology is not limited to PTSD, and milder and transient reactions are more frequent than lingering PTSD. Even within PTSD, the disorder can be expressed in a myriad of ways and with different configurations of its qualifying symptoms. PTSD, therefore, should be thought of as a prototypical reaction, a psychobiologic trap in which what, during healthy trauma recovery, helps in elaborating and overcoming the traumatic experiences (e.g., recall and reappraisal of traumatic experiences, self-protection, and adequate attention to existing stressors) becomes senseless, timeless, intolerable, and inescapable.

Some researchers have suggested that PTSD is best construed continuously rather than categorically. According to this view, PTSD merely represents the endpoint of a stress response continuum, whereas

partial PTSD would represent a subsyndromic degree of severity somewhere between no or mild response and full-blown PTSD. Recent work, however, suggests that distress and impairment do not smoothly vary as a function of increasing symptoms; those victims who meet full criteria for PTSD are more impaired than those who merely qualify for partial PTSD, a finding more consistent with a categorical rather than a dimensional construal of the illness. A recent longitudinal study has shown that PTSD symptom severity fluctuates with time in the disorder's first years, during which time survivors eventually lose and then regain their formal PTSD diagnosis. Clinicians should be aware of such fluctuations and of the consequent need to attend to distressed or impaired help-seeking PTSD survivors as clinically required, including those with subthreshold symptoms.

Controversies Concerning PTSD's Validity and Social Origin

PTSD was born at an age of increased sensitivity to social justice, human rights, protective networks, and duties of care. From its inception, therefore, the disorder was associated with advocacy and a sense of mission among many of its proponents. PTSD has also been used extensively to identify and infer psychological damage and claim compensation. Surpassing its intended role as a descriptor of a mental disorder, PTSD has become a social, cultural, and economic phenomenon.

Additionally, because of its captivating simplicity, PTSD was quickly reified. Rather than a descriptor of an underlying condition, PTSD became the condition itself. Referring to PTSD as a real and distinct entity overlooks the difference between a set of symptoms and an underlying condition. This distinction is too frequently forgotten.

By another DSM rule, complex clinical presentations that follow trauma are subsumed as comorbidities that are, coexisting but distinct disorders. PTSD and major depression, for example, overlap in over 40% of the cases at any given time and co-occur in 95% of the cases in a lifetime perspective. PTSD and major depression are nonetheless seen as distinct entities, particularly when it comes to defining research groups and/or therapies. The amount of information lost by anchoring research and practices to categorical entities is hard to estimate.

Similarly, in a typical posthoc attribution error ("after this, therefore because of this"), the association between PTSD and the traumatic event

is quickly perceived as causal. Part of the popularity of PTSD is due to its symbolizing such highly desirable, simplified, intuitive causal attribution.

A recent effort to supersede DSM-5 diagnostic categories with a cross-diagnostic grid of neurobehavioral dysfunctional dimensions–the **Research Domaine Criteria (RDoCs**) initiative–has redefined recent PTSD research strategies and goals and fostered studies of PTSD subcomponents. However, the RDoCs system is yet to deliver a compilation of illness dimensions translatable to clinical practice. To fully apprehend the tension between RDoCs dimensional approach and DSM-5 diagnostics, one should remember that PTSD diagnostic criteria are clinical indicators of an underlying and complex neuropathology which, heuristically (that is, toward better problem-solving and discovery), can be parsed into contributing dimensions. The RDoCs tentative approach is such an effort, and as such, it doesn't truly challenge the role of clinical diagnostic practices.

PATHOLOGY AND LABORATORY EXAMINATION

PTSD epitomizes a mental disorder occurring at the junction between external reality and a responsive brain: it is a maladaptive outcome of a host-environment interaction gone wrong. Several clinical features of PTSD inform the underlying CNS mechanisms: the disorder emerges after exposure to traumatic events, and therefore must centrally involve new learning and CNS plasticity. Its core symptoms of re-experiencing and avoidance directly involve reminders of the traumatic event, which implies acquisition, consolidation, and conservation of aversive memories. The presence of hypervigilance, hyperarousal, and cognitive and emotional alterations extend the range of symptoms beyond direct responses to reminders and suggest an overgeneralization of aversive learning and dysregulation of emotions. Acute PTSD symptoms often emerge shortly after trauma exposure and do not remit in survivors who develop PTSD, making PTSD a likely "disorder of recovery," and evoking alterations of fear extinction and inability to process safety signals. PTSD patients remain exceedingly reactive to ongoing life stressors and thus show altered perception of threat signals and heightened threat sensitivity.

Not surprisingly, studies of the neurobiology of PTSD have been extremely productive. To make sense of that abundant literature, this chapter addresses three layers of findings: (a) how the CNS mediates

known PTSD symptoms and related behavior, (b) alteration in neuroregulatory biologic systems (e.g., neuroendocrine, neuropeptide, inflammatory) that moderate CNS responses, and (c) basic neurobehavioral alterations, genetic endowment, and epigenetic regulation, often present before the traumatic event, and increasing CNS' vulnerability to develop PTSD.

In reading that literature, one should bear in mind that, while several biologic perturbations have been associated with PTSD, none has proven to be characteristic of the disorder in all affected individuals or account for the large proportion of the disorder's causation. Such a gap between group-based trends and findings and individual causation characterizes complex and multicausal disorders, in which there are many pathways to an outcome and individual-specific convergences of risk factors. To fully translate the complex biology of PTSD into practical prediction, diagnostics, or therapeutics, one must resort to advanced bioinformatics models, which are currently being developed. This section covers the existing evidence and the few newly discovered links between layers of biologic alterations and environmental pressures.

Psychophysiologic Studies

Bearing different names (e.g., Soldier Heart; Shell Shock), the historical equivalents of PTSD have been associated with "physical" or "physiologic" symptoms. Studies performed during World War I (1917 to 1918) recorded exaggerated heart rate responses to gunfire, sulfuric flames, epinephrine injection, and CO_2 inhalation among war veterans with combat stress reactions. Abraham Kardiner, whose description of War Neurosis inspired the DSM-III definition of PTSD, defined these conditions as "physio-neuroses," involving bodily alarm responses to stressful combat reminders. Shortly after the inclusion in DSM-III, PTSD was equated with a "conditioned emotional response," similar to those observed in animal experiments of fear conditioning. Studies performed established the script-driven imagery protocol (having PTSD patients listen to a verbal description of their traumatic events while measuring their heart rate, perspiration, and facial muscle tension) as a standardized and reliable procedure to elicit physiologic responses to individual trauma memories and showed that these responses were significantly higher in trauma survivors with PTSD, relative to those who did not develop PTSD. Another

line of studies, initiated in Jerusalem in 1992, showed heightened auditory startle responses in PTSD.

Psychophysiologic measurements added an objective dimension to PTSD. As such, they have helped deflect some of the initial skepticism regarding the disorder's validity. They have also opened ways to experimentally elicit PTSD symptoms, which was later used in functional brain-imaging "symptom provocation" experiments (refer to *Functional Brain Imaging*). Psychophysiologic measurements have also shown that PTSD patients fail to extinguish conditioned fear responses, which is in line with their inability to recover from the early responses to traumatic events. Studies have also shown that PTSD patients fail to retain extinction, once they have acquired it, and return to reacting to adversity despite having safely recovered from it. Additionally, studies indicate an association between elevated heart rate shortly after traumatic events (e.g., during emergency department admission after injury) and subsequent PTSD, an association that reflects the intensity of the unconditioned responses (UCRs) during trauma exposure. Finally, decreased heart rate variability (HRV) has been robustly associated with PTSD and linked to emotional cognition and emotion regulation.

CNS Mediation of PTSD Clinical Manifestations

Several brain circuits have been implied in the mediation of PTSD clinical manifestations Those include *fear learning, emotion regulation, executive control,* and *contextual learning* (see Fig. 17–1). Experimental methods used to explore these circuits encompass psychophysiology, neurocognitive assessments, and brain imaging.

FIGURE 17–1. Brain regions implicated in the pathophysiology of post-traumatic stress disorder (PTSD). Shown are the known connectivity paths within four dysfunctional circuits that play a part in the psychopathology of PTSD: emotion regulation and executive function, threat detection, contextual processing, and fear learning. (From Shalev A, Liberzon I, Marmar C. Post-traumatic stress disorder. *NEJM.* 2017;376(25):2459–2469. Copyright © 2017 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society. doi:10.1056/NEJMra1612499.)

Fear Conditioning Theory of PTSD. This model equates the acquisition and the maintenance of PTSD symptoms with the

consolidation and extinction of conditioned fear responses. Within this model, the traumatic event is the conditioned stimulus (CS), the immediate responses to trauma are UCRs, and stimuli (sights, sounds) present during the traumatic event acquire the ability to elicit conditioned responses (CRs) resembling the UCR in the absence of real threat. A series of psychophysiologic studies has buttressed the fear-conditioning model of PTSD by consistently showing intense physiologic responses to trauma reminders in PTSD.

CNS Circuits Involved in Fear Conditioning. *Fear conditioning* and *extinction* are adaptive learning processes. The neural circuitry that mediates these processes is essential to survival and conserved across species. It commands the body's hard-wired, involuntary, instantaneous defensive responses to imminent threat (a "species-specific defense response"). This highly conserved stress response system includes sympathetic and parasympathetic system activation, cardiovascular, and respiratory reactions, activation of the hypothalamic–pituitary–adrenal (HPA) axis, defensive fight, flight, and freezing behaviors, and changes in information processing. It is orchestrated by the central nucleus of the amygdala, a brain structure that connects to critical brain areas responsible for response execution. The activity of the central nucleus is modulated by layers of midbrain nuclei capable of filtering and evaluating threat stimuli (such as the basolateral amygdala [BLA]) and further by cortical and subcortical structures, such as the hippocampus, insula, and prefrontal structures. Each of these modulatory layers is highly plastic and therefore subject to new learning throughout life. PTSD is thought to involve new learning in these modulatory systems as follows.

During exposure to extreme threat, previously neutral stimuli overlapping in time with threat stimuli pass through the thalamus to the basolateral nucleus of the amygdala, which activates the central nucleus of the amygdala to enable defensive responding. The association between threat or "unconditioned" stimuli (US) and the previously neutral but currently CS is made in the basolateral nucleus of the amygdala. Once formed this association enables an exposure to the CS to trigger a defensive response. The magnitude of the defense response is modulated by brainstem serotonergic, noradrenergic, and dopaminergic neurons in the ventral tegmental area, dorsal and median raphe nuclei, and locus coeruleus. These monoamines affect both the magnitude of UCRs and

the consolidation of US–CS associations. The balance of neurotransmitters and neuromodulators activated during unconditioned response also influences the extent to which contextual stimuli, more loosely associated in time with the US, may contribute to later overgeneralization of threat stimuli.

Activity within the amygdala is under inhibitory control of the prefrontal cortex (PFC). Specifically, glutamatergic neurons from the PFC activate inhibitory interneurons within the BLA, which in turn suppress BLA outputs to the Central Nucleus of the Amygdala. The monoaminergic effects are further modulated by neuroactive steroids and neuropeptides released by the adrenal gland during stress that further magnify, mitigate, or otherwise shape fear acquisition, extinction, and recall.

Consolidation, Extinction, Extinction Recall, and Reconsolidation. Associations encoded in the amygdala during traumatic events tend to be robust and resistant to change. Their behavioral expression, however, is subject to extinction, which typically occurs when the CS is no longer associated with threat in a safe environment. Neuronal mechanisms underlying extinction include PFC inhibitory input to the BLA. Extinction involves active learning and as such is subject to recall and forgetting. Prolonged stress after the traumatic event can compromise the PFC ability to efficiently extinguish fear memories, whereas soothing interpersonal contacts and a safe environment may enhance it. In the aftermath of traumatic events, therefore, high levels of continuing stress and absence of soothing contacts may decrease the likelihood of efficient extinction and contribute to the risk of developing PTSD.

Threat Detection and Emotion Regulation

Other specific circuits implicated in PTSD development mediate *threat information processing,* mediated by the amygdala, dorsal Anterior Cingulate (dACC), and insula cortex, and *regulatory control mechanisms* that involve the hippocampus and medial and lateral PFC regions (dMPFC and dLPFC). These regions undergo plastic modifications upon exposure to potentially traumatic events, which in turn modify future processing of stressful encounters. The amygdala assigns rapid “threat-potential” tagging of environmental cues, and its high reactivity may be a risk factor for PTSD. The amygdala-associated PFC regions and insula have been implicated in detecting stimulus saliency and biasing attention

to threat. *Emotional regulation* circuits select appropriate response to threat—including emotional response—and involve the medial prefrontal cortex (MPFC) and dorsolateral prefrontal cortex (DLPFC). Evidence from neuronal network studies demonstrates segregation among a *salience network* (SN) involving regions of the insula, ACC, and amygdala, an *attention network* (AN) involving the DLPFC and VLPFC, and a *default mode network* (DMN) including the MPFC and hippocampus.

Neuroimaging findings in PTSD patients found abnormalities in threat detection and emotion regulation regions with increased reactivity of the extended amygdala, insula, and dorsal ACC regions, and decreased regulatory activity in subregions of the prefrontal lobe. In both PTSD and MDD, fMRI studies have shown excessive reactivity to potential threat stimuli in the amygdala and insula and hypoactivation of the PFC. Prefrontal deficits involving ventromedial prefrontal cortex (vmPFC) have been implicated in emotion regulation during changing environmental demands in PTSD, MDD, and generalized anxiety disorder. Resting state connectivity studies in PTSD similarly show reduced network coupling within the DMN, greater coupling within the SN, and decreased segregation of the DMN and the SN, suggesting an overengagement of saliency detection in PTSD. Recent studies further suggest that trauma exposure alters DMN connectivity shortly after its occurrence.

Context Appraisal and Update

Among the core clinical features of PTSD is the persistence of fear-driven avoidant behavior, heightened reactivity to reminders, and hypervigilance despite reaching safety and living out of danger. Such symptoms have been interpreted as reflecting an impaired capacity to update one's contextual appraisal from threat to safety. Inappropriately and persistently interpreting situations and signals as threatening and dangerous and difficulty in differentiating safety from threat may result from improper contextual update processing. Contextual processing is mediated by the vmPFC, the hippocampus, and the thalamus and requires low adrenergic drive during sleep. A diminished functional activity of the vmPFC in patients with PTSD has been linked to abnormal processing of contextual information, as well as to impaired extinction recall.

Cognitive Control, Memory, and Attention

Salient PTSD symptoms include inability to concentrate, memory disturbances, and difficulties planning and monitoring one's activity. Activity in dACC and frontoparietal attentional networks have been implicated in cognitive control, including performance monitoring, response inhibition, task shifting, working memory, attention, and memory. This type of regulation also disengages medial prefrontal–medial parietal DMN regions involved in internally oriented, self-directed mentation. DMN regions are overactive or underdynamic in PTSD, resulting in poorer ability to disengage from threat responses and discriminate truly threatening stimuli from remote reminders of traumatic experiences.

Modulatory Processes Underlying PTSD Neuropathology

Neuroendocrine Modulation. Several "stress" hormones have been implied in the etiology, pathogenesis, and psychopathology of PTSD, but none are disorder-specific and together they exercise complex and sometimes opposing neuro-modulatory effects. The HPA axis and sympathetic nervous system are important stress-reactive systems and thus central to understanding the disorder. They contribute to brain information processing, reactivity, and behavior in response to threat. Briefly stated, stress pathways involving cortisol signaling via the HPA axis are altered with blunted cortisol responses to stressors as a result of enhanced negative feedback from increased glucocorticoid receptor sensitivity in PTSD, with consequent influences on the HPA axis, sympathetic nervous system, brainstem, amygdala, and potentially accounting for co-occurring diagnostic patterns (PTSD, depression, chronic pain, refractory substance dependence).

Neurosteroids. Cortisol is centrally involved in stress response, and its regulation in PTSD has been extensively studied. Schematically, a surge in cortisol secretion by the adrenals follows the initial adrenergic response to stress. This surge, then, downregulates the brain's initial adrenergic response, via negative feedback mechanism, thereby attenuating the acute response to stress and the related US–CS pairing. Early studies revealed a pattern of low cortisol output and increased sensitivity to glucocorticoid negative feedback in PTSD, but the finding has not been consistent across samples of PTSD patients, and during the acute aftermath of traumatic events. Sources of the variability in these studies include different experimental designs, population characteristics, trauma

characteristics (e.g., single occurrence vs. prolonged exposure [PE] to stressors) and variation in individual genetic endowment. Differences between findings may, therefore, reflect *differences between individuals' HPA axis sensitivity,* which accounts of whole groups are unable to discern. In other words, altered HPA axis response to stress may affect some individuals (e.g., those with history of child abuse, variation in genetic endowment, or different epigenetic regulation history) but not others. It is also important to evaluate the roles of cortisol in the pathophysiology of PTSD in the context of other relevant neurohormonal responses as follows:

Neuropeptide Y (NPY) has anxiolytic and stress resilience effects in numerous animal models and human studies. It stimulates neurogenesis in the hippocampus and as such may support recovery from stress. For example, higher plasma NPY levels during distressing mock captivity training were associated with stress resilience. NPY has also several bodily trophic effects including efficient restoration of homeostasis, improved sleep quality, lower heart rate response to adrenergic stimulation, and better energy balance, all of which may affect the recovery from early PTSD symptoms.

Allopregnanolone/Pregnanolone are neuroactive steroids that selectively enhance the effect of the brain principal inhibitory neurotransmitter GABA. They also have neuroprotective effects such as increased myelination, decreased apoptosis (programmed cell death), and increased neurogenesis. Studies have shown lower levels of these hormones in PTSD and depression and negative correlations with symptom severity.

Dehydroepiandrosterone (DHEA) is the immediate precursor for androgen. It is secreted from the adrenal gland along with cortisol in response to adrenocorticotropic hormone (ACTH). DHEA antagonizes $GABA_A$ receptors and facilitates *N*-methyl-D-aspartate (NMDA) receptor function. In humans, an increasing DHEA level under stress appears to confer psychological and neurocognitive resilience and may protect against negative health outcomes.

Catecholamines. Exaggerated noradrenergic signaling is related to deficits in frontal lobe executive function resulting in undermodulated amygdala reactivity as well as sleep fragmentation and nightmares, which are common in PTSD. An exaggerated adrenergic response during

trauma exposure and in the hours following exposure may contribute to the formation of more durable emotional memories. Evidence concerning the presence of sympathetic system hyper-reactivity in PTSD has been generally consistent. Noradrenergic hyper-reactivity may be a pretrauma vulnerability trait in some individuals or may develop as a result of trauma exposure in others. Factors that may contribute to the increased release of norepinephrine (NE) in response to traumatic stress or conditioned reminders of the trauma include decreased expression, affinity, or function of alpha 2-adrenergic auto receptors, or genetic or stress-induced decrements in NPY. Factors that may enhance amygdala reactivity may include a downregulation of intra-amygdala synaptic GABA receptors or reductions in GABAergic neuroactive steroids such as allopregnanolone.

Illustrating the role of catecholamines in maintaining PTSD symptoms, the alpha 2-antagonist yohimbine induces extreme hyperarousal, flashbacks, vivid intrusive memories, panic, and increases in heart rate and systolic blood pressure in male combat veterans with PTSD. Yohimbine also suppresses frontal lobe metabolism to a greater degree among PTSD patients. Resulting from these observations, alpha 1-adrenergic postsynaptic receptor antagonists, such as prazosin, have been used for the treatment of nightmares in PTSD and evaluated as an early prevention of PTSD (see “Treatment” section).

Dopamine release in the amygdala promotes the expression of unconditioned and conditioned stress responding. Additionally, dopamine may inhibit PFC projections into the BLA and thus diminish the inhibitory control over learned fear responses and lead to increasing hypervigilance and sensitivity to environmental cues. Dopamine is also highly relevant to reward signaling in the nucleus accumbens, a process that appears to be downregulated in PTSD (see also PTSD criterion D symptoms).

Neuropharmacologic treatment and genetic epidemiologic studies suggest that the serotonin (5-HT) system impacts both PTSD risk and symptom severity. Administration of meta-chlorophenylpiperazine (mCPP), which interacts with multiple 5-HT receptor subtypes and with the 5-HT transporter to release 5-HT, provokes anxiety, panic attacks, and PTSD symptoms, including flashbacks, and cognitive changes that are reversible by mixed 5-HT1c/5-HT2 antagonists. Selective serotonin reuptake inhibitors, however, do not reduce the likelihood of developing PTSD when administered shortly after trauma exposure.

Genetic Contribution to PTSD Pathophysiology

The genetic contribution to PTSD is multifactorial, person-specific, and significantly affected by early life experiences. The inheritance of PTSD is polygenic, with no single gene variant explaining more than a small percentage of the variance. Nonetheless, a large twin study has shown significant (>30%) inheritance of PTSD and PTSD symptoms, but reanalyses of the same database reported substantial genetic overlap between MDD and PTSD. As in other areas of psychiatry, the translation of heritability to specific gene variants is a work in progress, and the distance between genetic endowment and clinical expression is currently insurmountable. Studies to date have, therefore, focused on gene variants that affect neuronal and neuro-modulatory processes leading to PTSD.

Gene variants in the *NPY and noradrenergic signaling* pathways have been found to impact physiologic processes of relevance to PTSD, such as heart rate, blood pressure, NE release, and negative emotional reactions in response to low-dose yohimbine. These sympathetic system stress reactions would be expected to increase risk for PTSD, but whether any of these latter gene variants influence risk for PTSD is yet to be examined. Similarly, to the extent that the BDNF gene affects synaptic plasticity, neurogenesis, and cognition, it might indirectly affect the likelihood of developing PTSD or remaining resilient in the aftermath of traumatic events. Numerous genes have polymorphisms that affect corticotropin-releasing factor (CRF), ACTH, or cortisol responses to stress (e.g., polymorphisms of genes for the mu-opioid receptor, catechol-O-methyl-transferase [COMT]) and angiotensin I–converting enzyme (ACE-I), the glucocorticoid receptor, the ACTH receptor, and CRF and the CRF receptor.

Gene–environment interactions that affect PTSD risk have been associated with the short allele of the serotonin transporter gene promoter region (SLC6A4). In a group of Rwandan genocide refugees, the SLC6A4 gene promoter region polymorphism was found to increase the risk for PTSD development in the context of relatively low-trauma load. In 582 European American and 670 African American individuals, possessing either one or two alleles of the SLC6A4 promoter polymorphism interacted with adult trauma and childhood adversity to increase the risk for PTSD, especially for those with high rates of both types of trauma exposure. Similarly, both childhood trauma *and* FKBP5 lower expression are required to increase PTSD risk.

It is currently clear that *PTSD is a disorder with a highly polygenic architecture.* Thus, to capture a substantial portion of the genetic contribution, effects from many gene variants need to be aggregated. Recent studies of polygenic risk score (PRS) offer a new way to use genetic endowment to infer PTSD risk. PRS is an estimate of an individuals' genetic liability to develop a disorder, given their genotype profile and available GWAS. PRSs also assess shared etiology between phenotypes and evaluate the clinical utility of genetic data for complex disease. The Psychiatric Genomics Consortium—Post-traumatic Stress Disorder Group has recently reported an analysis of 20,730 trauma survivors with or without PTSD in which they found a PTSD polygenic risk profile that overlapped with that for schizophrenia.

Epigenetic Changes Associated with PTSD

The epigenetic regulation of gene transcription may provide new opportunities for understanding PTSD. Epigenetic effects consist of coordinated modification of gene promoters and chromatin such that access to the gene by regulatory elements is either enhanced or limited, including lower methylation of the glucocorticoid receptor gene F1 promoter in peripheral blood cells in veterans. Of note, research has shown differences between groups of persons with and without PTSD in methylation patterns of DNA in white blood cells. A cluster of unmethylated immune system function genes also characterized PTSD, which otherwise showed a greater number of methylated genes in general. In addition, there were group differences in methylation of the dinucleotide methyl transferase (DNMT) type 3 beta and 3L genes, which are involved in *de novo* rather than maintenance methylation, suggesting that specific adaptive epigenetic capacities themselves may be altered in PTSD.

The extent to which epigenetic mechanisms, operating after trauma exposure, underlie some of the persistent effects of exposure is an exciting new perspective. Research showed that immobilization stress in rodents *reduced* expression of BDNF gene transcripts I and IV in the hippocampus in association with decreases in the level of histone acetylation of the P1 and P4 promoters. Conversely, research has shown that extinction of conditioned fear was accompanied by an *increase* in the levels of histone acetylation of the gene promoters for BDNF transcripts I and IV. Together this work suggests that activation of specific PFC circuits

in combination with agents that facilitate epigenetic processes that enhance synaptic plasticity and stabilization of new neuronal circuits may contribute to the persistence of PTSD and recovery from PTSD. Recent studies have shown that several epigenetic features of PTSD are modified after successful treatment or following spontaneous recovery. A successful treatment of PTSD was accompanied by significant changes in DNA *methylation at 12 differentially methylated regions in one study.*

Structural and Functional Neuroanatomy

Structural Brain Imaging of PTSD. The first reported structural abnormality in PTSD was a reduced left hippocampal volume in Vietnam veterans with PTSD. This finding had been interpreted as reflecting the hippocampus' vulnerability to excessive stress hormone levels due to prolonged stress. Numerous studies subsequently reported left, right, or bilateral hippocampal volume reduction in PTSD. Other studies, particularly in younger veterans, have failed to replicate this finding, but meta-analyses generally support the existence of reduced hippocampal volume in PTSD. Findings of smaller hippocampus volume in PTSD, however, lack disorder specificity (similar findings have been shown in schizophrenia and affective disorders). There is also a controversy regarding their relationship with PTSD. Originally thought to be a consequence of developing PTSD due to a neurotoxic effect of protracted or "allostatic" stress, a longitudinal study of hippocampal volume in early PTSD has not shown a hippocampus shrinking effect and an elegant twin study of Vietnam veterans found smaller hippocampi in unexposed identical twins of war veterans with chronic PTSD, thereby positioning smaller hippocampi as a vulnerability factor, rather than a consequence of PTSD.

More recent studies reported white matter volume reductions in the corpus callosum and gray matter reduction in the amygdala and the insula. The evidence concerning structural alterations of the amygdala is quite weak. Two meta-analyses reached somewhat different conclusions. One found that there is overall evidence for smaller left amygdala volumes in adults with PTSD, but not in pediatric PTSD, whereas the other did not find significant volumetric alteration in either population (Fig. 17–1).

Several studies have pointed to abnormal structural characteristics in the *anterior cingulate cortex (ACC),* including reduced ACC gray matter volumes or white matter abnormalities of the cingulum. These reduced

volumes may be particularly characteristic of the rostral and subcallosal portions of the ACC, rather than the dorsal ACC. Rostral ACC volume has been found to predict response to cognitive behavioral interventions such that larger volumes were associated with greater symptom reduction. A study of pregenual ACC volumes in monozygotic twins discordant for PTSD suggested that reduced volumes might reflect an acquired trait of PTSD rather than a vulnerability factor.

Functional Brain Imaging. Functional neuroimaging studies of PTSD include both resting and activation studies. The latter include symptom provocation and processing of both emotional and neutral stimuli. Within the limbic core, differences between PTSD and controls have been reported for the amygdala, and less so for the hippocampus. Outside the limbic core the vast majority of reported differences in activation between PTSD and controls occur in the posterior, dorsal, and anterior cingulate, occipital and MPFC, and dorsolateral PFC. The same overall pattern can be detected for neutral tasks: most abnormal activations appear to occur in the dorsal trend. There are, nonetheless, several differences: the rostral ACC and subcallosal ACC do not show unique patterns of activity in neutral conditions, and only the dorsal ACC appears to be recruited differently in PTSD compared with controls. There is also less consistency across studies, which may reflect the more varied tasks and smaller number of published studies.

Sleep

Up to 90% of people with PTSD report sleep disturbances such as nightmares and insomnia. In studies examining the physiologic basis for sleep disturbances in PTSD, both *macrolevel* sleep architecture (i.e., time spent in various sleep stages overnight) and *microlevel* physiologic measures of autonomic system activity during sleep (i.e., heart-rate variability, electrodermal activity) have been implicated. The frequent nightmares that are often the hallmark of PTSD are thought to occur in rapid eye movement (REM) sleep. Additionally, REM has also been shown to play a role in the maintenance of fear memories. Sleep abnormalities also characterize the early phases of PTSD: while it is unclear why some survivors develop PTSD and others do not, persistent sleep abnormalities, which are present in upwards of 66% of those who develop the disorder, have been suggested as a contributing factor. More

specifically, recent studies have shown that sleep disturbances, measured prior to exposure to traumatic stress, predict the development of PTSD.

Summary of the Biology of PTSD

Arguably the most intriguing feature of PTSD is its persistence, that is, its nonextinction despite the absence of further stress. Longitudinal studies have confirmed a frequent pattern of immediate expression of PTSD symptoms followed by recovery in most of those exposed, and persistence of symptoms in those who "develop" chronic PTSD. The conditioned fear analogy similarly predicts extinction in the absence of reinforcement, which does not occur in PTSD. A neurobiologic account of PTSD, therefore, must also consider the disorder's maintaining factors. Several theoretical models account for the persistence of PTSD, including a *kindling hypothesis,* according to which patterns of pathologic neuronal coactivation become "entrenched" by repeated use; an *allostatic stress hypothesis,* presuming a "wear and tear" of CNS emotional-control systems (e.g., the hippocampus) by chronic stress, and what might be referred to as a *subsystem clash* or *truncated response* view, according to which one brain subsystem blocks another from achieving the full processing of its inherent tasks.

DIFFERENTIAL DIAGNOSIS

PTSD cannot be diagnosed in the absence of exposure to a traumatic stressor. Indeed, it is the memory of trauma that generates and knits together the otherwise disparate symptoms of PTSD, many of which overlap with other mood and anxiety disorders. Hence, identifying the etiologically significant trauma is the crucial starting point for differential diagnosis. The symptoms must persist for at least 1 month following exposure to the stressor, thereby distinguishing PTSD from acute stress disorder, whose symptoms, by definition, cannot persist for longer than 1 month. PTSD arises in response to a traumatic stressor, whereas the diagnosis of adjustment disorder is suitable for people who experience anxiety, mood, or other symptoms following exposure to nontraumatic life events, such as loss, separation, or illness.

PTSD comprises two kinds of symptoms: event-related and nonevent-related responses. Intrusive thoughts, nightmares, flashbacks, and avoidance of reminders are event-related and thereby facilitate differential

diagnosis by distinguishing PTSD from other syndromes that develop or are exacerbated after exposure to traumatic stressors. For example, OCD intrusive thoughts concern current and future threats, such as contamination. Likewise, generalized anxiety disorder involves envisioning and worrying about threats that lie in the future.

PTSD nonevent-related responses lack direct reference to the traumatic event. These include loss of interest in activities, a sense of foreshortened future, difficulty in experiencing loving feelings toward others, exaggerated startle response, difficulty sleeping, difficulty concentrating, and irritability. These symptoms present two challenges during differential diagnosis. First, the assessor must determine that these symptoms followed in the wake of trauma rather than predating exposure to trauma. Many people have sleep problems, are irritable, and so forth, and one cannot automatically assume that the presence of these problems signifies PTSD. Indeed, a person exposed to a trauma who exhibits irritability, difficulty concentrating, and insomnia must not be assumed to have "PTSD symptoms" unless these difficulties postdate the trauma or are exacerbated by the trauma and are accompanied by trauma-related symptoms. Automatically interpreting insomnia in a trauma victim as a "symptom of PTSD" makes no more sense than calling coughing a "symptom of bacterial pneumonia" in the absence of a confirming culture.

The other challenge arises when assessors must determine whether apparent PTSD symptoms are direct consequences of memory for trauma, or if they signify the presence of another disorder. For example, sleep disturbance, irritability, difficulty envisioning one's future, loss of loving feelings, and loss of interest in activities are common symptoms of MDD—a condition often comorbid with PTSD. Likewise, other symptoms, such as hypervigilance and startle, may occur in other anxiety disorders as well. As a rule, therefore, PTSD requires a fuller presence of typical symptoms and a substantiated link in both content and timing to trauma exposure.

PTSD seldom occurs by itself, and the presence of other DSM-5 mental disorders does not preclude PTSD. For example, researchers studying Vietnam veterans found that 84% of outpatients, as well as inpatients with PTSD, met criteria for comorbid conditions, often alcoholism and antisocial personality. In another study of help-seeking veterans, researchers diagnosed current major depression, panic disorder, bipolar disorder, and social phobia more often among those with PTSD than

among those without PTSD. Comorbidity is also extremely common in epidemiologic samples. In the NVVRS, 98.8% of the men who had a lifetime diagnosis of PTSD also qualified for at least one other mental disorder, whereas only 40.6% of those without PTSD did so. The most common comorbid disorders were alcohol abuse, depression, and generalized anxiety disorder. Comorbidity is common in epidemiology studies of civilian PTSD as well. In one study conducted in the Detroit area, about 80% of subjects with PTSD had at least one other disorder at some point during their lives. In a representative survey of the U.S. population, the lifetime comorbidity rates were 88.3% in men and 79% in women with PTSD. Major depression and alcohol dependence (AD) were common comorbid conditions. Retrospectively reported ages of onset suggested that other anxiety disorders often predated PTSD, whereas alcohol and mood disorders usually developed after PTSD.

In cases of comorbidity, clinicians are often challenged by identifying the primary disorder, or, in better terms, the disorder, or the configuration of symptoms that requires the most urgent attention. Studies of PTSD suggest that treating “secondary” substance misuse is critical for addressing PTSD in treatment, ideally prior to initiating PTSD treatment. When not possible, simultaneously treating PTSD and substance use disorders (SUDs) is feasible, thus emphasizing harm reduction when abstinence cannot be achieved. Similarly, PTSD patients with prominent depression, suicidal ideation, severe impulse dyscontrol, or paranoid features should first be protected from the immediate consequences of these symptom configurations.

COURSE AND PROGNOSIS

Immediately following exposure to a traumatic event, many people experience shock, nightmares, intrusive thoughts about the trauma, and so forth. Indeed, it would be surprising if severely trauma-exposed individuals had no emotional reaction whatsoever to horrific events. Accordingly, a diagnosis of PTSD requires symptoms that persist for at least 1 month following the trauma.

For most people exposed to trauma, symptoms do wane. For example, in a study of help-seeking rape victims, researchers found that 95% met PTSD symptom criteria within 2 weeks of the rape. Yet the proportion of victims who still met symptom criteria at 1, 3, and 6 months after the rape

declined to 63.3%, 45.9%, and 41.7%, respectively. Among victims of nonsexual assault, 64.7% met PTSD symptom criteria 1 week after the trauma, whereas the proportion still meeting criteria at 1, 3, 6, and 9 months after the assault declined to 36.7%, 14.6%, 11.5%, and 0%, respectively.

Epidemiologic data from the National Comorbidity Study (NCS) indicate that the median time for PTSD to remit is 36 months for individuals who sought help for any mental health problem (not necessarily for PTSD) and about 64 months for individuals who never sought help for a mental health problem. Approximately one-third of those who qualify for PTSD had a chronic course.

A recent review of studies concerning delayed-onset PTSD confirmed that *symptom* onset is almost never delayed. This is a striking contrast to the original claim in the text of DSM-III that symptoms often only surface months or years after the trauma. In some rare cases, a person may develop immediate symptoms but fall just short of meeting full criteria for PTSD. A worsening of symptoms several months or years later may result in the person finally qualifying for the diagnosis. At first glance, this would appear to constitute a delayed onset of the PTSD *syndrome,* but it is not as if the person has been wholly asymptomatic during the period following the trauma and prior to meeting full criteria. For example, in one study of Israeli combat veterans, most cases of apparent delayed-onset PTSD involved either exacerbation of chronic, subsyndromic symptoms or delayed help-seeking in those with chronic PTSD. For example, some veterans finally met full criteria for PTSD after receiving notice that they were about to be reactivated for military service. Studies of war and holocaust survivors have documented an emergence of PTSD symptoms upon aging or during illness. Stressful or traumatic events reminiscent of the original trauma may trigger a re-emergence of disabling PTSD symptoms in individuals previously expressing limited distress or dysfunction.

TREATMENT

Psychological Treatment of PTSD in Adults

A review of 70 studies of psychotherapies involving a total of 4,761 participants showed that many of the studies were rated as being at risk of bias, and sample sizes were generally small with limited follow-up data.

There was evidence that individual trauma-focused cognitive behavior therapy (TFCBT) including PE therapy, which focuses on re-experiencing the traumatic event through repeatedly engaging with the memories (imaginal exposure) and everyday reminders (in vivo exposure) rather than avoiding triggers, eye movement desensitization and reprocessing therapy (EMDR), which includes repeatedly recalling distressing images while receiving sensory inputs, and non-TFCBT including present centered therapy (PCT), which focuses on current relationship and work challenges rather than the trauma, are equally effective immediately post-treatment, with some evidence that TFCBT and EMDR are superior to non-TFCBT between 1 and 4 months following treatment. Individual TFCBT, EMDR, and non-TFCBT were found to be more effective than other therapies. There was evidence of greater dropout in active treatment groups. There is also evidence that cognitive processing therapy (CPT), which emphasizes correcting faulty attributions including post-traumatic overgeneralizations of the world as dangerous, uncontrollable, and unpredictable, is effective for adults with chronic PTSD. A recent study in adults with PTSD reported that IPT, focusing on role expectations in dyadic relationships, was comparable to PE for treatment completers, with fewer dropouts in the IPT group for participants with comorbid depression. This study raises the provocative question, “Is exposure necessary” ? for successfully treating PTSD.

Treatment delivery has become a focus of research following the COVID-19 prohibition of face-to-face therapies and other known logistics and cost challenges of delivering direct-contact therapies. A 2021 Cochrane review of internet-based cognitive or behavioral therapy (I-C/BT) for PTSD found some beneficial effects of I-C/BT for PTSD. The certainty of the evidence was very low due to the small number of included trials.

Psychotherapy for Military-Related PTSD

A review of 37 controlled trials found that military-related PTSD is complex and difficult to treat. Trauma-focused treatments and CPT are associated with improvement in symptoms in approximately 60% of veterans but are limited by relatively high dropout rates, and treated patients often remain symptomatic, with more than two-thirds retaining their diagnosis. Non–trauma-focused treatments, which are less demanding for patients and

professionals, provide a reasonable option over trauma-focused therapy, particularly if this leads to continued willingness to remain in care.

Psychological Therapies for the Treatment of PTSD in Children and Adolescents

A review of 14 controlled studies, including 758 participants exposed to sexual abuse, civil violence, natural disaster, domestic violence, and motor vehicle accidents, found no study was rated at high risk for selection or detection bias but a minority were rated at a high risk for attrition, reporting, and other bias. Across all psychological therapies, improvement was significantly better within a month of completing psychological therapy compared to a control group. The psychological therapy for which there was the best evidence of effectiveness was CBT, with greater improvement lasting up to a year.

Pharmacotherapy for Adults with Chronic PTSD

A meta-analysis was conducted to compare the efficacy of different medications for treating PTSD. The largest body of evidence for short- and long-term efficacy of medication currently exists for SSRIs, and the strongest evidence is for sertraline and paroxetine which are approved by the FDA for adults with PTSD. There are promising findings for the noradrenergic and serotonergic reuptake inhibitor venlafaxine and the atypical antipsychotic risperidone. Evidence for the effectiveness of benzodiazepines is lacking, despite their continued use in clinical practice. Finally, the alpha 1-adrenergic antagonist prazosin and the atypical antipsychotics show some efficacy in treatment-resistant PTSD, and prazosin shows preliminary efficacy for treating nightmares. Insomnia is prevalent and disabling in chronic PTSD, with low-dose trazadone preferable to benzodiazepines. The recently developed orexin antagonist suvorexant is promising for managing trauma-related insomnia. Medications in the pipeline are targeting endocannabinoids, including fatty acid amide hydrolase (FAAH) inhibitors, nabilone, and cannabidiol, and other novel targets including glutamate, brain-derived neurotrophic factor (BDNF), and the oxytocin receptors.

In a recent systematic review of cannabis in the management of PTSD, cannabis was associated with a reduction in overall PTSD symptoms and improved quality of life. Dry mouth, headaches, and psychoactive effects such as agitation and euphoria were the commonly reported adverse

effects. Cannabis was generally well-tolerated, but small proportions of patients experienced worsening PTSD symptoms. Overall, evidence to date stems from low-quality and high-risk-of-bias studies, such that the use of cannabis in PTSD cannot be unequivocally recommended.

Pharmacologic Treatment of Comorbid PTSD and Substance Use Disorder

Researchers have reviewed advances in pharmacologic treatment of comorbid PTSD and SUD. A randomized clinical trial of sertraline did not show overall efficacy for comorbid PTSD and alcohol use disorder (AUD), although it may have efficacy among light drinkers. Another clinical trial demonstrated the efficacy of both disulfiram and naltrexone for the treatment of AUD in individuals with PTSD. A recent clinical trial suggested that NE reuptake inhibitors may also have efficacy for the treatment of comorbid PTSD and AUD. Noradrenergic medications that are promising for comorbid PTSD and SUD include prazosin, guanfacine, and atomoxetine. Promising glutamate/GABA medications include topiramate, memantine, acamprosate, N-acetylcysteine (NAC), and ketamine. The safety and efficacy of these medications for the treatment of PTSD and SUDs need to be tested in controlled clinical trials.

Combined Pharmacotherapy and Psychological Treatments for PTSD

Researchers have assessed whether the combination of psychological therapy and pharmacotherapy is more effective for treating PTSD than either of these interventions alone. Patients of any age or gender, with chronic or recent onset PTSD arising from any type of event relevant to the diagnostic criteria were included. Four trials were eligible for inclusion, one of these trials (n = 24) was on children and adolescents. All used an SSRI and PE or a cognitive behavioral intervention. There was no strong evidence for superiority of combined treatment over psychological therapy or pharmacotherapy used as monotherapy. The authors conclude that there is not enough evidence to support or refute the effectiveness of combined pharmacotherapy and psychological therapy compared to either of these interventions alone and that large randomized controlled trials are urgently required.

A recent study evaluated the effect of 3, 4-methylenedioxymethamphetamine (midomafetamine or MDMA) as add-on therapy provided in conjunction with CBT and found the combination

(MDMA + CBT) more efficiently reduced PTSD symptoms than CBT alone. MDMA is widely used as recreational drug (alias Ectasy, E, or Molly) for its hedonic, altered sensation and increased empathy, and energy. Chemically MDMA is a substituted amphetamine primarily increasing serotonin, dopamine, and noradrenaline transmission. Importantly, MDMA alone has no known therapeutic efficacy in PTSD and has a significant abuse potential.

Nontraditional, Alternative, and Complementary Treatments

There is preliminary evidence to support the efficacy of acupuncture, breathing and muscle relaxation, mindfulness meditation, and yoga in reducing PTSD symptoms and associated distress. A systematic review assessed the evidence for 15 novel interventions for the treatment of PTSD. The majority of the 19 studies were of poor quality, hampered by methodologic limitations, such as small sample sizes and lack of control group. There were 4 interventions, however, stemming from a mind–body philosophy (acupuncture, emotional freedom technique, mantra-based meditation, and yoga) that had moderate quality evidence from mostly small- to moderate-sized randomized controlled trials. Importantly, judging complementary interventions against PTSD symptom reduction might miss an important effect on well-being, self-monitoring, and self-confidence, which are critically important for many chronic PTSD patients.

Novel and Emerging Treatment Modalities

Recent advances in understanding PTSD neuropathology have identified specific brain areas mechanistically related to PTSD pathophysiology and expression. The latter constitute potential targets for electrical, electromagnetic, or biofeedback neuromodulation.

A meta-analysis of 13 studies (549 participants) of repetitive transcranial magnetic stimulation (rTMS) has shown that rTMS was superior to sham comparisons in reducing PTSD and depression severity. The quality of evidence, however, was limited by small samples sizes, treatment heterogeneity, inconsistent results, and an imprecise pooled effect. Further research is required to advance the evidence of this treatment.

Neurofeedback (NF) studies that train PTSD participants to reduce the amygdala activities are under development with promising preliminary results. Functional MRI and MRI-derived brain-area specific EEG NF

allow humans to voluntarily self-modulate neural patterns in specific brain areas, thereby opening the gate for brain-guided psychiatric interventions. This new framework, termed “process-based NF,” relies on targeting specific dysfunctional mental processes by modifying their underlying neural mechanisms via neuro-feedback interfaces. Studies targeting the amygdala as primary NF target in PTSD provided preliminary evidence for efficacy in reducing PTSD symptoms and for a sustained learning effect after treatment termination.

Early and Preventive Intervention

Unlike other mental disorders, PTSD often follows a distinct triggering event and has a clear onset point. Moreover, numerous trauma-exposed individuals are brought to the immediate attention of emergency care services and helpers. This creates a unique opportunity to identify individuals at risk and initiate preventive interventions.

Individuals’ reactions to traumatic events follow characteristic trajectories that include persistent lack of symptoms, initial distress followed by recovery, and nonremitting symptoms. A less frequent symptom trajectory consists of early resilience followed by delayed onset of symptoms. These trajectories define three primary goals for early interventions: (a) mitigate the development of early symptoms, (b) increase the likelihood of remission in survivors with initial symptoms, and (c) prevent the delayed emergence of PTSD. Studies addressing the first goal include “stress-management,” “preparation and training,” or “need-based assistance” (food, shelter, soothing human contact), as well as pharmacologic and psychological prevention provided immediately after trauma exposure. Studies addressing the second and third goals must identify survivors at risk and use specific intervention protocols.

Early Psychological Interventions

DEBRIEFING. Psychological debriefing, a widely used method in the 1980s to 1990s, aimed at preventing long-term post-traumatic symptoms by promoting emotional processing of traumatic events. Debriefing was offered unselectively to anyone exposed to a potentially traumatic event. The method typically involved a single session within several days of the trauma exposure, either in a group or individually, and included general education about the possible effects of trauma exposure, as well as

chronologic retellings of the recent traumatic event. The method has face validity and is still well-known, and therefore may be expected by laypeople when confronted with traumatic events. However, well-conducted studies showed no evidence of beneficial effects and even suggested that debriefing may have a negative effect on recovery. After a negative Cochrane review first published in 1997, most treatment guidelines have been updated to recommend against providing psychological debriefing on a routine basis for adults after trauma.

EARLY COGNITIVE BEHAVIORAL THERAPY. Cognitive-behavioral therapy (CBT) can involve different strategies with distinct aims. *Exposure-based CBT,* exemplified by the PE protocol, aims to achieve and maintain fear extinction through repeated exposure to trauma-related stimuli in a safe context, thereby providing a sense of control over reactions and reducing avoidance. *Cognitive-based CBT* approaches aim to change the way patients continue to react to trauma-related reminders and to behavioral restrictions and rules derived from the traumatic experiences, and to negative appraisal of self and others by challenging the patient's beliefs about the meaning and current implication of the trauma. CBT is offered individually or in a small group to people who report symptoms (else there are no "intervention targets") and typically involves several weekly sessions, homework, and in vivo training exercises. The treatment may continue for over 3 months and require significant skills from the therapists.

Exposure-based CBT efficiently reduces PTSD symptoms in selected samples. A study was conducted using modified PE in rape, assault, and motor vehicle accident survivors around 12 hours after trauma and found lower PTSD symptoms in the intervention group at 4 and 12 weeks after trauma, mainly for sexual assault victims. Another study found 5 weeks of exposure-based CBT to be effective in reducing PTSD in participants who meet acute stress disorder diagnostic criteria. Research has also found a reduction of PTSD symptoms at 13 months, but not 3 months, after the traumatic events. In the largest study to date, researchers showed that both exposure and nonexposure-based CBT efficiently reduced the prevalence and the intensity of PTSD symptoms 5 months after trauma exposure, and that the outcome of delayed CBT (starting 5 months after the event), assessed 9 months after trauma exposure, did not differ from that of treatment administered within a month of the traumatic event.

However, a small study with 3 weeks of PE did not find significant symptom improvement in the PE group compared to supportive counseling. Cognitive-based CBT has also shown effectiveness in some but not all studies. Researchers compared CBT to waitlist control subjects with acute PTSD, and found that CBT accelerated recovery, but made no long-term difference.

Modifications of CBT-based intervention showed varied results. A telephone-based CBT study in patients with a cardioverter defibrillator installed reported significant improvements in PTSD symptoms in the CBT group. Researchers developed a self-guided internet-based intervention (trauma TIPS) based on CBT to prevent the onset of PTSD symptoms. The result did not support the efficacy of trauma TIPS.

Cognitive behavioral therapy is currently the mainstay of early prevention of PTSD. Several considerations, however, make the systematic implementation of CBT a major challenge. First, a meta-analysis of early interventions has indicated that CBT is only efficient in participants with diagnosable PTSD at treatment onset. Other findings have similarly demonstrated that survivors with subthreshold PTSD symptoms recover as well with or without CBT. Furthermore, research has shown the known efficiency of CBT is limited to survivors of sexual assault, showing no effect among accident victims. Moreover, attempts to deliver diluted versions of CBT (such as telephone or web-based communication) yielded negative results. Interestingly, studies do not show a reduced effect of CBT when administered later in the development of PTSD (e.g., 5 months after trauma exposure instead of 1 month). CBT, therefore, is best positioned by current research as the treatment for ascertained clinical cases, optimally provided at some distance from the traumatic event. On the positive side, the early outcome of CBT is maintained over time, and thus this intervention is virtually the unique means to stop the progression of early PTSD into chronicity. In its best performance, however, early CBT leaves a substantial number of survivors unaffected, and thus should be supplemented by “second-step” interventions or by interventions specifically affecting participants in the nonremission trajectory.

Pharmacologic Interventions for Preventing PTSD. Various pharmacologic agents have been examined in the prevention of post-traumatic symptoms. A recent review article concluded that, in general,

there is moderate quality evidence for the efficacy of hydrocortisone, and no evidence for propranolol, escitalopram, temazepam, and gabapentin. This field is rapidly developing as the neurobiologic processes underlying symptoms start to be clarified by more studies.

HYDROCORTISONE. Hydrocortisone has been shown to be effective, especially in patients who have never been treated for psychiatric disorders. The underlying mechanism is not entirely understood. One hypothesis is that hydrocortisone can facilitate extinction learning through both nongenomic and genomic effects. Some also believe that high-dose exogenous hydrocortisone administered shortly after trauma may promote recovery through enhancing synaptic plasticity and connectivity. An animal model showed significantly increased dendritic growth and spine density, with increased levels of BDNF and obtunded postsynaptic density-95 (PSD-95) levels in steroid-treated stressed rats. Increasing cortisol levels also counters adrenergic activation, thereby reducing fear conditioning.

PROPANOLOL. Propranolol is a beta-adrenergic antagonist that crosses the blood–brain barrier and therefore is capable of reducing the CNS adrenergic drive associated with defensive threat responses. Experimental studies of propranolol in healthy subjects have shown that its administration prior to exposure to potentially traumatic narratives reduced the recollection of stressful elements of the narrative without affecting the general recall. It was proposed as a prime candidate to affect traumatic recall in PTSD. Early treatment with propranolol aims to preventing overconsolidation of traumatic memories by blocking the memory-enhancing influence of stress hormones. Theoretically, therefore, it should be initiated while memories of the trauma are being encoded and consolidated, preferably within hours of the traumatic event. However, controlled studies in the first hours after exposure have failed to show a preventive effect of propranolol on PTSD symptoms, although they showed a reduction in physiologic responses to reminders. The documented gap between propranolol's effect on physiologic responses to trauma reminders and its lack of effect of PTSD symptoms could be interpreted as suggesting that the pathogenesis of PTSD is not limited to amygdala-mediated threat conditioning and involves other brain areas and memory systems.

BENZODIAZEPHINES. Benzodiazepines are a group of GABA agonists and thereby enhance the inhibitory transmission in wide areas of the brain. They are used as tranquilizers and sleep inducers but also interfere with long-term potentiation, learning, and memory. As such they were positioned as capable of reducing excessive “learning” occurring during or following trauma exposure. However, three human studies have shown that participants receiving benzodiazepines fared worse than those not treated at all. An animal “predator stress” study found that administering diazepam shortly after predator odor exposure enhanced the acquisition of long-term fear responses. While the exact mechanism of benzodiazepines’ PTSD-enhancing effect is unknown, it is possible that these compounds interfere with postevent learning of extinction. Intriguingly, current data on benzodiazepines rely on small studies, while these compounds are widely used to mitigate distress following various stressors. Nonetheless, benzodiazepines are not recommended for use in the aftermath of traumatic events.

MORPHINE. Animal studies suggest morphine can produce retrograde amnesia for contextual conditioned fear, possibly through decreasing cAMP or activating NMDA receptors in the hippocampus. Observational studies of hospital patients also suggested a possible beneficial effect of morphine administration within 48 hours after trauma exposure to survivors who had pain, and a similar result was reported, retrospectively, in 696 military personnel with severe combat injury. Given the retrospective nature of most studies, more research is needed to separate a specific effect of morphine from a generic “analgesic” effect. Pain after trauma exposure is a potent predictor of PTSD. It is unclear, therefore, whether morphine has any preventive value in trauma survivors without physical pain.

Other and Investigational Approaches. Oxytocin is involved in emotion stress regulation, social engagement, and attachment, and preliminary studies suggest that it may buffer the development of PTSD when administered shortly after trauma exposure. NPY is another neuroendocrine candidate for early intervention. An animal study showed that delivery of NPY to rats’ brains has a pronounced effect on reducing the development of PTSD-like symptoms, possibly through modifying stress-triggered dysregulation of HPA axis and central noradrenergic

activity. Besides hormonal intervention, neurobehavioral retraining is also being tested for its capacity to reduce negative emotional processing and enhance executive control. Emerging evidence of impaired emotion regulation and executive functions in PTSD is likely to generate other early neurocognitive approaches.

Placing Prevention in Context. Most studies above summarize the "clinical" implementation of preventive interventions, that is, specialized care provided to survivors screened or formally diagnosed within a healthcare setting. They are therefore best construed as secondary and tertiary prevention. Studies to date, however, have not followed a primary prevention model. Challenging the restricted "clinical" model, Zatzick et al. evaluated a stepped collaborative care model, which introduced care managers to address each patient's unique needs and coordinated different components of interventions (e.g., CBT, motivational interviewing, pharmacotherapy). The care team repeatedly measured patients' symptoms and adjusted levels of care accordingly. Results showed the feasibility and effectiveness of the method, with reduced PTSD symptoms in the intervention group.

IMPLICATIONS AND FUTURE DIRECTIONS

Studies on PTSD prevention demonstrated significant variability in study methodology. Differences in methodology need to be carefully examined before one can infer from study results and determine the most effective intervention for a certain population. Current evidence from research also represents a great degree of heterogeneity in sampling. Different studies recruited people with different features (e.g., trauma types, injury severity, and peritrauma reactions). Among all traditional prevention methods, TFCBT has been mostly reported as an effective approach, but only in people with acute stress symptoms. Taking into consideration the heterogeneity of trauma survivors, people with different ages, genders, trauma types, and potentially different genetic features, childhood experiences, and recovery environments may need different optimal strategies. For example, brief TFCBT was reported to be more effective in victims of traffic accidents, and exposure therapy was shown to be more beneficial to sexual assault victims or people with high genetic risk. No intervention is effective for all trauma survivors.

Most importantly, PTSD is likely multicausal, and, as such, individuals with differing vulnerabilities and different exposure and postexposure circumstances may come to express the PTSD symptom complex through individual-specific pathways—and be responsive to individual-specific interventions. One way to advance the prevention of PTSD is to better map the variety of paths leading to this condition and map those paths into subsets of trauma-exposed individuals. Subtyping PTSD for treatment stratification is a promising strategy for advancing precision medicine. Once such knowledge becomes available, target-specific early intervention might replace generic treatment protocols applied to aggregates. Several steps should be taken in future studies. Psychiatrists need to step beyond diagnosis-based screenings and develop more complex and accurate methods to predict individual-level risks of chronic symptoms and impairment after traumatic events. By enhancing prediction models, intervention studies can take the important step to selecting the most relevant sample for a more rigorous study design and the best clinical interest. At the same time, research needs to continue exploring and confirming the underlying mechanisms of post-traumatic pathogenesis. Increasing knowledge to understand the mechanisms of post-traumatic psychopathology will open opportunities to explore more targeted interventions outside the range of traditional treatment-derived methods. These targeted intervention methods can allow clinicians to focus on both specific population and specific pathologic processes.

Somatic Symptom and Related Disorders

Javier I. Escobar, M.D., M.Sc., and Joel E. Dimsdale, M.D.

It is common to experience and communicate psychological distress in the form of physical symptoms and to seek medical attention for these symptoms. Often, these physical symptoms remain poorly explained and are associated with increased medical visits, unnecessary medical tests, and the performance of procedures that may result in iatrogenic complications. For many decades, the term “somatization” was used to describe these phenomena. This was gradually replaced by more descriptive terms such as “medically unexplained symptoms,” “unexplained symptoms,” and “functional somatic symptoms.” The word “idiopathic” (meaning “arising spontaneously or from an obscure or unknown cause”) is probably the most technically correct way to label the physical symptoms displayed by many patients with psychiatric disorders that remain poorly explained after detailed medical scrutiny and laboratory/radiologic assessments. The evidence for the “psychogenesis” of many of these somatic presentations was originally derived from theoretical postulates such as Wilhelm Stekel’s notion of somatization and has been nurtured by the frequent association of these symptoms with psychological distress and psychopathology. However, many of these somatic manifestations can arise spontaneously, and their causes can remain obscure or unknown. The most distinctive characteristic of many patients with somatic symptom disorders (SDDs) is not the symptoms they complain about but the way in which they present and interpret them. Despite the relevance that these idiopathic physical symptoms have to

medicine and psychiatry, their definition is difficult, and their classification remains controversial. This has led to frequent revisions of nomenclatures that alter the criteria used to designate “cases” and complicate the clinical recognition and management of these syndromes, recently and notably in *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5).

Everyone experiences somatic symptoms with a certain frequency, and most are able to cope with them effectively. However, some people’s lives are overwhelmed by their somatic concerns. Sometimes, the somatic concerns stem from well-established major medical illnesses; sometimes, the origins of the concerns are never quite clear. What is common in both situations is that patients’ lives are shadowed by disproportionate and excessive thoughts, feelings, and behaviors that center on the perceived somatic sensations. DSM-5 incorporated this perspective because the older perspective (simply counting or cataloging symptoms labeled as medically unexplained) embodied in the previous somatoform disorders’ category in DSM-III and IV, was unreliable and such perspective often put the doctor and the patient at odds over the question of the legitimacy and “reality” of the patient’s symptoms and personal suffering. In fact, research has shown that regardless of medical explanations, multiple physical symptoms predict disability and psychopathology (Fig. 18–1).

DEFINITION

According to the fifth edition of the American Psychiatric Association’s DSM-5, the key characteristic of SSDs is the presence of one or more persistent somatic symptoms that are associated with excessive thoughts, feelings, and behaviors related to the symptoms. The stipulation that these symptoms be medically unexplained has been removed because of the recognition that such a distinction in itself is unreliable and because psychiatrists commonly treat patients with medically established diagnoses who are troubled by or preoccupied with their physical symptoms disproportionately. Furthermore, DSM-5 acknowledges that frequently, SSDs co-occur with other psychiatric disorders. The diagnosis of a somatic symptom disorder is only made when there is significant distress or impairment associated with these chronic somatic symptoms.

In DSM-IV and earlier editions of the DSM, disorders such as factitious disorder and psychological factors affecting other medical conditions (PFAOMC) were grouped elsewhere. This led to some confusion in the

differential diagnosis. As a result, such disorders are now included within the rubric of the SSDs chapter. Due to its strong linkage and similarity to obsessive-compulsive disorders, body dysmorphic disorder has now been moved out of the SSDs and is now included in the obsessive-compulsive disorders group. Because pain symptoms are quite common and the requirement that symptoms be unexplained has been removed, pain disorder as a psychiatric diagnosis has been deleted in DSM-5, and these syndromes are now subsumed under somatic symptom disorder. Also, largely because of its pejorative connotation, the classical term "hypochondriasis" has been removed, and the disorder is renamed illness anxiety disorder in DSM-5 (Fig. 18–2).

Thus, the SSD group in DSM-5 includes the following disorders: "somatic symptom disorder," "illness anxiety disorder," "functional neurologic symptom disorder (conversion disorder)," "psychological factors affecting another medical condition," and "factitious disorder." Somatic syndromes that are below threshold are classified under two residual categories, "other specified" and "unspecified somatic symptom and related disorders."

In the DSM-5 field trials, somatic symptom disorder showed high levels of reliability, more robust even than those for more traditional diagnoses (Fig. 18–3).

HISTORY

Somatic presentations that have a presumed psychological origin have always mystified the medical establishment and have taken new forms and shapes as cultures evolve, and medical paradigms shift. Throughout the ages, multiple folk concepts and terms have been used to designate the phenomena, such as "hysteria," "hypochondria," "spleen," "English malady," "surmenage," "humoral disorders," "neurovegetative dysfunction," "neurasthenia," "neurovegetative dystonias," "psychosomatic disorders," and many others. The idea that psychological processes are involved in these somatic experiences appears to have ancient origins but waxed and waned periodically. In the 17th century, Thomas Sydenham attributed symptoms and signs such as "pain," "convulsions," "diarrhea," and "dropsy" to disturbances of the mind.

FIGURE 18–1. Whether medically explained or not, high levels of somatic symptoms augur psychopathology in general populations. (Data from Escobar JI, Cook B, Chen CN, et al. Whether medically explained or not, three or more concurrent somatic symptoms predict psychopathology and service use in community populations. *J Psychosom Res.* 2010;69(1):1–8.)

Hysteria and Hypochondria

The more dramatic somatic manifestations—"hysteria" and "hypochondria"—were key syndromes in traditional psychopathology and remained influential in medical discourse at the turn of the 20th century. The long survival of these labels (e.g., "hysteria," "hypochondria" in the United States, and "neurasthenia" in China) despite efforts to eliminate them attests to their historical and practical value, but also to the fragility and inadequacy of current classifications. Michel Foucault included "hysteria" and "hypochondria" among the four classic syndromes in psychopathology together with "mania" and "melancholia." He indicated that from ancient times, somatic presentations have not fitted well with the schemes of traditional psychopathology and have been viewed as outcasts in medicine and psychopathology.

Somatic Presentations in Classical Psychopathology

In his "History of Mental Symptoms," the psychiatric historian German Berrios describes how somatic syndromes (hysteria and hypochondria) were discarded in 19th-century nosologies and that terms such as "dysmorphophobia" and *cenestopathie* were the precursors of the psychosomatic syndromes.

Kurt Schneider viewed somatic presentations not as a separate group but as key components of other psychopathological syndromes. For example, he considered "anguish" as a corporal sensation localized in the chest. However, in Schneider's psychopathology, somatoform phenomena appear to have the best fit among his "psychopathic personalities," specifically the group he labeled "asthenic psychopaths." Schneider characterized them as "somatically labile" or "somatopaths"—individuals who completely focused their attention on their bodies, fatigued easily, and suffered from insomnia, headaches, and heart, bladder, and mental disturbances. Schneider also trivialized somatic presentations by asserting, for example, "occupation often dissipates all these problems."

FIGURE 18–3. Reliability of somatic symptom disorders relative to other DSM-5 disorders. (Reprinted with permission from Freedman R, Lewis DA,

Michels R, et al. The initial field trials of DSM-5: new blooms and old thorns. *Am J Psychiatry*. 2013;170(1):2.)

Karl Jaspers mentioned “hypochondria,” “hysteria,” and the “somatopsychic,” emphasizing the polarity that existed at that time regarding physical and psychological approaches to these problems. He affirmed that a healthy person lives in his body and does not think much of it and added that the great majority of physical suffering is due to psychological reflection and not to manifested physical disease. Thus, in Jaspers’ opinion, many of the somatic presentations tend to become fixed and repetitive and can be understood as part of personal experience, situations, and conflicts.

The Swiss psychopathologist Eugen Bleuler dedicated very little attention to somatic phenomena, considering them to be outside the “endogenous” realm to which he devoted the most attention in his psychopathology. While Bleuler alluded to “hysterical syndromes” and “neurasthenic syndrome,” he did not mention hypochondria or psychosomatic phenomena.

Henry Ey, an influential French psychiatrist and author of a well-known textbook on psychiatry in France, reflected the influence of psychoanalytic theories on European psychiatry during the first half of the 20th century. In his textbook, he devoted a full chapter to hysteria, which he defined as “the somatic hyper-expressivity of unconscious ideas, images, and affects.” Ey did not mention hypochondriasis but included a long list of psychosomatic disorders that he labeled “organ neuroses,” similar to the approaches of Otto Fenichel and other psychoanalysts who are well known in North America.

The Spanish psychiatrist Juan José Lopez-Ibor, strongly influenced by German psychiatry, was perhaps the first to highlight the somatic (“endogenous” or “biologic”) component of some forms of anxiety and depression, proposing antidepressant treatments for them as early as the 1960s and thus anticipating by a number of years the development of the panic disorder concept in North American psychiatry. As to phenomena relevant to somatic presentations, Lopez Ibor defined anxiety as “vital anxiety or anguish,” in his view, a corporeal sensation, coining the Spanish term *timopatia ansiosa* (anxious thymopathy), not referring to the thymus gland but to the Greek root *thymos,* meaning “soul, spirit, mind or temperament.” Lopez Ibor also placed “hysteria,” “hypochondria,” and “psychosomatic disorders” among his “disorders of mood.”

Briquet Syndrome

The description in 1859 of a syndrome with multiple motor and sensory symptoms by the French neurologist Pierre Briquet allowed an initial separation of somatization from conversion phenomena. This approach initiated a trend to emphasize the descriptive aspects of these syndromes, gradually detaching them from psychological causality and placing a particular focus on the process of eliciting individual physical symptoms. This would eventually lead to the “symptom counting process” that would characterize somatization disorder under the Feighner, research diagnostic criteria (RDC), and DSM (DSM-III and IV) criteria.

Somatization

The psychoanalyst Wilhelm Stekel used this term for the first time in 1911, defining it as the bodily expression of a deep somatic neurosis or the process of how neurotic conflicts are presented as physical symptoms. Although the term “somatization” is credited to Stekel, its formal entry into medical discourse is due to the work and influence of Zbigniew J. Lipowski, who provided a broader view of somatization, defining it as the tendency to experience, conceptualize, and/or communicate psychological states or contents as body sensations, functional changes, or somatic metaphors. By the time “somatization disorder” was enthroned as a full category in official nosology, an extensive body of research, principally conducted by investigators at Washington University/Barnes Hospital in St. Louis, had produced empirical evidence for the utility of its forbearer “Hysteria/Briquet syndrome” in tertiary care settings in North America.

The St. Louis Criteria

In 1951, James J. Purtell, Eli Robins, and Mandel Cohen, investigators from Washington University in St. Louis, compared the incidence of specific physical and mental symptoms among women with and without a diagnosis of hysteria and highlighted the polysymptomatic and chronic nature of this disorder. Next, Michael J. Perley and Samuel B. Guze, in 1962, formulated for the first time a numerical definition of the symptoms needed to diagnose hysteria, which included the presence of at least 15 individual symptoms distributed over at least 9 of 10 groups of possible symptoms. These criteria were a modification of those proposed by E.

Robins and P. O'Neal in a 1953 study of children that required at least 18 symptoms from at least 7 symptom groups. The St. Louis group began adding other physical symptoms, psychiatric symptoms, and personality characteristics on top of the "pure" neurologic symptoms that were included in the original Briquet syndrome. This grouping together of somatic and psychiatric symptoms was again used, with a few modifications, in the criteria proposed by John P. Feighner and collaborators for use in psychiatric research. In the Feighner criteria, the threshold for a hysteria diagnosis was elevated to at least 25 symptoms distributed in 9 of 10 possible groups. These criteria also required that the disorder should start prior to the age of 30 years.

COMPARATIVE NOSOLOGY

The Concept of "Somatoform"

Psychiatric nomenclatures (DSM-III and IV) relegated somatic phenomena to a secondary level and classified somatic syndromes of presumed psychological origin under the heading of "somatoform disorders," a category that is hierarchically inferior to other categories included in these nosologies (e.g., mood disorders). In the 1970s, the American nosologist Robert Spitzer coined the term "somatoform" (meaning somatic-like) to group these disorders among his RDC, which made its formal entry in North American psychiatry with the publication of the DSM-III in the 1970s. Although the creation of the somatoform disorders category was lauded as a nosologic advance by some investigators, in the real world, patients presenting with multiple unexplained physical symptoms did not fit neatly into the taxonomies provided by the DSM and international classification of diseases (ICD) systems. Even when somatoform criteria are met, there is also significant overlap with several other psychiatric syndromes, a reminder that nosologies are still quite imperfect and in need of continuous distillation. The restrictive quality of categorical somatoform diagnoses left out many of the "real cases," and this led investigators to propose dimensional classifications. These dimensions included broader, less restrictive categories as an alternative for research, such as "abridged somatization," "multisomatoform disorder," and others. The use of dimensional constructs rather than categories may have particular utility in primary care. In reviewing the literature on physical symptoms, it appears that

there are two main dimensions that may have practical value. One is characterized by high levels of physical symptoms (the former somatization) and the other by amplification of somatic presentations (hypochondriasis or health anxiety). This dimensional approach has been taken into account in the current nosologic revision (DSM-5) and is included in Section III of the manual (Table 18–1).

Differences between DSM and ICD Classification of Somatic Symptom Disorders

There were several differences between DSM-IV and ICD-10 in the way they classified these disorders. DSM-IV listed all these disorders under the somatoform disorders category. Chapter F45 of the ICD-10 included "somatization disorder" (this had a different symptom threshold from that in DSM-IV), "undifferentiated somatoform disorder," "hypochondriacal disorder," other somatomorph disorders, and somatomorph disorder not otherwise specified (note the use of "somatomorph" instead of "somatoform") and two disorders not listed in DSM-IV, "somatomorph autonomic dysfunction" and "persistent somatomorph pain disorder." In ICD-10, conversion and dissociative disorders were placed in a separate category under the heading of "dissociative disorders (conversion)" while two disorders not in DSM-IV, "neurasthenia" and "Briquet disorder," were listed in Chapter F48 under "other neurotic disorders."

Table 18–1.
DSM-5 Diagnostic Criteria for Somatic Symptom Disorder

300.82 (F45.1) Somatic Symptom Disorder

A. One or more somatic symptoms that are distressing or result in significant disruption of daily life
B. Excessive thoughts, feelings, or behaviors related to the somatic symptoms or associated health concerns as manifested by at least one of the following:
   1. Disproportionate and persistent thoughts about the seriousness of one's symptoms
   2. Persistently high level of anxiety about health or symptoms
   3. Excessive time and energy devoted to these symptoms or health concerns
C. Although anyone somatic symptom may not be continuously present, the state of being symptomatic is persistent (typically more than 6 months)

Specify if:

With predominant pain (previously pain disorder): This specifier is for individuals whose somatic symptoms predominantly involve pain.

Specify if:

Persistent: A persistent course is characterized by severe symptoms, marked impairment, and long duration (more than 6 months).

Specify current severity:

Mild: Only one of the symptoms specified in Criterion B is fulfilled.

Moderate: Two or more of the symptoms specified in Criterion B are fulfilled.

Severe: Two or more of the symptoms specified in Criterion B are fulfilled, plus there are multiple somatic complaints (or one very severe somatic symptom).

ICD-11. World health organization (WHO) released the ICD-11, with an implementation date of 2022.

ICD-11 classifies some of the disorders presenting primarily with somatic symptoms under the new category “disorders of bodily distress and bodily experience.” This label encompasses two disorders: “bodily distress disorder” and “body integrity dysphoria.” The replacement of ICD-10’s “somatoform disorder” with “bodily distress disorder” (BDD) was a major change in ICD-11.

ICD-11’s “bodily distress disorder” is characterized by the presence of bodily symptoms that are distressing to the individual and by an “excessive” level of attention directed toward the symptoms, which leads to repeated contact with health care providers. The disorder is conceptualized as existing on a continuum of severity and can be qualified accordingly (mild, moderate, or severe) depending on the impact on the level of functioning. It is important to emphasize that as in the case with DSM-5’s SSDs, BDD was defined primarily by the presence of essential psychological features, such as psychological distress and “excessive” thoughts and behaviors, rather than by the absence of medical explanations for the symptoms, as had been the case for somatoform disorders in ICD-10 and DSM-IV.

“Body integrity dysphoria” is another newly introduced diagnosis in ICD. It is a rare and severe disorder (there are only about 200 cases of BID recorded in the medical literature) in which patients wish to cut off their healthy limb (e.g., one’s arm or leg) because they feel there is a mismatch between their mental and physical image. BDD has been included in the 11th edition of the (ICD-11) as a “disorder of bodily distress or bodily experience” together with “bodily stress disorder.”

The 11th Edition of the International Classification of Diseases (ICD-11) allocates somatic symptom syndromes into the following categories:

- *Disorders of Bodily Distress and Bodily Experience* (“bodily distress disorder”; “body integrity dysphoria”).
- *Obsessive-Compulsive and Related Disorders* (“hypochondriasis”; “body dysmorphic disorder”).
- *Factitious Disorders* (“factitious disorder”)
- *Psychological and Behavioral Factors Affecting Disorders or Diseases Classified Elsewhere.*
- *Dissociative disorders* (“conversion disorder”; “dissociative neurologic symptom disorder”).

In contrast, all the above-listed ICD-11 diagnoses (with the exception of BID and body dysmorphic disorder) are subsumed under the single category of “somatic symptom disorders” in DSM-5.

Functional Somatic Syndromes

Table 18–2 lists a conglomerate of syndromes frequently diagnosed in medical practice. These consist of clusters of “idiopathic” physical symptoms. Despite the fact that these functional diagnoses are “legitimately” used in many specialties, their association with psychopathology and psychological distress suggests that many of them would fall within the realm of SSD. Excellent reviews of these syndromes have appeared in leading journals on both sides of the Atlantic (e.g., *Lancet, JAMA*), highlighting their common ancestry, as well as their epidemiologic, clinical, and psychopathological aspects. Besides the high levels of idiopathic symptoms, these syndromes also share common elements such as the following:

- The absence of a gold standard against which a specific diagnosis can be confirmed or ruled out.
- No consistent explanation emanates from physical and laboratory assessments.
- The absence of clearly articulated pathophysiology, despite a panoply of putative mechanisms (e.g., symptom amplification, muscle contraction, catecholamine release, persistent neurobiologic dysfunction, neurologic hyper-reactivity, elevated cortisol, etc.).
- The simultaneous presence of multiple unexplained physical symptoms originating from several different organ systems.
- High levels of psychiatric symptoms and “comorbidities.”
- Comparable responses to certain psychological (e.g., cognitive-behavioral therapy [CBT]) and pharmacologic (e.g., antidepressants) interventions.

ICD-11. The EURONET-SOMA workgroup (European Network to improve diagnosis, treatment, and health care for patients with persistent somatic symptoms), a panel of 29 researchers from Denmark, the Netherlands, Sweden, Norway, Latvia, Belgium, United Kingdom, Germany, and Russia was charged with developing a research agenda and work toward a common understanding of the terminology, conceptualization, and management of persistent somatic symptoms and

for interdisciplinary agreement on a consistent diagnostic classification. This group recently proposed the new label, “Functional Somatic Disorders,” which they view as a more neutral construct, since in their view, “it is neither purely somatic nor purely mental.” This term would encompass a majority of the functional somatic syndromes listed in Table 18–2.

Table 18–2
Functional Somatic Syndromes across Medical Specialties

Specialty Area	Functional Syndrome(s)
Allergy	Food allergies
Cardiology	Atypical chest pain, noncardiac pain, mitral valve prolapse
Dentistry	Temporomandibular joint syndrome, atypical facial pain
Ear, nose, and throat	Tinnitus, dizziness, globus syndrome
Gastroenterology	Irritable bowel, nonulcer dyspepsia
Internal medicine	Chronic fatigue syndrome, chronic Lyme disease, hypoglycemia, chronic candidiasis
Military medicine	Gulf war syndrome, chronic multisymptom illness
Neurology	Tension headache, pseudoseizures
Obstetrics/Gynecology	Premenstrual syndrome, chronic pelvic pain
Occupational medicine	Multiple chemical sensitivity, sick-building syndrome, repetitive strain injury
Orthopedics	Carpal tunnel syndrome, chronic low back pain, chronic whiplash syndrome
Plastic surgery	Silicone-associated connective tissue disease
Pulmonary medicine	Dyspnea, habit cough, laryngeal dysfunction, hyperventilation
Rehabilitation medicine	Fibrositis, fibromyalgia
Urology	Interstitial cystitis

Data from Henningsen P, Zipfel S, Herzog W. Management of functional somatic syndromes. *Lancet*. 2007;369:946. doi:10.1016/S0140-6736(07)60159-7.

EPIDEMIOLOGY

When available, specific epidemiologic data will be provided for each individual disorder.

In general, somatic presentations are very common in all countries and cultures. A WHO study done in nine countries showed that only one-third of patients presenting to primary care had a documentable physical illness. At least one additional third had a mental disorder. Physical symptoms can be considered the most common presentation of mental disorders worldwide, and their frequency seems to be on the increase. Canadian historian Edward Shorter pointed out that the shift in somatic symptoms commonly presented in medical and psychiatric settings seems to be related to prevailing medical models. He noted that according to U.S. household surveys, there was a 150% increase in "episodes of illness" reported by the U.S. population between the 1930s and the 1980s, despite the enormous improvements in health care. According to the data, more than one-half of all patients presenting to primary care may present with "idiopathic physical symptoms." Yet, despite their predominantly somatic presentations, such patients do not appear to have a diagnosable physical illness. In fact, the proportion of patients in general medical settings with "idiopathic" physical symptoms for which no organic cause can be found has been estimated to be in the 20% to 80% range. It is quite common for these "idiopathic" physical symptoms to co-occur with psychiatric disorders—specifically with anxiety and mood disorders. With regard to recent data from countries outside the United States, more than 20% of the general population in Germany reported at least one "idiopathic" physical symptom leading to severe impairment. In Switzerland, about 80% of young adults reported somatic problems such as sleep disorders, backache, headache, and stomach or bowel complaints. In addition, research in primary care has shown that regardless of the presence or absence of medical explanations, as the number of individual somatic symptoms increases, so do the odds that the person will also meet the criteria for common psychiatric disorders, in particular depression and anxiety disorders.

Gender and Somatic Presentations

Epidemiologic studies in the United States show a higher prevalence of somatic symptom-related disorders (SSRDs) among females compared to males.

Somatic Presentations in Children and Adolescents

While the reporting of physical symptoms appears to increase with age, somatic presentations are also very common in children. Several reports, primarily from consultation-liaison child psychiatrists, highlight the relevance and frequency of DSM-5 SSRDs in children and adolescents in pediatric settings. According to these reports, SSRDs account for 15% to 20% of psychiatric consults in the pediatric hospital setting and have been reported as the second most common reason for psychiatric consultations related to suicide attempts. As part of a growing effort to standardize the evaluation and management of pediatric SSRDs, the American Academy of Child and Adolescent Psychiatry (AACAP) has published a clinical consensus pathway for SSRD evaluation and management.

However, general pediatricians continue to utilize such labels as “idiopathic’ or “amplified pain syndrome” (APS) in the case of children presenting medically unexplained musculoskeletal pain, complex regional pain syndromes, headaches, or functional stomach pain. Some disagree with such terminology because they regard it as stigmatizing.

ETIOLOGY

Somatic presentations of mental disorders should be conceptualized using a biopsychosocial model that includes genetic and biologic vulnerability, environmental influences, as well as psychological and behavioral elements. According to this model, a number of contributing factors converge into the final common pathway of “somatic presentations.” This appears to be a complex process in which genetic and biologic vulnerability (increased sensitivity to pain, proprioceptive acuity), early traumatic experiences (violence, abuse, deprivations), learning factors (attention obtained from having an illness, lack of reinforcement of nonsomatic expressions of distress) and psychological elements, lead to a characterologic style and a behavioral repertoire that focus on the somatic and conveys a diminished ability to express emotionally laden feelings. These traits may be more likely displayed in certain cultural/social frames that devalue or stigmatize psychological suffering in contrast to “genuine” medical disorders. This is reinforced or stimulated by psychiatric comorbidities, and in some instances, secondary gain (such as financial compensation).

Environmental and Cultural Factors

“Idiopathic” physical symptoms have been reported in most cultural groups, although the types of symptoms and their prevalence appear to differ across cultures. The phenomenon of “somatization” has also been well documented in international studies. Differences in medical care across cultures obviously affect the presentation, recognition, and management of these somatic presentations. In general, “idiopathic” physical symptoms appear to be more common among individuals from lower socioeconomic strata, patients from developing countries, and, in the United States, those from certain ethnic groups.

In the case of Hispanic populations, a relatively high frequency of SSRDs has been reported in epidemiologic studies, particularly among Puerto Rican and Mexican American populations.

In the case of Asian populations, both Asians in general and also Asian Americans, somatic symptom presentations also appear to be relatively common and are frequent manifestations of distress.

In these and other cultural groups, clinical presentations dominated by idiopathic physical symptoms may represent “idioms of distress.” Lay explanations embedded in culture concerning the origin of behavioral symptoms (e.g., *ataque de nervios* among Puerto Ricans) may play a role. Variations in symptom presentation are likely the result of the interaction of multiple factors within cultural contexts that affect how individuals identify and classify bodily sensations, perceive illness, and seek medical attention for them. Somatic presentations frequently follow traumatic events. Thus, somatic presentations can be viewed as expressions of personal suffering inserted in a cultural and social context. L.J. Kirmayer outlined a useful process for framing somatic symptoms that incorporates disease/disorder, symbolic expression of intrapsychic conflict, psychopathology, metaphorical expression of distress, positioning in the world, and formulation of commentary or social protest. According to Kirmayer, “somatization” and “psychologization” are not mutually exclusive ways in which to express distress. He advocated the adoption by clinical investigators of a sociocultural perspective to unravel the meaning of these somatic symptoms and to design effective therapeutic strategies.

Biologic Factors

There is surprisingly limited information on the biology of somatoform disorders. Neurophysiologic studies had suggested that somatoform and

functional somatic syndromes might be related to proprioceptive acuity, abnormality of autonomic and proprioceptive responses, problems with the pituitary–hypothalamic axis, and other nonspecific findings. More recent studies using brain imaging techniques point to interesting differences in patients with conversion disorder and functional somatic syndromes such as irritable bowel syndrome compared to controls or patients with demonstrated organic pathology. A study by Jon Stone and coworkers using functional magnetic resonance imaging (fMRI) showed a different type of brain activation in patients with conversion disorder, which suggested a more complex level of mental activity in conversion than in control patients. Another study by Bruce D. Naliboff and collaborators examined cerebral activation in patients with irritable bowel syndrome and control subjects during recto sigmoid stimulation. The results showed differences in the activity of the right hemisphere and hypoperfusion of the nondominant hemisphere in the patients with functional GI syndromes. A study on a large adolescent cohort (TRAIL study) suggested specific associations between cortisol responses and certain clusters of functional somatic symptoms. SSDs have generally not been studied in contemporary genetic research. However, epidemiologic studies have suggested that there is a familial predisposition in the case of functional syndromes such as fibromyalgia. Studies in the 1950s and 1960s had also suggested that conduct disorder during childhood predisposed toward hysteria (somatization disorder) during adulthood and that antisocial personality in males may be associated with hysteria in female relatives.

Using fMRI, Korean investigators assessed functional connectivity between different areas of the brain in patients with SSDs compared to controls. They report that in three of the four brain networks studied, functional connectivity was greater in the patients with SSD compared to controls. Scores on the somato-sensory amplification scale were correlated with the level of functional connectivity. Based on these findings, SSD may be related to changes in sensory processing of pain and other symptoms, a process that is influenced by emotional processing. According to the authors, “patients with SSD have a deficit in attention, leading to misperception of external stimuli and failure to regulate bodily functions aimed at interactions with external stimuli.” Such observations may lend new insights into the underlying neurobiology of SSD.

Psychological Factors

Psychological factors play a significant role in somatic symptom presentations. Such traits as suggestibility, dramatic demeanor, flair, and flamboyance were all related to the classic notion of hysteria. Some of these traits survived in more recent nomenclatures and were included in the personality disorders category ("hysterical personality" and, more recently, "histrionic personality"). The concept of "alexithymia," used to describe an inability to express and normally process emotions, has also been associated with a tendency to emphasize somatic rather than psychological symptom presentations.

Attitudinal/Behavioral Factors

Learned behaviors and the attainment of "secondary" or "psychological" gain and "advantages" derived from the assumption of the sick role are all factors that may also play a role in the initiation and maintenance of somatoform symptoms.

DIAGNOSIS AND CLINICAL FEATURES

Two separate case reports will be used here to illustrate typical presentations and degrees of severity of SSD. These case reports will highlight diagnostic, prognostic, and management issues for these syndromes.

MILD SOMATIC SYMPTOM DISORDER

Mrs. M, a 40-year-old immigrant from Latin America, presented to the primary care clinic with health anxiety and a number of specific somatic complaints. She had no previous psychiatric or medical history. She consumed alcohol occasionally but denied any other substance abuse. A systematic assessment disclosed the presence of several physical symptoms in the last few years, mostly related to pain, that she was constantly worried about and that had resulted in either medical consultation or significant distress. These included low back pain, stomach pain, pain in arms, headaches, and “dizzy” spells. Upon careful probing, these symptoms did not appear to have a clear medical explanation. Some of these symptoms had first occurred early in life (before the age of 15 years) and had continued intermittently. The primary care evaluation of mental disorders (PRIME-MD) elicited diagnoses of minor depression and anxiety disorder not otherwise specified. Depressive symptoms included diminished interest or pleasure, decreased energy/fatigue, and feelings of worthlessness. Anxiety symptoms included a subjective sense of worry, agitation, muscle pain, concentration difficulties, and irritability. These symptoms did not occur nearly every day but only a few days per week. Although she reported occasional thoughts that life was not worth living, she denied suicidal thoughts. The patient was managed in the primary care setting with a modified cognitive intervention that included relaxation techniques (diaphragmatic breathing, a recommendation for brief daily naps, etc.) and resulted in a relatively fast improvement of somatic, mood, and anxiety symptoms. She did not require psychotropic medications. Treatment was ended after the 10th weekly session, and the improvement in physical symptoms was maintained during a 1-year follow-up period.

SEVERE, PERSISTENT, SOMATIC SYMPTOM DISORDER

Mr. K, a white man in his mid-50s, consulted a general medicine clinic complaining of gastrointestinal problems. Major presenting symptoms were a long list of physical symptoms and concerns mostly related to the gastrointestinal system. These included abdominal pain, left lower quadrant cramps, bloating, persistent sense of fullness in stomach hours after eating, intolerance to foods, constipation, decrease in physical stamina, heart palpitations, and feelings that “skin is getting yellow” and “not getting enough oxygen.” A review of systems disclosed disturbances from virtually every organ system, including tired eyes with blurred vision, sore throat and “lump” in the throat, heart palpitations, irregular heartbeat, dizziness, trouble breathing, and general weakness. The patient reported that symptoms started prior to the age of 30 years. For more than a decade, psychiatrists, general practitioners, and all kinds of medical specialists, including surgeons, had seen him. He used the Internet constantly and traveled extensively in search of expert evaluations, seeking new procedures and diagnostic assessments. He had undergone repeated colonoscopies, sigmoidoscopies, computed tomographic (CT) scans, MRI studies, and ultrasound examinations of the abdomen that had revealed Barrett esophagus but no other pathology. He was on disability and had been unable to work for more than two years due to his condition. About 3 years before his visit to the clinic, his abdominal complaints and his fixed belief that he had an intestinal obstruction led to an exploratory surgical intervention for the first time, apparently with negative findings. However, according to the patient, the surgery “got things even worse,” and since then, he had been operated on at least five other occasions. During these surgeries, he has undergone subtotal colectomies and ileostomies due to possible “adhesions” to rule out “mechanical” obstruction. However, available records from some of the surgeries do not disclose any specific pathology other than “intractable constipation.” Pathologic specimens were also inconclusive. A complete physical and neurologic examination was normal except for an examination of the abdomen, which revealed multiple abdominal scars. Right ileostomy was present, with soft stool in the bag and active bowel sounds. There was no point tenderness and no abdominal distension. During the examination, the patient kept

pointing to an area of “hardness” in the left lower quadrant that he thought was a “tight muscle strangling his bowels.” However, the examination did not disclose any palpable mass. Skin and extremities were all within normal limits, and all joints had a full range of motion and no swelling. Musculature was well developed. Neurologic examination was within normal limits. The patient was scheduled for brief monthly visits by the primary care physician, during which the doctor performed brief physicals, reassured the patient, and allowed the patient to talk about “stressors.” The physician avoided invasive tests or diagnostic procedures, did not prescribe any medications, and avoided telling the patient that the symptoms were mental or “all in his head.” The primary care physician then referred the patient back to psychiatry. The psychiatrist confirmed a long list of physical symptoms that started before the age of 30 years, most of which remained medically unexplained. The psychiatric examination revealed some anxiety symptoms, including apprehension, tension, uneasiness, and somatic components such as blushing and palpitations that seemed particularly prominent in social situations. Possible symptoms of depression included mild dysphoria, low energy, and sleep disturbance, all of which the patient blamed on his “medical” problems. The mental status examination showed that Mr. K’s mood was rather somber and pessimistic, although he denied feeling sad or depressed. Affect was irritable. He was somatically focused and had little if any, psychological insight. The examination revealed the presence of a few life stressors (unemployment, financial problems, and family issues) that the patient quickly discounted as unimportant. The psychiatrist diagnosed DSM-5 Somatic Symptom Disorder, severe type. Although the patient continued to deny having any psychiatric problems or any need for psychiatric intervention or treatment, he agreed to a few regular visits to continue to assess his situation. He refused to have anyone from his family involved in this process. Efforts to engage the patient with formal therapy such as CBT or a medication trial were all futile, so he was seen only for “supportive psychotherapy” with the hope of developing rapport and preventing additional iatrogenic complications. During the follow-up period, the patient was operated on at least one more time and continued to complain of abdominal bloating and constipation and to rely on laxatives. The belief that there was a mechanical obstruction of the intestines continued to be firmly

held by the patient and bordered on the delusional. However, he continued to refuse pharmacologic treatment. The only medication he accepted was a low-dose benzodiazepine for anxiety. He continued to monitor his intestinal function 24 hours per day and to seek evaluation by prominent specialists, traveling to high-profile specialty centers far from home in search of solutions.

Comorbidity of Somatic Symptom Disorders

Patients with SSDs present complicated social histories, including instances of abuse and neglect. The presenting symptoms can be quite broad, including features of mood, anxiety, personality disorders, and, to some extent, substance use disorders (at least the abuse or misuse of prescription medications). In primary care studies, greater than 90% of patients presenting with high levels of physical symptoms qualify for a depression or anxiety diagnosis. The comorbidity with other disorders is also quite elevated, indicating significant overlap across the various categories. Thus, greater than 60% of patients with a dissociative disorder also meet the criteria for somatization disorder.

DIFFERENTIAL DIAGNOSIS

Because SSDs are placed at the crossroad between physical and mental disorders, their differential diagnosis tends to be quite inclusive and elaborate. However, there are several features of these disorders that can help the differential diagnosis. Research in primary care has shown that as the number of physical symptoms increases, so does the likelihood that those individuals will also meet the criteria for a psychiatric disorder, not a medical disorder.

The following features can help in deciding whether idiopathic physical symptoms may have a psychiatric etiology:

- The symptoms coexist with major psychiatric disorders such as depression or panic.
- The symptoms closely follow traumatic events.
- The symptoms lead to psychological “gratification” or “secondary gain.”
- The symptoms represent predictable personality traits (coping mechanisms).

- The symptoms become persistent, join a conglomerate of other symptoms, and convey such attitudes as overuse of medical services and dissatisfaction with medical care.

The more of the foregoing features that are present, the more likely it is that symptoms may be classified as SSD. Differential diagnosis from other psychiatric disorders is also difficult because many of the somatic symptoms may be related to a psychiatric disorder such as depression (e.g., pain symptoms), anxiety (e.g., cardiorespiratory and GI symptoms), or even psychotic disorders (somatic delusions). However, the presence of a high level of idiopathic physical symptoms has to be taken into account even if they appear in the context of what is viewed as another primary disorder such as depression or anxiety because they are likely to affect symptom severity, treatment response, and level of disability.

COURSE AND PROGNOSIS

The course of most SSDs tends to be chronic, which is to be expected in the case of syndromes so closely associated with personality and cognitive styles. Epidemiologic studies have shown that the type and number of physical symptoms often change during follow-up periods, suggesting a certain inconsistency in symptom presentation. However, according to international studies, although idiopathic symptoms change, the number of symptoms present appears to remain high. The presence of high levels of idiopathic physical symptoms appears to be very disabling, leading to higher levels of disability than those reported for most medical and psychiatric disorders. Research in primary care has shown that psychiatric disorders such as depression or anxiety become more severe and disabling if they are associated with high levels of medically unexplained physical symptoms.

TREATMENT

Establishing an Alliance

Patients with severe and protracted somatic syndromes, as in the case presented earlier, approach medical encounters with a mixture of magical, unrealistic expectations, pessimism, and distrust of the profession. These attitudes are based on their previous experiences with physicians

conveying a lack of interest or disbelief in the patient's complaints and suffering. Building a trusting alliance in this context must begin with respect for the patient's symptoms and an acknowledgment of their validity. Active, receptive listening, tolerance for repetition, and a "neutral" approach (avoiding being dismissive, confrontational, or overly reassuring) are essential skills. It takes time and persistence to develop a trusting, therapeutic partnership.

Taking the History

Many of these patients usually bring with them "thick" charts. These include descriptions of many clinical encounters and multiple tests and procedures that are often redundant and ordered without clear rationale. The prospect of reviewing these medical records is challenging and often leads to a negative attitude from the physician. The physician should keep an open mind, despite forewarnings in the medical records, and perform an independent assessment of the patient. An emphasis on psychological questioning and interpretations should be avoided at this stage. Premature reassurance, although seemingly appropriate from the physician's perspective, may be perceived by the patient as disinterest or dismissiveness.

Reassurance

The humanistic principles of the medical profession are well summarized in the maxim attributed to Oliver Wendell Holmes that the role of the physician is "to comfort always." Beyond the specificity of diagnoses and the effectiveness of treatments, the traditional practice of medicine gave high importance to bedside manners and interpersonal issues. However, 21st-century medicine, with its reliance on technology and the changes in practice patterns (e.g., managed care and complex electronic medical records), leaves little time for face-to-face interactions, which is gradually eroding the doctor-patient relationship. It would appear that the profession has drifted away from the role "to comfort," meaning "to give strength and hope; to ease the grief or trouble; to cheer," to "to reassure," simply meaning "to assure anew; or restore to confidence." In this new context, "reassurance" simply means letting patients know that their symptoms do not appear to be caused by physical disease. Unfortunately, this does not seem to work very well in the case of many patients presenting with "idiopathic" physical symptoms. The timing and degree of reassurance

must be based on the adequacy of data and the trust and security of the relationship.

Physical versus Psychological Focus

Patients with SSDs appear to feel most comfortable providing details of symptoms in physical or somatic terms. However, they may also bring a repertoire of significant events (e.g., losses, trauma, disappointments, and deprivations) that may be related to the onset or persistence of symptoms and need to be explored at some point. However, many patients do not readily acknowledge or recognize “emotional” issues and will feel more comfortable dealing with questions related to their physical symptoms than questions related to psychological issues. Taking a history of multiple physical complaints can be carried over into subsequent appointments. A thorough physical examination should follow history taking at the initial visit, and briefer physical assessments should be performed in subsequent visits. An inclusive drug history, including prescription and nonprescription remedies, also should be completed. As history taking moves along, attitudes, beliefs, and attributions should become clearer and patterns of interaction and illness behavior discernible. Distorted beliefs, contradictory ideas, and fears can be addressed at several points during the process of gathering historical data.

General Therapeutic Approach

Because of the refractoriness of idiopathic physical symptoms to traditional interventions, physicians and therapists tend to be more successful when adopting a “caring” rather than a “curing” approach with these patients. Restraint in the use of medication is advised unless these are clearly indicated for the relief of comorbid affective and anxiety symptoms. Clear assignment of appointment times at regular but relatively infrequent intervals (about once per month) is preferable to random appointments based on whim or fluctuation in symptoms. A clearly spelled-out treatment plan is highly desirable. As the rapport and trust increase, the patient may be more willing to discuss their social world, family relationships, and the “stressors” that may be contributing to the symptoms. Although true insight may never fully develop, some awareness of emotional components could make the patient more receptive to referral for specialized behavioral intervention. Even if a referral is successful, the patient should continue to see both the primary

care physician and the psychiatrist. An ongoing working collaboration between the psychiatrist and the primary care physician should lead to better outcomes.

SPECIFIC SOMATIC SYMPTOM AND RELATED DISORDERS

Somatic Symptom Disorder

In DSM-III, “somatization disorder” was the direct descendant of the hysteria/Briquet syndrome diagnosis described in the pioneer studies of the St. Louis group as one of the few valid diagnoses in psychiatry. This separated the concept of multiple idiopathic physical symptoms from the concepts of conversion and dissociative hysteria, which became separate diagnostic entities in the new nosologies. Once incorporated into the DSM process, “somatoform disorder” underwent various changes during the subsequent revisions of the nomenclature up to DSM-5. In clinical practice, somatization disorder appeared to be quite rare, and there was disillusionment about its relevance in primary care settings and, in general, pervasive pessimism about its treatment and prognosis. “Full” somatization disorder (in DSM-III and IV) represented the severity extreme in dimensional models of somatization, and there was ample debate in the field about its survival in future editions of the DSM. Indeed, DSM-5 eliminated this diagnosis, merging it into the broader category of somatic symptom disorder.

As discussed earlier, hysteria was the precursor of the concept of somatization and also of the DSM diagnosis of somatization disorder. In the golden age of descriptive psychopathology, the formal description of a syndrome with multiple neurologic symptoms/complaints without organic findings (still called hysteria) was made by Pierre Briquet in France in 1859, and this began the separation of this polysymptomatic disorder from conversion hysteria. Toward the middle of the 20th century, North American nosologists from Washington University and Barnes Hospital in St. Louis started using a systematic approach to validate psychiatric diagnoses. One of their first targets was the diagnosis of hysteria. These investigators proposed a “revised” Briquet syndrome that included many other physical symptoms besides the neurologic ones, as well as psychiatric and behavioral components. In the DSM classification, before

DSM-III established the syndrome as somatization disorder, it had been called “conversion reaction” in DSM-I (1951) and “hysterical neurosis, conversion type” in DSM-II (1968).

Comparative Nosology

EVOLUTION OF THE DIAGNOSIS OF SOMATIZATION DISORDER. The confusion that arose in differentiating hysteria from hysterical conversion reactions in DSM-III was at least temporarily resolved by retaining Briquet hysteria as somatization disorder and hysterical conversion as conversion disorder. Briquet virtual encyclopedia of purely neurologic symptoms was reduced in DSM-III to 14 symptoms for women and 12 for men out of a possible 37 symptoms attributable to several organ systems (cardiorespiratory, musculoskeletal, genitourinary, neurologic, and GI). Rather arbitrarily, DSM-III-R revised the criteria to require 13 symptoms for both males and females. Finally, in DSM-IV, the criteria were changed once again. This time the revisions were stimulated by a need to simplify the criteria and by the reliance on epidemiologic data sets from outside of the United States. The same data set of adopted Swedish community residents for whom detailed medical records were available and which had led to the distinction of subtypes of somatization in the 1980s (high-frequency vs. low-frequency somatizers) was used again for this purpose. A method based on discriminant analysis was derived to detect “somatizers,” and this led to four discrete sets, including bodily pains, GI symptoms, pseudo neurologic symptoms, and sexual or menstrual symptoms, that were the basis for the new diagnostic formulation. Thus, DSM-IV continued the deflationary trend and modified the criteria to have at least eight physical complaints referable to four pain sites or functions (e.g., back, chest, urination), two nonpain GI symptoms (e.g., nausea, bloating), one nonpain sexual or reproductive system symptom (e.g., menstrual irregularity, loss of libido), and one pseudo neurologic symptom (e.g., urinary retention, aphonic, blindness). Somatic symptoms should remain medically unexplained to quality as somatoform disorder symptoms, although “exaggerations” of ordinarily expected symptoms of coexisting physical disease can also be considered in the symptom count. Somatoform disorder symptoms generally occur over a period of several years and are accompanied by significant impairment of social and occupational function and high utilization of medical resources, usually resulting in either

ineffective and/or unnecessary medical/surgical treatments as illustrated in the case presented earlier.

DSM-5'S SOMATIC SYMPTOM DISORDERS. DSM-5 took a new tack, completely redesigning this category, renaming it "somatic symptom and related disorders." There was concern about the very limited use of somatoform disorder diagnoses both in psychiatric practice and primary care. Somatization disorder in DSM-III and IV was a restrictive category, based on simple counts of medically unexplained symptoms, thus neglecting important attitudinal and behavioral elements. Moreover, the reliance on an absence of medical explanations to catalog symptoms was not precise or practical. Therefore, DSM-5 added key attitudinal and behavioral requirements (B criterion) and no longer require that symptoms be medically unexplained.

ICD-11'S BODILY DISTRESS DISORDER (BDD). As briefly described above, BDD is characterized by the presence of bodily symptoms that are distressing to the individual, but the diagnosis also requires that the individual places "excessive" personal attention on the symptoms. Thus, a key feature of both BDD and SSD is the specific focus on psychologic/emotional features of these disorders, such as excessive thoughts, feelings, or behaviors related to the symptoms and associated health concerns. Similar to what was the case with SSD in DSM-5, BDD frequently involves multiple bodily symptoms, but a single, severe symptom such as pain is acceptable for diagnostic purposes.

DELETING, RENAMING, AND MERGING OTHER DSM-IV SOMATIC CATEGORIES IN DSM-5. In DSM-IV, *hypochondriasis* overlapped with *somatization disorder,* and the label itself was stigmatizing. *Pain disorders* were quite nonspecific, and these diagnoses were predominantly used in settings devoted to pain management. The most common somatoform diagnoses used in practice were *undifferentiated somatization disorder* and *somatoform disorder not otherwise specified (NOS),* both quite imprecise and rather meaningless labels. Thus, DSM-5 eliminated a few categories, renamed most, and merged others (see Table 18–1 for criteria for DSM-5's somatic symptoms and related diagnoses).

Epidemiology. The prevalence of somatic symptom disorder is not yet known. Because "medical explanation" for the symptom is no longer an

exclusion and the somatic symptom threshold is much lower than that of DSM-IV, it has been argued that the prevalence of the DSM-5 disorder could be much higher than that of “full” somatization disorder in DSM-IV. However, the requirement in DSM-5 for “disproportionate and excessive thoughts, feelings, and behaviors” in addition to the reported somatic symptoms makes the criteria more restrictive, and this may affect its overall prevalence in the opposite direction, that is, lowering the prevalence. This conundrum will only be resolved after numerous well-designed, systematic studies are performed in various communities and clinical settings. These studies may require the use of more sophisticated instruments such as the Schedules for Clinical Assessment in Neuropsychiatry-Present State Examination (SCAN-PSE) that can elicit both the symptoms and the psychological/behavioral components of this disorder.

Worldwide, a large majority of the comparative surveys that examined the old diagnosis of somatization disorder consisted of simple counts of physical symptoms with some effort made to rule out medical explanations. In many studies, the presence of high levels of physical symptoms was derived from physical symptom inventories such as those included in the symptom checklist 90 (SCL-90), the general health questionnaire (GHQ), and particularly the diagnostic interview schedule (DIS) and the Composite International Diagnostic Interview (CIDI). The somatic syndromes were articulated as either “full” or “abridged” somatization disorders. Problems with these studies include variations in key instruments, ways of survey administration, format of answers, and the reliance on lifetime rather than current symptoms. In general, somatoform disorder and abridged somatoform disorder have been reported to be more common among females, individuals from lower socioeconomic strata, and, in the United States at least, among people from certain ethnic groups, such as Latinos. In addition, the comorbidity of high levels of these symptoms with psychiatric syndromes such as depression and anxiety has been well documented for most cultures and ethnic groups, although there appears to be cross-cultural variation in frequency and severity of the associated physical symptoms.

GENERAL POPULATIONS. Studies in the United States, Puerto Rico, Germany, and Italy found lifetime prevalence rates of “full” somatization disorder ranging from 0.1% in the United States to 0.8% in Germany,

whereas lifetime rates of “abridged” somatization disorder ranged from 5.6% in Germany to 19% in Puerto Rico. Much greater prevalence rates have been reported for more broadly defined somatic symptom clusters. For example, 22% of the general population in Germany reported at least one unexplained physical symptom leading to severe impairment. Unfortunately, some of the most recent large-scale epidemiologic studies in the United States and elsewhere, such as the national comorbidity survey (NCS), the national epidemiologic survey of alcohol and related conditions (NESARC), and the world mental health surveys, did not systematically assess unexplained physical symptoms, possibly due to the time and effort it takes to go through long and tedious physical symptom inventories.

Etiology

GENETIC AND BIOLOGIC FACTORS. Some of the early family studies of the St. Louis group had suggested an association between hysteria/Briquet syndrome in females and antisocial personality in their male first-degree relatives. In addition, studies of adopted-away children highlighted the presence of alcoholism and violence in biologic fathers of women with somatization disorder. However, no family studies have been performed since the new diagnostic criteria were developed.

Treatment

GENERAL CONSIDERATIONS. Historically, the treatment of patients with severe SSDs has been considered difficult and frustrating. Encounters of these patients with their physicians generally evoke frustration on both sides. When Freud began his practice as a clinical neurologist in Vienna, many of his patients (clearly many of those on whom the original theories of psychoanalysis were based) were “difficult” patients with dramatic physical presentations who were referred by other physicians who had failed to help them. Although the form of symptoms has been reshaped by cultural change and shifts in medical paradigms, this situation is not that different from the realities faced by many physicians today. Such a context represents a profound challenge to the most well-intentioned, dedicated physicians.

Besides the numerous physical symptoms, somatic symptom disorder embodies traits that complicate therapeutic encounters and may render

patients refractory to treatment. These traits include denial of psychological components; chronicity; lack of response to traditional types of reassurance; unshakeable belief about the presence of physical disease; high/inappropriate utilization of medical resources; risk of “occult” medical comorbidities; sensitivity to rejection; and frequent dysfunctional patient-physician relationships. Therapeutic goals should be modest at first and be limited to small, attainable gains such as a decrease in medical visits, a commitment to a single primary care physician, and the avoidance of unnecessary tests and procedures. The physician must be prepared for a long-term commitment to the patient. Specialist consultations should be limited and restricted to cases with evidence of comorbid physical conditions. Some of the elements of CBT, such as diary keeping, should be incorporated into the primary care physician’s treatment strategy. Recommendations of such activities as exercise, yoga, relaxation, meditation, and massage may be useful and are generally better accepted by these patients than psychological recommendations. The major challenge, therefore, continues to be finding practical and effective ways to help primary care physicians to recognize, understand, and manage these patients in the context of a supportive doctor-patient relationship at the primary care site. The current emphasis on learned behaviors leads to the choice of cognitive-behavioral interventions, whereas other conceptualizations may encourage more relational, interpersonal, or psychodynamic approaches. Psychopharmacological approaches may be used independently or combined with other interventions. Until recently, interventions with somatoform disorder patients generally had a pessimistic outlook, and there was a paucity of well-controlled studies. Other issues that delayed effective interventions included the fact that somatoform disorder patients were more likely to be seen in primary care settings where therapists may be poorly prepared to work with demanding, frustrating patients, and comorbid physical disease and psychiatric disease are frequent confounders.

PHARMACOTHERAPY. Medications have a limited role in the management of the patient with somatoform disorder except in the presence of clearly delineated anxious, depressive, or psychotic symptoms. Despite the development of new pharmacologic agents such as dual (norepinephrine and serotonin) reuptake inhibitors and a preliminary report on the possible

efficacy of gabapentin, there have been relatively few studies that employ a purely pharmacologic approach in treating somatoform or SSDs.

SMITH'S CONSULTATION LETTER. A groundbreaking controlled study by Richard Smith and colleagues at the University of Arkansas for Medical Sciences demonstrated the effectiveness of a rather simple intervention. This consisted of a brief "consultation letter" intended for primary care physicians providing them with "dos and don'ts" regarding their encounters with patients with multiple medically unexplained physical symptoms and briefly instructing them on the use of a few key management techniques. The letter urged the physicians to see these patients during regularly scheduled appointments, perform brief physical examinations focusing on the area of discomfort at each visit, avoid unnecessary diagnostic procedures, invasive treatments, and hospitalizations, and avoid using statements such as "symptoms are all in your head," and briefly allow/encourage patients to talk about "stressors." Although patients did not show a significant change in terms of somatic symptom relief per se, their functional capacity improved significantly, and there was a decrease in their utilization of health resources that generated significant cost savings.

REASSURANCE AND SUPPORTIVE THERAPY. It is generally accepted that patients with somatoform disorder respond poorly to the simple reassurance that there are no positive findings in the physical and laboratory workup. Although no adequately controlled studies of psychotherapeutic intervention for "full" somatoform disorder existed prior to the study by Smith and colleagues, a number of studies of undifferentiated forms of somatoform disorder had suggested therapeutic benefits from the presence of an accepting attitude in the therapist, a shift in the patient's attention from somatic to emotional features, and the use of group approaches focusing on explanation, support, relaxation, and cognitive-behavioral approaches emphasizing adaptation to chronic somatic distress.

PSYCHOTHERAPY. There are reports indicating that brief psychodynamic therapy of unexplained somatic symptoms may be effective, and at least one of these studies was a randomized, clinical study comparing brief psychodynamic therapy to regular medical treatment alone. However,

most of the recent evidence in terms of randomized clinical trials involves CBT.

Cognitive-Behavioral Therapy. A body of research has reported on the efficacy of CBT for the treatment of full somatization disorder and related syndromes. CBT-type interventions appear to help patients by modifying thoughts and behaviors associated with somatization. In the typical CBT program, patients are systematically exposed to a number of behavioral techniques, which include relaxation training and graded increases in activities. From a cognitive perspective, CBT helps these patients to identify thoughts that contribute to increased stress, inactivity, and health concern. Often, patients with somatoform disorder syndromes may have a tendency to think catastrophically about their physical symptoms. Such thoughts lead them to conclude that they are sick and must limit physical activity, creating a cycle that perpetuates the somatic process. There are several large, well-designed studies that support the use of CBT-type interventions for patients suffering from somatization disorder and related syndromes. In primary care settings, studies between 1995 and 2000 strongly supported the efficacy of CBT for functional somatic syndromes.

In Germany, the group led by Professor Winfried Rief did a study in 140 primary care patients randomized to either *one* session of CBT or "standard medical care" and reported excellent improvement and very good acceptance of CBT. It must be noted that in Germany, there exist psychosomatic units in hospitals that specialize in managing these patients (and have the time and the needed resources to do so thoroughly). It is generally acknowledged that to effectively treat patients with somatic symptom disorder, the primary physicians must be recruited as participants. In the United States, Robert Smith and colleagues reported on a randomized clinical trial of patients with "high service utilization" due to high levels of medically unexplained symptoms treated with cognitive-behavioral and pharmacologic interventions administered by primary care clinicians (nurses). This intervention led to significant clinical improvement in mental and physical functioning.

Pivotal Study. In a 2006 study performed at a mental health care system in New Jersey by L. A. Allen and coworkers, 84 patients meeting full criteria for somatization disorder were randomly assigned to either standard medical care augmented by a psychiatric consultation letter or to

a 10-session, manualized, individually administered CBT added to the psychiatric consultation letter. The primary outcome measure was the severity scale of the clinical global impression scale for somatization disorder (CGI-SD). Secondary outcome measures were responder status as determined by clinical ratings, self-report measures of physical functioning and somatic symptomatology, and health care utilization assessed via medical records. Results of this study showed that 15 months after baseline, somatization symptoms were significantly ($P < .001$) less severe in the group treated with CBT. Patients treated with CBT also were significantly more likely to be rated as either “very much improved” or “much improved” than patients treated with only augmented standard medical care (39.5% vs. 4.9%). CBT was associated with greater improvements in self-reported functioning and symptomatology and led to a greater decrease in healthcare costs. The authors concluded that for patients diagnosed with somatoform disorder, CBT might produce clinical benefits beyond those that result from current state-of-the-art treatments.

Illness Anxiety Disorder

Together with conversion hysteria, the old notion of hypochondria has had a long and eventful history in psychiatry. Given the stigma attached to the original term, the name changed in DSM-5. DSM-5 recognizes that most cases of hypochondriasis can be subsumed under the rubric of SSD. However, a minority of patients with hypochondriasis (~20%) are now given a diagnosis of illness anxiety disorder. The distinction lies in the severity of the somatic symptoms. Where somatic symptoms are relatively minor, and patients instead focus on concerns that they will get sick or have an undiagnosed illness, the diagnosis is illness anxiety disorder. When there is a preoccupation with health concerns superimposed by substantial somatic symptoms, the diagnosis is somatic symptom disorder. Phenomenologically, health anxiety can be broken down into several components, including idiopathic physical symptoms, such as amplification of bodily sensations; certain characterologic features, such as low self-esteem, guilt, passivity, and personal suffering; and learned behaviors, such as the assumption of the sick role. The core features include disease conviction, disease fear, and bodily preoccupation.

Definition. In DSM-5, key features of health anxiety are preoccupation with physical symptoms and the belief that they may be due to a serious physical illness that persists despite medical reassurance or objective evidence on the contrary. Some experts subscribe to a dimensional concept of health anxiety, according to which these symptoms exist on a continuum from the heightened awareness of bodily function to extreme delusional bodily preoccupation. Indeed, the fear of disease can become so intense that it has been given a phobic connotation, as is the case with historical terms such as “syphilophobia,” “thanatophobia,” “acquired immunodeficiency syndrome (AIDS)-phobia,” and several others. These fears are particularly prevalent at times when certain diseases are thought to be incurable or terminal. The preoccupation with health issues can also become fixed and reach delusional (psychotic) proportions.

History. Hippocrates suggested that this disorder had its anatomical origin in organs located under the hypochondrium—literally below the cartilage or ribcage—and this notion was expanded by other classical Greeks such as Plato and Diocles. In the 16th and 17th centuries, Robert Burton, Thomas Willis, and Thomas Sydenham attributed the origin of hypochondria to “disturbances of the mind,” and it was viewed by some as the male equivalent of hysteria. Since those early times, clinical descriptions of hypochondria have seemed very consistent with those formalized in modern diagnostic systems. In the mid-1600s, the French dramatist Molière in his satire “Le Malade imaginaire,” depicted a hypochondriac who feared the ministrations of physicians. Ironically, Molière, who suffered from pulmonary tuberculosis, collapsed on stage while playing the lead role and died later that evening.

Comparative Nosology. In DSM-5, illness anxiety is defined as the preoccupation with fears of having, or the idea that one has, a serious disease based on the person’s misinterpretation of bodily symptoms, with a duration of at least 6 months. The preoccupation persists despite appropriate medical evaluation and reassurance; the belief is not of delusional intensity and is not restricted to a circumscribed concern about appearance. The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning, and the preoccupation is not better accounted for by another disorder such as anxiety disorder or depressive disorder.

ICD-11 retained the diagnosis of “hypochondriasis” and defined it as “a preoccupation with or fear about the possibility of having a serious, progressive or life-threatening illness, accompanied by either repetitive and excessive health-related behaviors, such as repeatedly checking the body for evidence of illness or maladaptive avoidance behavior.” ICD-11 included “hypochondriasis” under the *obsessive-compulsive and related disorders* grouping based on shared phenomenologic features (e.g., repetitive thoughts about having an illness, repeated/excessive behaviors driven by the preoccupation) and similar treatment response. In ICD-11, the presence of somatic symptoms is not an essential feature of “hypochondriasis.”

Epidemiology. The prevalence of health anxiety can vary according to how it is defined, how the criteria are elicited, and the type of settings studied. It has been estimated that it may affect as many as 4% to 6% of all patients. Health fears seem quite common in the general population. A national study in Germany found that 10% of the population reported “health anxiety” or the conviction of having a serious disease in the absence of medical explanations. A study in Italy reported a 1-year prevalence of health anxiety of about 5%. In primary care, studies using various methodologies have shown prevalence rates of health anxiety in the 3% to 7% range. Psychiatric comorbidities are quite common among patients with health anxiety, including depression (40%), panic disorder (10% to 20%), OCD, and generalized anxiety disorder (5% to 10%). Longitudinal studies have also shown that the course of health anxiety can become chronic and incapacitating, with a majority (greater than 60%) of the cases still showing symptoms after several years of follow-up.

Treatment

REASSURANCE. The role of reassurance in health anxiety disorder has been a controversial one. Although the criteria include the inability to reassure the patient as a criterion for diagnosis, virtually all therapeutic interventions include reassurance as one of their main features. The ease with which patients with health anxiety can be successfully reassured may be related to patient factors such as chronicity, the severity of symptoms, and personality characteristics, and also to the attitudes and treatment style of the therapist. Recommendations for approaching patients with health anxiety are generally similar to those already given for approaching

patients with somatic symptom disorder. However, in general, patients with health anxiety seem less demanding than those with somatic symptom disorder, at least the severe types, and some may even respond to properly conveyed reassurances. Once patients with health anxiety are systematically engaged in a therapeutic relationship, opportunities for insight development may arise.

PHARMACOLOGIC TREATMENT. Little information is available on the pharmacologic treatment of hypochondriasis. Most reports have been anecdotal, single-blind studies. Such agents as tricyclics, selective serotonin reuptake inhibitors (SSRIs), and nefazodone (Serzone) have been reported to be clinically useful, particularly in health anxiety associated with depressive symptoms. In secondary syndromes, symptoms of health anxiety have been reported to improve in parallel with anxiety or depressive symptoms. Antipsychotic agents such as risperidone have been recommended for delusional syndromes. No study has established the superiority of one drug over another in managing health anxiety. Brian Fallon and colleagues conducted a double-blind, placebo-controlled clinical trial in patients with health anxiety (hypochondriasis). Following a placebo run-in, the investigators randomly assigned patients to receive fluoxetine (Prozac) in dosages ranging between 20 and 80 mg per day or a placebo. Fifty-seven patients were enrolled. Twelve were discontinued during the placebo run-in, and 45 were randomized to either fluoxetine or placebo for 12 weeks. Responders to acute treatment (much/very much improved in CGI) entered a 12-week maintenance phase to week 24. Sustained responders at week 24 entered a double-masked discontinuation phase. More patients improved on fluoxetine compared to placebo starting at week 8 (50% vs. 19%, $P = .03$). The acute response was maintained until week 24, with more responders. The authors conclude that fluoxetine is a moderately effective and well-tolerated treatment for hypochondriasis.

PSYCHOTHERAPIES. Various group and individual therapies, including psychodynamic types, have been proposed over the years to manage patients with health anxiety. Unfortunately, there is a paucity of controlled studies. Robert Kellner, one of the pioneers in the treatment of somatic symptom syndromes, was one of the first to report positive results of

behavioral interventions in health anxiety by focusing on patients' misinformation and cognitive distortions.

Cognitive-Behavioral Therapy. Several recent controlled studies have confirmed the earlier suggestions of the efficacy of CBT interventions. This substantive evidence places CBT as the prototype, first-line treatment for this condition. For example, a review of several controlled studies showed that CBT-treated patients improved significantly more than control subjects in a great majority of the studies, with a "trend" toward improvement observed in the remaining trials.

Pivotal Study. In a 2004 study by Barsky and Ahern, patients from primary care practices and volunteers responding to public announcements, all with high hypochondriasis scores, were assigned to one of two treatment groups, either a six-session, individual CBT intervention or a "medical care as usual" group. The CBT was accompanied by a consultation letter sent to the patient's primary care physician. Main outcome measures included hypochondriacal beliefs, health fears, somatic symptoms, role function, and impairment. One hundred and two individuals were assigned to CBT, and 85 were assigned to "medical care as usual." At the 12-month follow-up, CBT patients had significantly lower levels of hypochondriacal symptoms, beliefs, and attitudes ($P < .001$) and health-related anxiety ($P = .009$) than those in "medical care as usual." They also had significantly less impairment of social role functioning ($P = .05$) and intermediate activities of daily living ($P < .001$). Hypochondriacal somatic symptoms were not improved significantly by treatment. Barsky and Ahern concluded that this brief, individual CBT intervention, developed specifically to alter hypochondriacal thinking and restructure hypochondriacal beliefs, appears to have significant beneficial long-term effects on the symptoms of hypochondriasis.

Functional Neurologic Symptom Disorder (Conversion Disorder)

In DSM-IV, conversion disorder is the closest remnant of the old concept of hysteria. In its classic form (a motor or sensory deficit), it now appears to be a rare disorder, at least in Western societies. Although it was a key component of the classic syndrome of hysteria, conversion was separated from hysteria, starting with the Briquet and the St. Louis criteria, and

passed as a separate category into the DSM system. In DSM-IV, the diagnosis of conversion disorder continued to invoke etiologic assumptions (psychological factors) against the otherwise “atheoretical” background of the system. DSM-5 made two crucial modifications in diagnosing this condition. First, it changed the principal name of the disorder (“functional neurologic symptom disorder”) in recognition that this term is more familiar to neurologists and arguably more acceptable to patients. Second, it clarifies that the diagnosis is made when the symptom is incompatible with known neurologic disorders. This “incompatibility” criterion is important because clinicians can be led astray by cognitive bias in evaluating such patients.

Definition. A conversion reaction is a rather acute and temporary loss or alteration in motor or sensory function that is incompatible with known neurologic disorders. Because the onset frequently coincides with psychological issues (conflict), early theorists speculated that such issues were “converted” to neurologic symptoms. The problem is that stress is omnipresent in life, and many patients present with conversion when no stressor has been demonstrated. The classic syndromes resemble neurologic syndromes. Conversion motor symptoms mimic syndromes such as paralysis, ataxia, dysphagia, or seizure disorder (“pseudoseizures”), and the sensory ones mimic neurologic deficits such as blindness, deafness, or anesthesia. There also can be disturbances of consciousness (amnesia, fainting spells). However, many clinicians continue to reserve the term conversion reaction for syndromes mimicking a neurologic disease. In ICD-10 but not DSM-5, dissociation and dissociative disorders are attached to the somatoform category, closely linked to conversion syndromes. Patients with conversion disorder usually present with symptoms suggestive of neurologic diseases such as muscle weakness, gait disturbance, blindness, aphonia, deafness, convulsions, or tremors. About one-third of patients diagnosed with conversion disorder presenting with motor symptoms also meet criteria for other Axis I psychiatric diagnoses and 50% meet criteria for Axis II diagnoses.

History. The concept of *hysteria,* derived from the Greek word for womb or uterus, implied an unwanted migration of the organ to higher sites. It was apparently known even to ancient Egyptians. In the Middle Ages, hysterical symptoms were attributed to demonic influences, and their placement at the moral level retarded the medical debate. During the

Renaissance, hysteria returned to medicine and was considered a somatic disorder by physicians, who implied a connection or pathway between the uterus and the brain. By the middle of the 19th century, Briquet provided a detailed clinical description of a somatic syndrome affecting young women to which he gave the name hysteria and whose origin he situated in the brain. Charcot described the classic form as “la grande crise hystérique,” which included phases such as the “prodromal,” “epileptoid,” “trance,” and “terminal or verbal” phases. He also proposed the term “functional lesion” in an effort to resolve the absence of physical findings. His followers, Babinsky, Janet, and Freud, continued to emphasize psychological factors. By the time Freud proposed his psychodynamic theory, Paracelsus, Thomas Willis, Sydenham, Mesmer, and Pinel had already suggested that hysteria had a psychogenic origin. Freud and Breuer jointly reported the first case of hysterical conversion, the case of Anna O. They theorized that symptoms of hysteria represented unwanted emotional distress or conflict that was suppressed and kept unconscious by the individual, only to appear in the form of medically unexplainable bodily symptoms. Freud named this process “somatic compliance” or “conversion,” and thus, with the case report of Anna O, both “conversion hysteria” and the “talking cure” were born. Since then, however, conversion hysteria has gradually lost its central role in psychopathology, being more loosely described as hysteria, hysterical conversion, or simply conversion, and the term is often used in situations without clear evidence of psychological determination.

Comparative Nosology. In DSM-I (1951), hysteria became conversion reaction; in DSM-II (1968), hysterical neurosis, conversion type; and finally, in DSM-III (1980), conversion disorder. In DSM-IV, conversion disorder is defined as the presence of one or more symptoms or deficits affecting voluntary motor or sensory function, suggesting a neurologic or other medical condition; judged to be associated with psychological conflict or other stressors, not intentionally produced or feigned; and not fully explained by other medical conditions, use of substances, or cultural nuances.

Although DSM-IV purported to be atheoretical, it continued to pay homage to psychodynamic tradition in this instance. DSM-5 emphasizes that the neurologic symptoms are incompatible with recognized neurologic

or medical disorders and provides a specifier to denote whether or not a psychological stressor has been identified.

Epidemiology. The epidemiologic information on conversion disorder is limited. Estimates vary broadly: Less than 1% in the general population, 5% to 14% among general hospital medical/surgical referrals to psychiatry consultation services, and 5% to 25% in treated psychiatric outpatients. The disorder appears to be more frequent in females and can be seen in children as young as 7 or 8 years old. It is rare after the age of 35 years.

Etiology

PERSONALITY FACTORS. Some of the traditional features of hysteria included a detached, unemotional, calmed attitude in front of what appears to be a severe and turbulent illness, a trait known as “la belle indifference.” “Histrionic personality” is currently the term that summarizes the drama, flair, flamboyance, and exhibitionism attributed to these patients. However, none of these is given any relevance for the DSM-5 diagnosis of conversion disorder.

BIOLOGIC FACTORS. The neurophysiologic conceptualization speaks of an inherent defect in certain brain functions, especially those in the dominant hemisphere, that may interfere with verbal associations. In addition, functional MRI studies have shown differences in brain activation between patients with conversion disorder and controls.

PSYCHOLOGICAL FACTORS. The behavioral theory attributes conversion disorder to faulty childhood learning, with the nonadaptive behavioral responses used for secondary gain and control of interpersonal relationships. The psychoanalytic theory, on the other hand, describes symptoms as compromise formations with a primary gain of conflict resolution through the partial expression of the conflict without conscious awareness of its significance. Some have suggested a strong relationship between childhood traumatization by sexual or physical abuse and a later propensity for conversion disorder. Other studies, however, do not confirm such an association.

Treatment. Although a variety of explanations and treatments have been reported in the literature, systematic research on the treatment of

conversion disorder has lagged behind the treatment of other disorders such as depression. Improved guidelines for treatment would be an important contribution, but these need to wait on methodologically controlled studies and long-term follow-up. Although psychological etiology is a requisite of DSM-IV diagnosis, it is often difficult to identify it early in treatment and may not reveal itself until extensive additional history is obtained. Screening methods for assessing trauma, dissociative experience, and post-traumatic stress disorder (PTSD) should be helpful in this process. Any assessment of conversion symptoms must take into account idiosyncratic cultural or religious beliefs that may require specific culture-bound interventions for the resolution of conflict and symptom amelioration. DSM-5 requires that careful examination document that the neurologic symptom is incompatible with known neurologic disorders.

APPROACH TO THE PATIENT. The usual caveats on history taking described for other disorders also apply here. There should be special attention given to a history of trauma, sexual and physical abuse, and a family history of conversion symptoms. The physical examination must pay particular attention to ruling out neurologic diseases such as multiple sclerosis and other peripheral and central nervous system disorders. Routine laboratory studies are indicated, as well as electroencephalograms (to distinguish between epilepsy and psychogenic nonepileptic seizures) and other special studies (e.g., MRI, X-rays, spinal tap, etc.) to rule out other possible organic etiologies.

REASSURANCE. Many conversion syndromes have an acute, benign course and may remit spontaneously with understanding and support. Early intervention can forestall potential chronicity and the progression into a well-entrenched somatization disorder.

HYPNOTHERAPY. This is perhaps the oldest treatment used for conversion disorder. However, there are very few randomized, controlled trials, and these seem to be inconclusive because hypnotizability was not predictive of treatment outcome.

SODIUM AMYTAL. The use of sodium amytal for diagnosing conversion disorder, uncovering traumatic events, and providing therapeutic relief was for some time a common approach to the patient with conversion

hysteria. However, it is now rarely used because a number of observations questioned its clinical value.

PSYCHOTHERAPY. Once chronicity has developed, intensive treatment may use all treatment modalities, including hospitalization, individual or group therapy, insight-oriented therapies, behavioral techniques, hypnosis, sodium amytal interview, physical therapy, biofeedback, relaxation training, and medication (primarily for comorbid anxiety, depression, or other somatoform disorders). Psychological interpretations or explanations do not work well early in the process, but reassuring patients that critical tests are normal and that symptoms will eventually improve may be helpful. Any implication to the patient that they are malingering is counterproductive. Behavioral interventions should focus on improving self-esteem, the capacity for emotional expression and assertiveness, and the ability to communicate comfortably with others. It can be helpful to explore the patient's illness beliefs, predisposing vulnerabilities, precipitants, and perpetuating factors.

PHARMACOLOGICAL TREATMENT. Accompanying comorbid depression, anxiety, and behavior problems may respond to pharmacologic interventions. The use of hypnotic or narcoleptic techniques, if these are being considered, must be tentatively offered to patients whose fear of passivity or loss of control may induce overwhelming anxiety.

PHYSICAL THERAPY. With chronic conversion, muscle contractures can occur, and physical therapy is necessary. Even in the absence of such contractures, however, many conversion patients find that physical therapy can be helpful for muscular symptoms or balance problems. The process of slowly progressive exercises and activities can help restore functioning.

Definition. SSD patients presenting predominantly with pain symptoms: These patients complain of severe, persistent pain in one or more physical areas that are of sufficient severity to warrant clinical attention and cause significant impairment in function. Like the other presentations of SSD, there is no assumption that the symptom is psychogenic or that there can be a clear-cut distinction between "physical" pain and "psychological" pain. The diagnosis of SSD with pain as a specifier is made when the symptoms of pain are accompanied by extensive

cognitive, affective, and behavioral repertoires. Differential diagnosis of “psychologically” versus “physiologically” induced pain is difficult. This task is made more complicated by incidental findings such as arthritic and degenerative changes in joints, vertebral disc problems, muscle spasms, and so on. In the presence of other psychiatric disorders such as depression or anxiety, it is often impossible to ascertain whether the pain is primary or secondary (due to the other disorders).

Theories of psychogenic pain formation invoke neural pathways, but they can be best understood if they are framed within a more comprehensive biopsychosocial model. The type and quality of pain response have been attributed to genetic and physiologic vulnerabilities by some authors, whereas others emphasize psychosocial factors as the major determinants of the symptoms, including behavioral mechanisms. The notion of a “pain-prone personality” has waned in recent years, but it was part of a psychodynamic concept of chronic pain, with pain viewed as a psychological defense against guilt and anxiety possibly representing self-punishment. Patients with chronic pain often meet the criteria for DSM personality disorders, but no specific personality profile has emerged as more relevant than others. Pain in the context of other depressive symptoms and in the absence of dysphoria or sadness was often called “depressive equivalent” or “masked depression,” but this has never been officially endorsed. For a long time, psychogenic pain complaints were considered to be closely related to hysterical phenomena and described as part of classical hysterical syndromes. In previous classifications, a pain of unclear origin had been called “idiopathic,” a term that continues to have relevance in recent classifications of pain in specialties such as neurology. In the United States, pain was separated from conversion disorders, and the category of “pain-prone disorder” was first proposed in the RCD, possibly stimulated by a proliferation of pain treatment programs in the 1970s and 1980s. This led to the DSM category. DSM-III defined it as “psychogenic pain,” DSM-III-R as “somatoform pain disorder,” DSM-IV as simply “pain disorder,” and DSM-5 merging it into SSD.

Those who subscribe to the pathophysiologic relevance of brain neurotransmitters to pain syndromes are likely to focus more on the pharmacologic management of pain disorders. For decades, tricyclic antidepressants, particularly the more serotonergic ones (e.g., amitriptyline has been used in open trials, and the evidence suggests that they are effective for pain syndromes) at doses lower than the ones

traditionally prescribed for depression (e.g., amitriptyline 75 to 100 mg per day).

There have been several randomized, controlled clinical studies on various pain syndromes. A placebo-controlled study of low-dose imipramine in patients with unexplained chest pain ("abnormal cardiac pain perception") showed significantly better improvement in pain scores among patients receiving imipramine. In a placebo-controlled study of phenelzine, imipramine, and placebo in patients with mixed pain/depression syndromes, phenelzine was found to be more effective than imipramine and placebo. A recent meta-analysis of controlled studies on various functional pain syndromes showed a robust effect of antidepressant medications, particularly tricyclics, on pain and functional symptoms. It has long been noted that pain is often associated with depression. Yet, Smith found only 13 studies from 1975 to 1990 that explored this relationship. Of these studies, only four addressed the treatment of depression and coexisting pain. All were open-trial designs, with and without antidepressants (amitriptyline or doxepin), and comprehensive "pain programs." All showed impressive rates of response to depression scores when pain was the focus of the treatment in these comorbid states. The development of dual antidepressants such as duloxetine has reawakened interest in examining somatic components of depression such as unexplained physical pain. Although this may have begun as a marketing strategy, it has served to reinforce the observation of clinicians of a significant association of depression with somatic syndromes such as pain.

Cognitive-Behavioral Therapy. CBT in noncardiac chest pain was studied in a randomized, controlled trial by a British group. Thirty-seven subjects agreed to participate in the study after being reassured by a cardiologist that they did not have heart disease. The study found superiority of CBT over the control group in improving functional limitation and decreased tendency to worry about physical symptoms. A meta-analysis of 25 trials of treatment with CBT in various functional syndromes, including pain, showed that CBT was effective for a variety of chronic pain conditions. Additional studies comparing different therapeutic modalities may help to sharpen their specificity. Although psychodynamic treatments have fallen somewhat into disfavor, the assessment of pain programs that have this orientation can help shed light on the quality of

patient-therapist interactions that predict good outcomes. Finally, collaborative approaches between mental health professionals and primary care physicians should contribute to more integrated treatment approaches that may ease the burden of the therapists and maximize the therapeutic gains.

Psychological Factors Affecting Other Medical Conditions (PFAOMC)

According to DSM-5, the A criterion for this condition is the presence of a medical symptom or condition while the B criterion, the essential feature, is the presence of one or more clinically significant psychological or behavioral factors that adversely affect a medical condition by increasing the risk for suffering, death, or disability. Severity ranges from “mild” to “extreme.”

Psychological or behavioral factors include psychological distress, patterns of interpersonal interaction, coping styles, and maladaptive health behaviors such as denial of symptoms or poor adherence to medical recommendations.

Common clinical examples include denial and refusal of treatment for an acute condition (such as myocardial infarct or abdominal emergencies) by individuals with certain personality styles (e.g., domineering or controlling), the exacerbation of asthma or irritable bowel attacks by anxiety, and the manipulation of insulin by an individual with diabetes, or diuretics in the case of hypertensive patients, in efforts to lose weight.

The diagnosis should be only made when the effect of the psychological factor on the medical condition is unambiguous and leads to documentable effects on the course and outcome of the medical condition.

The reverse situation, the psychiatric or psychological consequences of having a medical condition, is more properly classified as adjustment disorder. The prevalence of PFAOMC is unknown. In mental health systems, the diagnosis is most frequently made in consultation-liaison psychiatry settings.

The differential diagnosis can be complex and should include other somatic symptom disorders (somatic symptom disorder, conversion disorder, factitious disorder), as well as personality disorders (e.g., borderline personality disorder).

Treatment. Treatment frequently involves communication with the patient's primary medical team as well as family. The psychoeducational intervention clarifies the role that emotional and behavioral factors play in aggravating the underlying medical condition. Medication to treat another underlying psychiatric disorder may be necessary.

Mr. A, a 55-year-old man, was hospitalized in the intensive care unit (ICU) following a cardiac arrest. He had been experiencing severe substernal chest pain but "ignored it." He became diaphoretic and reported reluctantly to a nearby emergency room, where he had a cardiac arrest while awaiting evaluation. He was successfully resuscitated and transferred to the ICU. He emphatically rejected having had a heart attack, took his EKG leads off, and was preparing to leave the unit against medical advice. The psychiatric consultant obtained a history that the patient's father and brother had died of coronary disease. At the time of the initial assessment, the patient was irritable and somewhat anxious. He agreed to stay in the ICU overnight after his wife insisted that he stay, and the psychiatrist explained the tests further. He was given a low dose of a benzodiazepine, and on the next day, Mr. A was agreeable to remain in the hospital for further treatment.

Factitious Disorder

This category was listed as a separate category in the previous DSM editions.

DSM-5 added it to the somatic symptom and related disorders category because the symptoms these patients present with are most frequently somatic, and a differential diagnosis with other SSDs such as conversion disorder (functional neurologic disorder) is essential.

These patients feign, misrepresent, simulate or cause signs or symptoms of physical illness on themselves. A subtype of factitious disorder is factitious disorder imposed on another (previously known as factitious disorder by proxy).

DSM-5 distinguishes factitious disorder from malingering. According to DSM-5, malingering is differentiated from factitious disorder by the intentional reporting of symptoms for personal gain such as financial compensation or getting time off work. Thus, a distinguishing feature of

factitious disorder in DSM-5 is the falsification of signs or symptoms or the induction of disease such as skin lacerations, adding blood to urine, inducing GI bleeding, laxative-induced diarrhea, induced fever, and many others in the absence of obvious external rewards.

Conversion disorder is an important differential diagnosis in patients presenting with neurologic symptoms (fits, convulsions, paralysis, anesthesia, and so on), as unequivocal evidence of voluntary and deceptive fabrication of symptoms may be difficult to obtain.

Historically, simulated physical symptoms have been recorded since the time of the Greeks (Galen's report of induced physical symptoms such as vomiting or rectal bleeding). In recently released Vatican archives, self-induced stigmata, discovered as part of inquisition trials, is an interesting observation. In more recent times, factitious disorder was known as "Munchausen syndrome" following the 1951 publication by Asher in the *Lancet*.

The epidemiology of Factitious Disorder is not known. Etiologic factors are generally not clear, except in cases where religious beliefs or familiarity with the health field play a role in symptom formation. A common denominator nowadays is that these patients tend to be avid medical service seekers, curiously not a criterion included in defining the disorder.

Treatment is basically conservative, aimed at preventing further complications.

Other Specified Somatic Symptom and Related Disorders

Included here are below threshold somatic syndromes, including brief somatic symptom disorder, brief illness anxiety disorder (both with less than 6 months duration of symptoms), illness anxiety disorder without excessive health-related behaviors (criterion D not met), and pseudocyesis.

Unspecified Somatic Symptom and Related Disorders and Other Below-Threshold Somatic Symptom Syndromes

Several investigators responding to the expressed need of clinicians and researchers, particularly in primary care, have proposed below-threshold subtypes that may capture many of the patients often seen in primary care who do not meet the full criteria for somatic symptom disorder.

Definition. Syndromes that fall below the threshold for an SSD may include the old notions of “somatization syndrome,” “abridged somatization disorder,” and “polymorphous,” “multisomatoform,” or “polysomatoform” disorder.

History. Because of the difficulty in applying the unwieldy diagnostic criteria of full DSM-IV somatization somatoform disorder in primary care, based on a clinical study, Escobar proposed an abridged construct of somatization that used a threshold of four idiopathic physical symptoms for males and six for females. This construct was shown to have similar discriminating power as the full somatization disorder. The abridged construct was systematized in 1987, incorporating the physical symptoms elicited with the DIS. Using these criteria, Kirmayer and Robbins in 1991 outlined three nonoverlapping syndromes in patients seen in a primary care service. They reported that the majority of patients presenting with medically unexplained somatic symptoms fitted one of the three definitions, each implying a different pathogenic process. In 1993, TK Craig and collaborators in the South London Somatization Study also used the abridged criteria for somatization and proposed four syndromes in primary care: “psychologizers,” “somatizers,” and “mixed” and “physical” cases. The notions of “psychologizers” and “somatizers” were also used in Spain by A. Lobo and collaborators. Other authors, such as K. Kroenke in the United States and W. Rief in Germany, also proposed abridged constructs of somatization.

Epidemiology. Overall, it has been estimated that in up to two-thirds of patients presenting to primary care, no allopathic disease entity can be differentially diagnosed and unequivocally established as the principal determinant of the presenting somatic complaints. In the United States, the proportion of patients with full DSM-IV somatization disorder and abridged somatoform disorder in primary care settings has been estimated to be 3% and 20%, respectively. Of the 20% or so primary care patients with high levels of idiopathic physical symptoms, most of them (75% or so) meet the criteria for a major psychiatric disorder, lending credence to the statement that idiopathic physical symptoms may be the most typical way for common psychiatric disorders such as depression and anxiety to manifest themselves in primary care. An international study sponsored by the WHO that took place in 14 different countries examined in detail somatic symptoms, as well as various concepts of somatization in

primary care, and how these related to depression and other syndromes. The study found that idiopathic physical symptoms defined either as a somatoform disorder or abridged somatoform disorder were extremely common (range 53% to 65%). No major differences were noted across countries when somatization was defined as either denial of psychological symptoms or reporting of medically unexplained somatic symptoms. However, when somatization was defined according to presenting symptoms, the study found greater variation among the centers. An important observation of this study was confirming that reports on lifetime somatic symptoms are unstable, particularly when somatic symptom thresholds are high (somatoform disorder). Lower symptom counts (abridged somatoform disorder) fared better, but even here, half of the symptoms reported at the initial interview were forgotten one year later. Because, according to this research, diagnoses based on lifetime recall appear to rest on an unreliable foundation, the use of current rather than lifetime somatic symptoms should be the rule. Idiopathic symptoms may be simply a reflection of the availability of particular health services in a given region, as suggested by the WHO collaborative study mentioned above. There is also some evidence that there are fewer “somatizers” in settings in which a more personalized type of care is common than in those settings in which it is rare.

Treatment

GENERAL OUTLINE FOR TREATMENT OF IDIOPATHIC PHYSICAL SYMPTOMS IN PRIMARY CARE. The primary care setting has been dubbed the “de facto mental health system,” and because this is more readily available across cultures than the more formal mental health system, comparative international studies have often taken place in that setting. Studies in primary care are also of particular importance with regard to somatic presentations because physical symptoms presented at this level can be taken to have clinical importance to the person experiencing them. In the 1920s, Francis W. Peabody, Harvard Professor of Medicine at Boston City Hospital, wrote that teachers and students are at risk of “serious error in their attitude toward a large group of patients who do not show objective, organic pathologic conditions, and who are generally spoken of as having nothing the matter with them.” Peabody stated that treatment was the

responsibility of the internist and general practitioner and that its effectiveness resided in the quality of a caring patient–doctor relationship.

Although some of these “difficult” patients eventually end up in psychiatric clinics, many remain in primary care. Over the years, the care of these patients has been negatively affected by the lack of an integrated healthcare system. Given the dimensional characteristics of these disorders, having a broad range of symptoms, symptom severity, and functional impairment, the “one size fits all” approach is grossly unrealistic. Therefore, a personalized, multistage approach should be developed. In primary care, patients with idiopathic symptoms often have symptoms of common mental disorders such as depression and anxiety. The initial step should focus on providing symptom relief for the very complaints that prompted patients to seek treatment in the first place. In the case of these patients, these are somatic complaints that frequently express idioms of distress. One would then expect that a positive effect on physical symptoms would make nonpsychologically minded patients more amenable to psychiatric approaches and interventions. Thus, the first steps in this process seem crucial.

- *Step 1:* This starts with detailed scrutiny of medically unexplained physical symptoms that will identify patients in primary care who are likely to be in need of mental health treatment.
- *Step 2:* This entails the use of simple, brief modules, such as psychoeducation, biofeedback, and stress reduction instructional videos. These should target primarily the type and intensity of physical symptoms with which a given patient presents, under the supervision of primary care providers (e.g., nurse practitioners) who have been trained to assess patients and even provide some simple interventions.
- *Step 3:* If symptoms do not improve with the first two steps, the next one entails greater onsite involvement by mental health specialists. It may include expert assessment and referral to a time-limited, CBT-type intervention administered on-site in primary care that focuses on the physical symptoms and has been shown to be beneficial for both physical symptoms and, secondarily, symptoms of depression and anxiety.
- *Step 4:* This and subsequent steps include a menu of options for the continuing care of such patients, including psychotherapy and drug treatments either alone or in combination. These may require referral

to mental health clinics and treatment coordinated by a team of mental health clinicians.

Pivotal Study. A 2007 study by Escobar and coworkers tested the effectiveness of a CBT-type intervention delivered in primary care for patients presenting with medically unexplained physical symptoms. Patients were randomly assigned to receive either the new intervention in addition to a consultation letter or "usual clinical care" plus a consultation letter alone. All treatments and assessments took place at the same primary care clinic where patients sought care. The results showed that a significantly higher proportion of patients in the intervention group had their physical symptoms rated as "much–very much improved" compared to those in the other group (60% vs. 25.8%; odds ratio, 4.1; 95% confidence interval [CI], 1.9 to 8.8; $P < .001$). The intervention on unexplained physical symptoms was best noticed at treatment completion, led to significant relief of symptoms in more than half of the patients, and persisted for up to 6 months after the intervention, although its effectiveness did gradually diminish. The intervention also led to significant improvement in self-reported physical symptoms, self-ratings of physical symptoms, and clinician-rated depression scales at the post-treatment assessment. The authors of the study concluded that a time-limited CBT-type intervention significantly ameliorated presenting physical complaints of patients seen in primary care and offer an alternative for managing these common and problematic presentations in primary care settings.

GENERAL GUIDELINES FOR TREATMENT OF SOMATIC SYMPTOM DISORDERS

Reviews of controlled studies have shown a good efficacy of psychotherapy, particularly of CBT type, and some evidence for the efficacy of drug therapy in the treatment of a number of SSD and functional somatic syndromes. This should dispel the therapeutic nihilism that has surrounded the treatment of these patients for quite some time. Moreover, in a recent update (up to 2006), Kroenke found 34 randomized clinical trials on somatoform disorders, which included more than 1,000 patients. Of these, 13 were CBT trials, 5 were antidepressant trials, and 16 involved other modalities. Overall, CBT showed the highest efficacy,

with virtually all reported studies showing a significant effect of CBT on symptoms compared to no treatment. Results were particularly favorable in the case of patients with various functional symptom syndromes and high levels of medically unexplained physical symptoms, as well as for patients with hypochondriasis and body dysmorphic disorder. Antidepressants seem to work in painful syndromes, and the data favor older antidepressants (tricyclics) over new ones (SSRIs). Other interventions, including CBT, the use of a psychiatric consultation letter, brief psychodynamic therapy, exercise, and biofeedback, have also shown beneficial effects on some of these syndromes. A word of caution should be added, however, to temper the enthusiasm on the efficacy of CBT. Even though the pivotal CBT trials described here were randomized clinical trials, in most instances, the comparison group was restricted to a "medical care as usual" group or to the simple addition of the consultation letter. Thus, it cannot be ruled out that the better outcomes in the CBT-treated patients may be at least partly related to the increased attention and the additional time and effort invested in the case of the experimental (CBT) treatment. Therefore, future trials should rigorously control for this factor.

THE FUTURE OF SOMATIC SYMPTOM DISORDERS—TOWARD A NEW DIAGNOSTIC CLASSIFICATION?

Psychological causation and modulation, as well as behavioral and attitudinal aspects, of the somatic symptom syndromes, have been neglected in past diagnostic systems, possibly because they are difficult to define operationally. In an influential book, McHugh and Slavney stated that a somatic presentation ("hysteria" in this instance) "is *not something the patient has; it is something the patient does; that is, it is a behavior.*" To some extent, this perspective was incorporated into the new criteria delineated in DSM-5. The tendency to always view certain somatic presentations as the physical expression of a primary mental disorder was evident in criteria such as those proposed by Bridges and Goldberg in England, which emphasized the need for a proper psychiatric diagnosis made by a competent clinician to confirm that the somatic presentations are or are not connected to a psychiatric disorder.

Other interesting models to dissect ambiguous somatic symptom syndromes have been proposed. For example, Richard S. Brown

separates somatic presentations according to three explanatory themes, namely “dissociation, conversion, and somatization.” Harold Merskey and Francois Mai distinguish two types of somatic symptom presentations. The first comprises symptoms such as unexplained pain and “functional” cardiovascular or GI symptoms, which are involuntary, automatic, related to autonomic arousal, and appear in temporal relationship to the experience of “stress” or jointly with depression/anxiety syndromes. This type seems particularly common in primary care. The other and more ambiguous set depends on thoughts, embodied intentions, or ideas that are not recognized or acknowledged, expressed as unexplained neurologic symptoms. This subtype may represent the more severe, polymorphous, treatment-refractory syndromes that are more likely to be seen in specialty mental health environments but are also seen in medical and surgical tertiary care centers. These models make sense intuitively, but they have not been assessed in systematic studies. A European study showed that the expression of physical and psychological complaints is ubiquitous, starting at an early age and that they seem to follow separate paths regarding their expression, evolution, and recognition.

NIMH Research Domain Criteria (RDoC)

This alternative diagnostic approach, developed by Bruce Cuthbert and Thomas Insel at NIMH, relies on behavioral neuroscience, brain “circuits,” “cells,” and “self-report scales.” RDoC is a dimensional approach for use in research, and its main goal is to define clinical characteristics that may reflect the biology of the illness with greater precision, hopefully leading to more specific therapeutic targets compared to the broad overlapping categories of the DSM. While not yet proposed by the RDoC workgroup, it may be useful to consider dimensional approaches as a new research strategy to examine SSD.

Instruments to Assess Somatic Symptom Disorders

The present state examination (PSE), a phenomenologically rich semistructured instrument that requires clinical expertise and significant training and includes excellent symptomatic descriptions, maybe a useful tool for assessing DSM-5 categories of somatic symptom and related disorders in both clinical and epidemiologic studies.

There are numerous widely used scales for assessing somatic complaints, but the diagnosis of SSD requires more than just chronic

distressing and impairing somatic complaints. Instead, it requires assessments of excessive dysfunctional cognitions (catastrophizing) and behaviors. A number of inventories such as the Whitley scale or the pain catastrophizing scale may be helpful, but the anchors and cut points need to be derived in careful research lest the diagnosis is overapplied.

Factitious Disorder

Davin K. Quinn, M.D., Dora Wang, M.D., M.A., Seth Powsner, M.D., and Stuart J. Eisendrath, M.D.

Patients with factitious disorder simulate, induce, or aggravate illness to receive medical attention, regardless of whether they are ill or not. These patients may inflict painful, deforming, or even life-threatening injury upon themselves, their children, or other dependents. The primary motivation is attention and care as a *patient*. Factitious disorder patients, in contrast to malingerers, lack an obvious external reward, such as avoidance of duties or financial gain.

Factitious means "artificial, false," from the Latin *facticius,* "made by art." The art and artifice of patients with factitious disorder often lead to high hospital drama. Clinicians may exclaim in frustration, "He's not really sick! He's doing it to himself!" and dismiss or refuse to treat patients with factitious disorder. Countertransference can be a major obstacle to the proper treatment of these patients who are at risk and suffering a psychiatric disturbance.

Factitious disorders can lead to morbidity or even mortality. Therefore, the medical and psychiatric needs of these patients must be taken seriously, even though presenting complaints are by definition falsified.

An operating room technician, the daughter of a physician, repetitively injected herself with *Pseudomonas,* which caused multiple bouts of sepsis, bilateral renal failure, and ultimately her death. Such deaths are not uncommon in severe factitious disorders.

In factitious disorder imposed on another, also known as factitious disorder by proxy, *Munchausen syndrome by proxy*, and "fabricated illness in a child," the patient seeks medical attention for another individual, most commonly their own preverbal infant. Factitious disorder imposed on another is recognized in all 50 states as child abuse, elder abuse, or abuse of a vulnerable, dependent adult. Clinicians must prioritize the safety of the victim, which may involve notifying government agencies responsible for the protection of these groups.

Factitious disorders imposed on self and imposed on another should not be considered diagnoses of exclusion but should be actively pursued, given the potentially high stakes, especially when dependent abuse is suspected. Clinicians should be mindful of minimizing unnecessary invasive medical procedures and of trying to steer patients toward the psychiatric care they may need in face-saving, nonthreatening ways. Indeed, factitious illness behavior often represents an underlying psychiatric disturbance, such as a personality disorder, mood disorder, or substance use disorder. Ironically, even patients presenting with factitious psychological complaints, such as feigned bereavement, usually suffer from another psychiatric condition for which they are not seeking help.

Limited empirical knowledge is available about the etiology, epidemiology, course, prognosis, and effective treatment of factitious disorders. Most knowledge comes from case reports, and this information is suspect given that these patients, by definition, falsify their histories. Methodologic problems are inherent in studying deceptive patients. Systematic studies of reported factitious disorder cases have inherent limitations, and federally funded investigation is nonexistent.

It is likely that every clinician will cross paths with a patient with a factitious disorder at some point in their career. A survey of the literature on factitious disorders may engender conclusions of therapeutic nihilism, given the few descriptions of successful treatment and the many examples of patients with recurrent factitious behaviors over decades. However, *Munchausen syndrome*, the prototypical factitious disorder and the first to gain wide medical interest, is now understood to be a chronic severe variant that

comprises only a small portion of all cases of factitious disorder. Clinicians may do well to remember that deception is a pervasive, normal behavior in human interactions and politics. In medical settings, patients may engage in a wide range of deceptive behaviors for a host of reasons, including as a coping strategy under conditions of stress, as exemplified by a moving first-person description of recovery from factitious disorder published by Bass et al. in 2013. Conceptualizing deception and excessive health care seeking on a spectrum of normal to abnormal behaviors will help clinicians understand that not all factitious illness behavior is as refractory or as chronic as that demonstrated by patients with Munchausen syndrome.

DEFINITION

The main clinical feature of factitious disorder is the falsification of physical or psychological signs or symptoms or the induction, or exaggeration of injury, or disease. It must be associated with identified deception and be evident in the absence of obvious external rewards, although at times, this may be difficult to determine. An individual may present oneself as ill, impaired, or injured, in which case the diagnosis is *factitious disorder imposed on self*. If an individual presents another individual as ill, the diagnosis is *factitious disorder imposed on another*. Table 19–1 summarizes the definitions in the text revision of the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and the International Classification of Diseases 11th Revision (ICD-11). Factitious disorders are now considered part of the somatic symptom and related disorders category, given that both disorders involve manifestations of predominantly somatic symptoms and are most often encountered in the medical setting. There are also many areas of overlap between these disorders in comorbidities and treatment.

Munchausen syndrome, the eponymous term coined by Richard Asher in his landmark 1951 publication, was known as *chronic factitious disorder with predominantly physical signs and symptoms* in the lexicon of DSM-IV. Some practitioners use the term Munchausen syndrome for a chronic, severe, refractory form of factitious disorder, in which deceptive illness behavior becomes a lifestyle, precluding stable relationships or employment. Munchausen syndrome comprises approximately 10% of all cases of factitious disorder. Constantly seeking medical care and hospitalization, such patients often assume grandiose false identities, sometimes claiming to be royalty, relatives of celebrities, or figures in important historical events. They travel from hospital to hospital, and when they become well known in one city, take their deception on the road to begin the behavior anew elsewhere. Previous terms applied to these patients included *hospital hoboes, hospital addicts,* and *professional patients.* Two distinguishing features of Munchausen syndrome beyond the simulation of disease are *pseudologia fantastica*—the telling of vague, self-aggrandizing, heroic tales often containing a kernel of truth—and *peregrination*—the tendency to travel widely. There is evidence to support a second durable phenotype of factitious disorder imposed on self, called *common factitious disorder,* in which factitious behavior is confined to one locality and a relatively circumscribed set of complaints. The prototypical patient tends to be young, female, socially connected, employed, and working in health care.

Table 19–1.
Factitious Disorder Imposed on Self

	DSM-5	ICD-11
Name	Factitious disorder	Factitious disorder
Duration		
Symptoms	**Factitious disorder imposed on self:** ▶ Act of falsifying symptoms and clinical findings in one's self ▶ Presenting one's self to others as ill ▶ Deceptive behaviors present outside of identifiable external reward or motivation **Factitious disorder imposed on another:** ▶ Act of falsifying symptoms/injury/disease and clinical findings in another individual ▶ Presenting individual in whom symptoms have been falsified to others as being ill ▶ Deceptive behaviors present outside of identifiable external reward or motivation	**Factitious disorder imposed on self:** ▶ Feigning, falsifying, or inducing signs, symptoms, or injuries ▶ Deceptive behaviors present ▶ If pre-existing disorder present, aggravates signs or symptoms or injuries associated ▶ Seeks treatment and presents as ill/impaired **Factitious disorder imposed on another:** ▶ As above, but enacted on another person
# Symptoms needed		
Exclusion (not the result of)	Another mental disorder	Excoriation disorder Malingering
Psychosocial impact		
Symptom specifiers		
Severity specifiers		
Course specifiers	**Single episode** **Recurrent episodes (**2 or more discrete events)	
Comments	*Note: In factitious disorder imposed on another, the perpetrator receives the diagnosis, not the victim.*	

In factitious disorder imposed on another, a person intentionally simulates illness in another individual, often someone who is dependent on the perpetrator for care. In 95% of all reported cases, the perpetrator is a mother feigning or producing illness in her own child. Factitious disorder imposed on another may also be committed against an adult, such as an elder or spouse. Epidemics of hospital deaths have been attributed to medical personnel inducing or exacerbating illnesses in patients. Because factitious disorder imposed on another almost always constitutes child abuse or criminal abuse, the forensic terms "perpetrator" and "victim" are used even in the medical literature. Subsequent to the DSM-5, factitious disorder imposed on another replaces the terms factitious disorder by proxy and Munchausen syndrome by proxy in psychiatric nomenclature. There is an ongoing debate in the pediatric literature about the appropriate terminology for the condition. *Caregiver-fabricated illness in a child* is the term used by the American Academy of Pediatrics Committee on Child Abuse and Neglect, as it focuses attention on the harm caused to a child and less on the motivations of the perpetrator, consistent with the approach to diagnosing other forms of child maltreatment.

HISTORY

In the second century of the Common Era, the Greek-born physician Galen wrote of patients inducing or simulating symptoms such as vomiting or rectal bleeding. The Bible relates accounts of self-inflicted injury. In the Middle Ages, “hysterics” reportedly put leeches in their mouths to simulate hemoptysis and abraded their skin to reproduce skin conditions. However, judging historical accounts through contemporary mindsets is often problematic, and it is difficult to say whether these accounts actually represent factitious disorder.

In 1838, the Scottish military physician Hector Gavin published an essay, “On the Feigned and Factitious Diseases of Soldiers and Seamen, on the Means Used to Simulate or Produce Them, and on the Best Modes of Discovering Impostors.” Although most of Gavin’s subjects were malingering to escape duty in the high-casualty Napoleonic Wars, he also noted that the motive of some was simply “to excite compassion or interest” and that “some soldiers, indeed, without any ulterior object, seem to experience an unaccountable gratification in deceiving their officers, comrades, and surgeon.”

Jean-Marie Charcot, around 1890, used the term *mania operativa activa* to describe a young girl who continually sought surgery for pain in a knee joint until her medical care seeking resulted in a surgeon amputating the leg. No pathology was ever found in the leg. In 1901, the Swiss physician Henri Secretan lent his name to a peculiar syndrome of nonhealing, traumatically induced edema of the dorsum of the hand. G. Reading, in 1980, confirmed that Secretan syndrome is factitiously produced. In 1934, Karl Menninger described “polysurgical addiction.”

Interest in factitious disorder increased markedly when the term Munchausen syndrome was coined by Asher in 1951 to describe three patients with false abdominal complaints, all of whom used multiple identities and sought care at multiple hospitals. In prefacing the case reports, he wrote:

> Here is described a common syndrome which most doctors have seen, but about which little has been written. Like the famous Baron von Munchausen, the persons affected have always traveled widely; and their stories, like those attributed to him, are both dramatic and untruthful. Accordingly, the syndrome is respectfully dedicated to the Baron and named after him.

Hieronymus Carl Friedrich Freiherr von Münchhausen (1720–1797) was a nobleman who served in the Russian army in the war against Turkey (Fig. 19–1). After retirement, he entertained friends with embellished stories of his war adventures. He was turned into a literary figure by the author Rudolph Eric Raspe, a friend of the Baron, who fled Germany for England when caught embezzling from a museum. To pay off debts, Raspe published an account of the baron’s tales in 1785. The spelling of the Baron’s name has evolved over time to its current most commonly used but likely misspelled form, Munchausen.

In 1968, Spiro noted that of the 38 cases of Munchausen syndrome then published, none involved a detailed psychiatric workup, and less than half were evaluated by a psychiatrist. He advocated a greater understanding of these patients and presented the first detailed psychiatric case study, confirming information with collateral sources. He criticized the “Munchausen” label and recommended the less pejorative term *chronic factitious symptomatology.*

Factitious disorder with psychological symptoms was first described by Alan Gelenberg in 1977, who mused that whereas other factitious disorder patients avoided psychiatrists, his patient, a war veteran, gained admission to more than 30 psychiatric hospitals within a few years, usually feigning depression and suicidality under various pseudonyms.

FIGURE 19–1. Hieronymus Carl Friedrich Freiherr von Münchhausen (1720–1797). **Left:** The baron wears military armor in this 1750 portrait by G. Bruckner. A nobleman who served the Russian army in the war against the Turks, the Baron entertained friends with embellished stories of his war adventures in his retirement. His tales gained fame when published by Rudolph E. Raspe. **Right:** The baron appears as a caricature in this drawing by 19th-century artist Gustave Doré. The Latin inscription running diagonally across the shield says "mendace veritas" (ambivalence between lie and truth). Like the Baron, patients with factitious disorders are real persons deserving of respect, even though they often present themselves as caricatures. (Portrait courtesy of Bernhard Wiebel, http://www.Muenchhausen.ch. The actual portrait was lost in World War II. Caricature from Gustave Doré. The Adventures of Baron Munchausen, One Hundred and Sixty Illustrations by Gustave Doré. New York: Pantheon Books; 1944.)

"Munchausen syndrome by proxy" was first described in 1977 by British pediatrician Roy Meadow. He described one mother who caused salt poisoning in her child and another mother whose repeated fabrications of urinary tract infections in her daughter resulted in 12 hospitalizations, more than 150 urine cultures, six examinations under anesthesia, five cystoscopies, and seven major x-ray procedures —all by the age of 6 years. When the girl was admitted for observation, the diagnosis of Munchausen syndrome by proxy was made based on urine samples that were bloody whenever collected by the mother but normal when collected by the nurse. Of note, the mother had also sought medical treatment for factitiously induced urinary tract infections in herself, an early indication of the intergenerational transmission of illness behavior that is often seen in factitious disorders.

COMPARATIVE NOSOLOGY

The DSM-III, in 1980, was the first edition of the DSM to recognize factitious disorder. It focused on Munchausen syndrome, calling it the "prototype" of all factitious disorders. Factitious disorder with psychological symptoms was also recognized, as well as a category called atypical factitious disorder that included what later was termed factitious disorder with predominantly physical signs and symptoms.

Subsequent editions of the DSM increasingly recognized the rarity of Munchausen syndrome and placed more emphasis on a greater spectrum of factitious disorders. The DSM-III-R recognized factitious disorder with physical symptoms and factitious disorder with psychological symptoms. The emphasis on Munchausen syndrome was lessened. Factitious disorder with combined physical and psychological symptoms made its appearance under the category of factitious disorder not otherwise specified (NOS).

In contrast, the DSM-IV defined a single category, factitious disorder, with three types: (1) with predominantly psychological signs and symptoms, (2) with predominantly physical signs and symptoms, and (3) with combined psychological and physical signs and symptoms. Factitious disorder NOS was exemplified by factitious disorder by proxy, a disorder cited as a category deserving of more research, with research criteria listed. The DSM-IV-TR criteria for factitious disorders were unchanged from the DSM-IV criteria.

DSM-5 in 2014 introduced several changes to the diagnostic category. First, it formally recognized factitious disorder by proxy by dividing the general category of factitious disorders into two groups: factitious disorder imposed on self and factitious disorder imposed on another. The diagnosis of factitious disorder NOS was eliminated. Second, there was no distinction made between physical or psychological presentations. Factitious disorders are specified as being a single episode or recurrent episodes. Third, the criteria no longer required that illness induction be conscious or intentional, recognizing the difficulty inherent in making such a determination. Instead, evidence of deception in the absence of clear material gain (also known as “secondary gain”) is sufficient to establish factitiousness. If secondary gain is present, such as financial remuneration, relief from duties or legal responsibility, or receipt of controlled substances or narcotics, the deceptive behavior is considered malingering, which is not considered a psychiatric disorder.

The ICD-11 is closely aligned with DSM-5. It lists factitious disorder under the category of “mental, behavioral, or neurodevelopmental disorders” and has subtypes of factitious disorder imposed on self (6D50), factitious disorder imposed on another (6D51), and factitious disorder, unspecified (6D5Z). Falsified illness manifestations are also listed separately under specific medical disorders, such as factitious hypoglycemia, urticaria, cheilitis, purpura, panniculitis, and hyperthyroidism. ICD-11 no longer includes “compensation neurosis” as a related disorder, which in ICD-10 was defined as the exaggeration of physical symptoms that are due to a confirmed physical disorder, caused by the psychological state of the individual in which distress and anxiety about prolonged or progressive disability feature prominently.

ICD-11 aligns with DSM-5 in its distinction between factitious disorder from malingering (QC30) as depending on the absence of external incentives or rewards.

In reality, intent, motive, and awareness are difficult to discern for a clinician with only brief or intermittent interactions with a patient, and each of these occurs on a spectrum. Although the DSM-5 and the ICD-10 and 11 require exclusion of malingering to diagnose a factitious disorder, these two conditions easily and frequently coexist: For example, patients who habitually gratify themselves in the sick role may discover that they can also receive disability payments concurrently or patients who initially fabricated illness to obtain narcotics for intoxication may continue to deceive even when such medications are no longer forthcoming.

Similarly, factitious disorders can coexist, particularly over time, with unconsciously produced illness behaviors such as functional neurologic symptom disorder, somatic symptom disorder, and dissociative disorders. This longitudinal shifting in the production and motivation of somatic symptoms and the difficulty in determining the exact contributors to any one behavior led to the categorization of factitious disorders as a type of somatic symptom disorder in DSM-5. Seen from the perspective of somatic symptoms as an expression of emotional distress, factitious disorder patients and somatic symptom disorder patients are both “engagement seeking.”

The evolution of factitious disorder nosology continues along several schools of thought. One perspective has argued for the greater incorporation of performance-validity and symptom-validity testing into diagnostic criteria. Another perspective put forth by Bass and colleagues argues that a person’s psychological and social milieu is a greater contributor to most factitious presentations than any specific psychiatric diagnosis. Third, neuroimaging studies on deception indicate the activation of distinct networks in individuals instructed to feign symptoms during functional magnetic resonance imaging (fMRI), hinting at the possible future use of such techniques to refine the diagnostic process.

Despite these theoretical controversies, factitious disorder imposed on another, still known as Munchausen syndrome by proxy in the legal literature, is well recognized in the legal system. All 50 states require the reporting of factitious disorder imposed on a child to protective services as a form of child abuse. Adults who, by virtue of a medical or psychiatric condition, are mentally or physically disabled or reliant on another individual for assistance with activities of daily living are also at risk for becoming victims of abuse via factitious disorder imposed on another. With recognition in the lay press and medical literature of adult dependents as potential victims of an individual with factitious disorder imposed on another, clinicians should be aware that required reporting also extends to older adult patients and to the developmentally delayed.

Neither the DSM-5 nor the ICD-11 makes mention of variants of factitious disorder imposed on another, in which individuals impose their psychiatric disorders or emotional needs upon their children,

dependents, spouses, or even entire communities. These phenomena can range from the mundane (*achievement by proxy*) to the mildly disruptive (*hypochondriasis by proxy* resulting in repetitive pediatric visits and unnecessary tests without fabrication or induction of illness) to the psychologically damaging (*gaslighting*) and the physically harmful (*anorexia nervosa by proxy* and *malingering by proxy*).

EPIDEMIOLOGY

Factitious Disorder Imposed on Self

The prevalence of factitious disorder is unknown, in part because of the role of deception in this population, but is estimated to be approximately 1% of the health care–seeking population. Estimates of prevalence are invariably skewed by methodologic limitations of the studies, such as the type of data studied (physician surveys, demographic databases), the study population and setting (hospital ward, outpatient subspecialist, disability office), small sample sizes, recall bias, and publication bias. Studies of specialists and disease-specific tests appear to overestimate prevalence, likely because factitious disorder patients are more likely to see subspecialists and undergo extensive testing, whereas large database studies and systematic reviews are likely to underestimate prevalence due to lack of clinician awareness. There is a large population of people who never present to medical care but engage in disease-simulating behavior, such as those who play the sick role with family, friends, coworkers, social service agencies, online communities, or veterinarians and thus would not be included in medical epidemiologic estimates. Online support groups, social media platforms, and the internet create ripe conditions for factitious disorder patients to garner attention, owing to the ease of creating false identities, lack of face-to-face interaction, and the ability to broadcast to large sympathetic audiences.

In Sutherland and Rodin's 1990 study of patients referred to a psychiatric consultation service in a general hospital, 10 out of 1,288 patients met the criteria for factitious disorder, resulting in a prevalence of 0.8%. A review by Kocalevent et al. in 2005 of 18 studies reporting a prevalence of factitious disorder found estimates varied from a minimum of 0.032% to a maximum of 9.26%, with a weighted mean of 0.9%. In a 2012 occupational medicine clinic sample of 400 patients tested for maximum grip strength, 32 were found to be deceptive in their performance, but only 3 were diagnosed with factitious disorder (0.75%). Fliege et al., in 2007, surveyed 109 senior physicians from internal medicine, surgery, neurology, and dermatology for the estimated prevalence of ICD-10 factitious disorders in their yearly practice. The mean estimated prevalence was 1.3%, the modal prevalence was 1%, and individual estimates ranged from 0.01% to 15%. In 2010, Swanson et al. surveyed 213 physicians regarding their estimates of rates of patients with medically unexplained symptoms. Out of all 4,159 patients seen in 1 day by these physicians, only 1.5% of patients were diagnosed with either a somatoform or factitious disorder diagnosis, with the majority likely somatoform disorders.

Psychiatric settings are somewhat less likely to engage factitious disorder patients: Bhugra et al. estimated psychiatric Munchausen syndrome at 0.5% of adult psychiatric admissions younger than the age of 65 years, based on four diagnoses of Munchausen syndrome out of 775 admissions. In a study of 4,500 visits to a psychiatric emergency room, only 7, or 0.15%, represented factitious disorder. Similarly, a 1994 study estimated the prevalence at 0.14% in a community sample. In a reflection of the overlap between somatic symptoms and factitiousness, Fliege prospectively followed 194 patients admitted to a psychosomatic unit and found 9.7% (19) manifested factitious illness behavior.

Database studies yield significantly lower rates of factitious disorder. In 2013, the DSM-5 working group on factitious and somatoform disorders examined data from the National Hospital Discharge Survey to determine the assignment rate of various psychiatric disorders. Out of more than 3.8 million discharges tracked, a factitious disorder diagnosis was assigned in approximately 9 cases per 100,000, far below the expected prevalence estimate. It was theorized that making a factitious disorder diagnosis was likely unpalatable to physicians and could negatively affect insurance reimbursements. However, all psychiatric disorders, including depression and generalized anxiety, were assigned at rates below their expected prevalence, indicating that a factitious disorder diagnosis is not necessarily less acceptable than any other psychiatric diagnosis. In a study of 28 million military health care visits from 2005 to 2011, Lande and Williams found that only a minuscule number (89 patients) were diagnosed with

factitious disorder. However, it is worth noting that in the military, malingering and self-harm are prosecutable offenses.

Profiles of patients with factitious disorder have increased in the last 5 years. Krahn et al. retrospectively reviewed 93 cases of factitious disorder diagnosed over a span of 21 years in a general hospital. Seventy-two percent were female, with a mean age of 31. Two-thirds of the female factitious disorder patients possessed health care training or jobs. Follow-up and treatment engagement were sparse in this group, and only 17% ever acknowledged simulating illness. Reich et al. found a similar profile in their series of 41 cases over 10 years: predominantly female, unmarried, with an average age of 33 years, working in medical jobs, and manifesting emotional and sexual inhibition. Yates, in 2016, performed a comprehensive systematic review of 455 adult factitious disorder cases published between 1965 and 2015.

Of these, 33% involved males, the mean age was 34.2 years, and in 122 cases, the patient had a health care or laboratory job, most commonly nursing. Of the cases with a history of health care work, 114 of these were female, confirming this particular patient profile known as “common factitious disorder” or “nonperegrinating factitious disorder” by some groups. In contrast, Munchausen syndrome features peregrination or frequent wide-ranging travel to seek medical care and *pseudologia fantastica.* In the same series described above, the male patients were predominantly middle aged, unemployed, and unmarried, with antisocial traits or histories, and 61% engaged in peregrination.

Factitious Disorder Imposed on Another

Factitious disorder imposed on another is most commonly perpetrated by mothers against infants or young children. The estimated incidence is approximately 0.5 to 2.0 cases per 100,000 children under age 16. In the United States, it accounts for less than 0.04%, or 1,000 of 3 million cases of child abuse, although it may well be underrecognized. Of infants brought to an Australian clinic for apparent life-threatening episodes, an estimated 1.5% represented factitious disorder imposed on another. A clinical practice at Great Ormond Street Hospital in England reported that in 20 years, 43 children from 37 families were diagnosed as having induced illnesses.

Rosenberg’s review of 117 cases of factitious disorder imposed on another revealed valuable information about the typical perpetrators and victims. Male and female children were equally victimized. The mean age of a child at diagnosis was 3.3 years, with the onset of symptoms occurring at a mean of 1.24 years earlier. All perpetrators were mothers, with 98% being biologic mothers and 2% adoptive. Paternal collusion was suspected in only 1.5% of the cases. In half of the cases, illness was actively produced in the child, whereas in 25%, illness was simulated without direct infliction on the child. In 25% of the cases, illness was both simulated and produced.

In the same review, 10% of perpetrators were thought to have Munchausen syndrome themselves, and an additional 14% showed features of the syndrome. Data collected from the Great Ormand Street Hospital clinic over a 20-year period indicated that about one-third of perpetrating mothers also had a history of factitious disorder imposed on self. Nearly half of them described serious marital problems. About half of the perpetrating caregivers had a history of psychiatric symptoms, and one-third gave histories of emotional neglect or physical abuse. Fathers were generally absent or peripheral.

Bass and Jones examined 28 individuals referred for the treatment for factitious disorder imposed on another. Fifty-seven percent had evidence of a DSM-IV somatoform disorder, and 64% had a history of a factitious disorder imposed on self. Thirty-two percent manifested pseudoseizures and 61% engaged in pseudologia fantastica. Early abuse experiences were seen to lead to pathologic lying and finally to the fabrication of illness in the victim.

ETIOLOGY

Factitious Disorder Imposed on Self

The etiology of factitious disorder is unknown, and a variety of causes likely explain the wide spectrum of factitious illness behavior. The underlying motivations for the behaviors are believed to be unconscious, although this aspect of the disease is becoming increasingly irrelevant for diagnosis. Two factors underlie most cases of factitious disorder: (1) an affinity for the medical system and (2) poor,

maladaptive coping skills. A majority of factitious disorder patients have medical training, such as in nursing. In a review of six case series comprising a total of 165 patients, Reich and Gottfried found that 60% worked in a medical profession. This approximate ratio of two-thirds having medical background has been confirmed in systematic reviews by Yates et al. and Caselli et al., as well as single-site case series by Ximenez et al. in 2020. The subjects seemed motivated toward their career choices by genuine lifelong preoccupations with health. Indeed, many with factitious disorder see health care providers as allies, not adversaries. In this case series, many patients had personal ties with their physicians, having worked in their offices or having babysat for them. Having a medical background also permits a patient to engage in more sophisticated fabrications of illness and to conceal their deceptions more skillfully.

Coping deficits are widely noted. Many factitious disorder patients seem to come from large families or to have been neglected as children. They may have grown up without consistent nurturing conducive to the development of mature coping. The poor coping skills of these patients are often symptomatic of an Axis II disorder, such as borderline, narcissistic, dependent, or antisocial personality disorder. Increasingly, factitious disorder is being placed within the broader concepts of “illness behavior” and the “sick role,” which include conditionally acceptable and socially advantageous behaviors that persons engage in as part of a therapeutic contract between themselves and the health care system (“the doctor tries to heal the patient; the patient tries to get better”). Physical diseases are more readily accepted as entries into the sick role compared to emotional or psychological diseases; thus, factitiousness is seen as a type of adaptive behavior to enter into and maintain a therapeutic contract that confers psychological sustenance, while secretly undermining it in order to prolong it.

Factitious disorder may be the presenting symptom of an Axis I disorder. Many case reports indicate a lessening or alleviation of factitious illness behavior when major depression is treated. Other case reports point to illness anxiety disorder, previously known as hypochondriasis, as an underlying factor. For example, a 27-year-old physician simulated insulinoma by injecting himself with insulin. When insulin and a syringe were found in a toilet tank, he confessed that he was preoccupied with the thought that he had pancreatic cancer and was trying to provoke further investigation. A 15-year-old boy who was convinced he had a lesion in his urogenital system simulated hematuria to encourage investigation. These vignettes highlight how factitious behavior may be deployed in the service of getting the attention of medical professionals to focus on a perceived concern. Substance abuse, and to a lesser degree psychotic disorders, and developmental disorders have also been implicated in factitious illness behavior.

No genetic or familial inheritance pattern has been shown. Intergenerational transmission of susceptibility to factitious disorder is possible, as cases and reviews highlight how families in which a child of a parent with factitious disorder goes on to develop factitious disorder as an adult.

While intact neurologic and cognitive functioning is observed in most factitious disorder patients, a neurobiologic basis of some factitious behaviors is suggested by reports of abnormal brain scans and deficits in neuropsychological testing in several studies. Pankratz and Lezak, in 1988, reviewed 25 cases of factitious disorder in which neuropsychological testing was obtained. Approximately one-third of those patients manifested significant neuropsychological deficits. Lawrie et al. in 1993 described a case of a 34-year-old woman who developed personality change and a full-blown Munchausen syndrome after a cholecystectomy. Electroencephalogram demonstrated focal slowing in the right temporal lobe, and testing revealed attentional and memory deficits with a significant visuospatial constructional apraxia. Single-photon emission computed tomography (SPECT) demonstrated reduced uptake in bilateral frontal and left temporal cortices. Mountz et al. in 1995 reported the results of a SPECT scan in a woman with severe Munchausen syndrome. Regional cerebral blood flow in the right hemithalamus was markedly increased, in line with a theory of right hemisphere abnormalities in factitious disorder put forth by Pankratz.

There is one case report of fMRI performed by Spence et al. in a woman convicted of child abuse as a result of factitious disorder imposed on another. She was scanned both while endorsing her version of events in which she is innocent and while she endorsed the account of her accusers. Longer response times and greater activation of ventrolateral prefrontal areas were observed on repeated scans when she endorsed her accusers’ version of events, indicating a change in brain state depending on “truthful”

versus “false” endorsement. While this, of course, cannot be considered a biomarker for innocence or guilt, this finding confirms what has been found in studies using neuroimaging to study simulation.

Zheltyakova found regions such as the bilateral temporoparietal junction, right superior temporal sulcus, and left precuneus to have increased blood oxygen level–dependent signal during actions with deceptive intentions, Different and more complex patterns of activation were observed by Stone et al. in bilateral frontal and subcortical areas when patients with conversion weakness attempt to move the paretic limb versus when healthy controls are asked to simulate a weak limb. This line of research suggests that while clinical assessment and treatment of somatic symptom disorders and factitious disorders are converging, deception may involve different brain functions than somatic symptom disorders.

Psychodynamic theories have focused on the concepts of mastery, masochism, and mothering. Striving for mastery may especially apply to factitious disorder patients with predominantly psychological signs and symptoms. For example, patients with factitious psychosis often progress to develop a genuine psychotic disorder, which suggests that the feigning of psychosis may represent a defense or a way of feeling in control of initial psychotic symptoms. Because many patients with factitious physical symptoms seem to have suffered traumatic illnesses as children, adult factitious illness behavior may represent an attempt to master and to feel in control of situations in ways in which they never did as children. They demand or refuse procedures and leave the hospital against medical advice when they feel they are losing control.

Masochism may be a reason that patients repetitively endure painful or deforming surgeries and procedures, such as amputations of limbs and fingers or exploratory abdominal surgeries that result in extensive scarring. The patient relives childhood physical or emotional abuse at the hands of the medical staff in a repetition compulsion. The physician and the medical system at large become symbolic parents against whom the patient re-enacts dependency, idealization, and anger. The system responds with caring, but also with ostensible physical (e.g., surgery) and emotional (e.g., caregiver anger) abuse and, too often, ultimately with rejection and abandonment. Indeed, for those with chronic factitious disorder, the medical system becomes the main object relation.

Factitious illness behavior often occurs when a patient experiences a loss, such as the death of a relative or an occupational loss. Securing the attention of medical clinicians, family, and friends may be a way of obtaining emotional solace without directly confronting the loss. Dependency and narcissistic needs are fulfilled. Factitious illness behavior may also serve the function of providing some patients a role, identity, or purpose. In the role of a patient, they are masterful orchestrators of medical drama. In practicing *pseudologica fantastica,* they often construct desirable and interesting identities.

Behavioral theories postulate that early in life, these patients received positive reinforcement when sick and perhaps gained nurturing from the medical community that they did not receive at home. Perhaps they learned to see the medical system as a source of caring and emotional support. Alternatively, many of these patients lived in large, neglectful households and became the center of focus only when ill.

Factitious Disorder Imposed on Another

Psychodynamic theories predominately explain factitious disorder imposed on another as objectification of the child to serve the parent’s psychological needs. Schreier and Libow called factitious disorder imposed on another a *perversion of mothering* in which a child is dehumanized by the mother and instead serves as a fetishized object through which the mother’s dependency needs are met. Eminson and Postlethwaite argued that two axes are at play: the desire to consult and the inability of the parent to distinguish parental needs from the child’s needs.

Rosenberg noted a *disorder of empathy* among perpetrating mothers, along with pervasive themes of loneliness and isolation, often under circumstances of uninvolved or absent husbands. The mother seeks a relationship with the physician, who substitutes for the uninvolved husband. The relationship with the physician is often ambivalent, characterized by idealization and belittling. The more severe the child’s alleged illness, the more the mother fulfills her own need for caretaking, both vicariously through the child and more directly in her relationship with the physician.

A common view is that those who impose factitious disorder on another have suffered a loss, such as spousal abandonment or loss of contact with another child. Whether perpetrating mothers tend to have suffered abuse is controversial because many such reports of abuse have subsequently been disqualified by collateral sources. Four factors that suggest a caregiver at risk of fabricating illness in a child include (1) appearing to need or thrive on attention from physicians; (2) insisting the child cannot cope without the caregiver's ongoing attention; (3) being directly involved in a medical profession or having expertise or familiarity with medical knowledge and terminology; and (4) having a history of factitious or somatic symptom disorder. It should be noted that these characteristics overlap with those of caregivers who are advocates for children with genuine illnesses and that a caregiver with factitious disorder imposed on another may manifest none of these traits.

DIAGNOSIS AND CLINICAL FEATURES

Table 19–1 summarizes the definitions in the text revision of the DSM-5 and the ICD-11.

Factitious Disorder Imposed on Self

The diagnosis of factitious disorder should be actively pursued and not considered a diagnosis of exclusion. This is recommended for the following reasons: (1) satisfactory exclusion of all other possibilities may be difficult to accomplish or impossible; (2) early diagnosis can minimize the patient's self-harm, as well as harm through iatrogenic complications; (3) confirmation of deceptive behavior requires positive proof that is usually not forthcoming without proactive investigation, and (4) failure to consider the diagnosis is the most common reason for missing a diagnosis of factitious disorder.

Table 19–2 lists reported presentations of factitious disorders along with means used to simulate illness, features suggestive of fabrication, and possible means of detection. The list is a testament to the creativity and resourcefulness of these patients, as well as to their willingness to undergo pain, injury, and inconvenience. Diseases of every organ system have been simulated, limited only by the patient's creativity, knowledge, and access to technologic means. Often, the factitious patient's knowledge of disease exceeds that of the evaluating physician, given the tendency of the patient to be medically trained, as well as the tendency to present to emergency rooms or clinics during evenings or weekends when less experienced resident physicians and staff are on duty. It has been noted by Sinha et al. that factitious patients may emphasize signs and symptoms leading to protocol-driven or "fast-track" admission workups and may be attracted to specialties with more complex disorders and overlapping differential diagnoses.

Factitious symptoms can be (1) *fabricated,* for example, by giving a false history of cancer, acquired immune deficiency syndrome (AIDS), or another illness; (2) *feigned,* for example, by faking symptoms such as pain or seizures; (3) *induced,* by actively producing symptoms through self-infliction of injury or through injection or ingestion; or (4) *aggravated,* such as by manipulating a wound so that it will not heal.

Table 19–2.
Methods of Factitious Symptom Production, Suggestive Signs, and Confirmatory Tests by Systems

Symptom	Method of Factitious Symptom Manufacture	Signs Suggestive of Factitiousness	Test for Factitious Method
Infectious Disease			
Fever	Injecting infectious material into vein/intravenous line	Higher than 41°C	Monitoring while temperature taken
	Ingesting thyroid hormone	Not accompanied by other vital sign abnormalities	Using electronic thermometer reading skin surface
	Drinking hot fluids	Does not follow diurnal pattern	Recording oral and rectal temperatures simultaneous
	Manipulating thermometers with lightbulb or heating pad	No diaphoresis with rapid defervescence	Noting thermometer brand names/serial numbers
	Substituting another thermometer		Measuring fresh urine specim temperature
	Warm wax/wet cotton in ears		
Bacteremia	Injection of contaminated substance	Polymicrobial bacteremia	Culture, whole-genome sequencing to establish reinfection vs. relapse
		Absence of urologic/biliary/GI obstruction	
		Stool flora/pet flora noted	
HIV/AIDS	False history/reports	Normal CD4 count/undetectable viral load/Antibody negative	Repeat HIV ELISA, western b viral load
			Confirm test results with laboratory
Gastrointestinal			
Diarrhea	Laxative abuse (magnesium, castor oil, phenolphthalein)	Metabolic alkalosis	Detection of laxative in urine c stool (usually need multiple tests)
		Acute hyperchloremic metabolic acidosis with normal anion gap	3-day stool collection
		Decreased serum bicarbonate with metabolic acidosis	Urine screen for phenolphthaleins, anthraquinones, bisacodyl
		High daily stool volume	Stool screen for magnesium > mmol/L, phosphate
		Melanosis coli on sigmoidoscopy	
		Cathartic colon on barium enema	

		Low urine potassium concentration	
		High fecal fluid potassium concentration	
		Fecal fluid osmolality <290 mOsm/kg	
	Adding water to stool sample	High stool osmolar gap >125 mOsmol/kg	
Vomiting	Ipecac/cathartic abuse	Hypokalemia	Detection of ipecac in stool by chromatography
		High urine potassium concentration	Serum/urine emetine levels
		Low urine chloride concentration	EKG with abnormalities c/w ipecac toxicity
		Metabolic alkalosis with increased serum bicarbonate	
Pancreatitis	Spitting into urine sample (salivary amylase)	Hyperamylasuria with normal serum amylase	Obtain monitored sample
GI bleeding	Injection of blood from transfusions	Nasogastric tube shows blood despite normal endoscopy	Radiolabeling transfusions
	Ingestion of NSAIDs/salicylates	Single-stripe sign-on colonoscopy	
Obstruction	Ingestion of loperamide		HPLC of serum/stool for motil slowing agent
Renal			
Diuresis	Diuretic abuse	High urine potassium concentration	Detection of diuretics by chromatography
Bartter syndrome	Loop diuretic abuse	Hypokalemia, urine chloride low or variable	Renal biopsy for juxtaglomeru hyperplasia
	Self-induced vomiting		Screen urine for diuretics
Metabolic			
Hypervitaminosis A	Vitamin A abuse	Increased gamma-glutamyltransferase	Increased serum/tissue levels vitamin A, retinoic acid derivatives
		Increased bilirubin	
Hypokalemia	Laxative abuse	See above	
Hyperkalemia	Injection of urine into blood sample	Potassium level incompatible with life	Monitoring sample gathering yields normal result
Hypernatremia	Salt load	Fractional excretion of sodium high	
		Gastric aspirate salt concentration >200 mmol/L	

Urologic			
Hematuria	Adding blood from another wound/meat	Lack of red blood cell/hemoglobin casts	“3-tube” urinalysis (more bloo first tube if urethral trauma)
	Traumatizing urethra	Lack of distorted red blood cells	Physical examination
	Inserting foreign bodies into the bladder		Radiography
	Ingestion of anticoagulants		
	Addition of coloring to urine		
Proteinuria	Injection of egg protein in bladder	Large day-to-day variations in urine protein concentration	Electrophoresis of urine protein/pure albumin
		Serum albumin concentration remains in normal range	Large albumin band on UPEF without transferrin increase
		Lack of other signs of nephrotic syndrome	Antibody confirmation of huma albumin
Bacteriuria	Injecting bacteria into bladder or urine specimens		
Urinary calculi	Adding pepper grains to urine		Infrared spectrophotometry
	Inserting stones into bladder		Chemical analysis
	Submitting quartz, feldspar as samples		X-ray diffraction
			X-ray crystallography
Hematologic			
Anemia	Self-bloodletting	Decreased serum iron, ferritin, iron-binding capacity	Iron 59 elimination studies
		Decreased bone marrow iron concentration	Urine/stool iron levels
		No evidence of bleeding	Blood typing
Sickle cell crisis		Serum protein electrophoresis normal	Genetic testing
			Hemoglobin electrophoresis
Pancytopenia	Ingestion of chemotherapy		
Hemorrhage/purpura	Ingestion of anticoagulant (rodenticide/coumadin)	Prolonged prothrombin time (PT)	Warfarin/brodifacoum/heparin assay
	Heparin injection	Prolonged partial thromboplastin time (PTT) with normal PT	PTT measured every 2 hours under observation

			Reversal with protamine sulfa
			Normal reptilase time
			Failure of PTT to correct in 1: mixture with normal plasma
			Correction of PTT with hepari removal measures
	Ingestion of quinidine	Purpura with thrombocytopenia	Detection of quinidine-depenc antiplatelet antibodies
Endocrine			
Hypoglycemia	Injection of insulin	Serum insulin concentration >100 mU/L	Normal proinsulin levels (increased in insulinoma)
	Ingestion of oral hypoglycemic (sulfonylurea)		High insulin/low C-peptide lev
	Ingestion of tolbutamide		Insulin/C-peptide ratio >1.0
	Manipulation of testing strips		Extreme elevations in insulin levels
			Insulin antibodies (less reliabl with human recombinant insulin)
			Failure of glucagon to produc peptide
			Glyburide assay in serum/urin
			Tolbutamide assay in serum
Hyperglycemia	Insufficient administration of insulin		
Hyperthyroidism	Ingestion of thyroid hormone	Goiter/eye findings absent	Serum thyroglobulin low-norm or undetectable
		Increased thyroxine or liothyronine levels	Radioactive iodine uptake low
		Low TSH in thyroid storm	
Cushing syndrome	Injecting/ingesting glucocorticoid	Plasma/urinary cortisol increased	Detection of synthetic glucocorticoids in serum/uri
	Adding glucocorticoid to urine	Plasma ACTH low/undetectable	
		Normal corticosterone/high cortisol	Serum cortisol and corticoster levels
Pheochromocytoma	Injection of epinephrine, isoproterenol	Normal chromogranin A level	Epinephrine/norepinephrine levels in serum/urine
	Ingestion of stimulant	Lack of metabolites of epinephrine (metanephrines)	Metanephrine/normetanephrir levels in serum/urine
	Injection of epinephrine into urine sample	Lack of norepinephrine increase after	Provocative (glucagon)/suppression

		glucagon	(clonidine) tests
		Normal response to clonidine suppression test	44-metaiodobenzylguanidine nuclear scan
Hyperaldosteronism	Ingestion of black licorice/glycyrrhizic acid	Treatment-resistant hypokalemia	Serum glycyrrhizic acid level
		Metabolic alkalosis	
		Hypernatremia	
Cardiovascular			
Arrhythmia	Rearranging of EKG leads	Unusual pattern on EKG	Supervise placement of EKG leads
	Ingestion of digitalis, beta-blockers, calcium channel blockers		Serum levels of drugs
			Electrochemiluminescence assays detect BBs in urine
Hypertension	Valsalva maneuver	Office BPs normal, home BPs high	Observe BP checks
	Ingestion of stimulants		Serum/urine assay for pseudoephedrine
Infarction	Beating self with towel to raise creatine kinase	EKGs don't change	Repeat EKGs
		Enzymes do not rise appropriately	Repeat troponins
Dermatologic			
Cheilitis granulomatosa	Self-inoculation with polyvinylpyrrolidone (PVP)		Liver/lymph node biopsies sho PVP in histiocytes
Dermatitis artefacta	Self-mutilation	Distribution of lesions in reachable areas	Skin biopsy shows mechanica trauma, necrosis, blood
Erythematous lesion	Applying alcohol to lesion		
Nonhealing wounds	Injection of air/contaminants/foreign bodies	Heal when casted	Apply fluorescein to wound, examine hands/nails for fluorescence
		Resistant to treatment	
		Subcutaneous emphysema	
Obstetrical			
Ectopic pregnancy	Injection of hCG	Negative urine b-hCG	Negative ultrasound
		Widely varying b-hCG levels	
Vaginal discharge	Intravaginal insertion	Inconsistent pH	
		Vaginal wall shows abrasion/denies intercourse	

Neurologic			
Movement disorders	Ingestion of neuroleptics to induce parkinsonism	MRI/EEG/EMG inconsistent	Serum levels of neuroleptic
		Hoover sign/tremor entrainable/distractable	
		Prolactin elevated with antipsychotics	
Multiple sclerosis		Examination inconsistent	CSF protein electrophoresis
Pseudoseizures		History inconsistent	Video EEG
		Semiology inconsistent	
		Never observed seizing by others	
Pulmonary			
Asthma	Tape interfering with pulse oximeters	Intractable hypoxia	Lung biopsy
	Inhalation of irritant (talc)	Intractable status asthmaticus	Serum salicylate level
	Ingestion of allergens		
Cystic fibrosis	Manipulation of sweat test	Normal x-rays	Sweat potassium
		Normal examination/lack of clubbing	
Hemoptysis	Ingestion of anticoagulants	Normal bronchoscopy/lack of blood	
	Cough abrasion of lung		
	Self-induced trauma to respiratory tract		
Respiratory failure		Incongruous arterial blood gas	
		Marked hypocapnia	
Rheumatologic			
Arthritis	Insertion of metal fragments in joints		X-rays
			Synovial aspirate analysis
Lupus	Feigned history/borderline positive ANA	Repeat serum autoimmune tests negative	Repeat serum tests
		Normal complement in active flare	
Vasculitis	Injection of contaminants to create purpura		Tissue biopsy of lesions revea foreign material
Ophthalmologic			
Conjunctivitis	Instillation of foreign substance	Purulent discharge purposely left on skin and eyelashes	Corneal examination/conjunct biopsy

		Severity of discharge greater than severity of redness Severity of swelling less than severity of redness Mainly inferior conjunctival involvement Cornea uninvolved
Anisocoria	Instillation of atropine eye drops	

HPLC, high-performance liquid chromatography; UPEP, urine protein electrophoresis; ACTH, adrenocorticotropic hormone; ANA, antinuclear antibody.

Table 19–3 lists clues that should trigger suspicion of factitious disorder. Factitious disorder should be suspected whenever medical signs or symptoms defy conventional medical understanding or when they do not respond to usual medical treatment—for example, when a wound refuses to heal or when test results show a pattern inconsistent with usual disease presentation. Factitious disorder patients may also demonstrate an exceptional eagerness to undergo invasive or extensive testing. They may deny access to collateral sources of information, refuse to sign releases of information, and refuse to give contact information for family, friends, or former physicians. An extensive medical history, evidence of multiple surgeries, and reports of multiple drug allergies are also clues for the astute clinician. These patients often have jobs in the medical profession, have few visitors, and have been known to forecast the progression of their symptoms. They may supply falsified transcripts, test results, medical records, photos, personal documents, and physician reports. There are even cases of patients bringing in pictures and x-rays of pathologic conditions downloaded from the internet and purported to be their own.

Simply considering factitious disorder is the first important step toward diagnosis. Subsequently, information supporting the diagnosis should be collected. A review of past medical records is mandatory and may reveal inconsistencies. Collateral information from family, friends, or other health care providers may likewise show inconsistencies. Ward clerks may be the first to notice waxing and waning levels of distress depending on when the patient thinks clinicians are observing. The collection of laboratory specimens under close observation can minimize contamination or manipulation of samples. Laboratory values can provide diagnostic clues, as when microbiology reports reveal unusual pathogens or polymicrobial findings without apparent cause.

Table 19–3.
Clues That Should Trigger Suspicion of Factitious Disorder

1. The patient has sought treatment at various different hospitals or clinics
2. The patient is an inconsistent, selective, or misleading informant; they resist allowing the treatment team access to outside sources of information
3. The course of the illness is atypical and does not follow the natural history of the presumed disease
4. A remarkable number of tests, consultations, and medical and surgical treatments have been done to little or no avail
5. The magnitude of symptoms consistently exceeds objective pathology, or symptoms have proved to be exaggerated by the patient
6. Some findings are discovered to have been self-induced or at least worsened through self-manipulation
7. The patient might eagerly agree to or request invasive medical procedures or surgery
8. Physical evidence of a factitious cause might be discovered during the course of treatment
9. The patient predicts deteriorations, or there are exacerbations shortly before their scheduled discharge
10. A diagnosis of factitious disorder has been explicitly considered by at least one health care professional
11. The patient is noncompliant with diagnostic or treatment recommendations or is disruptive on the unit
12. Evidence from laboratory or other tests disputes information provided by the patient
13. The patient has a history of work in the health care field
14. The patient engages in gratuitous, self-aggrandizing lying
15. While seeking medical or surgical intervention, the patient opposes psychiatric assessment

Factitious psychological symptoms are more challenging to diagnose because of the lack of clear objective markers for psychiatric symptoms. Methods of confirmation applicable with factitious physical disorders, such as contradictory laboratory results or findings on room searches, are difficult to apply here. Nevertheless, certain features of the patient's presentation can alert the psychiatrist that the patient may be simulating illness. As with physical factitious disorders, the patient may present with unusual symptoms that fail to correspond to any recognizable diagnosis. For example, one patient reported no other psychotic symptoms except seeing the entire cast of a television show emerge from her closet. Other features include worsening of symptoms when the patient is aware of being observed, inconsistencies in the patient's story over time, and the patient's overeagerness to recount symptoms of the illness. Such patients are often suggestible and readily admit to additional symptoms on questioning. They may refuse to cooperate with obtaining collateral information, and untraceable prior health care providers are not unusual. On admission to the ward, patients may reveal familiarity with hospital routine while denying previous hospitalizations. They may exhibit dramatic and unusual reactions to medications. They may demonstrate attention-getting tactics by breaking ward rules. Visitors are usually few or absent. Symptoms may acutely worsen when discharge is imminent.

In contrast to patients with physical factitious disorders, who tend to avoid psychiatric care, patients with factitious psychological symptoms actively seek contact with the psychiatric system and readily acknowledge the presence of a psychiatric disorder, even if it may not be the one from which the patient actually suffers. Feigned bereavement and then psychosis appears to be the most common presenting symptoms. Ironically, one patient sought psychiatric admission for his Munchausen syndrome, claiming that he feigned physical illness when in fact, there was no evidence of this.

In a series of 20 patients who presented with factitious bereavement, 15 also exhibited a history of factitious physical symptoms. A majority of them met the criteria for other psychiatric disorders. They typically reported recent, dramatic, violent, and often multiple deaths of loved ones, whereas collateral information showed that, in fact, no deaths had occurred. Another series of 12 cases of factitious bereavement yielded similar findings of complaints of violent, dramatic deaths and referral from medical wards for supposed physical illness. Although the complaints of bereavement were factitious, these patients exhibited prominent symptoms of depression. A theory about factitious bereavement is that

patients are expressing the underlying truth of their emotional state, if not the factual truth. In contrast to the stigma associated with psychiatric illness, sympathy and care are usually offered to those in mourning. This may be why factitious bereavement is the most commonly seen factitious psychological disorder. One patient stated that she fabricated the complaint of bereavement to rationalize her depression.

In a series of 219 consecutive cases of psychosis, 9 (0.04%) met the criteria for factitious disorder. All nine patients demonstrated severe personality disorder. These patients were doing poorly when followed up 4 to 7 years later, with multiple hospitalizations and poor quality of life. Their outcome was no better than for schizophrenics concurrently followed. In another study of six patients who presented with feigned psychosis, five of the six were diagnosed with schizophrenia on follow-up 3 months to 10 years later. Consistent with psychodynamic theories about factitious disorders representing an attempt to feel mastery, feigning psychosis may have been an attempt to feel control over early psychotic symptoms.

In patients who complain of neuropsychiatric or cognitive symptoms, neuropsychological testing can be useful in establishing response bias, unusual patterns of deficits, poor levels of effort, or overreporting of symptoms in a manner that suggests a motivation to appear ill. As in the assessment of malingering, these tests may come in the form of embedded tests or stand-alone symptom validity tests and have been extensively reviewed and approved for this use by the American Academy of Clinical Neuropsychologists. Examples of embedded tests include subscales and indices within the Personality Assessment Inventory (PAI); the Meyers index, which uses seven subscales of the Minnesota Multiphasic Personality Inventory (MMPI); the Fake Bad Scale, drawn from 43 questions on the MMPI that correlate with simulation; reliable digit span tests of memory. Stand-alone tests for simulating symptoms include the Structured Inventory of Malingered Symptomatology (SIMS), the Structured Interview of Reported Symptoms (SIRS), and the Miller Forensic Assessment of Symptoms Test (M-FAST), and the Test of Memory Malingering (TOMM). Important in the use of neuropsychological testing to supplement the diagnosis of factitious disorder is an understanding of its limitations: While a set of given tests can detect a pattern suggestive of simulation, it cannot ascertain motivation or etiology of the pattern. In other words, neuropsychological testing cannot make a diagnosis of factitious disorder—assessment by the clinician is required.

Conclusive confirmation of factitious disorder can be difficult. Covert surveillance, hidden video cameras, or searching the patient's belongings for syringes or illness-inducing substances can be employed after considering the patient's right to privacy and the bounds of the patient–doctor relationship. Internet searches and scans of social media may uncover pictures, text, news articles, or legal records that contradict the patient's history or presentation. Legal counsel is advisable, and in some cases, court orders should be obtained. Consultation from a bioethics team can help weigh the benefits and risks of violations of privacy versus morbidity from factitious disorder. This phase of acquiring information to confirm a diagnosis is often a time of conflict for staff, who may have split opinions about the patient and about the means being employed to confirm the diagnosis. Regular interdisciplinary meetings are helpful.

However, the obtaining of this collateral and confirmatory information to aid in the diagnosis of a factitious disorder brings up several ethical dilemmas:

1. Privacy: Patients have a right to privacy concerning their personal health information and activities, and providers are bound by biomedical ethical principles such as nonmaleficence (doing no harm) and patient autonomy. On the other hand, providers must also consider ethical principles of beneficence (doing what is good for the patient) and justice (doing what is right for society), and patients are expected to participate in their health care in good faith. When the risk of harm from suspected self-induced behavior becomes great enough, decisions to override patient preferences and seek information from covert searches or videotaping may be made, typically in consultation with legal counsel.
2. Confidentiality: Patients with factitious disorder will frequently refuse to release medical records to their providers, hampering the ability to diagnose and manage factitious behaviors. The U.S. Health Insurance Portability and Accountability Act (HIPAA) allows health care providers to release medical records to one another for treatment purposes without an individual patient's consent, as long as

both health care providers had a relationship with the patient and the records pertain to that relationship. Unauthorized disclosing of information to third parties that are not covered entities under the HIPAA law will need legal vetting to ensure compliance. Searching pharmacy databases and electronic medical records exchanges outside of a health care system represent a powerful modern tool to identify evidence of factitious disorder, and should also be informed by consultation with legal counsel.

3. Stigma: Careful workup for genuine organic causes, judicious use of indicated testing, and application of evidence-based treatment must be performed even in circumstances where a factitious disorder is heavily suspected. Devising tests for factitious illness and obtaining a resistant patient's consent for such tests requires a skillful approach that is nonconfrontational but truthful. There is no role for deceptiveness on the part of the provider in the diagnosis of factitious disorder, such as misrepresenting the reasons for tests or giving placebos disguised as active treatment. The intense negative countertransference on the part of health care staff deceived by patients with factitious disorder is formidable and can result in distortions of usual care, violations of protocols and regulations, and even malpractice. If a patient becomes pejoratively labeled as a "faker" or "somatizer," it is very possible that a condition that has a genuine organic basis may go undetected or untreated.

Munchausen Syndrome

Diagnosis of Munchausen syndrome is often simpler than in other cases of factitious disorder because of the tendency for dramatic, exaggerated presentations. Treatment and management, however, are usually far more challenging. These patients often are new to a particular area, being prone to peregrination. Munchausen syndrome patients may appear eerily comfortable in hospital settings, immediately talking to nurses, physicians, and medical staff as peers. Some show up for hospital admission wearing surgical scrubs. They demonstrate *pseudologia fantastica,* a specific syndrome of autobiographical lying with four features as defined by King and Ford: (1) the stories are not entirely improbable and are built upon a basis of truth; (2) the stories are enduring; (3) the stories are not told purely for personal gain, and have a self-aggrandizing quality; and (4) they are not delusions, in that the patient can admit to falsehoods when confronted with conflicting facts. Munchausen patients often manifest hostility when their needs are not met, or they are confronted by staff regarding suspicions of deception and will then leave the hospital abruptly. They repeatedly present under different names to different hospitals, employing a repertoire of symptoms and presentations to gain admission and treatment. The cost of this disorder can be tremendous, as illustrated by the British report of a "million-dollar man" who, over a 13-year period, spent 1,300 days in psychiatric units, 556 days in prison, and 354 days in medical care for 261 hospital admissions. All diagnostic considerations that apply to factitious disorder also apply here. Because the risk of morbidity and mortality may be higher in these patients, it may be prudent to involve bioethics consultations and hospital legal counsel early.

Factitious Disorder Imposed on Another

Previously called *Munchausen syndrome by proxy,* the essential feature of this disorder is the intentional feigning or production of physical or psychological symptoms in another individual who is under the perpetrator's care. The perpetrator's motive is to assume the sick role by proxy. Mothers of preverbal infants are the most common perpetrators, although fathers, other family members, babysitters, and even medical professionals also have been implicated. Victims can also be spouses, older adult parents, hospital patients, or anyone under the care of a perpetrator. In all cases, this behavior is considered criminal abuse and is mandated to be reported to government authorities.

In an unusual case of adult factitious disorder imposed on another, a 34-year-old man drugged his wife with sleeping pills in her coffee, then injected gasoline into her skin to cause lesions from which she eventually died. Subsequently, he hired a female babysitter to care for his children and repeated his actions with her. In each case, he assumed the role of the concerned caretaker in the center of medical drama. He was finally arrested for murder, and in prison, he sought to work in the infirmary.

Factitious disorder imposed on another has also been cited as the etiology for epidemics of death at hospitals and nursing homes. Perpetrators have largely been nurses and aides who produced illness through various means, such as injection of insulin, lidocaine, digoxin, or other substances. In Great

Britain in 1993, pediatric nurse Beverly Allitt was convicted of killing four children under her care and was given 13 life sentences. Florida registered nurse Bobbie Sue Terrell was accused of a rash of murders at a nursing home where she worked, and in 1988, she plead guilty to reduced charges of second-degree murder. Apparently, after learning of her infertility, she began demonstrating self-injurious behavior and factitious disorder. Kristen Gilbert, a nurse at the Veterans Affairs Medical Center in Northampton, Massachusetts, from 1989 to 1996, was found guilty of having induced cardiac arrest in at least four patients by injecting epinephrine into their intravenous fluids and was suspected of potentially having sickened or killed hundreds of patients. Known as the “Angel of Death” because of the anecdotal increase in deaths during the shifts she worked, Gilbert was reported to have a history of pathologic lying in childhood, including faking a suicide note. During the investigation into the deaths, Gilbert called in a bomb threat to the hospital.

Most reported cases involve mothers and their children. The challenges of recognizing this condition are illustrated by unfortunate examples. Nancy Reagan presented a Mother of the Year award in 1988 to foster mother Yvonne Eldridge for her valorous care of ill children. Eldridge was later recognized as a factitious disorder imposed on another perpetrator and was convicted of child abuse in 1996. Hillary Rodham Clinton publicly recognized Kathy Bush’s dedication to her daughter. Bush was later recognized as a perpetrator of factitious disorder imposed on another and was sent to prison in 2002 for child abuse that had resulted in 200 hospitalizations, 40 surgeries, and 15 bouts of sepsis for her daughter.

Sudden infant death syndrome (SIDS) was initially thought to have a strong genetic component because it often occurred in siblings. Today, when siblings die of SIDS, infanticide is suspected. Indeed, a study of 81 children who died of SIDS or natural causes and who later were found to have died at the hands of their parents showed that half of the perpetrating parents had factitious disorder or another somatic symptom disorder. The comorbidity of factitious disorder and factitious disorder by proxy is estimated to be from 10% to 30%. When one child is victimized, there is a high likelihood a sibling will also be victimized, usually serially.

Table 19–4 lists clues that should trigger suspicion of factitious disorder imposed on another.

The variety of medical presentations of factitious disorder imposed on another is impressive. In the first comprehensive review of the disorder, published in 1987, Rosenberg described 68 induced or fabricated signs or symptoms. The most common presentations among 117 cases were bleeding (44%), seizures (42%), central nervous system depression (19%), apnea (15%), diarrhea (11%), vomiting (10%), fever (10%), and rash (9%). Many children had more than one presentation. Twenty-five percent of cases involved simulation of illness, 50% involved production of illness, and in the remaining 25%, simulation and illness production were concurrent.

Table 19–4.
Clues Triggering Suspicion for Factitious Disorder Imposed on Self

1. Diagnosis does not match the objective findings
2. Signs or symptoms are bizarre
3. Caregiver or suspected offender does not express relief or pleasure when told that dependent is improving or that dependent does not have a particular illness
4. Inconsistent histories of symptoms from different observers
5. Caregiver insists on invasive or painful procedures or hospitalizations
6. Caregiver's behavior does not match expressed distress or report of symptoms (e.g., unusually calm)
7. Signs and symptoms begin only in the presence of one caregiver
8. Sibling or another dependent has or had an unusual or unexplained illness or death
9. Sensitivity to multiple environmental substances or medicines
10. Failure of the dependent's illness to respond to its normal treatments or unusual intolerance to those treatments
11. Caregiver publicly solicits sympathy or donations or benefits because of the dependent's rare illness
12. Extensive unusual illness history in the caregiver or caregiver's family; caregiver's history of somatization disorders
13. Caregiver seeks other medical opinions when told the dependent does not have illness
14. Caregiver perseverates about borderline abnormal results of no clinical relevance despite repeated reassurance, or refutes the validity of normal results

Perpetrating caregivers usually appear to be concerned and interested in their children's care. They tend to be exemplary in their interactions with medical staff, enlisting support and sympathy, often crossing professional boundaries by eating meals with staff or helping nurses with duties. They may demonstrate unusual willingness or even excitement at the prospect of invasive procedures for their children. However, analyses of reported cases indicate that factitious behavior continued during hospitalization in 54.4% of cases and that the death of the victim was caused in 7.4% of cases, indicating the potentially fatal consequences if the perpetrator is not stopped in their abuse.

Factitious disorder imposed on another should not be a diagnosis of exclusion, but confirmatory evidence should be actively pursued with the goal of lessening the risk to the victim and assuring the victim's safety. The recommended steps for diagnosing a suspected factitious disorder imposed on another by the American Academy of Pediatrics are outlined in Table 19–5.

The gold standard for confirming factitious disorder imposed on another is covert video surveillance that may record a perpetrator causing harm. Examples of documented harms include caregivers suffocating children, causing fractures, and administering poisons, or injecting harmful substances into intravenous lines. Such videos have also shown mothers appearing concerned in the presence of staff but behaving indifferently toward their children when unaware of being watched.

Despite the benefits of objective documentation of abuse, the use of covert video surveillance is not without risk: (1) damage may be done to the child prior to health care intervention; (2) it may interrupt a potential therapeutic alliance; (3) some consider covert taping to violate the parents' right to privacy or represent entrapment; (4) video footage can be difficult to interpret and may result in false accusations; and (5) covert taping can be costly and require constant real-time monitoring to prevent harm. Covert video should only be undertaken after consultation with legal counsel because a court order may be legally required. A bioethics consultation can help weigh the potential benefits to the child versus compromises of privacy for the parent. An institutional protocol should be in place regarding covert taping, including plans for monitoring and interventions, if the child is found to be at risk.

Table 19–5.
Diagnostic Principles and Tools for Factitious Disorder Imposed on Another

1. Ask: Are the history, signs, and symptoms of disease credible?
2. Ask: Is the child receiving unnecessary and harmful or potentially harmful medical care?
3. Ask: If so, who is instigating the evaluations and treatment?
4. Multidisciplinary evaluation involving medical, psychosocial, child protective, and legal professionals
5. Consultation with a specialist in child abuse pediatrics/elder abuse
6. Complete review of the medical record
7. Construction of a chronologic summary of medical contacts with attention to:
   - use of multiple medical facilities
   - excessive or inappropriate pattern of utilization
   - pattern of missed appointments and discharge against medical advice
   - pattern of misrepresentation of opinions of physicians about the child's medical problems
8. Attribution of all medical information to its source (e.g., Did the nurse observe apnea or did the caretaker inform the nurse of it?)
9. Creation of a table with the following elements for each health contact: Name; date; location; reason for contact; reported symptoms as stated by caregiver; objective signs documented by physician; conclusions/diagnoses made; treatment provided; efficacy of treatment
10. Ask: Does the history provided by the caregiver match the history in the medical record and/or the diagnosis made by the physician?
11. Contact involved physicians and solicit concerns about possible fabrication of illness
12. Have all involved staff meet and develop a consensus management plan
13. Interview the child separately from the caregiver, if verbal, for their recollection of any symptoms, including when and where they occurred
14. Take a careful social and family history, including for any unusual or frequent illnesses in the extended family and siblings
15. Perform diagnostic testing for fabricated illness alongside tests for organic etiologies
16. Separate the child from the suspected caregiver and observe for improvement
17. Employ covert video surveillance while the child is hospitalized, with legal and ethical consultation

Other means of confirming factitious disorder imposed on another include searching a mother's belongings for illness-inducing agents, reviewing collateral information and past medical records for inconsistencies, gathering information on siblings, recording temporal associations between parental visits and a child's signs and symptoms, observing the child's well-being when they are removed from the parent's care, and analyzing specimens taken in the presence of the parent compared to those taken in the parent's absence.

The international literature on factitious disorder imposed on another indicates that signs and symptoms appear to be consistent across the world. Perpetrators are usually mothers, and serial abuse of children is common. This does not appear to be a phenomenon exclusive to medicalized societies.

Pathology and Laboratory Reports

No laboratory or pathology tests are diagnostic of factitious disorders, although they may help to confirm the diagnosis by demonstrating deception. In many cases, a laboratory finding may be the only objective sign that factitious behavior is taking place.

See Table 19–2 for laboratory tests that can be helpful in determining that a given sign or symptom has been artificially induced.

DIFFERENTIAL DIAGNOSIS

The lynchpin of diagnosis of factitious disorder imposed on self or another is the confirmation of deceptive behavior perpetrated by the patient in the service of simulating or exacerbating a disease.

An underlying physical or psychiatric disorder is the main consideration in the differential diagnosis of suspected factitious disorder. Unusual, inconsistent, or poorly characterized symptoms must still be

explored for nonfactitious etiologies according to best practices, evidence-based guidelines, and clinical indications.

A 46-year-old woman with type 2 diabetes manifested multiple episodes of hypoglycemia despite several inpatient hospitalizations to optimize her diet and insulin regimen. She was suspected of factitious disorder until it was discovered she had developed antibodies to insulin.

Underlying or prodromal psychiatric/neurologic illnesses may initially be mistaken for psychological factitious disorders. Several case reports document the development of full-blown psychotic disorder following the emergence of factitious illness behavior. Cognitive disorders due to cerebral lesions, neurodegenerative disorders, and delirium may lead to self-induced illness and deceptive behavior. In cases of frontotemporal dementia, the deceptions are usually unsophisticated, and the attempts to obfuscate inept. Neuropsychological and functional testing may help to delineate the cognitive deficits in such cases.

Even when deception is present, genuine comorbid illness is more often the rule than the exception in factitious disorders. Factitious disorder patients frequently aggravate an actual physical illness. Many patients who feign pseudoseizures also have true seizures. Many who manipulate blood sugars to produce symptoms are also diabetic. Munchausen syndrome patients may become addicted to narcotics or learn to seek disability payments and thereby also demonstrate substance abuse and malingering. One area of diagnostic differentiation concerns psychiatric disorders, which can present similarly to factitious disorder with unusual or inconsistent physical or psychological symptoms and may even be comorbid when deceptive behavior is positively confirmed.

In *somatic symptom disorder,* there are one or more physical symptoms that cause disproportionate distress manifesting in thoughts, feelings, or behaviors. If the physical symptom does not have a clear etiology or does not conform to typical clinical phenomenology, suspicions may be raised for factitious behaviors, but positive evidence for deceptiveness will be lacking. In *illness anxiety disorder* (formerly hypochondriasis), normal physiologic sensations are perceived as harbingers of dread disease despite negative tests and reassurance to the contrary. It is important to remember that a presentation that does not conform to an identifiable medical or mental disorder, or the diagnosis of factitious disorder, does not necessarily rule out the presence of a true *medical condition not associated with intentional symptom falsification.*

If a symptom is neurologic and is not consistent with neurologic pathophysiology, then *functional neurologic symptom disorder* (FND) should be diagnosed.

A 35-year-old man presented to emergency care with rapidly progressive lower extremity flaccid paralysis following a mild head injury. Medical workup, including electromyography, could not discern any neurologic disorder. There was no evidence of deception or material gain in this patient, but when a random loud noise startled him, the patient leaped off the examination table quite nimbly and was diagnosed with FND.

The use of video electroencephalographic monitoring allows for the rapid capturing and diagnosis of nonresponsive episodes mimicking absence seizures, complex partial seizures, or syncope.

Dissociative disorders such as *dissociative amnesia* or *dissociative identity disorder* may involve episodes of inability to recall important personal information too extensive to be due to ordinary forgetfulness. These episodes can resemble psychological presentations of factitious disorders in which amnesia or cognitive impairment features prominently. However, they do not involve deceptive behaviors.

The second area of diagnostic differentiation concerns self-inflicted harm. A patient with *borderline personality disorder* may engage in self-destructive, physically injurious, or psychologically damaging behavior resulting in illness (such as overdosing on acetaminophen or cutting one's arm) for the purposes of stress reduction, pain relief, or conveying distress. If the induction of injury is associated with deception, then factitious disorder may be diagnosed. However, patients who have attempted

suicide and caused physical harm may lie about their suicidal ideation, intent, plan, or the aftermath of the attempt. This may be in the service of avoiding detection or hospitalization and carrying out another attempt successfully. This is not factitious disorder nor malingering *per se,* but the expectable behavior of a person bent on suicide and must be screened for with a high level of suspicion.

If a patient's habitual behaviors contribute to worsening health, such as overeating leading to type 2 diabetes, work-related stress exacerbating hypertension, or cigarette smoking contributing to emphysema, and there is no overt deception in the patient's presentation for care, then the appropriate diagnosis is *psychological factors affecting other medical conditions.* This is a new somatic symptom disorder in DSM-5 and is meant to capture psychological states which complicate the course of a physical disease, interfere with its treatment, and represent a well-established health risk. When assessing whether deception is involved, it is important to remember that patients commonly minimize reporting of behaviors that they expect health care providers to criticize or that are not socially, culturally, or legally sanctioned. This should not automatically trigger a diagnosis of factitious disorder without a full exploration of the reasons for minimization. Likewise, ostensibly deceptive behavior may be a result of a lack of cultural understanding on the part of the health care provider, a language barrier between provider and patient, or due to violence or the threat of violence in the patient's life. As Bass and others have recommended, diagnosing a patient's deceptive behavior as a disorder is less important than understanding the underpinnings of the behavior.

A 48-year-old woman with intractable hypertensive urgency endorsed taking her medications faithfully to her primary care physician. However, with intensive case management involvement, it became clear she did not take her medications as prescribed. The team discovered that she was being forced into prostitution by her husband under threat of death, something that she never volunteered to her providers.

Once confirmed, if deceptive behavior is performed to obtain a material gain such as to procure disability payments, narcotics, or an excuse from work, *malingering* is the appropriate label. DSM-5 categorizes malingering as a "condition that may be a focus of clinical attention," defining it as the production of grossly exaggerated or feigned symptoms motivated by an external incentive. DSM-5 lists four conditions under which malingering should be strongly suspected, including medicolegal context, a discrepancy between self-report and medical findings, poor patient cooperation, and antisocial personality disorder; however, these are considered neither sensitive nor specific. Ganser syndrome, also known as "prison psychosis," presents a related challenge. It was first described in 1897, consisting of twilight states, memory disturbances, and *vorbeireden,* a German term loosely translated as "talking at cross purposes." Ganser syndrome is also known as the "syndrome of approximate answers," in which answers to simple questions are erroneous in a manner that implies knowledge of the correct answer. An example would be answering "3" to the question of "How many legs does a horse have?" Ganser syndrome may be due to dissociation, malingering, or organic causes.

In actuality, whether a behavior arises from external or internal origins can be difficult to discern. A clinician may be unaware of a patient's upcoming court date and thus potential gain from being sick. For these reasons, Feldman and coworkers argued that these disorders fall along a continuum: "there is little to be gained, and much to be lost, by the use of the current practice of viewing the somatoform disorders, factitious disorder, and malingering as discrete and distinct clinical entities." Conscious versus unconscious production of symptoms can be especially difficult to discern for psychological signs and symptoms, as there are few objective tests of mental status. It is for this reason that the DSM-5 no longer requires clinicians to determine that patients are explicitly aware of their deceptive behavior, only that there is deception, and not for evident secondary gain.

Mr. J, a 60-year-old man, presented to his local emergency department complaining of nausea, vomiting, and dizziness. He was admitted for possible bleeding peptic ulcer and was also found to have a skin rash and depression. His rash was diagnosed as scabies, but Mr. J refused to shower or change out of his dirty garments. He then requested to be discharged. Psychiatric consultation was requested for evaluation of depression.

Mr. J stated that he was grieving the deaths of his younger daughter and wife in a car accident 2 and a half years ago and that his life had been disintegrating since then. He was staying at friends' houses after leaving his home with his older daughter, as he "couldn't stand being there" any longer because of the grief. He had not sought treatment or professional help, he said, because "I don't want to bother my family or doctors with anything." However, he did endorse having "snapped" and having two "breakdowns" during which he could not remember where he was or who he was, and was hospitalized at a psychiatric unit in another state, but could not recall any details of this incident. He refused to give any contact information for family or friends, citing concerns about bothering them too much and refused treatment for depression.

His social history included employment as a chemical engineer in his own laboratory for the nearby military base, a PhD in parapsychology and forensic psychology, training as a paramedic, a father who was a fighter pilot, and a mother who was a physician. He wistfully recalled his family being stationed overseas. He related that his daughters both held advanced degrees, and his younger daughter was on her way to start a position at a prestigious university hospital when she was killed in the accident.

Inconsistencies between his presentation and his history prompted a search for records in the wider hospital system. Records filed under the same name and date of birth at another facility detailed a significantly different history. When he was approached with these disparate facts, he angrily denied them. He was discharged the next day after it was determined he was not a danger to himself or others.

Two weeks later, Mr. J presented with worsening altered mental status, shortness of breath, abdominal pain, nausea, cough, dysphagia, and vertigo. He was found to have pneumonia, a posterior inferior cerebellar artery (PICA) stroke, a pulmonary embolus, bilateral lower extremity venous thromboses, and esophagitis causing gastrointestinal bleeding. He was treated with antibiotics, anticoagulation, inferior vena cava filter placement, and gastric tube placement. Magnetic resonance brain imaging revealed an old left temporal lobe infarct with encephalomalacia and gliosis, in addition to the PICA infarct.

Psychiatric evaluation after Mr. J's stroke revealed significantly impaired cognition (12/25 on the Montreal Cognitive Assessment) with deficits in short-term memory, attention, and executive function. He could not recall what he was being told by hospital staff about his condition and needed frequent repetition of information. He then revealed that he could not recall any remote memories about his early life, such as schooling, family possessions, or even where he was born. He continued to refuse to speak with family or friends. However, hospital staff had to contact his daughter so that someone could serve as a surrogate decision-maker.

Over several weeks, Mr. J became more attentive and his short-term memory improved. He revealed that, in fact, his wife and daughter had not died in a car accident 2 years ago, that this was a story lifted from the life of his friend "Bill." He could offer no explanation for why he had given this as his life history. He also recounted that he was interested in parapsychology but denied having an advanced degree or practicing in this field. He seemed surprised by the details of his life that were obtained from outside hospital records. Interestingly, he complained that the hospital staff was "keeping secrets" from him. He was transferred to the outside hospital, familiar with his history, for longer-term care.

Three months later, Mr. J presented to the local hospital with a supratherapeutic level of anticoagulation and pain in his lower extremities. It was discovered that when Mr. J had been transferred to the subacute facility 3 months prior, the facility received a telephone call from a hospital in another state, stating that Mr. J was in fact not Mr. J, because the "real" Mr. J was admitted at their facility—family positively confirmed that their relative was the person at the other hospital.

The patient who had suffered scabies, cerebellar stroke, and pulmonary emboli was not the person he said he was, nor was he the person the outside hospital thought he was—he was Mr. R.

When Mr. R was interviewed about his identity, he could not recall any episodic history of his life prior to his hospitalizations, nor could he recall his parents' names, wife's name, whether he had children, where he hailed from, or his employment history. He did not recall his previous deceptive stories. When presented with pictures of famous persons and allusions to famous world events, he denied knowing anyone named Hitler, Marilyn Monroe, or Ronald Reagan. He stated that he recognized Jesus from having read the Bible at the outside hospital and also knew of Martin Luther of the Reformation from reading. His short-term memory, attention, praxis, and executive function seemed very intact. He was able to recall numerous accurate details about his recent hospitalizations. He refused to give details of where he had been living and who had been helping him, always out of a concern to "not bother them."

Mr. R was hospitalized on a psychiatric ward out of concern that his amnesia, whether factitious or organic, was interfering with his ability to manage his medical issues, in particular the anticoagulation. He refused to engage in formal cognitive testing but accepted treatment for depression and aftercare planning and was discharged with appropriate appointments and services in place.

After discharge, Mr. R regularly attended an anticoagulation clinic, physical therapy, wound clinic, and psychiatric appointments. During his mental health appointments, he endorsed that parts of his remote memory were coming back, including how his family lived overseas, his father served in the military, and his mother was a physician. However, he could not call to mind any memory of his family's appearances or names. He later claimed that at his living situation (a group home, but what he termed "someone's garage"), he fixed computers that others brought to him, that others said he was "trained as a paramedic" and that he was "head of an Information Technology department."

DISCUSSION

Mr. R was finally diagnosed with *factitious disorder imposed on self* based on his deceptive behavior (giving a false name and history) in the service of simulating disease (feigned grief and amnesia). Mr. R admitted that he had acted deceptively, making this a conscious, willful act, although he never articulated his motivation. His life history contained fantastical elements, and he tended toward embellishment and confabulation (*pseudologia fantastica*). No clear material gain was ever established.

This case serves as a cautionary tale against assuming that deceptive behavior implies a lack of organic pathology. Mr. R had an ischemic stroke and evidence of prior strokes causing organic cognitive and memory impairment, but he also gave a false identity.

The available information makes it impossible to determine whether Mr. R's previous amnestic episodes during times of stress were real; one may rightly wonder what effect his old temporal lobe stroke had on his memory and whether it played any role in his deceptive behavior.

Factitious Disorder Imposed on Another

When considering the differential diagnosis of this disorder, in addition to the considerations for factitious disorder imposed on self, clinicians should keep in mind the wide range of behavior among normal parents who seek medical care for their children. Again, according to Meadow, "exaggeration and mild deception are part of everyday behavior." The possibility of factitious disorder and malingering by children themselves should be considered, especially in older children and teenagers. Approximately 14% of victims of factitious disorder imposed on another were found to be in collusion with the perpetrator. Other *by-proxy* possibilities should also be considered because children may manifest psychopathologies of their parents. For example, in hypochondriasis by proxy, a hypochondriac mother preoccupied with her child's health may repetitively seek pediatric care leading to unnecessary procedures and iatrogenic illness for the child. In anorexia nervosa by proxy, an anorexic mother may restrict her child's food due to fears of excessive weight in her child. A mother with malingering by proxy

may put her child through multiple evaluations to maintain disability or welfare payments. A paranoid father with a history of psychosis feared that his son was being poisoned by breast milk and insisted that the emergency room check his son's hair for mercury. It is important to remember that putting a child through unnecessary tests or treatments which can cause harm is medical child abuse, regardless of the perpetrator's motives.

Other *by-proxy* syndromes described in the literature include *masquerade syndrome* (in which illness fabrication results in the child's increasing dependency on the mother), *mothering to death* (in which the child is confined to a sick role as if the child were ill while avoiding physicians and agencies), *extreme illness exaggeration* (in which a parent exaggerates their child's symptoms in an effort to increase a pediatrician's attention to the child), and *achievement by proxy* (as in youth sports). *Gaslighting* is a nonmedical term used to indicate when a person induces another to doubt their own sanity through psychological manipulation, even to the point of being hospitalized. It may be a form of malingering by proxy when external incentives are present.

COURSE AND PROGNOSIS

Factitious Disorder Imposed on Self

The course of factitious disorder is difficult to determine, as many patients drop out of treatment once a factitious disorder has been raised. The wide spectrum of this disorder should be kept in mind when considering course and prognosis. At one end of the spectrum, factitious illness behavior could be considered within the normal range, as when a patient magnifies his symptoms to seek reassurance from a physician or when a patient lies about completing her antibiotic course for cellulitis in order to maintain positive regard. Further along the spectrum, factitious illness behavior becomes a maladaptive coping mechanism but not a chronic pattern of deception. These less pernicious cases may respond to a clinician's sensitive inquiry into the precipitants to factitious behavior and coaching the patient to find more adaptive solutions. Concurrent mood, anxiety, or substance abuse disorders bode a better prognosis; comorbid personality disorders, especially antisocial personality disorder, bode a poorer prognosis. According to some experts, many factitious disorders remit around the age of 40 years, corresponding to the age of remission for many with borderline personality disorder. Unfortunately, Munchausen syndrome tends to have an unremitting, refractory course and is associated with substantial morbidity and mortality. After efforts to engage a patient in treatment fail, management should be directed toward harm reduction rather than cure.

In Sutherland and Rodin's series of ten patients diagnosed on a psychiatric consultation service with factitious disorder, only one out of nine patients confronted with the diagnoses admitted to factitious behavior, and only one engaged in psychiatric treatment. In Krahn's series, only one in six of confronted patients admitted to factitious behavior, and only 12% agreed to psychiatric treatment. These studies would seem to support the contention that confrontation is unlikely to helpfully engage a patient. However, in Reich and Gottfried's series of factitious disorder patients, of 33 confronted with the diagnosis, the majority improved, including four chronic cases (only 13 ever acknowledged their role). A "supportive confrontation" conceptualization may help to frame the interaction as an attempt to ally with the patient's and provider's common goals when the willingness of the patient to engage in rehabilitation is perceived to be favorable. In more resistant patients, nonconfrontational approaches may permit the patient to save face while maintaining the therapeutic relationship. At times, confrontation is unavoidable, as in cases when "therapeutic discharge" is required to prevent further harm and mischief from occurring when a patient is refusing to leave. It should be remembered that this population is at high risk of self-injurious behavior when attempting to confront factitious behavior, and plans for preventing self-harm should be in place prior to the confrontation.

The course of factitious disorder is usually intermittent: Isolated events and frequently recurring/unremitting episodes are less common. Onset is usually in early adulthood, often after hospitalization for a medical condition or a mental disorder. In individuals with recurrent episodes of falsification or signs and symptoms of illness and/or induction of injury, this pattern of successive deceptive interactions with medical personnel may become lifelong.

Once clinicians recognize a factitious physical disorder, they should be alert to the possibility of patient-initiated litigation to defend the “realness” of their self-induced illness. Litigation often fulfills the same psychodynamic motivations that led to the original factitious illness behavior. Actions brought against clinicians may provide an additional outlet for the patient’s anger, as well as provide an increased level of care or attention. Litigation may be initiated by the patient’s family, who may not understand that the patient’s illness is self-inflicted. Litigation may be a marker for increased risk of death. In a study of 20 factitious disorder patients with concurrent lawsuits, 4 cases ended in death.

In general, psychological presentations of factitious disorder imposed on self have a poor prognosis comparable to that of Munchausen syndrome. A 1982 study of patients with factitious psychosis showed that 4 to 7 years later, these patients functioned at a level comparable to that of schizophrenic patients in the same study. Other studies found that feigned psychosis is commonly a precursor to actual psychosis, leading Hays to comment, “Acting crazy may bode more ill than being crazy.”

Mr. K is a 43-year-old male who has presented repeatedly since age 26 to regional tertiary care hospitals across two states. His initial presentations in emergency departments consisted of repeated rattlesnake, cobra, and viper bites, which he said occurred because of working as a volunteer “snake wrangler.” His work reportedly entailed catching snakes, raising them, feeding them, and giving them medications, but he also reported bites from picking up snakes he found by the road, sometimes while inebriated.

His past psychiatric history was noteworthy for several hospitalizations as a child for suicidal ideation and behavior, which Mr. K attributed to “wanting to get out of the house while [his mother] was menopausal.” He had been given a diagnosis of conduct disorder. Even as a teenager, he was noted to frequently sustain snake bites and to not comply with recommended treatment.

FIRST STAGE

Since his early 30s, Mr. K presented in excess of 30 times for the treatment of snakebite envenomation. He received experimental antibody-fragment antivenin preparations without ill effects so frequently (>150 vials) that his treatment was reported as robust evidence of the safety of the preparation. Complications of his snake bites included anaphylaxis, often requiring intensive care, compartment syndromes in both his arms treated with fasciotomies, and finger and toe amputations. Mr. K denied any intent to be bitten, saying these bites came as a result of his normal snake handling. Yet, he expressed no remorse or desire to change his behaviors. He stated during one admission that snake handling was his only source of income, although he also described performing construction work at other times. Over the course of his hospitalizations for anaphylactic symptoms of snakebite, he began to decline antivenin, withhold history, and request escalating amounts of pain medication. During one admission, he assaulted a health care worker because he did not feel he had been given enough analgesic.

SECOND STAGE

At age 37, he presented to the emergency department with chandelier lightbulbs in his rectum, stating that they were inserted by assailants in the city park. These were removed fully intact, but he presented again 2 weeks later, saying glass shards were retained in his rectum, adamantly denying he had inserted them himself. Proctoscopy revealed glass shards that could not be removed, and colectomy with colostomy was performed.

At age 39, he presented with accidental ethylene glycol ingestion, which he said he mistook for his energy drink while working on an automobile engine with a friend. The next year, he presented having ingested 13 shards of glass and two razor blades, which he told an admitting physician were shoved down his throat by the same assailants who had inserted the lightbulbs in his rectum. He later told another physician that he had been working construction, holding screws in his mouth, and had accidentally ingested them. An x-ray confirmed the presence of several bolts and screws in his stomach.

At age 41, he presented having swallowed fishhooks and screws and inserted a lightbulb into his rectum. This was the first time he admitted that this was self-inflicted. He endorsed depression and anxiety as factors driving him to perform these acts.

THIRD STAGE

In his 42nd year, he had 15 admissions at a local tertiary hospital for intentionally ingesting nail clippers, bottle tops, nails, screws, scissors, tent stakes, and knives and inserting lightbulbs into his rectum. He presented with snake bites, but less frequently than earlier in his history. He admitted that he had thoughts of intentionally getting bitten in order to kill himself. He occasionally complained of auditory command hallucinations telling him to ingest objects, such as a letter opener, but this was infrequent. On most admissions, he was able to say that negative feelings such as depression, loneliness, stress, or anxiety triggered the impulse to harm himself.

During stages two and three, psychiatric consultations were obtained every admission. The consultants attempted to assess without confrontation, to address reinforcing factors such as pain and sedative medications, to identify and address psychiatric symptoms that might prompt Mr. K’s behaviors, and to build his coping skills. Of note, medication trials including fluoxetine, buspirone,

lorazepam, aripiprazole, olanzapine, and trazodone were uniformly ineffective, or Mr. K did not take them. He continually asked for benzodiazepines for anxiety and opiates for chronic pain.

FOURTH STAGE

At age 43, from the fall into that winter, he had no presentations to the local tertiary care hospital. Then he presented having swallowed a tent stake, resulting in esophageal tear and pneumothorax treated with thoracotomy and multiple chest tubes. During that admission, he cited factors such as having an apartment, roommates, and friends caring for him, which kept him from ingesting objects for that span of time. It was evident that social support and positive relationships aided in Mr. K's sense of stability, whereas ruptures in these areas led to further self-destructive behaviors. Of note, an interview with one of these friends indicated she thought he was diagnosed with cancer and had been hospitalized with a collapsed lung.

At age 44, during the spring, Mr. K did not present to the tertiary center. In June, he presented after swallowing brush bristles. By this time, he had a caseworker, disability income, and a representative payee. The precipitant for his relapse was eviction for not following his landlord's rules.

Of note, a review of controlled substance prescriptions indicated that at age 43, Mr. K had visited 13 local providers between April and September, including eight dentists, obtained 36 prescriptions for oxycodone, hydrocodone, or alprazolam. None had written for longer than a week's worth of medication, and the prescriptions involved seven separate pharmacies.

DISCUSSION

Mr. K manifested factitious disorder imposed on self. At least initially, there was no identified gain except to play the role of a patient. Later, narcotic analgesics appeared to become a motivator for Mr. K. His eventual presentations with swallowed and inserted objects went far beyond what is typical for narcotic-seeking malingerers. He eventually admitted to fabricating stories, which confirmed the conscious and willful dimension of his behavior. He fit the typical profile of a patient with Munchausen syndrome: a young male with antisocial traits, who demonstrated a prolonged, chronic course with intermittent hostility, travels to multiple institutions and practitioners (peregrination), and deceptive stories that strained one's credulity (*pseudologia fantastica*).

This case exemplifies how a factitious behavior can be a prequel or sequel of several other disorders during a course of illness. What seemed to start as an occupational hazard (bites while handling snakes) became a source of narcotics (malingering). One behavior became a grab bag of self-destructive acts (ingesting and inserting objects), about which Mr. K was untruthful (factitious disorder). Finally, when Mr. K admitted to his self-destructive tendencies, these appeared to be stereotyped emotional responses accompanying poor distress tolerance (personality disorder). Mr. K's presentations became less frequent with interventions for personality-disordered patients: stable living and financial arrangements, a sympathetic support system, and case management with frequent contacts. In addition to the phenomenologic similarities between factitious disorder, malingering, personality disorders, and somatic symptom disorders, the fact that treatment of factitious disorder bears similarity to treatment for somatization and personality disorder may support the perspective that factitious behavior is simply a dimension of other disorders and not a separate entity.

Factitious Disorder Imposed on Another

Victims of factitious disorder imposed on another are at very high risk. Mortality rate estimates of victims range from 6% to 22%, with deaths commonly occurring through suffocation or poisoning. In Rosenberg's 1987 review, 10 of 117 children died, yielding a mortality rate of 9%, with the youngest children being the most vulnerable to death. A sobering statistic is that in 20% of the deaths, caretakers were confronted with the diagnosis of factitious disorder imposed on another, but the children were not removed from their custody. Of the survivors, 8% suffered long-term morbidity, including destructive joint changes, limp, cerebral palsy, cortical blindness, and psychiatric problems. Approximately 75% of the morbidity was precipitated by caregivers' behaviors occurring while the child was hospitalized. In 25% of the cases, morbidity was solely iatrogenic, caused by medical procedures and investigations.

Factitious disorder imposed on another is often recurrent. In a 1998 follow-up study by Davis et al., 17% of victims who returned home without restrictions were abused again. In cases where the child was poisoned or suffocated, repeat abuse rates were as high as 50%, in some cases leading to death. These statistics reinforce the importance of prompt diagnosis, proper intervention, and protection.

Siblings of victims are at great risk. Studies indicate that 9% to 29% of siblings die, underscoring the importance of checking and protecting all children of a given perpetrator. Siblings tend to be the focus serially rather than simultaneously, and so clinicians should always be alert for past and future victims. In 1990, Meadow studied 27 young children suffocated by their mothers. Over 13 years, nine died, and one suffered severe brain damage. These 27 children had 18 siblings who had died "suddenly and unexpectedly in early life." In another study of 32 children presenting with factitious epilepsy, 21% of siblings (7 of 33) had died of SIDS. In a study of suffocation cases, 21% of siblings (3 of 14) had died unexpectedly. In another study of 56 victims of factitious disorder imposed on another, 39% of siblings were subjected to illness fabrication. Among Rosenberg's review of 117 cases, 10 siblings had died under "unusual circumstances."

TREATMENT AND MANAGEMENT

Guidelines for the treatment and management of factitious disorder are given in Table 19–6.

Factitious Disorder Imposed on Self

Three major goals should guide the treatment and management of factitious disorders: (1) to reduce the risk of morbidity and mortality, (2) to address the underlying emotional needs or psychiatric diagnosis that may be driving factitious illness behavior, and (3) to be mindful of legal and ethical issues.

1. Risk reduction: The Hippocratic doctrine of "first do no harm" should be foremost. Prompt recognition of factitious disorder can reduce morbidity or mortality. Active pursuit of the diagnosis and timely management are essential. For example, in the case of a woman who reported an extensive family history of breast cancer and sought prophylactic mastectomy, early suspicion of factitious disorder may have prevented the unnecessary bilateral mastectomies that were performed. Recognition of factitious asthma or arthritis prevents the administration of steroid medications, which pose significant side effects. Invasive, potentially harmful tests, procedures, and treatments can be minimized. Once symptoms are confirmed as factitious, clinicians should administer medical treatment according to their clinical judgment, considering objective evidence and keeping in mind that the patient's complaints and requests can be deceptive.

Table 19–6.
Guidelines for Management and Treatment of Factitious Disorder

Keep in mind that active pursuit of a prompt diagnosis can minimize the risk of morbidity and mortality.
Minimize harm. Avoid unnecessary tests and procedures, especially if they are invasive. Treat according to clinical judgment, keeping in mind that subjective complaints may be deceptive.
Arrange regular interdisciplinary meetings to reduce conflict and splitting among staff. Manage staff countertransference.
Consider facilitating healing by using the double-bind technique or face-saving behavioral strategies such as self-hypnosis or biofeedback.
Steer the patient toward psychiatric treatment in an empathic, nonconfrontational, face-saving manner. Avoid aggressive direct confrontation.
Treat underlying psychiatric disturbances such as Axis I disorders and Axis II disorders. In psychotherapy, address coping strategies and emotional conflicts.
Appoint a primary care provider as a gatekeeper for all medical and psychiatric treatment.
Consider involving risk management and bioethicists from an early point.
Consider appointing a guardian for medical and psychiatric decisions.
As a behavioral disincentive, consider prosecution for fraud.

Management of countertransference is a priority to reduce risk because a clinician's negative feelings can interfere with appropriate patient care. If possible, psychiatric consultation should be promptly obtained. Good communication among all involved is essential because these patients are prone to cause confusion and splitting of caretakers. Regular interdisciplinary meetings are helpful.

Psychiatrists should be aware of their own countertransference reactions and help medical clinicians cope with their own reactions to these patients who falsify symptoms but who also have genuine needs. Negative countertransference can lead to therapeutic nihilism, breaches of confidentiality, inappropriate treatment, or denial of care. Countertransference feelings of frustration and anger can more constructively be understood as projective identification and, thus, a window toward understanding the patient's longstanding feelings. It is essential to preserve good staff communication and to formulate a clear management plan involving the whole team to minimize splitting. Allowing staff to express negative views and emotions at team meetings while providing empathic support and helpful formulations of the patient can reduce unintended retribution against the patient. The psychiatrist or psychotherapist may also be prone to negative countertransference arising from feelings of being "duped" or manipulated and should seek appropriate supervision.

On an outpatient basis, all medical care should be directed through a single primary care physician through whom all care is coordinated. This *gatekeeper* can minimize the unnecessary repetition of tests and treatments. However, it should be remembered that the patient may seek care from clinicians in another system, in another city, or even in another state or country. Appointments with the gatekeeper primary care physician should be regular and frequent and not dependent on medical crises. This fosters object constancy while minimizing the patient's need to induce illness to seek medical attention. As a means of last resort, legal disincentives might be pursued. In Arizona, a woman with factitious disorder was prosecuted for fraudulent procurement of medical, psychiatric, and dental services: she pled guilty. Laws in several states specifically address this type of action.

2. Addressing psychiatric issues: Allowing the patient to save face is essential toward establishing a therapeutic alliance and toward preventing the patient from simply taking the factitious illness behavior elsewhere. This is especially true because factitious disorder patients usually have immature personalities or personality disorders that make them especially sensitive to narcissistic injury. Direct or aggressive confrontation is generally not effective. The patient usually responds with anger and denial and may leave the hospital against medical advice, only to perpetuate their factitious illness behavior elsewhere. This kind of confrontation may amplify the patient's psychological need for mastery through deception. Clinicians should keep in mind that confession is not a necessary aspect of management or treatment.

Several behavioral strategies have been successfully used to facilitate the healing of factitiously produced symptoms in face-saving ways. Eisendrath advocated a *double-bind* technique whereby patients are told that if the symptoms are genuine, then they should improve with the treatment administered. If the symptoms do not improve, then they must be factitious. This technique can be used with nonhealing wounds, factitious paralysis, or psychological factitious symptoms that should improve with medications. For example, factitious patients who chronically induce or worsen wounds can be informed, "This treatment should heal your wound. If it doesn't, we have no choice but to conclude that this is due to a factitious disorder."

Self-hypnosis and biofeedback can allow a patient to relinquish factitious behavior in a face-saving manner. For example, a patient can be told that under self-hypnosis, blood flow to a wound can be increased and healing promoted. In this manner, the patient can take control of healing the wound rather than seek control by worsening symptoms. Positive feedback should be given to patients when their efforts result in healing. Biofeedback can be used in a similar way.

Once factitious disorder is confirmed, or evidence is deemed sufficient, the patient should be gently and artfully steered toward ongoing psychiatric treatment in a sympathetic manner acceptable to the patient. For example, the patient can be told that their factitious illness behavior is an expression of great emotional need or distress. The clinician can make empathic statements about the neglect, abuse, or trauma that the patient may have undergone. The patient should then be engaged in care in a psychiatric setting in which underlying emotional issues can be addressed and where the risk of morbidity and mortality is substantially less than in a medical setting. Because these patients may crave to be understood and to have their emotional needs recognized, this type of sympathetic confrontation that focuses on addressing the patient's genuine rather than factitious needs can be well accepted by patients.

Psychiatric treatment should first focus on underlying or comorbid psychiatric disorders or on the emotional distress that might have precipitated the factitious illness behavior.

Comorbid mental illnesses must be recognized and treated appropriately. For example, most cases of feigned bereavement are comorbid with major depression. One patient claimed to have feigned bereavement to justify depression. Another falsely claimed to have been recently raped and sought help for post-traumatic stress disorder. Although she was not recently raped, she had suffered longstanding childhood sexual abuse. Feigned mental illnesses may express an emotional truth for the patient, if not factual truth. Comorbid personality disorders are more common than affective or psychotic disorders. Borderline personality disorder is the most common comorbid diagnosis. Antisocial personality traits are also common, especially in patients exhibiting *pseudologica fantastica* and Munchausen syndrome. Pharmacologic and psychotherapeutic treatments should be employed according to the diagnosis. Substance abuse and dependence may require intensive outpatient or residential inpatient treatment. Other than targeting comorbid psychiatric disorders, there is no standard pharmacologic treatment for factitious disorder.

Once in psychiatric treatment, the greatest challenge is getting the patient to engage and commit to long-term therapy. Brief regularly scheduled contact on a time-contingent rather than a distress-contingent basis is the mainstay of therapy. Consistent long-term psychotherapy is aimed at enabling patients to express their feelings, gain insight and coping skills, and provide a reliable and supportive outlet for communication.

Relapses of factitious behavior should be expected, just as with substance abuse. Clinicians should not despair at relapses but instead, take them as opportunities to further understand the patient. For example, if a patient has a pattern of relapsing under conditions of new romantic involvements or arguments with authority figures, this provides insight into the patient's vulnerabilities and may be addressed in psychotherapy.

3. Managing legal and ethical issues: Early involvement of risk management experts and bioethicists is prudent in the care of factitious disorder patients. Patients' right to privacy and implicit injunctions against unwarranted searches and seizures are major issues. The once-common practice of alerting all emergency rooms about factitious disorder patients is no longer routinely utilized because of heightened sensitivity about confidentiality rights. Nevertheless, this kind of widespread alerting can be done with the consent of the patient. For example, once a patient acknowledges having factitious

disorder, the patient can be asked, “I’d like to minimize harm to you. Can I have your permission to alert emergency rooms and some doctors in the community?”

Similarly, the patient’s right to confidentiality should be respected when gathering collateral information in nonemergent situations. Verbal permission or, preferably, signed releases of information should be obtained prior to contacting collateral sources, except in emergency situations. Clinicians should be careful about revealing information to the patient’s employers, friends, or family. The diagnosis of factitious disorder must never be revealed, even to spouses or significant others, without a patient’s explicit permission, as this will likely lead to accusations of a confidentiality breach. Searching a patient’s hospital room or personal belongings for illness-inducing means may facilitate diagnosis and lessen morbidity, but this should only be done after consulting with risk management or other legal counsel because it goes beyond the contractual and fiduciary bounds of the doctor–patient relationship. Covert surveillance should only be undertaken after careful legal consultation. It should also be kept in mind that simply because an action is legal, it is not necessarily ethical. Therefore, the involvement of bioethicists can be helpful.

Factitious Disorder Imposed on Another

Protection of the victim is the first priority. Active pursuit of the diagnosis and then prompt intervention is essential for minimizing the risk of morbidity and mortality to the victim, who is usually a vulnerable child, as over 50% of reported cases described ongoing induction of illness in the hospital setting. Because young children are the most commonly victimized, Table 19–7 will prioritize the management of pediatric factitious disorder imposed on another.

Table 19–7.
Pediatric Factitious Disorder Imposed on Another—Basic Principles of Management

Make sure the child is safe.
Make sure the child’s future safety is also assured.
Allow treatment to occur in the least restrictive setting possible.
A pediatrician should serve as “gatekeeper” for medical care utilization.
All other physicians should coordinate care with the gatekeeper.
Child protective services should be informed whenever a child is harmed.
Family psychotherapy and/or individual psychotherapy should be instituted for the perpetrating parent and the child.
Health insurance companies, school officials, and other nonmedical sources should be asked to report possible medical abuse to the physician gatekeeper. Permission of a parent or of child protective services must first be obtained.
The possibility should be considered of admitting the child to an inpatient or partial hospital setting to facilitate diagnostic monitoring of symptoms and to institute a treatment plan.
The child may require placement in another family. The perpetrating parent may need to be removed from the child through criminal prosecution and incarceration.

When gathering clinical information and evidence, clinicians should keep in mind that if the mother feels that she is suspected or is losing control of the situation, she is likely to remove the child and seek care elsewhere. When evidence of factitious disorder imposed on another is felt to be sufficient, both parents should be informed together. In this manner, a nonperpetrating parent, usually the father, might be enlisted as an ally.

Child protective services should be informed, and a legal hold should be instituted if clinicians feel that parents might flee with the child. If harm has been done to the child, reporting of factitious disorder imposed on another to child abuse protection authorities is mandatory in all 50 states.

In Rosenberg’s review of 117 cases of factitious disorder imposed on another, 9% of the involved children died, several of whom were sent home with their parents after parents were confronted with the diagnosis. Given the high rate of mortality and morbidity, children should be removed from the parents until further assessment indicates that it is safe for the family to be reunited. Child protective services

usually take responsibility for this action. When this is done, there is a high likelihood that the mother will need intervention for suicidal ideation. Investigation into possible abuse of siblings should also be initiated.

After separation, the child must be treated for ongoing medical problems, as well as for psychological problems. For many children, longstanding refractory medical illnesses will resolve once they are separated from perpetrators. Many such children suffer from post-traumatic stress disorder and should be treated. As is typical of those with post-traumatic stress disorder, many victims avoid medical care as adults. On the other hand, others develop factitious disorder. By adolescence, many victims of factitious disorder imposed on another collude with parents in perpetrating deception.

The perpetrator, usually the mother, should also undergo treatment to diagnose and address underlying psychiatric conditions. The perpetrator should be evaluated to determine whether it is likely that they will ever achieve “good enough” parent status and whether reunification with their child is a realistic goal. Those who actively induce illness in their children are less likely to ever be adequate parents. If reunification is unrealistic, then psychotherapy should focus on the parent’s underlying psychopathology, as well as the loss of a child. If reunification is the goal, then treatment should address emotional maturation, the ability to put the child’s needs before their own, relinquishing the defense of denial, and learning to seek help and to express themselves in more appropriate ways.

Sanders et al. in 2019 outlined a system of therapeutic goals for perpetrators to adhere to, the ACCEPTS treatment model:

ACKNOWLEDGE (AC): acknowledgment and taking responsibility for inappropriate behaviors that harmed or could have harmed the child by describing their maladaptive behaviors in detail and to accept and understand how these behaviors placed the child victim(s) at risk.

COPING (C): development of a wider range of effective coping strategies to manage personal emotional needs, recognizing that abusive behavior is no longer a coping option.

EMPATHY (E): development of the ability to empathize with the child and experience an appropriate emotional response to the harm and suffering that the child experienced as a result of the abuser’s past maladaptive behaviors.

PARENTING (P): development of appropriate parenting skills and the ability to prioritize the child’s needs over those of the abuser.

TAKING CHARGE (T): recognition of the perpetrator’s own power and how to utilize it appropriately.

SUPPORT (S): As abusive behaviors may persist despite intervention, a support and monitoring system by child protective services and/or health professionals is necessary. If reunification occurs, a primary pediatrician should act as a gatekeeper who monitors and approves all medical care.

Although the literature on factitious disorder imposed on another focuses on the most severe cases, mild cases do occur. Meadow advocated that in these mild cases, parents should be supported and prevented from putting their children through needless investigations and treatments. Psychotherapy should be undertaken. The prognosis in these cases may not be so grim. Factors associated with positive outcomes according to Bools et al.’s study included (1) continuous positive input from spouse or grandparents; (2) successful short-term foster care before returning to live with the perpetrating caregiver; (3) the perpetrator’s long-term relationship with a social worker; (4) successful remarriage for the perpetrator; (5) early adoption of the victim; and (6) long-term foster care placement.

There is little literature on the treatment of factitious disorder imposed on another between adults. In these cases, removal of the victim through legal means is usually not an option if the victim is a legally independent adult, even if they might be emotionally dependent on and enmeshed with the perpetrator. Unless the victim has a legally dependent status, adult victims must initiate separation. Psychiatric comorbidity in the victim, if severe enough, may render the individual incapacitated and requiring hospitalization or even guardianship. Adult protective services and/or agencies overseeing the protection of developmentally disabled individuals must be notified when adult factitious disorder imposed on another is suspected.

In cases in which health care providers are suspected of perpetrating illness among their patients, legal prosecution should be instituted. Simply removing the provider is not adequate because the

perpetrator is likely simply to seek another job, where more patients will be at risk.

FUTURE DIRECTIONS

Further studies are needed to elucidate risk factors for developing factitious disorder, best practices for management, and outcomes of specific treatments. With an understanding that deception in the medical setting is commonplace, research into the underpinnings of this behavior may help to identify means of reducing episodes of deception both in patients with factitious disorders and in the general public.

Dissociative Disorders

Richard J. Loewenstein, M.D., Roberto Lewis-Fernández, M.D., M.T.S., and Paul Frewen, Ph.D., C.Psych.

The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition, Text Revision (DSM-5-TR) conceptualizes dissociation as a disruption, interruption, and/or discontinuity of the normal, subjective integration of potentially any aspect of experience and cognition, including behavior, memory, identity, consciousness, emotion, perception, body representation, and motor control. In more acute pathologic dissociative presentations, dissociation is primarily related to traumatic and/or overwhelming experiences. In lifelong dissociative adaptations such as dissociative identity disorder, dissociative symptoms can occur both in traumatic contexts and for nontraumatic events in everyday life. Overall, in dissociation, aspects of psychobiological functioning that should be associated, coordinated, and/or linked are not. This does not occur randomly but is due to potentially explicable psychobiological processes. Dissociation is described as both a dimensional, adaptational process and as a set of categorically distinct psychopathologies. In general, contributions to the literature on dissociation do not make this crucial distinction. This has led to conceptual confusion and, at worst, almost a Tower of Babel effect between different schools of thought writing about dissociation (see the sections on Nosology and Etiology).

The DSM-5-TR dissociative disorders are dissociative identity disorder, dissociative amnesia; depersonalization/derealization disorder; other specified dissociative disorders; and unspecified dissociative disorder. The International Classification of Diseases, 11th Edition (ICD-11) aligns

the definition of dissociation more closely with the DSM-5-TR definition, particularly as compared with ICD-10. In ICD-11, “Dissociative disorders are characterized by involuntary disruption or discontinuity in the normal integration of one or more of the following: identity, sensations, perceptions, affects, thoughts, memories, control over bodily movements, or behavior.” Unlike DSM-5-TR, ICD-11 continues to place conversion disorder as dissociative neurologic symptom disorder, whereas the DSM-5-TR persists in classifying these conditions under somatic symptom disorders as functional neurologic symptom disorder (conversion disorder). In addition to the DSM-5-TR dissociative disorders and functional neurologic symptom disorder, ICD-11 includes trance disorder, possession trance disorder, partial dissociative identity disorder, and secondary dissociative syndrome, where dissociative symptoms are “a direct pathophysiological consequence of a health condition not classified under mental and behavioral disorders,” for example, focal seizures with impaired awareness (focal unaware seizures in ICD-11 [previously complex-partial seizures]).

In the following sections, many issues common to all the dissociative disorders are discussed together, and then each of the dissociative disorders is reviewed in greater depth.

HISTORY

The history of dissociation and dissociative disorders traverses the modern history of psychiatry from its very beginning to the present time. Embedded in this history are some of the most complex, important, and often controversial issues in psychiatry and some of the most important figures in the early development of the field of psychiatry, like Pierre Janet and Sigmund Freud. From the beginning of the study of dissociative disorders, controversies have also related to larger social, political, and cultural issues. Indeed, since the early 19th century, these disorders have generated media attention and led to an awareness of the public about them and debates about them. Controversies about dissociation and dissociative disorders will be addressed in later sections of this chapter.

The modern study of dissociation begins at the end of the 18th century with the shift of interest in phenomena of trance and possession from the religious to the medical realm, at least for the individuals in the scientific, medical, and increasingly secularized parts of society. Within the Western

world, to this day, dissociative trance and possession experiences have continued to be normative in some religious groups and cultural contexts. From the 19th century until the present time, various forms of the paranormal and the supernatural, including spiritism, mediumship, astrology, and occultism—often associated with dissociative types of experiences—have continued to evoke interest among many members of the public.

In 1791, Eberhardt Gmelin described a German woman who allternatively exchanged her peasant personality for that of an aristocratic French lady, each amnesic for the other's existence. By the early 19th century, such cases, with diagnoses of dual, double, or duplex consciousness, were being regularly reported on both sides of the Atlantic. In 1811, Benjamin Rush, considered the father of American psychiatry, included a classic example in his medical school lectures. Rush proposed that dual personality reflected a functional disconnection between the two cerebral hemispheres. In the same year, the case of Mary Reynolds, who became the American archetype of dissociative identity disorder for the remainder of the century, was first published.

In Europe, the disciples of Franz Anton Mesmer developed the first systematic descriptions of what is now called *hypnosis.* These thinkers developed an interest in *magnetic diseases* (from Mesmer's theories of animal magnetism): Amnesia, fugue, somnambulistic states, and alternating or multiple personality that could be treated with *artificial somnambulism,* that is, hypnosis. These *magnetizers* were mostly outside the mainstream of European academic medicine, and their works are not widely known. Among them, Antoine Despine, a French family doctor, wrote systematic case studies and reports about several series of multiple personality patients and their treatment, including child and adolescent cases. In his cases, Despine alluded to childhood histories of sexual abuse that could not be written about. Also, he described multiple personality cases with numerous self-states, beyond the dual and triplex cases described in most case histories of the time, as well as posttraumatic and conversion symptoms. Many other 19th-century patients also had an extensive conversion and somatoform symptoms as part of the clinical presentation.

Psychiatric historians have charted the shift in interest from somnambulism to multiple personality to hysteria and back over the course of the 19th century, with *hysteria* finally seen as a unifying concept

for all these conditions. Many 19th-century debates about dissociation prefigured those that continue into the 21st century. Paul Briquet, who wrote a famous study of hysteria in the mid-19th century, disputed the prevailing notion that the disorder was caused by female sexual frustration or hypersexuality. He viewed hysteria as a disorder of the brain, not the uterus. Briquet documented that traumatic, overwhelming, and grief-engendering experiences were strongly associated with hysteria. Mid-19th century France also witnessed the rise of popular movements such as spiritism, which attempted to study trance states and other dissociative activities (e.g., automatic writing) as forms of spirit communication. The work of Allan Kardec (pseudonym for Hippolyte de Rivail) was disseminated widely, sparking healing movements targeting—and mediated by—spirit possession, particularly across Latin America.

The famous 19th-century French neurologist Jean-Martin Charcot synthesized the teachings of the magnetizers with those of the more accepted medical and psychiatric establishment, including Briquet's etiologic theories. Charcot influenced major figures in psychiatry and neurology, such as Sigmund Freud, Pierre Janet, Georges Gilles de la Tourette, and Joseph Babinski. As is well known, he gave public demonstrations of female hysterical patients and hypnosis at his Paris hospital La Salpetrière, where the neuropsychiatric wards primarily housed indigent women. Charcot's weekly demonstrations of hysterical symptoms were open to the public and were considered major social events in Parisian society of the time. Hysterical individuals were depicted in numerous highly popular French plays, novels, short stories, and poetry; some of Charcot's patients became celebrities, as did Charcot himself.

Through these demonstrations and frequent interaction with Charcot and his associates, hysterical patients were readily prompted in various ways to perform spectacularly for him since gaining favor with Charcot often led to better treatment by the staff. Despite the relatively poor conditions for patients at La Salpetrière, these were often a considerable improvement over the poverty and misery of their outside lives. Some were magnetized (i.e., hypnotized) on the wards or encouraged by sycophantic followers of Charcot to act as dramatically as possible for the great man.

After his death, two of Charcot's most important successors, Babinski and Janet, took divergent views of hysteria. Babinski took the radically

nihilistic view that all hysteria was caused by *suggestion* and could be removed by *persuasion* or *countersuggestion*. He coined the term *pithiatism* as a substitute for hysteria. The Nancy school of hypnosis, led by Hippolyte Bernheim, believed that hypnosis was not necessarily a sign of pathology, as Charcot believed, but an effect of suggestion. Babinski and Bernheim argued that the symptoms of Charcot's patients were artifacts of suggestion and contagion, not of bona fide disorders. This view continues today, most prominently in the thinking of Paul McHugh, a vehement critic of the current trauma-based theories of dissociation.

On the other hand, Janet, who remained at La Salpetrière after Charcot's death, emphasized the traumatic origins of hysterical symptoms. Janet's research and clinical theory, in particular the emphasis on the role of traumatic antecedents of dissociation, are widely regarded as the foundation for modern views of dissociation, although, during his lifetime, Janet never developed a school of followers to promulgate his ideas.

During Charcot's time, stage hypnotism began—as a pseudo-medical performance with a "doctor" and his "hysterical" subject, including subjects drawn from the audience. Many of the symptoms of Charcot's patients are duplicated today in stage hypnosis demonstrations. Modern hypnosis research has been concerned with separating what is essential about the hypnotic state and the hypnotic capacity of the subject with "demand characteristics," sometimes called sociocognitive aspects of hypnosis. The latter are the expectations subjects bring about how they are to behave while "being hypnotized"—that are different from the core features of the hypnotic state itself. In large part, demand characteristics account for the behavior of individuals in stage hypnotism demonstrations (see sections on Iatrogenic and Sociocognitive Model of Dissociation and Culture, Dissociative Disorders, and Sociocognitive Phenomena).

Trauma and the Patients at La Salpetrière

Recent scholarship has uncovered the medical records of the female patients at La Salpetrière during the 19th and early 20th centuries, including those studied by Charcot, Babinski, Janet, et al. in their research on hysteria—and some of Charcot's most famous demonstration cases. Supporting Janet's views, the hospital records document histories of multiple forms of severe trauma, loss, and social dislocation among the women.

These women were young, generally between 15 and 30 years old, and came from backgrounds of extreme poverty, illiteracy, violence, and traumatic loss. Many had brutal, incestuously abusive alcoholic fathers or stepfathers. Often, the women were the *de facto* caretakers for their younger siblings and witnessed the traumatic deaths of many of these children from tuberculosis, other infections, fevers, convulsions, etc., as well as witnessing the deaths of other family members. Some were illegitimate and shuttled between violent homes and religious institutions characterized by austerity and harsh discipline.

In addition, the later life histories of the hysterical women reported in the hospital records detailed rape, beatings, sexual exploitation by employers, and severe physical injuries due to trauma, in addition to earlier life traumas. Also, many had experienced wartime trauma during the 1870 Franco-Prussian war. They came from working-class neighborhoods directly involved in the street warfare in 1871 when the Paris Commune was crushed, a major fire devastated Paris, and thousands of communards were summarily executed in the streets of Paris. In addition, many of the "treatments" of the time were likely more traumatic than therapeutic: ovarian compression (often for hours) with a specific "ovarian compressor," applied electric currents and cervical cauterization with a hot iron. Drug treatment with opium, ether, chloroform, and/or amyl nitrate was also very common. Finally, based on the records, a number of these women were impregnated by Charcot's students. Nonetheless, the hospital was a more benign environment than their lives outside La Salpetrière. They were poor, massively traumatized, often uneducated, and, outside the hospital, were only allotted the most despised jobs in Parisian society. The accompanying case describes the history of profound trauma suffered by Blanche Wittmann, *la reine des* hystériques (the queen of hysterics), as well as her later life. She is also depicted in the classic painting: A Clinical Lesson at the Salpêtrière ("*Une leçon clinique à la Salpêtrière*") by Pierre Aristide André Brouillet (1857–1914) (see Fig. 20–1).

FIGURE 20–1. A Clinical Lesson at the Salpêtrière ("*Une leçon clinique à la Salpêtrière*") by Pierre Aristide André Brouillet (1857–1914). Center: Charcot, Joseph Babinski, Blanche Wittmann. Others include Theodule Ribot (far left), Georges Gilles de la Tourette (front in the apron), and Paul Richer (just to the right of Charcot's arm). (© Freud Museum London.)

Marie (Blanche) Wittmann had a history of profound medical, emotional, physical, and sexual trauma in her early life. This included severe illnesses and infections before the age of 2; a violent father who was committed for life to a psychiatric hospital when she was 12; losses of five of her eight siblings; and a mother who was "nervous" and died when she was 15. She was apprenticed to a furrier who repeatedly physically and sexually assaulted her. A young man she loved died suddenly when she was 15. She had behavioral problems from early childhood and could not remain in school; thus, she was uneducated and only could be employed in the most menial and despised jobs. She suffered from frequent hysterical attacks and was hospitalized as well as working as a "ward girl," someone who did the most reviled tasks in the hospital. Admitted to La Salpetrière in 1877 at age 18, she assumed the name "Blanche." She became famous in Paris for her symptoms during Charcot's public demonstrations of hypnosis and hysteria. However, in 1888, treated by Jules Janet, he discovered a classic "dual personality" with a second self-state completely free of all the hysterical symptoms and reactions. This self-state was grounded, had a positive outlook, and reported co-consciousness (awareness of the thoughts, feelings, and actions) with the hysterical, depressed state. He attempted to increase the dominance of this apparently healthier state with some success. After Charcot's death in 1893, Wittmann shifted states again. She denied her whole prior history and went to work in the radiology laboratory of La Salpetrière. There she experienced severe radiation burns and stoically underwent repeated amputations of her fingers, hand, and arm bilaterally until she died of radiation-induced cancer in 1913.

History of Dissociation in the 19th and Early 20th Centuries

At the end of the 19th century, Janet in France, Morton Prince and William James in the United States, and others across Europe were engaged in a lively transatlantic discussion about possible psychological and neurologic mechanisms underlying cases of multiple personality, amnesia, and fugue. The scientific investigation of dissociation dates to the experiments of Prince in 1908, using a crude polygraph to measure galvanic skin resistance (GSR) across the personality states of a dissociative identity disorder patient—a physiologic measure that remains of interest today.

Prince reported seeing differential GSR reactivity to words that were emotionally laden for one personality state but not for another. Over the next century, several dozen psychophysiological and cognitive performance studies were added to the literature. Many of these reported findings suggesting differential responses across dissociative identity disorder self-states. Medical models of the time-invoked phenomena such as sleep and dreams, hypnosis and somnambulism, epilepsy, and disconnections between the cerebral hemispheres to explain multiplicity.

As the 20th century began, however, interest in dissociation waned, subsumed under the somatoform hysteria construct. Alternative theories of hysteria, like those of psychoanalysis, began their ascendance. However, clinical interest in dissociative phenomena has reoccurred in every war since the turn of the century with the observation of amnesia, fugues, and conversion symptoms in traumatized soldiers. Subsequently, these observations tended to be forgotten by the psychiatric community as the wars themselves faded from memory.

For example, Babinski's ideas about hysteria, renamed "pithiatism"—a disorder defined by symptoms created and removed by suggestion—had considerable influence on European psychiatrists until the onset of World War I. At that time, with the development of the concept of *shell shock,* psychiatrists systematically reported that virtually all the symptoms of dissociation, amnesia, automatism, and hysteria could be found among battle-traumatized soldiers, plainly contradicting Babinski's ideas and supporting those of Janet. During World War I and its aftermath, many military psychiatrists adopted psychodynamic and/or hypnotherapeutic treatment models for shell shock patients. Following Babinski, other military psychiatrists viewed hysterical symptoms in combat veterans as signs of mendacity and cowardice. They adopted "treatments" like applying powerful electric shocks to body areas manifesting hysterical symptoms. Similar conflicts have persisted from subsequent wars to today. Despite the increasing acceptance of combat-related PTSD, skepticism about its legitimacy and/or frequency continues within the military, the U.S. Veterans Health Administration, and among some psychiatrists and psychologists.

Janet and Freud

Freud and Joseph Breuer's revered *Studies in Hysteria* (1893) referenced Janet's work, used similar notions of "hypnoid states," fixed ideas, and

traumatic etiology, and introduced the cathartic method of cure for hysteria. Anna O, the archetypal Freudian "hysteric," is specifically described as having a dual consciousness (personality) and a plethora of dissociative symptoms, such as complex amnesias for the current and historical experience; spontaneous age regressions and trances; depersonalization; fluctuations in handwriting, handedness, and language; and alternating states of consciousness (see the section on Diagnosis of Dissociative Identity Disorder).

Freud rejected his early dissociationist ideas, including the notion that hysteria and related conditions were caused by childhood sexual and/or physical violence (the "*seduction theory*"). Later psychoanalysts asserted that Janet dishonestly claimed priority for ideas related to hysteria, even though Janet's work clearly antedated Freud's, and Janet was referenced specifically in the *Studies in Hysteria.* Janet, for his part, was uncharacteristically publicly angry at this failure to acknowledge his work. Throughout his career, he remained critical of Freud and psychoanalytic ideas.

Despite the Janetian ideas found in early Freudian works on hysteria, until recently, psychoanalytic theory has had difficulty accounting for the phenomenon of dissociation. Freud's disciple Sandor Ferenczi wrote papers that described the sequelae of childhood sexual abuse and resulted in profound "splitting of the personality," analogous to modern descriptions of dissociative identity disorder. Ferenczi's insistence on the importance of actual traumas in psychopathology, as well as other issues, led to his expulsion from institutional psychoanalysis. British psychoanalysts from the Object Relations School, Harry Guntrip and Ronald Fairbairn, both had experience with sexually abused children. They emphasized the "splitting" of the ego as the result of these early traumas. Thus, the psychoanalytic term *splitting* frequently has been equated with dissociation, notwithstanding the criticism among some psychoanalysts of the reification of the splitting metaphor and the difficulty aligning the range of dissociative phenomena with the splitting concept.

David Rappaport, Merton Gill, Margaret Brenman, Charles Fischer, and Elisabeth Geleerd, among others, wrote important psychoanalytic papers and books on fugue, amnesia, hypnosis, and dissociation in the 1940s and 1950s, with Rappaport, following Janet, presciently enumerating the conceptual and phenomenologic differences between repression and dissociation. However, psychoanalytic thinkers have largely ignored this

work, as it was hard to align with psychoanalytic theory of the time, including the notions that incest reports were “fantasies” and that hypnosis was anathema in analytic psychotherapy since Freud rejected this technique early in his work. Recently, many psychoanalysts have again recognized the reality of childhood and adult trauma. They have attempted to reintegrate dissociation into psychoanalytic thinking. However, this has been problematic because of the persistence of the conceptual legacy of splitting and the difficulty of fitting the full spectrum of dissociative psychopathology into this and other psychoanalytic constructs. Psychoanalysts of the relational school, such as Phillip Bromberg, have broadened the dissociation concept so widely that it is seen as characteristic of human psychological processes in general and of the experience of the psychoanalyst in all psychotherapy, not just therapy of individuals with dissociative disorders.

It is unfortunate that disputes over the primacy of ideas led to a schism between Janet and the Freudians. Modern conceptualization of dissociative disorders often involves a synthesis of Janetian ideas and Freudian ones. For example, current theories of treatment include the Janetian notions of systematic work with traumatic memories, using adjunctive hypnotic and imagery techniques, and challenges to posttraumatic cognitive distortions, using cognitive and behavioral psychotherapy, psychoeducation, and building life skills. The psychoanalytic concepts of transference, countertransference, object relations, projective identification, intrapsychic defense, and conflict, among others, are also essential to understanding modern therapy of dissociative patients.

Based on his work with the severely ill patients of La Salpetrière, Janet viewed hysterics as liable to psychic disintegration with stress. Freud, working with well-to-do, bourgeois patients in his private practice, viewed hysterics as psychologically strong, attempting to survive extreme conflicts leading to symptoms. Both these ideas are relevant to the modern conceptualization of dissociative disorders and their treatment. Research has shown that dissociative disorder patients are often highly symptomatic and impaired. However, studies have also shown that early-life dissociation may be a resilience factor, particularly in the most severe, early-life onset dissociative disorder, dissociative identity disorder. Early psychological “compartmentalization” of traumatic experiences appears to allow more normal development in and preservation of cognitive and

creative abilities, along with a capacity for humor, hope, human attachment, and insight, despite reported histories of profound, repeated early life trauma (see the section on Personality Organization, Personality Disorders, and Dissociative Identity Disorder). Although requiring a more extended discussion than is possible here, clinicians and researchers typically do not identify that thinking about the mind typically involves physical metaphors like “splitting,” “compartmentalization,” etc. This may result in reification of the mind and may be a particular problem in conceptualization of dissociation and dissociative disorders, especially dissociative identity disorder.

Janet continued to be active in psychology and psychiatry until his death in 1947, writing on many different clinical, theoretical, and philosophical subjects. Janet never developed a formal school of psychology nor a group of disciples committed to his theories. He was deeply concerned with the protection of patient confidentiality, perhaps in part as a reaction to the excesses of the Charcot era. Accordingly, he had his library of detailed case histories, including those of the most famous classic hysterics, destroyed at his death. Because of this, and because of the primacy of the psychoanalytic theories in the latter part of the 20th century, his work was largely neglected until the recent resurgence of interest in dissociation.

Janet’s contributions to modern dissociation theory include (1) recognition of the causal role of trauma in dissociation in a stress-diathesis model; (2) the taxonometric approach—Janet believed that dissociation was not on a continuum from normal psychological experience; (3) recognition that the underlying mental mechanisms of somatoform and dissociative disorders were similar; (4) the role of *fixed ideas* in dissociative disorders and attempts to find the most fundamental problematic ideas that influence the patient’s behavior; and (5) treatment using a multimodal approach with hypnotic and trauma-focused methods combined with cognitive therapy, behavioral therapy, and life-skills building.

Dissociation During and After World War II

Clinicians treating battlefield casualties in World Wars I and II described dissociative symptoms, such as amnesia, fugue, automatisms, and somatoform symptoms, in traumatized soldiers as part of *traumatic war neurosis,* as it came to be known in World War II. The extent of amnesia

described in psychiatric battlefield casualties in World War II ranged from relatively brief periods of time to complete amnesia for life history and identity (generalized dissociative amnesia), as well as fugue episodes.

Treatment of these World War II amnesia cases included hypnosis, narcosynthesis with a mixture of hypnosis and sodium amobarbital (Amytal), individual and group psychotherapy, or a combination of these. Attempts were made to treat these soldiers on the front lines and return them rapidly to combat. Detailed case descriptions of dissociative amnesia and fugue can be found in clinical studies from that time, as well as studies of large cohorts of patients. Researchers have reported that soldiers from the Korean conflict and the Vietnam war also reported amnesia as part of the posttraumatic syndromes related to combat experiences and were treated with similar modalities. Dissociative symptoms, dissociative disorders, and/or the dissociative subtype of PTSD continue to be described in U.S. combat veterans from the Gulf War and U.S. and NATO veterans of the wars in Iraq and Afghanistan. Cross-nationally, dissociation and/or dissociative disorders have been reported among combat veterans with PTSD. These include Israeli combat veterans from the 1967 Arab-Israeli War, with significantly higher levels of dissociation in former prisoners of war; Iranian veterans with PTSD from the Iran-Iraq War (DSM-IV dissociative amnesia, dissociative fugue, depersonalization disorder); and Turkish professional soldiers with PTSD.

Waning Awareness of Dissociation

Despite the extraordinary interest in multiple personality throughout the 19th century, the study of dissociation mostly disappeared after the beginning of the 20th century. Authorities suggest that this was related to the dominance of Freudian paradigms of hysteria; the disrepute into which hypnosis fell at this time; the rise of the Bleulerian concept of schizophrenia, which may have subsumed dissociative patients (see the section on Other Dissociative Disorders); and the loss of interest in the works of Janet, Prince, and others who had been crucial in the development of models of dissociation. From the 1930s to the late 20th century, some classical Freudian psychoanalysts, and later the Sullivanian psychoanalysts, began to treat “schizophrenics” with psychodynamic therapy. Simultaneously, partly in reaction to some of the barbaric “treatments” of the time—insulin and metrazol shock, intrathecal horse

serum, colloidal gold infusions, and multiple daily ECT courses—there was a lack of concern about symptoms and diagnosis, viewing these as dehumanizing. This coincided with the expansion of the diagnosis of schizophrenia to encompass a wide swath of patients, following Bleulerian concepts of the relative unimportance of "surface" symptoms. Case studies of "successful" psychodynamic treatments using these models suggest that the responsive cases better fit the symptoms, trauma histories, and dynamics of dissociative disorder presentations, not those of individuals with psychotic disorders.

Nonetheless, throughout much of the 20th century, the psychiatric, psychological, and psychoanalytic literature described individual cases or small case series of individuals with dual or multiple personality and/or generalized dissociative amnesia, with and without dissociative fugue. From the 1890s to the present (but declining since the 1920s), newspaper accounts have documented numerous individuals with amnesia and fugue who were brought to hospitals without recall of their past history and/or personal identity. Conventional wisdom still held that these disorders were extraordinarily rare, especially multiple personality; thus, individual case studies, such as the famous *Three Faces of Eve,* were not only published in the professional literature but entered popular media as well. Nonetheless, systematic reviews of the literature periodically supported the validity of the diagnostic construct of dissociative identity disorder.

History of Depersonalization/Derealization Disorder. First described by Maurice Krishnaber in 1872, depersonalization was formally named in 1898 by Ludovic Dugas, who sought to convey "the feeling of loss of ego." Freud, Janet, Eugen Bleuler, and other 19th- and early 20th-century authorities reported patients with symptoms of depersonalization and derealization. Freud himself described his own symptoms of depersonalization and derealization in 1904 as part of his self-analysis, when he finally was able to visit the Acropolis. A monograph by Paul Schilder in 1914 is regarded as a turning point in psychiatric interest. Classic studies by Wilhelm Mayer-Gross in 1935, Harold Shorvonn in 1946, and Jerome Saperstein in 1949 furthered the delineation of a syndrome of chronic depersonalization. Brian Ackner enumerated the essential features of current diagnostic definitions in 1954. These include "(1) the feeling of unreality or strangeness apropos the self; (2) the retention of insight and lack of delusional elaboration; (3) the lack of

affective response ('numbness') except for the discomfort regarding depersonalization; and (4) the unpleasant property that may vary in intensity inversely with the subject's familiarity with the phenomenon."

Later 20th Century History

The interest in trauma and dissociation began anew in the 1970s and 1980s. Social and cultural factors leading to this revival are thought to include the return from war of the Vietnam veterans and the systematic academic study of their psychiatric problems; the recognition of the prevalence of childhood physical and sexual abuse with its associated mandated reporting; systematic research on child abuse and family violence; the rise of feminism with its critique of psychological theories that ascribed sexual abuse reports to fantasy; increased academic rigor in theories about hypnosis, such as Ernest Hilgard's *neodissociation* theory; greater acceptance of academic hypnosis research; popular interest in multiple personality owing to works such as *Sybil;* and the publication of DSM-III (1980), with its promulgation of diagnostic criteria for the dissociative disorders and posttraumatic stress disorder (PTSD).

Cornelia Wilbur. The contemporary era in the study of dissociative identity disorder began with the work of Arnold Ludwig and colleagues, including Cornelia Wilbur, at the University of Kentucky during the 1970s, primarily studying differential findings in the psychobiology of dissociative identity disorder self-states. Cornelia Wilbur, widely identified with the case of *Sybil,* was influential in describing the clinical features of the modern construct of dissociative identity disorder and identifying the role of childhood trauma as a major factor in the etiology of the disorder. In the mid-20th century, Wilbur, a psychoanalyst, described several cases of dissociative identity disorder, all with more complex self-state systems than the classical dual and duplex personality cases and all with histories of extreme early life maltreatment, including incest. However, her writings were rejected by psychoanalytic journals, primarily due to the prevailing *zeitgeist* that multiple personality and incest were one-in-a-million conditions, and that female reports of childhood sexual abuse were virtually all Oedipal fantasies. Finally, in frustration, Wilbur published the *Sybil* case in the popular press, with no expectation that it would be read widely, if at all.

DSM-III and Beyond

Since the publication of the DSM-III in 1980, substantial systematic research has developed about dissociative disorders, particularly dissociative identity disorder, dissociative amnesia, and depersonalization/derealization disorder. Many academic studies have also investigated dissociation as a quantifiable trait in clinical and nonclinical samples. Studies have also looked at the prevalence and phenomenology of amnesia, particularly as it relates to the question of delayed recall of traumatic experiences.

Beginning in the early 1980s, Frank W. Putnam, Jr. at the National Institute of Mental Health (NIMH) was one of the first to develop the modern scientific study of dissociative disorders and dissociation. He undertook the first contemporary systematic epidemiologic, phenomenologic, and psychophysiological studies of dissociative identity disorder, including attempts to repeat the classical studies of reportedly compartmentalized memory and differing psychophysiological responses of the self-states. Among his major findings were the *significantly greater variability* among dissociative identity self-states compared with simulating controls on a variety of psychophysiological variables such as event-related potentials (ERPs), 16-lead EEG, and autonomic functioning. He showed that the self-states did not exhibit the kind of test–retest similarity on these measures found in simulating control subjects. This was due to the inability of patients to maintain a specific state, shifting of states during research trials, and variably recurrent intrusion and interference among states during testing.

These findings led him to posit that dissociative identity disorder naturalistically existed more as "*the state of multiple states*," with state shifting leading to overlap, intrusion, and interference among personality states. The latter were described as constructed around specific emotions, a sense of self, and a group of state-dependent memories. This was different from the classical understanding of the disorder as characterized by several distinct, dramatically switching self-states that were highly defined, complex, and invariant when studied from one time to the next, maintaining "executive control."

Putnam and his colleague Eve B. Carlson developed the *Dissociative Experiences Scale* (DES), the first screening inventory for trait dissociation, and measured *dissociativity* in many diagnostic groups compared to normal controls, including individuals with PTSD, affective

disorders, psychotic disorders, anxiety disorders, personality disorders, and dissociative disorders. The DES has been translated into more than 40 languages, and studies across cultural settings reveal strong similarities between Western and non-Western samples, attesting to the universality of dissociation/dissociative disorders. Putnam also contributed major works on the diagnosis and treatment of dissociative identity disorder and was among the first to systematically study dissociation in children and adolescents, developing measures comparable to the DES for younger individuals. This led to his promulgation of the discrete behavioral states (DBSs) model of dissociation, discussed in depth in the sections on Etiology and on Dissociative Identity Disorder.

Putnam also began a groundbreaking, longitudinal case-control study of girls with documented histories of incest that, with a greater than 90% retention rate, has continued for over 25 years, now following the children of the original participants. This study includes diverse measures of hypothalamic–pituitary-adrenal (HPA) axis functioning, dissociation, hypnotizability, development of clinical disorders, and social and school functioning, among others. These studies established the biologic mechanisms underlying accelerated puberty, increased morbid obesity, and advanced epigenetic aging in sexually abused women and girls.

David Spiegel of Stanford University studied cases of dissociative identity disorder and wrote influential papers on the relationship between hypnosis, trauma, PTSD, dissociation, and dissociative disorders. He and his colleagues also conducted a series of studies on acute dissociation in victims of natural disasters in California. This work led to the DSM-IV diagnostic criteria for acute stress disorder (ASD), now subsumed in the DSM-5 trauma- and stressor-related disorders category. Under Dr. Spiegel's direction, the DSM-IV changed the names of the dissociative disorders to emphasize their dissociative character and make them more clinically and theoretically relevant. He also took the lead in the changes in diagnostic criteria for dissociative disorders in DSM-5. He led major studies on dissociation and PTSD and directed the international studies that were a major factor in the inclusion of a dissociative subtype of PTSD in DSM-5. Also, Dr. Spiegel helped coordinate the publication of major papers in support of the trauma model (TM) of dissociation that challenges the sociocognitive and fantasy models (SCM/FM) of dissociation and of dissociative identity disorder (see sections on Etiological Theories).

International and Cross-Cultural Research on Dissociation and Dissociative Disorders. Beginning in the 1980s, there developed major international research efforts on dissociation and the dissociative disorders. Judith Armstrong, Bethany Brand, Suzette Boon, Chui-De Chiu, Phillip Coons, Martin Dorahy, Nel Draijer, Milissa Kaufman, Ruth Lanius, Lauren LeBois, Roberto Lewis-Fernández, Richard J. Loewenstein, Alfonso Martínez-Taboas, Warwick Middleton, Colin Ross, Vedat Sar, Daphne Simeon, Marlene Steinberg, Masahiro Umesue, Onno van der Hart, Eric Vermetten, and other researchers in the United States, Canada, Europe, Australia, New Zealand, Latin America, Turkey, Japan, China, and Taiwan began systematic research studies on the phenomenology, epidemiology, diagnosis, psychobiology, and treatment of dissociative disorders, especially dissociative identity disorder, in children, adolescents, and adults.

As part of this globalized investigation of dissociation, anthropologically informed research on pathologic possession and other trance states began to be conducted cross-culturally with psychometrically sound measures of dissociation. These studies revealed notable similarities between well-characterized cases of pathologic possession and some features of dissociative identity disorder, such as loss of personal identity followed by assumption of an alternate (usually spiritual) identity, high indices of trait and state dissociation, and elevated trauma exposure. These research findings paved the way for the inclusion of some pathologic possession presentations under the rubric of dissociative identity disorder in DSM-5. In ICD-11, by contrast, possession trance disorder, along with trance disorder, are included as diagnostic categories distinct from dissociative identity disorder under the rubric of trance disorder and possession trance disorder (the rationale for this classification is presented in the section on Comparative Nosology). Research by Roberto Lewis-Fernández and colleagues on the dissociative nature of some acute reactions to traumatic events, such as some instances of *ataque de nervios* (attack of nerves) in Latin America, also led to the inclusion of an acute dissociation category under the other specified dissociative disorders section in DSM-5.

Richard P. Kluft made many contributions to the literature on dissociation and dissociative identity disorder. He wrote extensively about the psychotherapy of dissociative identity disorder and the phenomenology of the disorder throughout the life cycle. He was the first

to identify the high frequency in dissociative identity disorder of apparent *first-rank symptoms* (FRSs) of psychosis, albeit experienced quite differently in dissociative identity disorder and indicative of the overlap and interference of states described by Putnam. He is the only scholar to write extensively about the fusion and integration of self-states in the treatment of dissociative identity disorder.

The International Society for the Study of Trauma and Dissociation (ISSTD) began under a somewhat different name in 1984. This society has published three editions of Guidelines for the Treatment of Dissociative Identity Disorder in Adults (3rd revision in 2011) and Guidelines for the Evaluation and Treatment of Dissociative Symptoms in Children and Adolescents (2004). Both guidelines are currently under revision. Jennifer Freyd of the University of Oregon is the editor-in-chief of the ISSTD's journal, *The Journal of Trauma and Dissociation* (JTD). From 1988 to 1997, Richard Kluft and Catherine Fine edited the society's first journal, *Dissociation* (available at Scholarsbank.uoregon.edu/xmlui/handle/1794/1129). In 2006, Suzette Boon in the Netherlands and Bettina Overcamp in Germany chartered The European Society for Trauma and Dissociation (ESTD), now affiliated with the Association Francophone du Trauma et la Dissociation (AFTD). With Cyril Tarquinio as editor-in-chief, the ESTD publishes *The European Journal of Trauma & Dissociation / Revue Européenne du Trauma et de la Dissociation*,

Contemporary Study of Depersonalization/Derealization Disorder

Recent systematic research of two large cohorts of well-characterized participants with depersonalization/derealization disorder has yielded strikingly consistent findings. These were reported by Daphne Simeon of Mount Sinai Medical School in the United States and by Anthony David at the Depersonalization Research Unit (DRU) at the Maudsley Hospital, Kings College, London. Clinical features, course and prognosis, and cognitive and neurobiologic correlates have emerged that clearly distinguish this disorder from other psychiatric disorders with symptoms of depersonalization. Mauricio Sierra and German E. Berrios, also affiliated with the DRU, developed the most widely used instrument for screening and diagnosis of this disorder, the *Cambridge Depersonalization Scale* (CDS). Both the U.S. and the British groups have studied treatment and treatment outcomes of patients with depersonalization/derealization

disorder, including psychopharmacology and psychotherapy (see the section on Depersonalization/Derealization Disorder Treatment).

DISSOCIATIVE DISORDERS, MODERN SOCIETY, AND THE MEDIA

The study of dissociative disorders appears to be inseparable from the social and cultural ambiance in which it occurs. Contemporary academic interest in trauma and its clinical outcomes has been paralleled by social and religious movements focusing on self-identification as a victim of childhood abuse and the seeking of recovery through a variety of therapeutic and self-help modalities. Furthermore, some feminist theorists argued that healing from childhood sexual abuse mandated confrontation with alleged perpetrators in personal meetings, in the courts, or both.

Legal theorists concerned that victims of childhood maltreatment did not have the standing to sue for damages or to bring criminal actions under usual statutes of limitations lobbied state legislatures to expand the length of time that victims could seek legal redress. This was based on the idea that many survivors had amnesia for abuse or did not recognize the harm that had been done to them until many years after the abuse had occurred.

Many states did modify the statute of limitations for childhood sexual abuse, allowing the statute to begin to toll after the person “recovered” memory of the abuse or, alternatively, after recognizing the harm that had been done, whether amnesia was present or not. Successful legal actions were brought under these definitions, with courts accepting expert testimony concerning the validity of “repressed memory” for childhood maltreatment. Other state courts have explicitly rejected testimony based on delayed recall of traumatic memory.

In the 1980s, clinicians working with dissociative disorders began to report patient accounts of multi-perpetrator, multi-victim, organized sadistic abuse in the context of supposed underground cult groups. These chilling accounts were amplified by highly publicized daycare abuse cases that described multiple perpetrators, in some cases with elements of ritualized, occultist abuse. Several state governments developed commissions to investigate allegations of “ritual abuse” and claimed to have found evidence of these activities. The media also developed an intense interest with the publication of popular autobiographical accounts

of individuals with reported histories of occultist abuse, as well as frequent news stories and television specials on this and related topics.

Unfortunately, some clinicians working with these dissociative patients chose to respond to their patients' reports in a highly publicized and sensationalized manner rather than subjecting them to dispassionate and rigorous scrutiny. As discussed later, one of the classic countertransferences in trauma treatment, whether for combat veterans or dissociative disorder trauma survivors, is overidentification with the patient with loss of the treatment boundaries. The therapist takes on an advocacy role because of some "special" aspect of the patient's trauma(s). This situation invariably leads to negative outcome for the patient(s) and often for the therapist(s). Some of these clinicians painted themselves as crusaders against a vast criminal conspiracy that threatened the nation, presenting themselves and their patients on television and in the newspapers. Patients in some specialized dissociative disorder units shared detailed recollections of trauma in group therapy and in the hospital milieu, with relatively little concern for possible cross-contamination or confusion about the origin of accounts of trauma. Cautionary or critical voices among dissociative disorder researchers and clinicians were ignored or rebuked. Forensic and clinical research was disregarded that cast doubts on the veracity of some of these patients' accounts and suggested alternative mechanisms for many of these "ritual abuse" narratives. Simultaneously, police were involved in the arrest and prosecution of individuals accused of the sadistic sexual abuse of children in daycare settings.

Backlash

Ultimately, an extensive backlash occurred that included the dismissal of all the daycare cases, even those with solid, independent confirmation of the abuse, and increased skepticism about the reliability of children's reports of maltreatment, particularly for sexual abuse. Popular works that encouraged readers to work on recovery from abuse were castigated as suggesting abuse to millions when none had occurred. Allegations of delayed recall for childhood trauma (unfortunately often termed "*recovered memory*") in clinical and forensic cases were disparaged as based on erroneous views of human memory and cognition, although no one had questioned previously the phenomenon of amnesia related to combat, rape, or other types of traumas. The dissociative disorders

construct was dismissed completely as engendered by suggestion and sociocognitive factors (see the section on Etiology). Therapy based on working with traumatic memories was discounted as “risky.” The reports of an extensive prevalence of childhood abuse in the general population and its actual impact on psychopathology were questioned. Some critics raised doubts about the validity of the diagnostic construct of PTSD.

False Memory Syndrome. From 1992 until its demise in 2019, The False Memory Syndrome Foundation (FMSF) had a significant impact on this debate. The founders of this organization sought out “accused” families, like themselves, some of whom had had successful criminal or civil judgments brought against them because of their children’s allegations of abuse. This organization, accompanied by several attorneys, developed a legal theory that there was no such thing as a delayed recall for trauma or dissociative identity disorder. The organization’s argument went as follows: poorly trained clinicians convinced credulous (usually female) patients that their difficulties were all based on a history of repressed childhood abuse and engaged in risky therapeutic techniques (*guided imagery, hypnosis*) that led patients to believe that these confabulations were accurate. The patients then were mistakenly urged to confront or to stop all contact with family members accused of sexual abuse, ritual abuse, and other forms of maltreatment.

A group of attorneys and academic expert witnesses sought out patients and ex-patients to bring civil cases throughout the country in which therapists were sued for malpractice or were subject to licensing board complaints, or both, based on the FMSF position. Recanting former victims and/or “accused” parents sued mental health providers alleging malpractice and/or alienation of affections, respectively, based on the notion that there is no such thing as dissociation, amnesia, “repression” of memory, and dissociative disorders. The FMSF had a sophisticated public relations arm, and the media now became enthralled by weeping “recanters” reuniting with their previously abjured families. Many of these cases were settled. Several resulted in jury findings for the plaintiffs with significant damage awards. Others concluded with juries finding for the defendant’s doctors. A federal mail fraud case against several clinicians ended in a mistrial before the prosecution’s case had concluded, with the prosecution declining to retry the case.

Only one published study has systematically assessed recanters of abuse allegations, amnesia, and dissociative identity disorder. It found that virtually all these individuals had long psychiatric histories, with PTSD and dissociative symptoms predating contact with defendant clinicians. These patient plaintiffs had significant personality disorders in which they readily took the victim role and looked to forces outside themselves for an explanation of their problems. Previously, some had been involved in successful civil and criminal actions against their parents. Factitious elements were prominent in many patients' presentations. With treatment, most had *improved* with respect to their dissociative psychopathology, but not in their characterologic difficulties. Later, usually after the termination of treatment, the patients shifted their perception of victimization from their parents to their prior therapists, now putting their attorneys in the role of rescuer, usually with the promise of large sums of money if they prevailed in their lawsuits. The experience of many experts suggests that some therapies that resulted in false-memory lawsuits could have resulted in litigation for treatment below the standard of care for dissociative disorders.

Despite its popularity in the media and psychology textbooks, *false-memory syndrome* as a clinical construct has never been operationalized, studied, or validated. As the false-memory fad began to fade, the polarized, extreme views about the delayed recall of trauma have been better resolved through research and increased communication between trauma and cognitive researchers, who reject both the extreme false memory view as well as the extreme credulous view that holds that all reported traumatic memories are accurate (see the section on Etiology). "False-memory" experts continue to appear for the defense in high-profile sexual assault or murder cases against prominent, wealthy men and women, in civil and criminal litigation against accused pedophile clergy, and even in asbestos litigation to question the reliability of plaintiffs' memories. In these recent cases, most juries have found criminal defendants guilty and, in civil cases, liable for damages.

Persistence of Controversy About Dissociation and Dissociative Disorders

Despite the extensive body of systematic, international research on dissociation and dissociative disorders since the 1980s, passionate disagreements remain surrounding the disorders that evolved from classic

hysteria. These academic and social debates parallel many of those that polarized the field in the days of Babinski and Janet. No other group of disorders in psychiatry can evoke so much heated controversy, conflict, and fervent debate.

Skeptical pieces about dissociative amnesia, the nature of dissociation, and dissociative identity disorder continue to appear in the media and psychiatric journals. It is unclear why skepticism specifically focuses on disorders most associated with severe adversity during early life, primarily intrafamilial maltreatment. Some of the same authors have questioned data on the prevalence of combat trauma and PTSD in Vietnam veterans, as well as the validity of the PTSD diagnosis, suggesting that combat veterans with PTSD are mostly malingerers.

Why should there be such a passionate debate? Why should appeals to the results of scientific research not resolve it? More so than other psychiatric conditions, these disorders touch on many complex and contentious aspects of personal, political, philosophical, and even religious beliefs. These include the fundamental nature of the self, the mind, memory, volition, and consciousness, as well as the responsibility of individuals for their behavior. In psychiatry and psychology, dissociative disorders are the focus of controversies, including longstanding debates between mentalists and behaviorists; between *psychodynamically oriented* and *behaviorally oriented* clinicians; between various researchers in cognitive psychology; between cognitive researchers and clinical researchers and practitioners, and between different theoretical schools at odds over the nature of hypnosis. Some Western fundamentalist Christian clinicians view *actual* demonic possession as part of the differential diagnosis of dissociative disorders.

Issues here include the significance of early trauma for human psychopathology; the existence of *unconscious* mental life and *intrapsychic defenses,* such as *repression* and *dissociation;* the nature of memory; and the nature of hypnosis, and whether it involves altered states of consciousness or is only a “learned social role.” The existence of dissociative amnesias and delayed recall of reported traumatic childhood events raise difficult-to-answer questions about the reliability of traumatic memory.

When viewed from a larger sociopolitical perspective, dissociation theory intersects with many of the most controversial social issues of modern times. Recent systematic research consistently has found a

robust relationship between dissociation and traumatic experiences, increasing with earlier, more severe, and prolonged trauma, as well as for subgroups of severely maltreated individuals under conditions of captivity. The role of trauma, particularly intergenerational violence and sexual abuse, crosses into historically taboo subjects, such as rape, incest, child abuse, domestic violence, trafficking of both children and adults in prostitution and/or pornography, and their actual prevalence across societies. This leads to larger legal, social, and cultural questions related to peace and war, the meaning of violence cross-culturally, including differing religious views about the relationship between men, women, and children, and the nature of the family.

Dissociation and the Media

The media presentation of dissociative disorders also plays a role in controversies. From the mid-19th century to the present, the popular media has nurtured a public fascination with various forms of dissociation, especially "multiple personality" but also fugue, amnesia, and crimes committed under the influence of hypnosis or in somnambulistic states. Accounts of 19th-century cases were carried in popular magazines such as *Harpers,* and famous cases, such as Morton Prince's Miss Beauchamps (1905), became the subject of books and plays. Robert Louis Stevenson's fictional *The Strange Case of Dr. Jekyll and Mr. Hyde* (1886) is the most well-known of these works. Searches of newspaper archives from the mid-19th century onward show many cases of amnesia and fugue described in the popular press (now also on television and the internet), often with the goal of identifying the amnestic individual or reporting the successful identification of the person and reunion with the family.

Starting in the late 20th century, popular first-person accounts of multiple personality, such as *The Three Faces of Eve, Sybil,* and others, continued in this vein. The widespread use of multiple personality as a fictional plot device—generally to give a bizarre twist to the story—has contributed to the public and professional confusion that surrounds this disorder. Similarly, amnesia for life circumstances and for trauma is also a recurrent story mechanism in contemporary novels, films, and television—almost never portrayed accurately. Media stereotyping occurs for many forms of mental illness, but the distortions typical in most fictional depictions of dissociative disorders are particularly misleading.

Unfortunately, it often seems that most mental health practitioners also have received their training in dissociative disorders from the media, thus leading to misdiagnosis and mistreatment of dissociative patients, often accompanied by blanket skepticism: “I don’t believe in that.” Experts in dissociative disorders do not “believe in” these media portrayals either. As delineated throughout this chapter, the clinical phenomenology of dissociative disorders, as well as the evidence-based treatment models, bears little resemblance to these media depictions.

Highly publicized criminal and civil cases, such as the Hillside Strangler, the Franklin murder case, the Ramona case, and many others, have repeatedly brought additional media attention to claims of multiple personality, amnesia, and recovered memory. These contentious cases, with their warring academic experts and sensationalized media depictions, have also fueled popular stereotyping of dissociative disorders. Media spin about these cases has often been inaccurate and misleading.

Popular television interview programs have featured therapists and dissociative identity disorder patients, often with interviewers and the audience demanding to see the patients “switch.” The ISSTD treatment guidelines specifically enjoin clinicians from involving themselves and their patients in the media. Thus, for the most part, only poorly trained and/or exploitative clinicians have been involved in these media debacles. Due to their extensive traumatization, dissociative identity disorder patients are often highly susceptible to later exploitation, including involvement in the media without informed consent about how damaging this can be, as well as the permanent record that will be left in the age of the Internet.

Groups of individuals with dissociative identity disorder have developed “self-help” groups on social media. In general, these have resulted in disastrous outcomes when exploitative individuals have taken advantage of group members, group members have denigrated treatment for the disorder, and/or flaunted and encouraged eating disorders, nonsuicidal self-injury, and/or suicidal behavior.

More recently, individuals with dissociative identity disorder—or feigned dissociative identity disorder—have created YouTube, Tik-Tok, and/or Facebook channels to display their purported self-states, including individual Facebook pages for these entities. This may lead to increased skepticism of the disorder by viewers, antitherapeutic reinforcement of self-states as separate “people,” and vulnerability to exploitation. Also, there are reports that social media promulgation of the disorder has led to

cases of “imitative” dissociative identity disorder, where individuals who do not meet diagnostic criteria for the disorder—as well as their concerned others—come to believe that they suffer from this condition.

Institutional and Cultural Trauma

Across the world, the reported failure of many institutions to respond to reports of trauma has also led to intense, polarized, and often politicized controversies. For example, in addition to lingering controversy and stigma about combat-related PTSD, the presence of increasing numbers of women in the military and in the U.S. Veterans Health System has led to an awareness of military sexual harassment and sexual assault, affecting both men and women.

Clergy sexual abuse scandals have involved the Catholic Church and many other religious groups. Religious hierarchies have failed to respond appropriately to these abuse reports, sacrificing the well-being of children to that of the accused clergy. Internationally, a few clerical administrators have been removed from their positions, and some were prosecuted and convicted. The recent, highly publicized #Me-Too movement has led to an international, cross-cultural outcry from women about gender-based violence, including sexual harassment and assault, as endemic in virtually all societies across the world and tolerated, if not encouraged, by most institutions and industries. These include government, business, military, all levels of education, athletics, media, technology, religious, medical, mental health, and entertainment. Similarly, there is increased awareness of violence against gay, lesbian, and transgender people.

In Australia, Canada, and the United States, there are documented reports of institutional sexual, physical, emotional, spiritual, and cultural maltreatment of indigenous children who had been removed from their families and cultural groups. The goal was to instill Western cultural and religious beliefs and to extirpate indigenous societies. Children’s bodies who died under suspicious circumstances have been found buried on the grounds of the institutions. In parts of the United States and Europe, similar types of abuse and deaths have been described in secular agencies for juvenile lawbreakers and in religious institutions for unwed mothers and their babies.

At a broader societal level, these can be conceptualized in terms of the long-term, traumatizing effects of historical trauma as well as systemic racism, sexism, and heterosexism. There are clinical and research data

that systemic racism itself, including microaggressions, engenders symptoms of PTSD, dissociation, and depression.

Posttraumatic and Dissociative Responses to Institutional and Cultural Betrayal Trauma

Jennifer Freyd and her colleagues have evaluated the adverse effects of betrayal that results from childhood maltreatment by caregivers and/or others on whom the developing child must depend. Compared with traumatized individuals who do not report betrayal, these effects include higher levels of dissociation (particularly dissociative amnesia), alexithymia, anxiety, depression, nonsuicidal self-injury, and physical health complaints (see sections of Etiological Theories of Dissociation and Dissociative Disorders and sections on Dissociative Identity Disorder and Dissociative Amnesia).

Institutional Betrayal Trauma. Freyd and her colleagues have studied the adverse psychological effects of *institutional betrayal trauma*. This is defined as harm by institutions to those dependent on them, including failure to prevent or respond supportively to wrongdoings within the institution itself when there is a reasonable expectation of protection. Institutional betrayal can involve pragmatic harms (e.g., multiple adversities due to systemic racism) and psychological forms of distress. The pragmatic harms of racism can include multigenerational disparities in economic conditions; inadequate access to health care, particularly mental health care; lack of access to good educational resources; government policies that negatively affect social cohesion and support, such as the destruction of healthy neighborhoods of communities of color, replacing them with highways or other projects, with the dispersal of community members; de facto housing segregation into neighborhoods that are nearer to toxic pollution sources, more affected by adverse climate change, and with less access to safe water and adequate nutrition; higher violent crime rates along with a dearth of trust in police agencies, and many others.

Institutional betrayal trauma in sexually traumatized female college students was uniquely associated with dissociative symptoms and health problems, even when controlling for a history of personal betrayal trauma. In female military service members and veterans with a history of military sexual trauma, institutional betrayal was significantly associated with more

severe depression and PTSD symptoms, including dissociative flashbacks and avoidance, the latter involving dissociation. They were significantly less likely to seek treatment in the VA system because of institutional mistrust.

Cultural Betrayal Trauma. Jennifer M. Gómez has defined another form of betrayal trauma, *cultural* or *ethnocultural betrayal trauma.* Cultural betrayal negatively affects the sense of connection, attachment, and dependence that minoritized group members may rely on as a form of self-protection from the effects of systemic racism and related societal harms. Within-group violence in minoritized populations is an implicit violation of this in-group trust, a cultural betrayal. This is the first factor in cultural betrayal trauma as intra-cultural trust may be a protective factor against the societal institutional betrayals inherent in systemic racism. Also, intra-cultural pressure may lead to cultural betrayal when within-group dynamics in a minoritized group silence or punish victims of cultural betrayal trauma (e.g., because of fears that this victimization would reflect negatively on the entire minoritized group). An illustration is the public suggestion by the president of a historically Black university that female African American students not report rape by male African American students to protect the latter from the societal trauma of the mass incarceration of Black men and to keep the issue within the Black community. Studies using this model among some U.S. ethnoracial minoritized groups (e.g., African Americans, U.S. Latinx, Asian Americans) have found that, even when controlling for trauma (e.g., sexual assault), cultural betrayal and intra-group pressure can lead to significantly increased dissociation, posttraumatic stress symptoms, dissociative hallucinations, internalized prejudice, and trauma-related deformation of ethnic identity.

COMPARATIVE NOSOLOGY

Diagnostic Criteria: DSM III-DSM 5-TR

The modern conceptualization of dissociative disorders as a distinct group began with the introduction of the DSM-III in 1980. Although the DSM-I distinguished dissociative reactions from other reactions, the DSM-II subsumed dissociative conditions under the superordinate category of

hysterical neurosis. The latter was conceptualized as conversion or dissociative subtypes.

In the DSM-III, conditions that developed from the 19th-century construct of hysteria were distributed among different diagnostic categories: dissociative disorders, somatoform disorders—now somatic symptom and related disorders in DSM-5-TR—PTSD, and histrionic and borderline personality disorders. The DSM-III, as did the 10th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), took the stance that the label *hysteria* had become so imprecise and variously defined that it had become meaningless. In the DSM-III, these conditions were defined and organized separately so that systematic empirical research could better clarify their reliability, validity, and possible relationship to each other. The DSM-III dissociative disorders were psychogenic amnesia, psychogenic fugue, multiple personality disorder, and depersonalization disorder.

The evolution from the DSM-III conceptualization of dissociation and the dissociative disorders diagnostic criteria through DSM-III-R, DSM-IV, DSM-IV-TR, DSM-5, and DSM-5-TR has been based on an increasingly sophisticated body of international research on the phenomenology, course, etiology, treatment, and treatment outcome of the dissociative disorders (see subsequent sections). These data support the robust relationship between dissociative disorders with traumatic and/or overwhelming experiences (see sections on History, Epidemiology, and Etiology). This research has been buttressed by the development of a variety of symptom screening measures for dissociation and dissociative disorders, as well as clinician-administered interviews for dissociative symptoms and diagnosis of dissociative disorders. The most important of these measures are detailed in Table 20–1.

The DSM-III criteria for dissociative disorders were established by expert consensus. By the time DSM-III-R was published, systematic research on dissociative disorders had increased substantially. Little changed in the diagnostic criteria for depersonalization disorder, psychogenic amnesia, and psychogenic fugue between DSM-III and DSM-III-R. However, the criteria for multiple personality disorder changed considerably to make them more flexible, less reified, and more compatible with research findings on the phenomenology of self-states.

In the DSM-IV (and IV-TR), the names of most of the disorders were changed to specify their dissociative nature more clearly (e.g.,

psychogenic amnesia became dissociative amnesia and multiple personality disorder became dissociative identity disorder). The criteria for dissociative amnesia specified that the amnesia usually occurred for traumatic or stressful circumstances. Dissociative fugue now could be diagnosed in the absence of the assumption of another identity. Amnesia was added as a criterion symptom for dissociative identity disorder. The disorders were structured to reflect pathologies of memory, identity, and perception, respectively.

The DSM-IV (and TR) category of dissociative disorders not otherwise specified (NOS) contained several examples that became particular areas of attention in DSM-5: “Clinical presentations similar to dissociative identity disorder that fail to meet full criteria for this disorder. Examples include presentations in which a) there are not two or more distinct personality states or b) amnesia for important personal information does not occur;” “Derealization unaccompanied by depersonalization in adults;” and “Dissociative trance disorder…[and] Possession trance disorder…[where the]…dissociative or trance disorder is not a normal part of a broadly accepted collective cultural or religious practice.”

Table 20–1.
Most Commonly Used Reliable and Valid Screening Measures and Structured Diagnostic Interviews for Dissociation and Dissociative Disorders

	Characteristics	Structure	Use	Development
Self-Report Screening Measures				
Dissociative Experiences Scale (DES)[a]	Self-Report screening measure to assess trait dissociation in adults including items for amnesia, absorption, depersonalization, derealization; has been translated into more than 40 languages, with strong cross-cultural similarities for western and non-Western populations	Average score of 28 items rated 0–100% of the time experienced	Score ≥30 gives 0.85 hit rate for Dissociative Identity Disorder Diagnosis. Excellent convergent validity with other measures of dissociation; strong predictive validity for dissociative disorders, PTSD, and abuse	Developed by Eve B. Carlson, Ph.D. and Frank W. Putnam, M.D. See van Ijzendoorn MH, Schuengel C. The measurement of dissociation in normal and clinical populations: Meta-analytic validation of the Dissociative Experiences Scale (DES). *Clin Psychol Rev.* 1996;16(5):365–382.
DES-Taxon Scale (DES-T)[a]	Developed through Taxonic Analysis of DES scores of over 1,500 patients with many diagnoses, as well as nonpatient controls	Average score of a subset of 8 items from DES: Items: 3, 5, 7, 8, 12, 13, 22, 27. DES and DES-T calculator that gives the probability (not average score) that an individual fits the taxon can be downloaded at http://www.isst-d.org/default.asp?contentID = 66	Scores on the DES-T are lower than those on the DES for all groups in which pathologic dissociation is not a core syndromal feature…The within-sample variation on the DES-T is smaller than that for the DES for these same groups. Fits a typologic not a dimensional model	Waller NG, Putnam FW, Carlson EB. Types of dissociation and dissociative types: a taxonometric analysis of dissociative experiences. *Psychol Methods.* 1996;1(3):300–321.
Adolescent DES (A-DES)[a]	A version of the DES validated as a screening measure for trait dissociation in adolescents	Average score of 30 items, rated on a 0–10 scale from "never" to "always"	Score ≥4.0 predicts high levels of dissociation; scores of 4–7 predictive of dissociative identity disorder. Able to predict sexually abused vs. nonabused adolescents. Younger adolescents may have higher scores.	Armstrong J, Putnam FW, Carlson E, Libero D, Smith S. Development and validation of a measure of adolescent dissociation: The Adolescent Dissociative Experience Scale. *J Nerv Ment Dis.* 1997;185:491–497.
Child Dissociative Checklist (CDC)[a]	Parent, caregiver, teacher report for screening of dissociative symptoms in children 5–12 years of age	Average score of 20 items rated from 0 to 2, "not true" to "very true" of the child over the previous 12 months:	The CDC has high discriminant validity among four test samples including: normal control girls, sexually abused girls, boys and girls with (DSM-IV-TR) dissociative disorder NOS and boys and girls with dissociative identity disorder.	Putnam FW, Helmers K, Trickett PK. Development, reliability, and validity of a child dissociation scale. *Child Abuse Negl.* 1993;17(6):731–741.
Somatoform[a] Dissociation Questionnaire (SDQ-20)	SDQ measures somatoform dissociation: dissociative symptoms that phenomenologically involve the body; i.e., somatosensory and conversion symptoms common in dissociative patients. These include motor inhibitions, loss of function, anesthesias and analgesias, pain, and problems with vision, hearing, and smell.	Average score of 20 items scored from 1 to 5 "not at all" to "extremely"	Strong correlation with DES scores (0.85) but lower in some samples indicating incomplete overlap between psychoform and somatoform dissociations. Strongly discriminates dissociative identity disorder, other dissociative disorders; somatic symptom disorders; other disorders.	Developed by Ellert R.S. Nijenhuis, see Nijenhuis ER, Spinhoven P, van Dyck R, vander Hart O, Vanderlinden J. The development and psychometric characteristics of the Somatoform Dissociation Questionnaire (SDQ-20). *J Nerv Ment Dis.* 1996;(184):688–694.
Somatoform Dissociation Questionnaire-5 (SDQ-5)	5 items that screen for somatoform dissociation	Average score of 5 items from the SDQ-20, scored from 1 to 5 "not at all" to "extremely"	SDQ-5 has reasonable sensitivity, specificity, positive and negative predictive power for DSM-IV-TR dissociative disorders	Nijenhuis ER, Spinhoven P, van Dyck R, van der Hart O, Vanderlinden J. The development of the Somatoform Dissociation Questionnaire (SDQ-5) as a screening instrument for dissociative disorders. *Acta Psychiatr Scand.* 1997;96:311–318.
Peritraumatic Dissociative Experiences Questionnaire (PDEQ)	Measures the extent of dissociation at the time of a traumatic event. May consist of one or two factors including depersonalization/derealization	Exists in both Rater and Self-Report Versions (10 questions), as well as brief version (6 questions). Each item is scored from 1 (not at all true) to 5 (extremely true). The total score is the sum of all items. A score above 15 is indicative of significant dissociation.	Peritraumatic Dissociation strongly associated with later development of PTSD. PDEQ shown to be internally consistent, strongly correlated with other dissociation measures, and measures of traumatic stress response, but not with measures of general psychopathology	Developed by Charles Marmar et al. Marmar CR, Weiss DS, Metzler T. Peritraumatic dissociation and posttraumatic stress disorder. In: Bremner JD, Marmar CA. eds. *Trauma, Memory, and Dissociation*. American Psychiatric Press, 1998:229–252.

Self-Report Screening Measures				
Cambridge Depersonalization Scale (CDS)	Assessment measure for depersonalization and derealization symptoms	29 questions rated for frequency and duration over past 6 months. Score >70 indicative of depersonalization/derealization disorder. Significantly higher than patients with anxiety disorders, mood disorders, and partial-complex seizures. Dissociative identity disorder patients often score >200.	Four factors account for 73% of the variance on the CDS: anomalous body experience; emotional numbing; anomalous subjective recall; and alienation from surroundings	Developed by Mauricio Sierra and German E. Berrios. Sierra M, Berrios GE. The Cambridge Depersonalization Scale: a new instrument for the measurement of depersonalization. *Psychiatr Res*. 2000;93(2):153–164.
Comprehensive Self-Report (Diagnostic Measures)				
Multidimensional Inventory of Dissociation (MID)[a] There is also an MID for adolescents.	Diagnostic self-report for dissociative disorders, PTSD, somatic symptom disorders, borderline personality disorder features	218 items self-report rating how often someone experiences symptoms from 0 ("never") to 10 (always); only dissociation measure that has validity scales; 30–90 minutes. Scoring program available (see below)	The MID demonstrated internal reliability, temporal stability, convergent validity, discriminant validity, and construct validity. The MID also exhibited incremental validity over the DES.	Developed by Paul Dell, Ph.D. Dell PF. The multidimensional inventory of dissociation (MID): A comprehensive measure of pathological dissociation. *J Trauma Dissociation*. 2006;7(2):77–106.
Multi-scale Dissociation Inventory (MDI). Available at http://www.johnbriere.com/multiscale.htm	Multiscale measure of dissociation with a 5-point Likert format that generates six dissociative symptom subscales and a total dissociation scale. Normed on 444 trauma exposed individuals in the community	30 items; approximately 15 minutes to complete. Scales include disengagement; depersonalization; derealization; emotional constriction (numbing); memory disturbance; identity dissociation; and total dissociation score	The scales show their expected relationships to trauma history and to other known dissociation scales, including the DES. The MDI has very-good-to-excellent sensitivity and specificity.	Developed by John Briere, Ph.D. Briere J, Weathers FM, Runtz M. Is dissociation a multidimensional construct? Data from the Multiscale Dissociation Inventory. *J Trauma Stress*. 2005;18:221–232.
Clinician-Administered Dissociative States Scale (CADSS)	Clinician-administered inventory that measures current state dissociation; has 28 items rated by the interviewer from 0 ("never") to 4 ("extreme")	Administered by a clinician usually in the context of an experimental study, to assess symptoms of amnesia, depersonalization, and derealization. The CADSS has proven useful in pharmacologic studies (e.g., of the dissociative agent ketamine in the treatment of depression), and in military stress studies	The CADSS has good convergent validity with other measures of dissociation and high interrater and test–retest reliability.	Developed by J. Douglas Bremner. Bremner JD, Krystal JH, Putnam FW, et al. Measurement of dissociative states with the clinician-administered dissociative states scale (CADSS). *J Trauma Stress*. 1998;11:125–136.
Structured Clinical Interview for DSM-IV-TR Dissociative Disorders, Revised (SCID-D-R)- being updated for DSM-5	Semi-structured, clinician-administered interview; 276 questions on a 4-point scale; 1–3 hours, if dissociative symptoms are present; much less time for nondissociative patients. Widely seen as "gold standard" for research studies requiring a diagnosis, and for differential diagnosis clinical cases.	Assesses the presence and severity of amnesias, identity confusion and alteration, depersonalization, and derealization, and renders a DSM-IV-TR diagnosis for all five dissociative disorders and for acute stress disorder.	The SCID-D-R has good-to-excellent interrater and test–retest reliability and well-established validity in numerous studies. It has been translated into at least a dozen languages.	Developed by Marlene Steinberg, M.D. Steinberg M. The Structured Clinical Interview for DSM-IV Dissociative Disorders-revised (SCID-D-R). American Psychiatric Press; 1994.
Dissociative Disorders Interview Schedule (DDIS). Has been updated for DSM-5. The DSM-5 version is available at http://www.rossinst.com/ddis.html	Clinician-administered interview 132 items. Strict yes–no format for all questions; may limit utility in situations where feigning is a concern. Requires approximately 30–60 minutes to conduct with dissociative identity disorder patients.	Inquires about, in addition to dissociative symptoms, child abuse history, substance abuse, paranormal experiences, and symptoms of major depressive, somatoform, and borderline personality disorders; yes–no format limits utility for diagnosis of borderline personality disorder	Except for depersonalization disorder, inter-rater reliability is acceptable, and convergent validity includes strong correlations with the DES, the SCID-D, and clinical diagnoses of dissociative disorders.	Developed by Colin Ross, M.D. Ross CA, Heber S, Norton GR, Anderson D, Barchet P. The dissociative disorders interview schedule: A structured interview. *Dissociation*. 1989;(2):169–178.

DSM-5 (and TR) Dissociative Disorders and the DSM-5 (and TR) Trauma- and Stressor-Related Disorders

The DSM-5 made major changes to the classification of the posttraumatic and dissociative disorders that were retained in DSM-5-TR. PTSD, ASD, adjustment disorder, and several other conditions were placed in a separate category of trauma- and stressor-related disorders. Because of the robust relationship between dissociative disorders and antecedent trauma, dissociative disorders were considered for inclusion in the trauma- and stressor-related category. However, unlike the disorders in this new category, the diagnostic criteria for dissociative disorders do not require exposure to a stressor or a traumatic event as a diagnostic criterion.

Nonetheless, to show the strong relationship between dissociation and trauma, the DSM-5 (and TR) chapter on dissociative disorders is placed immediately after that of the trauma- and stressor-related disorders. This relationship was explicitly described in the introduction to the dissociative disorders section. The DSM-5 (and TR) diagnostic criteria for PTSD and ASD specifically describe flashbacks as dissociative. The PTSD criteria include a *dissociative subtype,* characterized by depersonalization and/or derealization in response to posttraumatic reminders, often, but not

invariably, alternating with the typical intrusive symptoms that characterize nondissociative forms of PTSD. The ASD diagnostic criteria include dissociative symptoms such as depersonalization, derealization, altered time sense, and dissociative amnesia. Recent studies suggest that there may also be a dissociative subtype of ASD. The World Mental Health Survey data from 25,018 respondents from 16 high, middle-high, and low/lower-income countries found a 12-month prevalence of the dissociative subtype of PTSD in 14.4% of individuals with PTSD.

As will be discussed later in this chapter, additional research has begun to clarify the relationship between the dissociative subtype of PTSD and other dissociative disorders.

Changes to the Dissociative Disorders in DSM-5 (and TR)

Significant alterations to the dissociative disorders' criteria in DSM-5 (retained in DSM-5-TR) include changes to the definition of dissociation, the diagnostic criteria for dissociative identity disorder, dissociative amnesia, and depersonalization disorder, and the examples included under other specified dissociative disorders.

The Definition of Dissociation

The definition of dissociation in DSM-5 changed considerably from prior editions of the DSM. The definition encompassed phenomena that may be relatively acute—such as an episode of dissociative amnesia that is recognized shortly after a soldier is removed from combat—as well as childhood-onset complex dissociative disorders that are frequently chronic, like dissociative identity disorder. As part of the latter, individuals may report or display a plethora of dissociative symptoms, including subjective self-division, chronic complex dissociative amnesia, dissociative fugue, overlap and intrusion among self-states, and depersonalization and derealization, among others. Also, the definition of dissociation had to encompass culturally diverse experiences of pathologic dissociation, such as pathologic possession (see below).

As described in the introductory section, the DSM-5 (and TR) definition states that dissociation can affect the normal integration of every aspect of psychobiological functioning. Also, dissociative symptoms can be classified as "negative" and "positive," similarly to the definition of psychotic symptoms. The definition specifies that dissociation can be experienced not only as an absence, failure, or lapse, such as an

awareness of dissociative amnesia (a negative symptom). But it can also be experienced as a disruption, interruption, and/or discontinuity suffered as recurrent, jarring, involuntary intrusions into executive functioning and sense of self. For instance, several minutes of rapid shifting of dissociative identity disorder self-states (a positive symptom). Negative and positive dissociative symptoms may occur sequentially. For example, after several minutes of shifting states, the individual with dissociative identity disorder may not recall what has just occurred.

DSM-5 (AND TR) DIAGNOSTIC CRITERIA FOR THE DISSOCIATIVE DISORDERS

Dissociative Identity Disorder

Studies of the phenomenology of over 1,000 dissociative identity disorder individuals studied mostly in the United States and Europe with the Structured Clinical Interview for DSM-IV-TR Dissociative Disorders (SCID-D-R), the Dissociative Disorders Interview Schedule (DDIS), or the Multiaxial Inventory of Dissociation (MID) found that over 90% of these individuals endorsed the following symptoms, in order of frequency: amnesia (100%); subjective self-alteration (98%); symptoms of overlap, interference, and intrusion among self-states, often characterized as variants of the FRSs of psychotic individuals (94%); awareness of the voices of self-states that are usually experienced within the mind (92%); and spontaneous trance behaviors (91%). Less commonly, dissociative identity disorder individuals described somatoform symptoms (83%), depersonalization (77%), and derealization (63%). In addition, these studies found that, unless the person was in crisis, only 15% of dissociative identity disorder individuals regularly showed clear-cut switching behaviors between distinctly differentiated self-states.

These and other studies found that over 40% of DSM-IV-TR dissociative disorder diagnoses were for dissociative disorder NOS, most commonly for Example 1 of the dissociative disorders NOS criteria. Clinicians familiar with dissociative identity disorder patients often used this NOS example *as a specific diagnosis*: a disorder with the clinical features, course, comorbidities, antecedent developmental trauma history, and treatment response of dissociative identity disorder but without “distinct” identities that take “control” of the person’s behavior through a

process of “switching,” often a subtle process in and of itself. This diagnostic option has been codified in ICD-11 as *partial dissociative identity disorder*; a controversial category described later in this section.

DSM-5 diagnostic criteria for dissociative identity disorder moved completely away from the notion of relatively stable (“enduring”) personality states that switch (“take control”) of behavior to a more user-friendly enumeration of the distinct subjective differences seen in dissociative identity disorder presentations. These can include marked discontinuity in the subjective sense of self or the self as an agent of behavior. In addition, the person may experience and/or display discontinuities in mood and affect; manifest behavior; apparent state of consciousness; availability of autobiographical, procedural, and/or semantic memory; perception of the environment; cognitive schema; and/or sensorimotor functioning. The latter may involve conversion symptoms, especially in some non-Western cultural contexts (see the section on Diagnosis and Clinical Features). Moreover, DSM-5 criteria allowed the diagnosis to be made based on reports by the patient or others of the self-state discontinuities, not only observed by the clinician of these states shifts. The DSM-5 diagnostic criteria for dissociative identity disorder also modified the amnesia criterion (B) based on phenomenologic studies. Changes in the amnesia criterion emphasize the complexity of reported memory disturbances and that patients often report amnesia for ongoing experience (see the section on Diagnosis and Clinical Features).

It remains a matter of clinical judgment just how “distinct” personality or possession states have to be or how “marked” the discontinuities in the sense of self and agency to meet the A criterion for dissociative identity disorder. Despite the use of terms like “distinct” and “marked” in the criteria, all the data on dissociative identity disorder supports the subtlety of the symptoms of this disorder. The *distinctness* of self-states does not necessarily refer to the secondary elaboration of the states into dramatically different manifest presentations (see the section on Dissociative Identity Disorder). Rather, the term refers to the extent of compartmentalized information manifested by the identity states, accompanied by a subjective sense of self and a capacity for behavioral enactment. Similarly, the term *marked* refers to the disruptiveness of the symptoms to the person, not necessarily to the dramatic presentation of dissociative symptoms.

In addition, after an extensive review of the cultural literature, the DSM-5 (and TR) integrated the DSM-IV-TR dissociative disorder NOS example concerning an experience of pathologic possession into the diagnostic criteria for dissociative identity disorder. (Non-possession dissociative trance remains as one of the examples for other specified dissociative disorder.) This decision was based on the phenomenologic similarity between dissociative pathologic possession states and dissociative identity disorder; their shared dissociative origin; the coexistence in the same patient of identities attributed to either possessing entities or to endogenously generated self-states; the occurrence of amnesia for the experiences during the possession experiences in pathologic possession; and shared risk factors, such as high rates of lifetime traumatic experiences. While pathologic possession states are often described as more transient and episodic than those of non-possession dissociative identity disorder, further research is needed to assess whether these presentations of pathologic possession represent the overt appearance of phenomena that persist in more subtle form over time. As described above, most non–possession-form dissociative identity disorder individuals may have subtle presentations of core dissociative identity disorder symptoms and/or may have a relapsing/remitting course and appear to be relatively asymptomatic unless experiencing a clinical decompensation.

DSM-5 and DSM-5-TR carefully elucidate that not all presentations of possession meet the criteria for dissociative identity disorder. In addition to meeting criterion A (description of dissociative symptoms), individuals with a presumptive presentation of possession-form dissociative identity disorder must also meet criterion B (amnesia), criterion C (the possession state must be pathological, that is, lead to distress or impairment) and criterion D (not a normal part of a broadly accepted cultural or religious practice). Most instances of possession experience in the world are normal, embedded in spiritual activities, or do not entail dissociative experiences, functioning instead to communicate distress in a spiritual language (e.g., as a cause of any number of physical or mental symptoms).

The addition of pathologic possession to the DSM-5 (and TR) dissociative identity disorder criteria indicates that, around the world, dissociative identity disorder presents in two main forms: non–possession-form or possession-form. These are not mutually exclusive: individuals in

one cultural setting may experience either form, or a single individual may experience both forms. Typically, in non–possession-form dissociative identity disorder, the personality states are experienced as *internal* aspects of the person. In possession-form dissociative identity disorder, by contrast, the alternative identities are typically experienced as *external* possessing agents, usually of supernatural or spiritual origin (e.g., demons, spirits). The main contrast between these two forms of the disorder appears to be shaped by the patient's sociocultural milieu. That is, possession-form dissociative identity disorder arises in contexts where possessing agents have ontologic validity (are considered "real"), such as in diverse traditional South Asian cultures or some fundamentalist religions in the United States. By contrast, non–possession-form dissociative identity disorder draws its alternative identities from individualistically focused experiences, such as stages of life (e.g., childhood) or symbolic, trauma-based intrapsychic dynamics (e.g., "protector," "sexualized") (see the section on Dissociative Identity Disorder).

Despite their phenomenologic similarities, several differences between dissociative pathologic possession states and non–possession-form dissociative identity disorder keep open the question of whether, as in ICD-11, pathologic possession states should be classified as a distinct nosologic category from a dissociative identity disorder. Most cases of "spirit possession" in two community studies in Africa did not report amnesia for the possession state. ICD-11 would include amnestic and nonamnestic cases under a single category of possession trance disorder, whereas they would be separated into distinct diagnoses in DSM-5-TR. Many individuals in these African studies also described alterations of consciousness consistent with ICD-11 trance disorder that predated the possession trance, linking the two disorders that were separated in DSM-5. Finally, very high rates of full therapeutic improvement have been reported for individuals with pathologic possession episodes participating in traditional healing, in contrast with the gradual improvement typical of dissociative identity disorder, possibly suggesting that the two conditions differ in severity. However, scant details on the course of these pathologic possession episodes are available to corroborate these claims of therapeutic success.

One pattern is so common as to be almost prototypical: presentations of dissociative possession states that are unwanted and cause distress only

to evolve, typically over a period of months, into experiences that are willed, controlled, and nondistressing, usually as functioning traditional healers. It remains unclear whether these conditions meet the criteria for dissociative identity disorder or should be considered transient episodes of distress that meet exclusion criterion D because they fulfill cultural expectations for broadly accepted cultural or religious practices of spiritual healing. This judgment may be more readily made in retrospect; the level of distress during the initial possession episodes of "healers-in-training" may resemble that of individuals who do not improve so quickly and completely. Additional research is needed to resolve these nosologic questions. In some clinical settings, the inclusion of possession-form presentations in DSM-5 appears to have improved detection and treatment response for individuals who otherwise would meet dissociative identity disorder criteria but whose identification might be missed due to clinicians' lack of familiarity with this presentation.

The evolution of the diagnostic criteria for dissociative identity disorder in DSM-III, DSM-IIIR, DSM-IV-TR, and DSM-5 (identical in DSM-5-TR) is found in Table 20–2.

ICD-11 Diagnostic Requirements for Dissociative Identity Disorder and Partial Dissociative Identity Disorder. It is beyond the scope of this chapter to extensively discuss the ICD-11 diagnostic requirements for the dissociative disorders. Besides the nosologic categorization of dissociative presentations of pathologic possession states, the ICD-11 diagnostic requirements for dissociative identity disorder differ in important ways from the DSM-5 (and TR) criteria. ICD-11 also emphasizes specific types of identity states, notably ones that "function in everyday life" and that "take executive control" of the person's behavior and interactions with others. In addition, ICD-11 has created a new *partial dissociative identity disorder* diagnosis. This is characterized by "…[O]ne personality state [that] is dominant and normally functions in daily life (e.g., parenting, work), but is intruded upon by one or more non-dominant personality states (dissociative intrusions)." This process may lead to symptoms of intrusion, influence, overlap, and interference but these "non-dominant" self-states only take "executive control" for limited times under specific circumstances.

Table 20–2.
Comparison of DSM-III, IIIR, ICD-10, DSM-IV-TR, DSM-5 Diagnostic Criteria for Dissociative Identity Disorder

DSM-III Diagnostic Criteria for 300.14 Multiple Personality Disorder (1980)	DSM-IIIR Diagnostic Criteria for 300.14 Multiple Personality Disorder (1987)	ICD-10 Diagnostic Criteria for (F44.81) Multiple Personality Disorder (1994)	DSM-IV-TR Diagnostic Criteria for 300.14 Dissociative Identity Disorder (1994)	DSM-5 Diagnostic Criteria for 300.14 Dissociative Identity Disorder (2013)
A. The existence within the individual of two or more distinct personalities, each of which is dominant at a particular time.	A. The existence within the person of two or more distinct personalities or personality states (each with its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and self).	A. The existence of two or more distinct personalities within the individual, only one being evident at a time.	A. The presence of two or more distinct identities or personality states (each with its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and self	A. Disruption of identity characterized by two or more distinct personality states, which may be described in some cultures as an experience of possession. The disruption identity involves marked discontinuity in sense of self and sense of agency, accompanied by related alterations in affect, behavior, consciousness, memory, perception, cognition, and/or sensorimotor functioning. These signs and symptoms may be observed by others or reported by the individual.
B. The personality that is dominant at any particular time determines the individual's behavior.	B. At least two of these personalities or personality states recurrently take full control of the person's behavior.	B. Each personality has its own memories, preferences and behavior patterns, and at some time (and recurrently) takes full control of the individual's behavior.	B. At least two of these identities or personality states recurrently take control of the person's behavior.	B. Recurrent gaps in the recall of everyday events, important personal information, and/or traumatic events that are inconsistent with ordinary forgetting.
C. Each individual personality is complex and integrated, with its own unique behavior patterns and social relationships.		C. Inability to recall important personal information, too extensive to be explained by ordinary forgetfulness.	C. Inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness.	C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
		D. Not due to organic mental disorders (F0) (e.g., in epileptic disorders) or psychoactive substance-related disorders (F1) (e.g., intoxication or withdrawal).	D. The disturbance is not due to the direct physiologic effects of a substance (e.g., blackouts or chaotic behavior during alcohol intoxication) or a general medical condition (e.g., complex partial seizures). **Note:** In children, the symptoms are not attributable to imaginary playmates or other fantasy play.	D. The disturbance is not a normal part of a broadly accepted cultural or religious practice. Note: In children, the symptoms are not better explained by imaginary playmates or other fantasy play.
				E. The symptoms are not attributable to the physiologic effects of a substance (e.g., blackouts or chaotic behavior during alcohol intoxication) or another medical condition (e.g., complex partial seizures).

Building on the psychobiological research at NIMH in the 1980s, the extensive phenomenologic studies that led to the DSM-5 diagnostic criteria showed that the naturalistic condition of dissociative identity disorder is one of multiple, simultaneously overlapping states, more like the ICD-11 partial dissociative identity disorder diagnosis. A recent study of 169 experienced clinicians who assessed the impact of the change from DSM-IV-TR to DSM-5 diagnostic criteria for dissociative identity

disorder found that diagnostic accuracy was improved in DSM-5 by removal of the requirement that self-states take control of behavior in any way.

Most presentations falling under the rubric of partial dissociative identity disorder in ICD-11 would thus qualify for a dissociative identity disorder diagnosis in DSM-5 (and TR). The new ICD categorization is based on the construct described by structural dissociation theory. Here it is postulated that the “personality” “splits”: into secondary and tertiary “structural dissociation” because of traumatic experiences of various degrees of severity, justifying separate diagnoses of partial and full dissociative identity disorder (see sections on Etiological Theories of Dissociation and Dissociative Identity Disorder for a full discussion). Nosologically, the “partial” rubric provides a specified diagnosis for patients who meet DSM criteria for dissociative identity disorder except for the amnesia criterion, now conceptualized under the “other” specified dissociative disorder category in DSM-5 (and TR). It remains a question for research whether the construct of partial dissociative identity disorder will allow clinicians to better identify subtle presentations of dissociative identity disorder. Alternatively, the division of dissociative identity disorder into two categories (“partial” and “full”) may prove confusing, as they suggest different severity. The DSM-5(and TR) diagnostic criteria were designed to decrease the high rate of diagnosis of DSM-IV-TR dissociative disorder NOS Example 1. The data on which this change was based did not find differences in symptoms, course, or treatment outcome between DSM-IV-TR dissociative identity disorder and most cases of Example 1 dissociative disorder NOS.

Structural dissociation theory is not accepted by many dissociation/dissociative disorder experts. Critique includes whether its language for mental processes is overly simplified, concrete, and reified, without sufficient acknowledgment that these are metaphorical constructs (e.g., “dissociated parts of the personality,” “retraction of the field of consciousness”); that it only describes mental “structure” without sufficient attention to process (e.g., dimensional aspects of dissociation); that it reasons backward from adults with dissociative identity disorder in creating an overarching etiological theory of dissociative, trauma- and stressor-related disorders, somatic symptom disorders, and borderline personality disorder; and that it conflates secondary structuring of dissociative identity disorder self-states (e.g., culturally accepted roles in

Western society like “functioning in everyday life”) with the basic phenomenology of self-states (see section on Discrete Behavioral States Theory and Dissociative Identity Disorder).

Other differences between ICD-11 and DSM-5-TR include that, after DSM-III, the subsequent DSM diagnostic criteria abandoned the notion of “executive control” by specific self-states. Due to the overlap/intrusion symptoms, “control” typically involves a summation of self-states that coordinate and cooperate versus self-states in conflict with these and/or other self-states. It is the internal conflicts that typically lead to increased symptoms and life difficulties. Dissociative identity disorder self-states tend to be organized not as a collection of separate states but into complex, dynamic self-state systems.

Thus, it is difficult for clinicians to define “control” of behavior in dissociative identity disorder other than by detailed moment-to-moment and/or exhaustive retrospective assessment of the subjective states of mind of the individual in specific situations. Even this is limited by the willingness of the individual patient to be forthcoming—or even have adequate awareness of what has led to a particular situation. Also, this exegesis is affected by the experience of the clinician in tracking state shifts and understanding the trauma-based psychodynamics that underlie dissociative identity disorder. Finally, the ICD-11 terms “control,” “executive control,” and “dominant”/ “non-dominant” self-states are difficult to operationally define (e.g., what is “executive control” in bipolar disorder?).

Dissociative Amnesia

There are few systematic studies of dissociative amnesia in the literature. Studies of severe PTSD in traumatized groups have shown very high rates of the PTSD dissociative amnesia criterion. Also, many studies have documented delayed recall of trauma and/or the association of autobiographical memory deficits with trauma. Based on close reading of these studies, many of the subjects would meet the diagnostic criteria for dissociative amnesia. In DSM-5-TR, dissociative amnesia is defined in terms of an alteration of *autobiographical memory* that can be either recent or remote but that typically presents as retrospective gaps and/or subjectively fragmented memory for life history. In some very severe cases of generalized dissociative amnesia, individuals have been shown to lose semantic and procedural memory as well (e.g., what is a contact

lens and how to use it). Also, the criteria now define the most common types of dissociative amnesia: localized, selective, or generalized dissociative amnesia (see Table 20–3 for types of dissociative amnesia). In ICD-11, following the diagnostic requirements in prior ICD editions, the autobiographical memory deficits are typically characterized by recent memory deficits associated with adverse life events, personal or interpersonal conflicts, or stress; more severe traumatic circumstances are associated with more persistent and refractory amnesia.

Dissociative Fugue as a Specifier of Dissociative Amnesia. There is little systematic literature on dissociative fugue, and the best studies remain detailed descriptive case series from the 1940s and 1950s. Both DSM-5-TR and ICD-11 agree that there are insufficient data to validate dissociative fugue as a disorder distinct from dissociative amnesia or dissociative identity disorder. Prior DSM versions of dissociative fugue included a criterion of "assumption of a new identity (partial or complete)." In DSM-5-TR and ICD-11, the development of a "new identity" during a fugue episode would meet diagnostic criteria for dissociative identity disorder. Other individuals with dissociative fugue do not differ clinically from those who meet diagnostic criteria for generalized dissociative amnesia other than for their peripatetic behavior.

Diagnostic Criteria for Depersonalization/Derealization Disorder

As opposed to DSM-IV-TR, the ICD-10, ICD-11, and DSM-5-TR agree that this disorder is typified by both depersonalization and derealization. Also, ICD-11 now includes depersonalization/derealization disorder among the dissociative disorders. This is based on research showing that depersonalization and derealization are prevalent in other dissociative disorders such as dissociative identity disorder. Depersonalization and derealization are quintessential responses to acute trauma (*peritraumatic dissociation*) and have been reported as highly prevalent in those subjected to motor vehicle accidents, emotional/verbal abuse, and imprisonment, among other exposures (see the section on Epidemiology). The dissociative subtype of PTSD is based on the symptoms of depersonalization and/or derealization in response to trauma cues.

Table 20–3.
Types of Dissociative Amnesia

Localized	Inability to recall events related to a circumscribed period of time
Selective	Ability to remember some, but not all, of the events occurring during a circumscribed period of time
Generalized	Failure to recall one's entire life
Continuous	Failure to recall successive events as they occur
Systematized	Amnesia for certain categories of memory, such as all memories relating to one's family or to a particular person

Several authorities have proposed that depersonalization is a "hard-wired" inhibitory response—part of the human psychobiological survival system—that allows for attenuation of anxiety and psychobiological hyperarousal to help preserve adaptive behavior and conservation of physical resources under conditions of threat and danger. Disorders related to depersonalization and derealization may represent the generalization and persistence of this response outside the context of immediate threat, just as PTSD fear reactivity can be understood, in part, as a generalization of the adaptive conditioned fear response beyond the immediate context where it was generated.

Studies of two large cohorts have persuasively documented a consistent nosology for DSM-5-TR depersonalization/derealization disorder. These studies described consistent age of onset, acute and remote antecedents, as well as distinct symptom clusters, cognitive organization, course, treatment response (primarily *lack* of treatment response), and gender ratio. Factor analysis from these studies suggests that symptoms of depersonalization/derealization disorder are characterized by four to five factors: numbing, unreality of self, unreality of other, temporal disintegration, and perceptual alterations, including micropsia/macropsia, out-of-body experiences, and feelings of unreality of objects and of one's own body.

Mr. J, a high-functioning professional without a psychiatric history, described that, while a college student in a geology class, he was involved in a field trip where he was excavating a small cave. He was working inside the cave when a landslide blocked the entrance. Although there was complete darkness in the cramped space, he noticed, with an unemotional sense of detachment, that he could observe himself as if from a distance. He reported having no sense of time. He did not experience fear or concern about his situation. He noted with interest the sounds of his classmates and professor shouting and digging at the front of the cave. He recalls that, as soon as he saw a beam of light come into the cave, he felt that he had re-entered his body, and suddenly felt anxiety and pain, and noticed bleeding where the rocks from the avalanche had struck his face. He still suffers from a partial facial nerve paralysis due to this event. He denies any subsequent depersonalization or derealization experiences.

Other Specified Dissociative Disorder

In DSM-5-TR, this category includes four examples: (a) chronic and/or recurrent mixed dissociative symptoms, such as identity disturbance associated with less-than-marked discontinuities in the sense of self and agency or alterations of identity or episodes of possession in an individual who reports no dissociative amnesia. This aligns somewhat with the ICD-11 partial dissociative identity disorder diagnosis; (b) identity disturbance in response to *coercive persuasion*; (c) *acute dissociative reactions to stressful events*, typically encompassing brief episodes of mixed dissociative symptoms that occur in the context of trauma or extreme stress. These are distinct from brief episodes of monosymptomatic dissociative disorders (e.g., dissociative amnesia) by combining a mix of dissociative symptoms but without the identity alteration of dissociative identity disorder. These episodes show substantial cultural variation. Some presentations of cultural concepts of distress included in DSM-5-TR (e.g., *ataque de nervios*) may meet the criteria for this condition; and (d) dissociative trance characterized by acute narrowing or complete loss of awareness of immediate surroundings manifesting as profound unresponsiveness or insensitivity to environmental stimuli. The trance state may be accompanied by minor stereotyped behaviors (e.g., finger

movements) of which the individual is unaware and/or that (s)he cannot control, as well as transient paralysis or loss of consciousness. As in prior editions of the ICD, ICD-11 places conversion disorders in the dissociative disorders section as a dissociative disorder of movement, sensation, or cognition. These conditions are included in the DSM-5-TR somatic symptom disorders section as functional neurologic symptom disorder (conversion disorder).

VALIDITY OF THE DISSOCIATIVE DISORDERS

As noted in the section on History, despite substantial systematic research about dissociation, the dissociative disorders and their relationship to trauma, debate continues about the validity of the dissociation concept, dissociative amnesia, and dissociative identity disorder.

Validity of the Dissociative Identity Disorder Construct

The debate about the existence of dissociative identity disorder has waxed and waned for more than a century. Sufficient data on pathologic dissociation, in general, and on dissociative identity disorder itself have accrued to judge this condition by the same standards that are applied to the validity of other psychiatric diagnoses.

The validity of psychiatric diagnosis is not defined by a single, unitary construct. There are no absolute criteria, models, guidelines, or standards to determine whether a psychiatric diagnosis is “valid.” A summary of the literature on psychiatric diagnostic validity combines the following elements: the history of the disorder; a detailed clinical description of the disorder that is repeatedly and independently replicated (content validity); longitudinal studies of symptom stability over time; the existence of a syndrome (at least one criterion symptom has ≥50% probability of being accompanied by another); diagnostic criteria and validated diagnostic and screening measures (discriminant validity); laboratory studies and/or valid and reliable psychological tests consistent with the clinical picture (criterion validity); etiologic studies; family studies; treatment outcome studies; taxonomic analysis; and exclusion criteria (e.g., is not better explained by another disorder, does not cause distress, and/or is biased based on race/ethnicity, gender, or culture-related factors). Data supporting the validity of dissociative identity disorder will be discussed in-depth in later sections.

Dissociative identity disorder, described throughout the 19th and early 20th-century psychiatry literature, is one of the oldest diagnoses in the literature. In the early to mid-20th century, for a variety of reasons, dissociative identity disorder was subsumed under other constructs and thought to be, at best, vanishingly rare (see the section on History). Later 20th-century reviews of cases and case series supported the construct and historical validity of dissociative identity disorder. Subsequently, clinical phenomenologic studies of dissociative identity disorder—including from North and South America, Europe, the Middle East, and Asia—document the presence of a core dissociative psychopathology in dissociative identity disorder. Case series and prospective epidemiologic studies document both symptom stability over time as well as syndrome predictability. The core features of the disorder have been documented across the life cycle: in childhood, adolescence, adulthood, and geriatric cases.

Construct or discriminant validity requires that the disorder can be differentiated from other disorders. Structured interviews such as the SCID-D-R and comprehensive symptom-screening measures such as the MID show that dissociative identity disorder patients can be discriminated from normal individuals and patients with Cluster B personality disorders, PTSD, psychotic disorders, and mood disorders, among others. Likewise, psychological test batteries and experimental cognitive and psychophysiological studies have discriminated dissociative identity disorder patients from those with other disorders, including simulators.

Criterion-related validity requires that laboratory tests or reliable psychological tests be consistent with the defined clinical picture. This stipulation is met by the reliable and valid diagnostic interviews and scales increasingly used in dissociation research. Psychological assessment protocols show a unique psychological profile that discriminates dissociative identity disorder from schizophrenia, depression, borderline and other personality disorders, nondissociative forms of PTSD and ASD, feigning individuals, and normal controls, among others.

Studies using neurobiologic and psychophysiological measurements of dissociative identity disorder subjects compared to simulating controls have invariably shown significant differences between the real subjects and simulators. Also, actual dissociative identity disorder subjects generally show unique patterns of neurobiologic and/or psychophysiological variables uncharacteristic of other psychiatric

disorders. When assessed in rigorous hypnotizability research protocols, across studies, individuals with dissociative identity disorder score significantly higher than patients with borderline personality disorder, PTSD, anxiety disorders, mood disorders, schizophrenia, and nonclinical controls.

Etiologically, as discussed in detail in subsequent sections, every study of dissociative identity disorder in children, adolescents, and adults documents the highest rates of childhood maltreatment and adversity compared to any other clinical group. Some studies substantiate trauma reports with records from hospitals, schools, child protective services, and other agencies, as well as confirmation by siblings or other relatives. Small clinical case series demonstrate multigenerational dissociative disorders, including dissociative identity disorder, as well as substantiated multigenerational childhood maltreatment.

As described later in this chapter, every retrospective and prospective treatment outcome study utilizing the triphasic trauma treatment model for dissociative identity disorder has shown significant patient improvement in many important symptom and functional domains. Randomized controlled clinical trials are currently in development. Taxon analysis has defined a categorically distinct “pathologic dissociation” taxon, encompassing severe dissociative symptoms characteristic of the most severe, complex dissociative disorders, including dissociative identity disorder. From the syndrome perspective, studies find that the conditional probability of one DES-T symptom predicting another is 100%. Based on the DES-T, regardless of base rates across samples, the conditional probabilities among amnesia, depersonalization, derealization, identity alteration/confusion, and hearing voices were 0.92, 0.92, 0.93, 0.76, and 0.94, respectively. Finally, these patients are highly distressed, with substantial rates of suicide attempts and nonsuicidal self-injury. If anything, there is stigma and bias *against* this diagnosis in the professional community.

In summary, these unique findings cannot be better explained by another disorder. Dissociative identity disorder satisfies all of the widely accepted standards for psychiatric validity and should be regarded as a legitimate disorder requiring an informed diagnostic and treatment approach.

Validity of Dissociative Amnesia

Studies that address the validity of dissociative amnesia have primarily centered on the existence of the phenomenon, not on the study of the clinical disorder. As noted previously, *all* studies that have attempted to investigate the presence of amnesia for traumatic events have reported that it occurs. However, recent studies using the MID found that individuals with dissociative amnesia can be distinguished from those with dissociative identity disorder. The former described retrospective autobiographical memory deficits. The latter demonstrated *both* retrospective autobiographical memory deficits and contemporaneous memory lacunae for current, ongoing activities, well-learned skills, and acquisition of possessions. International case series of individuals with dissociative amnesia document the phenomenology, psychological and neuropsychological profile, and neurobiology of dissociative amnesia, as well as a consistent history of severe childhood and/or adult interpersonal trauma (see sections on Neurobiology and on Dissociative Amnesia).

Alternative hypotheses about trauma and memory claim that trauma virtually always causes an indelible inscribing of memory in the brain and that dissociative amnesia cannot exist. This debate has also focused on the existence of hypothesized psychological mechanisms for the reported amnesia, such as repression or dissociation. Critics suggest that more mundane processes, such as failure to report, cognitive avoidance, or ordinary forgetting, might account for the apparently delayed recall, although it is difficult to understand how these alternative mechanisms could account for the repeatedly documented findings of acute or delayed amnesia resulting from trauma such as combat or rape. Also, dissociative amnesia remains a criterion symptom for both PTSD and ASD. Most critics of the dissociative amnesia concept do not appreciate that breakdown of dissociative amnesia generally results in intrusive PTSD symptoms: intense, highly disturbing perceptional, somatosensory, and emotional intrusions, and/or full flashbacks, with a fragmented narrative, not linear, quotidian autobiographical memory. The construct *of state-dependent learning and memory*, as shown in international phenomenologic, neuropsychological, and neurobiologic studies of dissociative amnesia, provides support for the view that trauma can be *both* registered in the brain in some form and can be relatively inaccessible to retrieval.

Research shows that individuals who report problems with the recall of trauma may describe several subjective processes, including difficulties

recalling some or all traumatic life events and/or life periods in which the trauma occurred. Others report deliberate attempts to avoid thinking about the traumatic events due to subjective distress or shame. Others describe a lack of ability to appreciate the abusive nature of trauma until they were older and became aware of the devastating effects of trauma on their lives. In clinical practice, *all* these mechanisms may account for aspects of dissociative amnesia in an individual patient.

Studies have corroborated the traumatic events recalled by individuals with dissociative amnesia. Types of corroboration include contemporaneous records from medical, social service, and diocesan church sources; verbal or written admission by perpetrators; criminal convictions or civil judgments against perpetrators; reports by family members; and information from witnesses or other victims of the same perpetrator. Meta-analyses show no significant differences in the accuracy of delayed recall of trauma compared to accounts of individuals who report continuous memory for trauma. Contrary to stereotype, studies show that delayed recall of trauma most frequently occurs outside of psychotherapy. Corroboration studies of delayed trauma memories also show that recall may be generally accurate, partially accurate, or completely confabulated. There are no significant differences in accuracy between delayed recall and reportedly “continuous” memories of traumatic events. Finally, the concept of dissociative amnesia for combat or other trauma was widely accepted—even by clinicians and researchers who later eschewed belief in it—until the issue led to litigation around childhood sexual abuse (see the section on History).

EPIDEMIOLOGY OF THE DISSOCIATIVE DISORDERS

Epidemiologic studies in North America, Europe, Africa, Asia, Australia, Latin America, and Turkey find that pathologic dissociation and dissociative disorders are common in samples of the general population, as well as in psychiatric inpatients, outpatients, emergency department patients, patients in alcohol and substance abuse treatment, and in special populations with high rates of early childhood trauma, such as women in prostitution. Also, studies of both clinical and community populations with histories of trauma show a subgroup with substantial rates of dissociation and dissociative disorders.

GENERAL POPULATION STUDIES OF DISSOCIATIVE DISORDERS

Table 20–4 shows the findings for the prevalence of DSM-IV-defined dissociative disorders in three representative general population samples ascertained by structured diagnostic inventories: Winnipeg, Canada, New York State, USA and a female sample in Sivas, a city in central Turkey. As shown in the table, the overall prevalence of dissociative disorders ranged from 9.1% to 18.3%. Based on these studies, one researcher has conservatively estimated the lifetime prevalence of dissociative disorders in the community at about 10%.

A random sample of 1,055 adults in Winnipeg, Canada, were given the DES, and a subsample of 502 respondents that did not differ significantly demographically from the larger sample was subsequently reevaluated with the DDIS. Findings include a left-skewed distribution on the DES, with only a small subset of the population 3% to 5% endorsing many forms of dissociative experience, consistent with the construct of *pathologic dissociation* and a categorical taxon (see the section on Theories of Dissociation). This group was distinct from all other diagnostic categories, with symptoms characteristic of dissociative identity disorder and DSM-IV-TR dissociative disorder NOS. Overall, 12.2% of study participants met DSM-IV diagnostic criteria for a lifetime diagnosis of a dissociative disorder.

There was a 9.1% 1-year prevalence of dissociative disorders in a longitudinal, community-based study of 658 adults in New York State. DSM-IV Dissociative disorder NOS was the most common diagnosis, with a prevalence of 4.3%. Dissociative disorders were associated with clinically significant impairment and, as in other studies, with comorbid mood, anxiety, and personality disorders. Individuals with dissociative identity disorder were the most impaired of the dissociative disorders group.

Table 20–4.
Prevalence of Dissociative Disorders in General Population Samples Ascertained with Structured Diagnostic Instruments

Study	Ross (1997)	Johnson et al. (2006)	Sar et al. (2007)
Measures	DES and DDIS	Adapted from DES, SCID, SCID-II, and GAFS	DDIS, SCID-PTSD, and SCID-II
Number of subjects	502	658	628 (female)
Diagnosis	Subjects (%)	Subjects (%)	Subjects (%)
Dissociative amnesia	6.0	1.8	7.3
Dissociative fugue	0	0	0.2
Dissociative identity disorder	1.3	1.5	1.1
Depersonalization disorder	2.8	0.8	1.4
Dissociative disorder not otherwise specified (NOS)	0.2	4.3	8.3
Dissociative disorder NOS with multiple personality states			4.1
Dissociative disorder NOS with indirect cues for personality states			2.4
Derealization without depersonalization			1.1
Dissociative trance disorder			0.6
All dissociative disorders	12.2	9.1	18.3

DDIS, Dissociative Disorders Interview Schedule; DES, Dissociative Experiences Scale; GAFS, Global Assessment of Functioning Scale; SCID, Structured Clinical Interview for DSM-IV-TR Dissociative Disorders; SCID-PTSD.

Data from Ross CA. Dissociative Identity Disorder: Diagnosis, Clinical Features, and Treatment of Multiple Personality. John Wiley & Sons; 1997:109; Johnson JG, Cohen P, Kasen K, et al. Dissociative disorders among adults in the community, impaired functioning, and axis I and II comorbidity. *Psychiatry Res*. 2006;40(2):131; Sar V, Akyüz G, Doğan O. Prevalence of dissociative disorders among women in the general population. *Psychiatry Res*. 2007;149:169.

In a representative sample of 628 women in Sivas, Turkey, assessed with the DDIS, the PTSD module of the SCID-I, and the SCID-II, 18.3% met the criteria for a lifetime DSM-IV diagnosis of a dissociative disorder. Dissociative identity disorder represented about 1.1% of the sample; like in the New York State study, dissociative disorder NOS was the most prevalent dissociative disorder at 8.3%, with about half of these partially meeting criteria for dissociative identity disorder. Diagnosis of a dissociative disorder was significantly associated with other comorbid conditions such as PTSD, major depression, somatization disorder, borderline personality disorder, and a history of attempted suicide.

Pathologic Dissociation in the General Population

There are two Finnish general population studies of dissociation: a 3-year prospective study of 2,001 adults and a cross-sectional study of 1,424 adolescents ages 13 to 18. The adult studies used the DES, the DES-Taxon scale (DES-T), the Beck Depression Inventory (BDI), the Somatoform Dissociation Questionnaire (SDQ), the Toronto Alexithymia Scale (TAS), and an instrument based on measures used in the Adverse Childhood Experiences (ACE) study (discussed later in this chapter). A subset of the original adult cohort (N = 1,399) was followed up 3 years later with the DES, DES-T, and BDI. The adolescent participants completed the Adolescent DES (A-DES) and measures of academic performance, competence, social relationships, and alcohol and drug use.

In the adult study, just as in the Winnipeg study, the investigators found a skewed distribution of the DES, with about 3.5% of the general population fitting the taxonomic pathologic dissociation construct. Pathologic dissociation was strongly associated with depression, suicidality, alexithymia, and alcohol abuse. SDQ scores increased in a graded fashion with each ACE: childhood intrafamilial violence, including childhood emotional, sexual, and physical abuse; familial alcohol abuse; and poor relationship between the parents. The combination of high SDQ scores and high DES scores differentiated a specific subgroup with higher

depression and suicidality, as well as many life stresses and problems with work, finances, and health.

At 3-year follow-up, membership in the subgroup with high-dissociation scores was more stable than membership in the pathologic dissociation taxon. About a third of the original high-dissociation group still showed high-dissociation scores, but the other two-thirds had been replaced by an equal number of different individuals with DES scores above the cutoff of 20. However, only four of the original individuals who fit the pathologic taxon remained in the taxon, although the total number of individuals in the taxon remained the same (n = 39; 3.9% at 3 years). Improvement in depression and suicidality was associated with lower-dissociation scores, indicating that worsening dissociation may be a response to stressful events and greater levels of symptoms in several diagnostic domains. Problems with work performance and younger age also predicted consistently higher-dissociation scores.

In the adolescent sample, higher-dissociation scores were correlated with daily smoking, frequent use of alcohol, abuse of legal drugs, cannabis use, social isolation, and poor school performance. There was no assessment of maltreatment in these adolescents. In longitudinal studies of abused children smoking, alcohol and drug use, social isolation, and poor school performance are all associated with childhood adversity and maltreatment (see discussion of the ACE study below).

In the adults, higher-dissociation scores were associated with more ACEs and higher depression, suicidality, and life adversities. These findings are consistent with studies finding that, in many individuals, overt dissociative disorder symptoms occur with a remitting/relapsing course, only fully emerging during times of life stress, trauma, and/or adversity. These may be accompanied by increased PTSD symptoms, depression, substance abuse, and self-destructive and suicidal behavior—all associated with trauma.

An island-wide representative community study in Puerto Rico of 891 youth ages 11 to 17 examined the point prevalence of pathologic dissociation, defined by a cutoff on an 8-item version of the A-DES keyed to the pathologic taxon. As in the Finnish research, this study also found a skewed population distribution of dissociation, with nearly 53% of adolescents reporting an A-DES score of 0. Pathologic dissociation was reported by 4.9% of adolescents, with no significant differences by age or gender. In multivariate analyses, pathologic dissociation was associated

with exposure to violence and elevated levels of physical abuse. Individuals exposed to multiple forms of victimization were significantly more likely to endorse pathologic dissociation.

Two community-based studies in Brazil examined the prevalence of dissociative disorders using standardized instruments. However, variations in inclusion criteria and clustering of specific disorders in reporting complicate cross-national comparisons. One representative community study of 3 large metropolitan areas in Brazil (*N* = 6,476) using a clinician-rated symptom screener based on DSM-III found a lifetime prevalence of 2.8% to 8.1% for "somato-dissociative disorders" depending on the urban area; however, the mixing of somatoform and dissociative categories complicates the interpretation of this finding. A different representative community sample in a large section of São Paulo (*N* = 1,464) examined ICD-10–defined dissociative disorders using the lay-administered Composite International Diagnostic Interview (CIDI), revealing a prevalence of 2.2% (lifetime), 0.5% (12 months), and 0.3% (1 month). However, ICD-10 differs substantially from DSM in the criteria for dissociative disorders.

Dissociative Identity Disorder

Across community-based studies, dissociative identity disorder had a prevalence of about 1% to 1.5% in the general population. In the New York and Turkish studies, DSM-IV-TR dissociative disorder NOS was the most frequent diagnosis, 4.3% and 8.3%, respectively. In the Turkish study, about half of these NOS individuals (4.1% of the whole sample) were described as similar to dissociative disorder NOS Example 1 in DSM-IV-TR, "Dissociative disorder NOS with multiple personality states" (see Nosology). Thus, the improved diagnostic precision of DSM-5-TR diagnostic criteria may increase the prevalence of dissociative identity disorder by decreasing prevalence of Example 1.

Dissociative Identity Disorder and Gender in the General Population. Developmental studies indicate that the ratio of female to male dissociative identity disorder cases steadily increases from 1 to 1 in early childhood to approximately 8 to 1 by late adolescence in North American samples. Proposed explanations include gender-related differences in the types, age of onset, and duration of maltreatment experienced by men and women; differences in clinical presentations (i.e.,

male cases are more likely to be missed); and the possibility that more male dissociative identity disorder cases end up in the criminal justice or alcohol and drug treatment systems, or both, rather than the mental health system.

However, this finding has not been replicated in Turkish studies of adolescents with dissociative identity disorder or in the WHO study of the PTSD dissociative subtype, where the male gender was more prevalent. The Finnish longitudinal study found a 1:1 ratio of male: female patients in the pathologic dissociation taxon. No significant gender differences were found in the Puerto Rico study of community-based adolescents. A study of the entire male and female population of Taiwanese prisons ($N \approx 60{,}000$) found that the most common diagnoses in *both* genders were among the ICD-10 dissociative/conversion disorders.

Sociocultural effects are implicated in these discrepant findings. Consistently in cross-national and cross-ethnic studies, men are less likely than women to seek mental health treatment. Due to clinical stereotypes, childhood maltreatment, especially sexual abuse, may be less frequently ascertained in men. Males may be even more reluctant than women to discuss childhood or adult rape. Traditional gender roles for men tend to increase the expression of externalizing behaviors compared to women, possibly skewing to higher rates of incarceration for traumatized men. Western/secular depictions of dissociative identity disorder are primarily based on media stereotypes, including popular first-person autobiographical accounts, movies, and television shows. The stereotypical dissociative identity disorder patient is a bright, creative, histrionic, sexualized White female, with theatrical switching among clearly defined, dramatically different personality states. Due to this inaccurate diagnostic framework, most female dissociative identity disorder patients are misdiagnosed, often for long periods of time. Males with dissociative identity disorder are even less likely to be correctly diagnosed. Media stereotypes depict men with this diagnosis as criminals, typically sexually sadistic serial killers. In the form of racism-based institutional betrayal by the mental health system—and despite well-known high rates of inner-city violence, trauma, and social adversities—men and women of color may be even *less likely* to be evaluated for trauma- and stressor-related and/or dissociative disorders. Men of color may be particularly profiled as antisocial and/or psychotic, leading to a

lack of appropriate diagnosis and treatment, especially for trauma/dissociative disorders.

Epidemiology of Pathologic Possession Form of Dissociative Identity Disorder

Cases of pathologic possession with dissociative symptoms have been reported in many countries, including China, India, Turkey, Iran, the Republic of Singapore, Brazil, Puerto Rico, Mozambique, and Uganda. Some case series of dissociative identity disorder in the United States and Canada have described patients who experienced self-states as possessing entities or were judged as possessed by co-religionists and subjected to exorcisms or similar practices to attempt to expel the personality states. In these cases, the phenomenology of dissociative identity disorder was influenced by these individuals' participation in religious groups that emphasized normative possession (e.g., Pentecostals, Charismatics).

Two epidemiologic studies in conflict regions of Africa shed light on the prevalence of pathologic possession trance. A randomized household study (N = 941) of individuals ages 13 to 60 residing in districts of rural Mozambique particularly affected by civil war revealed a point prevalence of 11% for "spirit" possession; distress was reported in 85% of cases, and loss of personal consciousness during possession in 95%. In 44% of cases, possession was attributed to more than one spirit, a characteristic associated with higher morbidity. However, amnesia was not assessed, preventing the application of full DSM-5-TR criteria. In multivariable analyses, individuals suffering from spirit possession were more likely than nonpossessed respondents to be women, have physical symptoms, and have suffered the loss of a child; there was also a trend for higher endorsement of traumatic experiences on the Harvard Trauma Questionnaire.

A community-based study (N = 1,113) of youth ages 12 to 25 living in randomly selected households in areas of Northern Uganda also torn by civil conflict examined the 1-month prevalence of pathologic spirit possession using DSM-IV research criteria for dissociative trance disorder. These pathologic possession experiences were attributed to *cen*, considered the spirits of individuals murdered in the civil war. Nine percent of respondents reported symptoms of identity alteration attributed to possession; the same proportion also endorsed the amnesia criterion.

Four or more criteria linked to DSM-IV dissociative trance disorder were endorsed by 8.2% of the sample, suggesting a high likelihood of meeting DSM-5-TR criteria for possession-type dissociative identity disorder; 45% of these also met DSM-IV PTSD criteria. Compared to individuals with low likelihood, those with a high likelihood of pathologic dissociation were significantly more likely to be female and to have suffered various forms of war-related trauma. In multivariable analyses, symptoms of spirit possession were significantly associated with functional impairment, suicide risk, perceived discrimination, and physical complaints.

An in-depth case series of 119 pathologic possession cases in Uganda confirmed the association between pathologic spirit possession and traumatic exposure, revealing significantly higher traumatic reports on standardized measures compared with 71 randomly selected mentally healthy inhabitants of the same villages. Scores on these trauma scales were strongly correlated with symptoms of pathologic possession and with higher levels of dissociative symptoms as measured by the DES and the SDQ.

Earlier epidemiologic studies also confirm the elevated global prevalence of pathologic possession experiences. In rural Indian communities, the period prevalence of pathologic possession has been estimated at 0.97% (over 6 months) to 3.5% (over 1 year), depending on the region, the sample, and the method of assessment. The period prevalence of culturally congruent, nonpathologic possession trance contributed an additional 0.2% to 1.8% over 6 to 12 months in the same studies. In a representative community sample of 4,129 residents of rural Baluchistan (southeast Iran), the point prevalence of a local pathologic possession state (“Djinnati”) among female residents ages 15 to 60 was 1%; no men reported the condition. Individuals who were Djinnati had significantly higher mean scores on the DES than a random subsample of nonaffected study participants.

In the Turkish study of 628 women in Sivas (previously discussed in this chapter), 20.2% of the women described paranormal experiences (e.g., precognition; encountering poltergeists or ghosts), and 2.1% reported dissociative possession experiences. Women with a dissociative disorder reported all types of paranormal and dissociative possession experiences significantly more frequently than those without. One subgroup composing 7.8% of the sample accounted for 91.6% of the reported possession experiences. They were characterized by the most severe trauma in both

childhood and adulthood; the most severe dissociative disorders (e.g., dissociative identity disorder and DSM-IV-TR dissociative disorder NOS); and multiple comorbidities commonly associated with trauma, such as major depression, PTSD, somatic symptom disorders, suicidal and self-destructive behavior, and features of borderline personality disorder. About half of the possession experiences were attributed to a dead or living person and the other half to supernatural entities (e.g., demon, jinn) or forces.

In the non–possession-form of dissociative identity disorder in secular psychiatric settings, patients frequently report the experience of "introject" self-states that literally embody other people in the patient's past or current life. These are sometimes experienced as a benevolent person, but mostly they represent prior or current reported perpetrators. This phenomenon may be experienced as so ego-alien that the person reports that they *feel* possessed. However, these individuals usually do not believe that they actually are possessed. Future studies will need to address the question of belief in possession as opposed to the dissociative individual *feeling* possessed.

Epidemiology of Dissociative Amnesia and the Dissociative Fugue Subtype of Dissociative Amnesia

Dissociative amnesia, as defined by the DSM-IV-TR, has been reported in approximately 1.8% (1-year prevalence) to 6% (lifetime prevalence) of general population samples, with 7.3% of the general population sample of Turkish women in Sivas meeting diagnostic criteria for dissociative amnesia in their lifetime. In these studies, there were low rates of the *dissociative fugue subtype:* 0% in Winnipeg and New York State and 0.2% in Sivas. The low prevalence of dissociative fugue in general population studies was one of the factors contributing to the decision to change this from a separate diagnosis to a subtype of dissociative amnesia.

Autobiographical Memory Disturbances for Childhood and Trauma

Childhood autobiographical memory disturbances (CAMD) are a common presentation of dissociative amnesia patients, with selective, localized, and, often, systematic amnesia for early life history (see Table 20–4). This finding has empirical support in data from the ACE study, a collaboration between the Centers for Disease Control (CDC) and Kaiser Permanente HMO in San Diego, CA, involving over 17,000 employed patients of a

California HMO. It is one of the largest population studies to assess the relationship between childhood adversities and later life medical, psychiatric, and behavioral problems. In the ACE study, during a comprehensive physical examination, patients filled out a questionnaire about 11 different childhood adversities and about their current health status. This included questions about recurrent childhood contact with sexual, physical, and/or emotional abuse; physical or emotional neglect; witnessing domestic violence; the presence of a substance-abusing member of the household; parental mental illness; parental incarceration; and parental absence or loss. The ACE study documented that increasing numbers of ACEs were, in a stepwise fashion, associated with a variety of adverse mental, physical, and behavioral health outcomes (see Tables 20–5 and 20–6 for a list of ACEs and their relationship to a variety of clinical disorders and behavioral problems). Studies show that ACEs are synergistic, with childhood sexual abuse being the most malignant ACE, pairing most frequently with other ACEs, followed by physical abuse, neglect, and intimate partner violence

A recent study from Hong Kong by Hong Wang Fong, Colin Ross and colleagues found that, in 202 outpatients from outpatient mental health clinics, just as in Western samples, increasing numbers of ACEs predicted both psychoform and somatoform pathological dissociation, as measured by the DES, DES-T, and the SDQ.

As part of the ACE study, CAMD was ascertained in a cross-sectional subsample of 9,460 relatively healthy adults in relationship to 8 different ACEs. Participants were asked: “Are there any large parts of your childhood after age 4 that you cannot remember?” This question is like the mental status questions for dissociative amnesia described in the section on clinical diagnosis. Also, the question is congruent with the DSM-5 Criterion A for dissociative amnesia: “An inability to recall important autobiographical information, usually of a traumatic or stressful nature, that is inconsistent with ordinary forgetting.”

If respondents reported affirmatively to this question, they were then asked to identify periods in 2-year increments, between the ages of 4 and 18, for which they had memory deficits. Overall, the age-standardized lifetime prevalence for CAMD was 18% (N = 1,502); the lifetime prevalence was 15% among men and 19% among women. Strong associations were observed between CAMD and each ACE. For both men and women, as the number of ACEs increased, the prevalence of CAMD

increased in a graded fashion. Overall, adults with an ACE score ≥6 had nearly six times the odds of having autobiographical memory deficits compared to adults with an ACE score of zero. Seventy-seven percent of those reporting CAMD identified memory deficits for ages 4 to 6; 57% for ages 7 to 9; 32% for ages 10 to 12; 15% for ages 13 to 15; and 9% for ages 16 to 18.

Table 20–5.
Types of Adverse Childhood Experiences from the ACE Study

- Abuse
  - Physical abuse
  - Sexual abuse
  - Psychological abuse
- Neglect
  - Emotional neglect
  - Physical neglect
- Household dysfunction
  - Mother treated violently
  - Household substance abuse
  - Household mental Illness
  - Parental separation or divorce
  - Incarcerated household member

Table 20–6.
Psychiatric, Behavioral, and Medical Outcomes of Childhood Traumas and Adversities: From the Adverse Childhood Experiences Study and Other Studies (Outcomes marked with an asterisk are from the ACE study)

Psychiatric

Depression*
Posttraumatic stress disorder (PTSD)
Pathologic dissociation
Alcohol and substance use disorders*
Panic and anxiety disorders*
Suicidal and self-destructive behavior*
Death by suicide*
Somatic symptom disorders
Eating disorders
Personality disorders
Multiple DSM diagnoses*
Hallucinations*
Autobiographical memory disturbances*

Behavioral

Multigenerational victimization and abuse
Victim of repeated sexual assaults
Violent behavior
Intimate partner violence—both as victim and perpetrator*
Smoking*
Impaired school/worker performance*
High-risk sexual behaviors in women*
Earlier sexual behaviors*
Early pregnancy as either father or mother*—teen pregnancy*
Unexpected pregnancy*
>30 Sexual partners in women*

Medical

Reduced health-related quality of life*
Greater healthcare utilization
HPA-axis dysfunction
Heart disease—ischemic heart disease*
Lung disease—COPD*
Liver disease*
Autoimmune diseases*
Kidney Disease

Chronic pain
Dementia (older adult Japanese cohort)
Morbid obesity*
Headaches*
Gastroesophageal reflux disease
Early menarche
Pregnancy complications and higher risk of children with autism spectrum disorders (risk factor: childhood sexual abuse)
Spontaneous abortions and fetal death*
Children with behavioral health problems

Data from Loewenstein R, Brand B, Gilbert LE, et al. Treating complex trauma survivors. *Psychiatric Times*. 2014;31:40–45.

Sexual and physical abuse in childhood were strongly related to autobiographical memory deficits. For women, the odds of reported amnesia in the sexually abused group were approximately double that of the nonabused group. Among abused men, the odds for CAMD were about 1.5 times higher than for the nonabused group. Sexual abuse frequency and severity were significantly related to autobiographical memory deficits, as was a close relationship between victim and perpetrator. Similarly, the presence of childhood physical abuse significantly increased the amnesia reports. Here again, women and men had, respectively, 2 and 1.5 times the odds of reported amnesia compared to individuals not reporting physical abuse. The combination of sexual and physical abuse was associated with a significantly greater extent of CAMD than a single type of abuse. The effects of comorbid depression could not fully explain the reported amnesia, as nondepressed individuals with higher rates of sexual and/or physical abuse showed significantly higher rates of CAMD than nondepressed, nontraumatized individuals. The authors concluded that ACEs, particularly sexual and physical abuse, have a specific, overarching effect on autobiographical memory, not just an effect on recall deficits for specific traumatic events. They hypothesized that, in the individuals reporting memory loss, cumulative traumatic experiences were encoded differently than ordinary autobiographical memory.

Table 20–7.
Factors Leading to Dissociative Amnesia after Traumatic Experiences

Trauma caused by human assault rather than natural disaster
Repeated traumatization as opposed to single traumatic events
Longer duration of trauma
Fear of death or significant harm during trauma
Trauma caused by multiple perpetrators
Close relationship between perpetrator and victim
Betrayal by a caretaker as part of maltreatment, especially sexual abuse
Threats of death or significant harm by perpetrator if the victim discloses their identity or information regarding the traumatic experience
Violence of trauma (i.e., physical injury caused by the trauma)
Earlier age at onset of trauma

Note: No factor has exclusively been associated with dissociative amnesia.

Adapted with permission from the *Treatment of Psychiatric Disorders*. 3rd ed. Vol 2. American Psychiatric Association; 2001.

Factors thought to predispose to trauma-related amnesia are listed in Table 20–7. However, none of these factors has been shown to exclusively distinguish individuals with amnesia for trauma from those without amnesia.

Delayed Recall for Early Life Trauma

Over 70 studies have confirmed the presence of delayed recall of sexual abuse, physical abuse, or both in clinical, community, and forensic populations, including retrospective, prospective, and longitudinal study designs. In various studies of clinical populations and individuals who identified themselves as survivors of childhood abuse, 16% to almost 100% reported amnesia for the abuse at some time in their lives, averaging approximately 30% across studies, though at a later point, they were able to recall the abuse. Lower prevalence was found in outpatients relative to inpatients. In studies of college undergraduates and women in the community, the prevalence of amnesia for abuse ranged from 13 to more than 50%.

A random sample of 505 men and women in the general population found that approximately 21% reported a history of childhood sexual

abuse. Of these, 20% described full amnesia, and 22% reported partial amnesia for the abuse at some time in their lives. Somewhat lower rates of amnesia for physical and emotional abuse have been reported in clinical and nonclinical samples: about 20% of participants endorse this finding across studies.

Longitudinal and prospective studies, primarily following up large samples of individuals with childhood sexual trauma documented in court or medical reports, have found that almost 40% of respondents failed to recall a forensically or medically documented episode of childhood sexual abuse when interviewed 20 years or more later, even though, in some cases, other episodes of trauma or maltreatment were recalled. Some respondents with documented trauma denied any history of maltreatment at all.

Studies have compared both delayed recall and continuous memory for sexual abuse in a variety of studies. These have included studies of sexually abused individuals whose perpetrators admitted to the sexual abuse and many of whom had physical injuries related to the abuse. In these and other studies, researchers have concluded that, when corroboration is obtained, there is *no difference in accuracy between trauma memories that are continuous compared to those with delayed recall. Either type of memory may be essentially accurate, partially accurate, or wholly confabulated.*

Epidemiology of Dissociative Fugue Subtype of Dissociative Amnesia. As noted above, community studies have found almost no cases of dissociative fugue. Dissociative fugue is thought to be more common during natural disasters, wartime, or times of major social dislocation and violence, although no systematic data exist on this point. Most of the pre—DSM-III cases are difficult to assess because the diagnostic conventions are so different. Most cases in the literature describe men with dissociative fugue, primarily in military samples, although historical studies describe an “epidemic” of apparent dissociative fugue in men in late 19th-century France. Dissociative fugue is usually described in adults, although 20th-century case reports have described adolescents with fugue behaviors. Dissociative fugue as a disorder or as a symptom of other dissociative identity disorder may be harder to discern in children, as children may have a much more limited living space in which to wander in an altered state of consciousness.

Prevalence of Amnesia in Traumatized Populations

A variety of studies have looked at the prevalence of amnesia for specific types of traumatic experiences: combat, sexual abuse, physical abuse, and emotional abuse. Other studies have reported amnesia along with other symptoms of PTSD in various traumatized groups, including survivors of genocide.

Across studies of active-duty soldiers in World War II, the average point prevalence of amnesia in the immediate aftermath of the combat ranged from 5% to 35%. Only a small percentage of these soldiers were reported to have suffered significant head injuries as a direct cause of their amnesia. In one study of 1,000 soldiers just after the Battle of Dunkirk, 35% of those exposed to the most intense combat had amnesia for the battle. On average, 14.4% of the soldiers in this sample reported amnesia. Past or family history of dissociation or hysterical symptoms was associated with amnesia in soldiers with minimal battlefield exposure.

Semi-structured interview data using the SCID-D-R have shown significantly higher amnesia scores in Vietnam-era veterans with PTSD compared to combat veteran controls without PTSD. Studies of Nazi Holocaust survivors, Korean War veterans, Vietnam-era combat veterans with PTSD and adult survivors of childhood sexual abuse have repeatedly documented deficits in explicit memory on standardized memory tests as compared to matched controls.

Forty percent of a sample of 50 randomly selected survivors of the Cambodian Holocaust endorsed amnesia on PTSD diagnostic inventories. The average DES score in this group of severely traumatized individuals was 37.1. Amnesia was reported in 3% to 10% of Nazi Holocaust survivors assessed with a PTSD inventory. The highest prevalence was found in tattooed survivors of Auschwitz. Studies of natural disasters, such as the San Francisco earthquake in 1989, have found that 3% to 5% of survivors report amnesia for at least some aspects of these events.

Epidemiology of Depersonalization and Derealization Symptoms

Transient experiences of depersonalization and derealization are common in normal and clinical populations. They are the third most reported psychiatric symptoms after depression and anxiety. Transient symptoms of depersonalization/derealization in the general population are common, with a lifetime prevalence of 26% to 74% and 31% to 66% at the time of a traumatic event. A survey of a random community-based sample of 1,000

adults in the rural South found a 1-year prevalence of 19% for depersonalization and 14% for derealization. Several studies have identified age as a significant factor for transient experiences of depersonalization and derealization, with adolescents and young adults reporting the highest rates in normal population samples, although a recent German community sample did not find such a difference. In one study, 46% of college students reported at least one significant episode of depersonalization within the prior year.

Depersonalization/derealization can also occur with illicit drug use, especially marijuana, hallucinogens, ketamine, and 3,4-methylenedioxymethamphetamine (MDMA or ecstasy). Studies have found that about 15% of depersonalization/derealization disorder cases are triggered by drug use. Transient depersonalization has also been described after certain types of meditation, deep hypnosis, extended mirror or crystal gazing, and sensory deprivation experiences. It is common after mild-to-moderate head injury, where there is little or no loss of consciousness, but significantly less likely if unconsciousness lasts for more than 30 minutes. One study estimated that at least 20% of minor head injury patients experience significant depersonalization and derealization. Depersonalization/derealization symptoms also occur in patients with epilepsy, both as a manifestation of the aura as well as during the seizure itself, particularly in focal impaired awareness seizure (previously labeled complex-partial seizure) patients.

Depersonalization/Derealization during and after Life-Threatening Experiences. Acute depersonalization/derealization is also common after life-threatening or near-death experiences, with or without serious bodily injury. Several studies of accident victims have found that up to 66% of individuals with a life-threatening experience report at least transient depersonalization during the event or immediately thereafter.

As will be discussed further in the section on etiology, measures of depersonalization and derealization increased significantly in studies of general infantry and Special Forces soldiers after undergoing survival school training, including experiences of uncontrollable stress, semi-starvation, sleep deprivation, lack of control over hygiene, and external control of movement, communications, and social interactions.

Depersonalization/Derealization and the Dissociative Subtype of PTSD. Individuals with PTSD who experience depersonalization and

derealization symptoms in response to trauma cues appear to be suffering from a distinct dissociative subtype of PTSD (see the section on PTSD). Studies have found that 15% to 30% of individuals with PTSD will meet the criteria for the dissociative PTSD subtype. Individuals with the dissociative subtype have specific fMRI and autonomic nervous system patterns when exposed to personal trauma scripts, including activation of medial prefrontal cortex and dorsal anterior cingulate; decreased activation of amygdala and insula; and no change, or even decrease, in heart rate. Individuals with this subtype have been found in a number of studies, including an international WHO study of 16 high, upper-middle, and low-middle income countries, respectively, with over 25,000 participants. In this study, the dissociative subtype of PTSD was associated with multiple types of earlier trauma, male sex, severe PTSD flashbacks, role impairment, disability, and suicidality, among other factors. Recent research has expanded our understanding of the neurobiology of the subtype, involving many other brain areas, for example, the periaqueductal gray.

Epidemiology of Depersonalization and Derealization Disorder

Community-based prevalence of DSM-IV-TR depersonalization/derealization disorder ranged from a 1-year prevalence of 0.8% in New York to 2.8% lifetime prevalence in Winnipeg. The Turkish study found a lifetime prevalence for DSM-IV-TR depersonalization/derealization disorder of 1.4%, but also included lifetime prevalence for DSM-IV-TR dissociative disorder NOS Example 2: “derealization without depersonalization” (prevalence 1.1%) (see Table 20–4). The DSM-5 depersonalization/derealization disorder diagnostic criteria specify that the presence of either or both symptoms is sufficient to make the diagnosis (see the section on Nosology). The actual general population prevalence of depersonalization/derealization disorder based on this sample could be around 2.5%, similar to that found in Winnipeg. Further evidence for this comes from a representative sample of the German population (N = 2,512), where the 6-month prevalence of depersonalization/derealization disorder was 3.4%. In this study, there were no age or gender differences in caseness for depersonalization/derealization disorder. The disorder was strongly associated with depression and anxiety. However, principal component analysis clearly showed that depersonalization/derealization disorder is a

separate psychopathological entity, and not just a concomitant of anxiety and/or mood disorders.

STUDIES OF DISSOCIATIVE DISORDERS IN CLINICAL POPULATIONS

The frequency of dissociative disorders in clinical populations varies depending on the type of population studied (e.g., state hospital vs. private psychiatric hospital), assessment methodology, and geographic setting. Most studies use a two-tiered approach, where the DES is used to screen the target population, followed by a diagnostic interview (the DDIS and/or the SCID-D-R for individuals above a DES cutoff score, generally 20 to 30). These studies have been criticized for using relatively high cutoff scores that are more likely to capture individuals with the most severe dissociative psychopathology, such as dissociative identity disorder, not those with dissociative amnesia or depersonalization/derealization disorder. Very few cases of dissociative fugue have been found in any of these studies. In general, across all these studies, high rates of childhood and adult trauma are significantly associated with high-dissociation scores on the DES and dissociative disorder diagnoses. Types of traumas include sexual abuse, physical abuse, emotional abuse, neglect, medical trauma, adult rape, adult physical assault, intimate partner violence, and traumatic bereavement.

Many of these studies employed the DDIS as the diagnostic interview, which uses a simple “yes–no” format to inquire about the presence or absence of depression, somatic symptom disorders, and features of borderline personality disorder, as well as history of various forms of childhood maltreatment. All of these are common comorbidities in patients with dissociative disorders. Subsequent U.S. and Turkish DDIS studies of dissociative identity disorder found that high rates of borderline personality disorder symptoms indicate a decompensated patient with severe posttraumatic and dissociative symptoms, not an actual, reliable diagnosis of borderline personality disorder.

Inpatient Studies

In studies of over 2,300 adult and adolescent inpatients from Canada, China, Finland, Germany, Switzerland, the Netherlands, Turkey, and the United States, between 12% and 30% of patients scored above the DES

screening target score. These studies report a wide range in point prevalence of dissociative disorders—between 1.7 (China) and 40.8% (United States) (mean = 15.8%; median = 12%)—although no study failed to find individuals with dissociative disorders. Across these inpatient studies, the frequency of dissociative identity disorder ranged from 0.4% of admissions to a Swiss hospital to 7.5% of admissions in a private psychiatric hospital in the United States (mean = 3%; median = 2%). In one Turkish inpatient study, almost half of patients diagnosed with DSM-III-R dissociative identity disorder (then, multiple personality disorder) believed themselves possessed by a jinn, a specific type of possessing entity from Islamic folklore.

The point prevalence of dissociative amnesia in psychiatric inpatients has been reported as 0.2% to 11%, depending on the sample, with the lowest rate in an inpatient sample in China. The point prevalence of depersonalization/derealization disorder in psychiatric inpatients ranges from less than 1% to 16%, depending on the sample and the method of assessment. Earlier studies reported higher rates of the symptom as these failed to differentiate carefully between depersonalization/derealization disorder or this as a symptom of other disorders, for example, schizophrenia or panic disorder.

A recent systematic study of a mixed group of Swiss outpatients and partial hospital patients, using standardized measures of disability, confirmed the finding of the New York State community sample: marked disability in the dissociative disorder group, with greatest disability in patients meeting structured interview, DSM-IV-TR diagnostic criteria for dissociative identity disorder, or dissociative disorder NOS, Example 1. This study concluded that the dissociative disorder patients fit the construct of *severe mental illness.*

Outpatient Studies

In studies of over 800 adult and adolescent outpatients in various settings from the United States, Europe, Turkey, and China, the point prevalence of dissociative disorders ranged from 12% to 29% (mean = 14.8; median = 13.8), with 2% to 6% meeting diagnostic criteria for dissociative identity disorder (mean = 5; median = 2.5). The point prevalence of DSM-IV-TR dissociative amnesia has been between 1.3% and 10% of adult outpatients. The point prevalence of DSM-IV-TR

depersonalization/derealization disorder has been reported to range from <1% to 5% of adult outpatients.

In a study of 116 adolescents ages 11 to 17 admitted to a Turkish outpatient clinic who were assessed with the A-DES and the SCID-D for DSM-IV-TR, 45.2% had a dissociative disorder, 16.4 had dissociative identity disorder, and 28.8% had dissociative disorder NOS (primarily Example 1). There were high rates of traumatic experiences among dissociative adolescents, but not significantly higher than among adolescents who did not meet diagnostic criteria for a dissociative disorder.

Dissociative Disorders in Non-Western/Secular Settings. Shekhar Saxena and colleagues reviewed chart information on more than 4,000 Indian outpatients; 104 had a diagnosis of a dissociative disorder. Only 5% to 10% of these outpatients received a specified dissociative disorder diagnosis according to DSM-III or DSM-III-R. By contrast, 85.5% of dissociative disorder cases were covered by the specified dissociative diagnoses in ICD-10. Seventy-four percent of patients had dissociative convulsions, 9.5% trance and possession disorders, and 2% dissociative movement disorder. This supports the observation that, outside of Western/secular settings, dissociative disorders frequently come to clinical attention due to conversion and/or trance/possession symptoms.

Emergency Department. In a study of Turkish emergency department patients, about a third of 43 consecutive patients screened with the DES subsequently met DSM-IV-TR diagnostic criteria for a dissociative disorder when subsequently administered the DDIS. Of these, 13% met diagnostic criteria for dissociative identity disorder, 13% for dissociative disorder NOS, and 7% for dissociative amnesia. These patients also had high rates of childhood trauma and self-destructive and suicidal behavior; the latter frequently leading to treatment at more restrictive levels of care. Failure to recognize and treat these acute presentations of dissociative disorders may lead to extended periods of costly and ineffective treatment (see section on Treatment).

Dissociative Disorders in Substance Use Disorder Populations

Dissociative disorders and childhood and adult trauma are frequently found in studies of inpatient and outpatient substance abuse treatment

programs. This is consistent with the high rate of current or past comorbid substance abuse in patients with dissociative disorders from other clinical settings. In a series of studies in the United States, Canada, Germany, and Turkey, 985 detoxified inpatients and outpatients in substance abuse treatment were screened for pathologic dissociation and DSM-III-R or DSM-IV-TR dissociative disorders with the DES and the DDIS and SCID-D, respectively. Males predominated in the samples. Rates of dissociative disorders ranged from 15% to 39% (mean = 24.3; median = 21.6); with 6% to 14% for dissociative identity disorder (mean = 8.25; median = 6.5); 0.5% to 27% for dissociative amnesia or dissociative fugue (mean = 8.6; median = 3.45); and 0.5% to 16% for depersonalization/derealization disorder (mean = 4.65; median = 1). The remainder received a diagnosis of dissociative disorder NOS. The wide range of findings in these studies likely reflects differing methodologies. These include varying DES cutoffs, diverse male/female ratios across samples, differences between DSM-III-R and DSM-IV diagnostic criteria, relative rate of alcohol abuse alone (associated with a lower prevalence of dissociative disorders in all studies), and younger age of participants (associated with higher rates of dissociative disorders).

Dissociative disorder diagnoses were strongly associated with a more refractory course—including more frequent treatment discontinuation, substance use, self-destructive and suicidal behavior, and history of childhood abuse and neglect. Women were more likely to receive a dissociative disorder diagnosis and had more severe and earlier forms of childhood trauma. Emotional abuse emerged as a particularly strong factor in the relationship between dissociative disorders and substance abuse. As in other clinical studies using the DDIS, the patients had high rates of comorbid depression, somatic symptoms disorders, and borderline personality features, the latter reflecting decompensation.

Dissociative Disorders in Samples of Women in Prostitution

In his treatise on hysteria, Briquet compared the prevalence of hysteria in nuns, house servants, and prostitutes. He found the highest rates in prostitutes, due, he speculated, to their traumatic and tumultuous lives, with intermediate rates in house servants and the lowest in the nuns. This comparison supported his view that hysteria was a brain disease, associated with stressful and traumatic life experiences, and not a disease of disordered sexuality.

In modern clinical studies of individuals with dissociative identity disorder, as many as 20% reported being in prostitution at some time in their lives. Contemporary studies of women in prostitution have found high rates of childhood abuse: 65% to 90% childhood physical abuse, 74% to 99% intrafamilial and/or extrafamilial childhood sexual abuse, and 98% emotional abuse. Similarly, women in prostitution suffer very high rates of adult rape, life-threatening physical assault, physical and neurologic injuries, homelessness, and emotional abuse/degradation by pimps, their associates, and clients.

Not surprisingly, very high rates of PTSD and dissociation have been found in samples of women in prostitution, with about 70% meeting diagnostic criteria for PTSD. Consistent with the pathologic dissociation construct, in some studies the DES scores of women in prostitution average >30, indicating severe dissociative psychopathology. Also, 67% of 40 women in prostitution (including exotic dancers) met diagnostic criteria for a dissociative disorder: 20% with dissociative identity disorder, 30% with dissociative amnesia, and 17.5% with depersonalization/derealization disorder.

GENETICS AND DISSOCIATION

Studies comparing child and adult cohorts of adoptive siblings, fraternal, and identical twins indicate that genetics account for around 45% to 50% of the interindividual variance in dissociative symptoms, with “non-shared,” stressful, and traumatic environmental experiences accounting for most of the additional variance. Genetic studies of dissociation suggest that there is a complex interplay between genetic factors and type, timing, and chronicity of trauma. Most studies indicating an epigenetic or candidate gene x maltreatment interaction related to dissociation (and for other stress-related disorders, e.g., depression, PTSD) are limited because of different study populations; differing ascertainment of types of maltreatment; retrospective, cross-sectional assessments of past events; and study of only one gene locus rather than interactions of multiple SNPs/epigenetic effects. Studies have linked dissociation to the interaction of early childhood trauma and chronic traumatic experiences with specific single-nucleotide polymorphisms (SNPs) in genes related to serotonergic (*5-HTTLPR*), dopaminergic (*COMT*), and BDNF systems, as well the HPA axis (*FKBP5*).

FKBP5 and Dissociation

Studies of GxE (e.g., maltreatment) interactions have focused on *FKBP5* as it is a glucocorticoid receptor (GR)-regulating co-chaperone of stress proteins involved in regulating the sensitivity and binding affinity of the GR. Induced by cortisol, *FKBP5* acts within a negative feedback loop to promote the transcription of ACTH and plasma cortisol. Specific *FKBP5* haplotypes and SNPs are associated with altered stress responsivity in healthy and psychiatric populations; non-suppression or hyposecretion of the HPA axis; and prolonged cortisol response after psychosocial stress in infants, adolescents, and adults. *FKBP5* genotypes are associated with alterations in brain function and structures (e.g., amygdala and hippocampus) in areas that affect emotional regulation, learning, memory, and inhibition. Although the direction of effects varies in different study populations—for example, by ethnicity, sex, outcome type—*FKBP5* gene variants are thought to act as a premorbid risk or protective factor for psychopathology in the context of environmental exposure to stress, specifically childhood adversity. Studies across ethnically diverse populations suggest that childhood adversity, but not adult adversity, interacts with *FKBP5* haplotypes and/or SNPs leading to adult PTSD and depression, both common outcomes of trauma.

In a study of 261 ethnically diverse, low-income women with a reported childhood maltreatment history, the *FKBP5 CATT* haplotype moderated indirect effects between maltreatment and symptoms of dissociation via "limbic irritability," with higher levels of dissociation in haplotype carriers exposed to maltreatment than noncarriers. "Limbic irritability" is a construct said to encompass non–seizure-based symptoms of focal unaware seizures (formerly partial-complex seizures): paroxysmal somatic disturbances, brief hallucinatory events, visual phenomena, automatism, and dissociative experiences—although all these symptoms are better conceptualized as dissociative.

In a cohort of hospitalized, severely injured children and adolescents after motor vehicle accidents, stabbings, gunshot wounds, or other traumatic events, two specific polymorphisms (*rs3800373, rs1360780*) in the *FKBP5* gene significantly mediated peritraumatic dissociation, an important risk factor for later PTSD.

In a large, prospective, community sample of carefully documented (e.g., social service substantiation) maltreated and nonmaltreated, low socioeconomic-status adolescents were grouped across four SNPs of

FKBP5. Dissociative symptoms were significantly higher among adolescents with no copies of the *CATT* haplotype who also experienced infancy-onset, chronic maltreatment over multiple developmental periods, compared to nonmaltreated adolescents or those with later-onset and/or less chronic maltreatment. There was a significant interactive effect of timing/chronicity of maltreatment and the *CATT* haplotype on dissociative symptoms. A secondary analysis suggested a protective effect from later dissociation of the *CATT* haplotype in adolescents with earlier and more chronic maltreatment.

Finally, a genome-wide association study of dissociative symptoms in individuals with combat-related PTSD identified 10 SNPs potentially related to a genetic basis for depersonalization and derealization symptoms, the most significant among which was r263232 located in the adenylyl cyclase 8 (*ADCY8*) gene on chromosome 8 which is known to be involved in long-term potentiation and synaptic plasticity. This finding may be relevant in clarifying specific learning and memory disturbance (e.g., dissociative amnesia) found in the dissociative disorders.

NEUROBIOLOGY OF DISSOCIATION AND DISSOCIATIVE DISORDERS

Neurobiologic study into the nature of dissociation does not fit tidily within the diagnostic system for dissociative disorders, but can be summarized more effectively along three major theoretical fronts. The first involves investigations into various trauma-related DBSs, including trauma-related altered states of consciousness (TRA; e.g., depersonalization and derealization) that are conceptualized as regulatory responses to fear or other extreme emotions in the context of perceived or actual threat (see section on Theories of Dissociation). These states are consistent with animal models of defensive responding and associated with objective behavioral markers including freezing and tonic immobility, cognitive nonresponse (e.g., blank stare or stupor, “trance-like behavior”), and increased pain threshold. However, TRASC are more adequately defined, following the research paradigm of *neurophenomenology,* by additionally appealing to their subjective experiential elements, which can include the 4-D model of trauma-related dissociation, an alteration in time sense (temporality seemingly “standing still”), flashbacks and “reliving” phenomena, voice hearing, depersonalization, and emotional numbing.

Acute, bottom-up, state-dependent stimulus-response processes most easily explain such states across sensorimotor, emotional, and somatosensory systems, including as peritraumatic dissociative responses and in the context of traumatic reminders. However, dissociative disorders can also be conceptualized as chronically evoked defensive states.

A second line of research investigates the biologic bases of dissociative amnesia, particularly for traumatic life events. Research is beginning to attribute to disturbances in specific neural systems the failed encoding, failed recall, and ultimate recovery of traumatic memories frequently observed in persons with dissociative disorders. The most implicated systems include hippocampal, amygdalar, and prefrontal modulation of amnestic barriers.

Finally, dissociation has also been described as a division or multiplicity of identity or sense of self. Such self/identity-state dissociation primarily implies a top-down organization of bottom-up processes via higher-order, superordinate "self" representations. Putative neurobiologic factors involved in TRASC, dissociative amnesia, and identity-state dissociation are elaborated below.

Neurobiology of Depersonalization and Trauma-Related Altered States of Consciousness

Several theorists have applied animal models as a basis for understanding dissociative responses in the context of peri- and posttraumatic experience. In general, their descriptions are consistent with the early concept of a "defense cascade" as evoked in sequenced fashion proportional to the physical closeness of a predator and the corresponding likelihood of its attack. After the animal orients toward the threat at a distance, a freezing response is usually elicited wherein the animal, while remaining alert of the predator's movements, keeps still to avoid detection. Flight or fight behaviors may ensue, however, when a predator signals impending attack, for example, by charging. However, if an organism determines it is unable to defend itself, it may assume a defensive posture of *submissive immobility,* which some authors term "freeze–fright" and "death feigning" responses. These defensive maneuvers have been regarded by some as the most likely behavioral counterparts to subjective experiences of dissociative TRASC such as including a distortion of temporal processing (altered time perception),

depersonalization, emotional and physical numbing, and subsequent amnesia (i.e., limited encoding) for events taking place during the dissociative episode (e.g., mind “going blank”). Such lower-order defensive responses are thought to be adaptive when reserved for dire circumstances during which active defense (fight or flight) is not possible or would likely occasion an increased likelihood of harm. However, these responses become maladaptive particularly when chronically evoked involuntarily as the primary recourse to repeated trauma exposure, such as in circumstances of ongoing intimate partner violence and childhood abuse. Different stages of the defensive cascade are associated with different neurophysiologic responses: ranging from those exciting vigilance and motor reactivity to those promoting motor inactivity, reduced cognitive awareness, and anesthesia. As the neurophysiology of early orienting, flight, and fight responses has been described elsewhere including in the chapters focusing on Anxiety Disorders and PTSD, the authors focus on the immobile, submissive responses here.

Maggie Schauer and Thomas Elbert have suggested that traumatic events that provoke marked psychobiological arousal may lead to a prolonged immobile defensive posture in humans, like the animal defense of “playing dead.” They hypothesize that this leads to functional sensory deafferentation at the level of the thalamus, gating what are otherwise overwhelming incoming visual, auditory, somatosensory, and proprioceptive information. This survival-based psychobiological process may compromise sensory integration and modulation at limbic (amygdala, hippocampus) and higher cortical centers (e.g., frontal cortex, anterior cingulate, occipital cortex), that is, dissociation at the neurobiologic level.

Jonathan Krystal and others have suggested that if these defensive postures are prolonged, they may present phenomenologically as quasi-catatonic states. However, these states are more appropriately understood as indicating a profound level of helplessness marked by hypoarousal, physical analgesia, and a lowering of level of consciousness. Thus, the lack of sensory/perceptual/affective integration and the disturbance in consciousness leads to unintegrated, fragmented encoding of events. This could underlie the posttraumatic alteration in memory processes described in the ACE study. Phenomenologically, this is experienced as dissociative amnesia (see sections on Epidemiology and Dissociative Amnesia).

Similarly, Steven Porges's *polyvagal theory* may offer another aspect of the psychobiology of these processes. Porges expanded the classical notion of the relationship between the parasympathetic and sympathetic components of the nervous system during the stress response. He differentiates between two vagal systems in the brainstem medulla: that is, between the ventral vagus that regulates cardiac output as a means of facilitating prosocial engagement and the dorsal vagus that responds to threat with behavioral immobilization, hypoarousal, and analgesia. The latter may be one mediator of the metabolically conservative defensive stance of the immobile, dissociative state. These freezing behaviors are commonly reported by individuals experiencing extreme trauma where they cannot fight or flee, for example, in situations of rape and/or captivity. Individuals with severe early life trauma histories with dissociative disorders often report involuntary immobilization and freezing in response to earlier life danger that persists into their later lives. Consistent with this, studies of autonomic response in dissociative disorder individuals, when hearing personal trauma scripts, show that some of these subjects decrease, or do not increase, heart rate, blood pressure, and related autonomic functions.

Also, hypoarousal has been observed in persons with depersonalization/derealization disorder in the form of lower skin conductance levels (SCLs) and slower response-time when viewing unpleasant stimuli, interpreted as autonomic blunting. Persons with depersonalization/derealization disorder were also unable to increase SCLs with real-time biofeedback.

HPA Axis Function and Depersonalization. In contrast, studies of HPA axis functioning in persons with dissociative disorders have evidenced both hyper- and hypoactivation, although discrepant study findings may be attributable to measurement of urinary versus plasma cortisol, as well as measurement of basal HPA axis functioning compared with measurement in response to stimulus-evoked stress responses. For example, in an initial study of persons with depersonalization/derealization disorder symptoms, dissociation was unrelated to cortisol levels under basal condition but there were increases in cortisol levels when subjects experienced acutely stressful stimuli. Some researchers have observed increased plasma and urinary cortisol in depersonalization/derealization disorder compared to individuals with PTSD and other disorders, and

greater resistance to, and faster escape from, dexamethasone suppression. However, an inverse relationship between severity of dissociation and cortisol stress reactivity has also been found, complicating interpretation of the data. The latter is consistent with Ruth Lanius and colleagues' conceptualization of dissociation as an "overmodulating" stress response that inhibits reactivity to trauma cues. Variable findings may also reflect the state-dependent nature of stress-response system reactivity in persons with dissociative disorders, including as a function of environmental context, as well as the presence versus absence of trauma triggers.

CNS Response and Depersonalization. In the 1950s, Penfield described "queer sensations of not being present and floating away" with stimulation of the superior and middle temporal gyrus in epilepsy patients. He insightfully theorized that these "illusions of unfamiliarity, strangeness and remoteness" involved an "alteration in the usual mechanism of comparison of immediate sensory perceptions with memory records." At the time, he claimed that such perceptual illusions could be produced by cortical stimulation "only in the temporal region, perhaps extending somewhat into the occipital cortex." Subsequently, in studies of persons without psychiatric illness undergoing neurosurgery, direct stimulation of the temporoparietal junction (TPJ) (particularly in the right hemisphere) also produced out-of-body experiences. Moreover, decreased response within the superior and middle temporal gyrus has been observed in depersonalization/derealization disorder in various studies, as well as decreased activity in orbitofrontal cortex, medial frontal cortex, left frontal-temporal cortex, and left caudate. In contrast, elevated activity has been found in parietal cortex and left occipital lobe, with certain effects contingent on specific symptoms such as negative affect.

In various social-cognitive neuroscience studies, the TPJ and extra-striate body area have been implicated in self-embodiment experiences. Accordingly, dysfunction in these areas figures prominently in neuroanatomical models for depersonalization experiences. Decreased volume of middle temporal cortex has also been observed as a function of suppressing emotional responses in depersonalization/derealization disorder, whereas prefrontal cortices may be increased in thickness, possibly associated with enhanced capacity for emotional suppression. Moreover, recent studies have shown that transcranial magnetic

stimulation of the left dorsolateral prefrontal cortex (DLPFC), ventrolateral prefrontal cortex (VLPFC), and TPJ lead to decreased symptoms in depersonalization/derealization disorder patients. On the other hand, during resting state in healthy volunteers, deep transcranial magnetic stimulation over the medial prefrontal cortex induced depersonalization and a lowering of self-awareness. It was hypothesized that this result was caused by introduction of an error signal to cortical midline structures implicated by neuroimaging studies in self-referential processing. These experimental treatments indicate that medial prefrontal, lateral prefrontal, and temporoparietal cortical regions are involved in depersonalization experiences and in a diminished sense of self-embodiment.

Mauricio Sierra and German E. Berrios put forth the “corticolimbic disconnection hypothesis” of depersonalization/derealization, positing bilateral corticolimbic disconnection with prefrontal activation and limbic inhibition, resulting in hypoemotionality and attentional difficulties. Lanius and colleagues also applied this model to understanding the contrast between a state of hypoarousal and “overmodulation” of emotion in dissociative PTSD and the hyperarousal and emotional “undermodulation” typically seen in nondissociative presentations of PTSD. This model has been described as a putative neurobiological basis for the dissociative subtype of PTSD.

Two distinct neurobiologic components of the depersonalization/derealization experience have been proposed, subsumed by distinct neurocircuitry: “visual derealization,” associated with occipitotemporal dysfunction and “body alienation,” associated with parietal dysfunction. A review of recent neurologic literature provides convergent data for significant roles for the temporal and inferior parietal lobes and other transmodal sensory cortical areas in mediating depersonalization-like experiences. Depersonalization/derealization is common in seizure patients, especially in temporal lobe epilepsy with left-sided foci. Inferior parietal and angular gyrus tumors can also manifest with depersonalization symptoms. Structural lesions underlying “neglect” syndromes have been found to be concentrated in the right inferior parietal lobule. Patients with parietal lobe epilepsy frequently report somatosensory aura, disturbances of body image, vertiginous sensations, and visual illusions overlapping with the symptoms of depersonalization/derealization disorder. Differences in the amplitude of distinct EEG oscillatory frequencies have also been found to be gross

markers of different arousal states in persons with dissociative disorders. For example, the slower waves of the theta frequency band (4 to 7 Hz) were associated with increasing dissociative states in a control population. However, contrasting results implicating decreasing dissociative symptoms with increasing amplitude of theta frequencies were observed in a psychiatric sample with mixed diagnoses. In summary, disturbances in bilateral inferior frontal, medial prefrontal, cingulate, insular, and temporoparietal cortex are all implicated in engendering experiences of depersonalization/derealization.

Neurochemical Systems and Depersonalization/Derealization. Dissociative experiences presenting in the form of TRASC have also been proposed to be dependent on specific neurochemical systems. Such hypotheses are informed by a considerable literature describing dissociative experiences in the context of illicit drug use, including depersonalization/derealization and a distorted sense of time. Drugs that have been reported to produce these dissociative symptoms include marijuana, hallucinogens, opiates, cocaine and its relatives, and dissociative anesthetics such as ketamine (Ketalar) and its relatives. Studies also implicate neuromodulators including serotonin and norepinephrine. The array of implicated pharmacologic pathways and their putative range of neurochemical actions would suggest that several neurotransmitter systems might be involved in producing dissociative reactions.

A series of studies using ketamine, an *N*-methyl-D-aspartate (NMDA) antagonist that increases glutamate release, has suggested that dysregulation of the NMDA glutamate receptor may play a central role in dissociative symptoms. Ketamine produces dose-dependent increases in dissociative symptoms including slower perception of time, tunnel vision, derealization, and depersonalization. Excess glutamatergic activation may contribute to structural changes in the hippocampus evidenced in MRI studies of patients with dissociative identity disorder. Pretreatment with a benzodiazepine or with lamotrigine, an anticonvulsant that decreases glutamate release, reduces by about half the dissociative effects of ketamine. NMDA receptors are widely distributed and have excitatory functions at hippocampal and cortical association areas. They also promote neuroplasticity and potentiate new learning. Krystal has proposed that NMDA-mediated integration of various brain areas may be necessary

for cohesive conscious experience and therefore that dissociation may involve disruption of corticocortical, thalamocortical, amygdalocortical, and hippocampocortical connectivity.

Perceptual changes, derealization, depersonalization, and other acute dissociative symptoms have also been proposed to have a negative relationship with levels of neuropeptide Y (NPY) which is known to have anxiolytic effects. Charles A. Morgan and colleagues performed a series of naturalistic studies of soldiers undergoing high stress training in preparation for entry into the special forces, 95% of whom experienced acute dissociative symptoms as measured by the CADDS (see section on Theories of Dissociation). They found that NPY was elevated during these stresses and *higher* in Special Forces soldiers after 24 hours of stress than in general recruits. NPY levels were *inversely* correlated with self-reported dissociation severity. NPY was also correlated with cortisol and more adaptive behavioral responses. NPY is a neurotransmitter/modulator found in high concentration in cell bodies and terminals of the amygdala. In preclinical studies, NPY has shown anxiolytic and stress-lowering effects. Levels of NPY in Special Forces soldiers were inversely correlated with measures of dissociation, but positively correlated with both cortisol levels and behavioral performance under stress. Twenty-four–hour levels of NPY were at normal baseline in Special Forces soldiers but significantly lower than baseline in the other soldiers. The findings on this stress-hardy group underscore the importance of psychological adaptation to prior trauma on responses to current stressors. The NPY findings may suggest a neurobiological protective system that antedated stress and/or a neurobiological system demonstrating a more resilient adaptation to stress. NPY may have a role in regulation of anxiety and dissociation in high-stress situations. Higher levels of dehydroepiandrosterone sulfate (DHEA-S) in plasma were also associated with lower self-reported dissociation and improved behavioral adaptation to stress.

Norepinephrine is a neurotransmitter central to facilitating alertness, selective attention, and enhanced memory encoding under stress. Several studies support the notion of noradrenergic system involvement in depersonalization/derealization symptoms. Daphne Simeon and colleagues observed that decreased urinary norepinephrine is associated with increasing depersonalization/derealization symptom severity. In a small sample with chronic depersonalization/derealization, 24-hour urine norepinephrine was found to be strongly inversely correlated to

dissociation severity. Similar findings have been reported in a sample with acute peritraumatic dissociation. In another study, administration of a norepinephrine reuptake inhibitor–induced depersonalization/derealization, while discontinuing the drug resulted in improvement.

Other studies suggest that depersonalization/derealization can be induced by serotonin agonists. Neurochemical challenge studies with the 5-HT_{2C} agonist m-chlorophenylpiperazine have demonstrated the induction of depersonalization/derealization in subjects with various diagnoses including social phobia, borderline personality disorder, and OCD, as well as the induction of flashbacks and dissociative symptoms in a subgroup of patients with PTSD. A PET imaging study with the hallucinogenic 5-$HT_{1A/2A}$ agonist psilocybin resulted in increased dopamine in striatum that correlated with depersonalization/derealization severity.

Other neurochemical systems putatively implicated in depersonalization and derealization include the cannabinoid system. Cannabinoids, such as marijuana, have been consistently shown to induce depersonalization/derealization, with a pronounced component of temporal disintegration. In addition to their action at the cannabinoid CB receptors, cannabinoids block NMDA receptors at sites distinct from other noncompetitive NMDA antagonists. A PET study using intravenous tetrahydrocannabinol (active compound in marijuana) found that cerebral blood flow increases in the right frontal and anterior cingulate cortex correlated with depersonalization/derealization severity, while there was a subcortical cerebral blood flow decrease in amygdala, hippocampus, basal ganglia, and thalamus.

The opioid system has also been implicated in depersonalization/derealization disorder states. The endogenous opioid system mediates stress-induced analgesia. In PTSD patients, analgesic response to combat stimuli can be blocked by pretreatment with the opioid antagonist naloxone. The κ opioid agonist enadoline induces a depersonalization-like syndrome in healthy subjects compared to placebo, with perceptual disturbances and a sense of detachment. Along these lines, opiate antagonists have been reported to reduce dissociation, such as high-dose naltrexone in borderline personality disorder and intravenous naloxone in chronic depersonalization/derealization. The opioid antagonist

nalmefene has been reported to decrease emotional numbing in veterans with PTSD.

Dissociative Amnesia

As described in the sections on Epidemiology and Dissociative Amnesia, traumatic events, particularly cumulative traumatic events during development, are associated with a variety of autobiographical memory deficits. However, there are few systematic studies of the underlying neurobiology mediating dissociative amnesia per se. Neurobiologic findings in clinical populations have been primarily reported in single case studies or small case series without adequate diagnostic assessment to rule out dissociative identity disorder, history of trauma, or comorbid disorders such as PTSD.

Nevertheless, neuroimaging studies in healthy persons and lesion studies in neurologic patients strongly implicate crucial roles for the hippocampus, temporal lobe, temporoparietal junction, posterior cingulate, precuneus, and medial prefrontal cortex in the formation and recall of episodic memories. As malfunctioning of these structures has variably been implicated in neuroimaging studies of dissociative disorders across various experimental paradigms, such disturbances may partially account for amnesia for traumatic events and an overall impoverishment of memory for childhood in traumatized persons with dissociative disorders. Deficits in encoding of traumatic events and/or inhibition of retrieval of memory for the events are important models to help explain dissociative amnesia. Both processes may be relevant to amnesia symptoms in a specific patient. However, for clarity, data on encoding and retrieval models of dissociative amnesia will be described separately.

Peritraumatic Dissociative Amnesia: Encoding. Stimuli that are mildly to moderately emotionally provocative are known to be associated with a memorial advantage over neutral cues, partially mediated by response in neural networks involved in salience processing that favor their attention during encoding, for example, via the amygdala, insula, and anterior cingulate. However, highly threatening experiences, such as traumatic events, may cause an individual to orient *away* from the source of threat in fear (e.g., by averting gaze) or to defensively retreat “inward” (i.e., emotional suppression) or “outward” (i.e., out-of-body experience, depersonalization) as automatic peritraumatic emotional self-regulation

strategies. Each of these emotion regulatory responses has been associated with a diminution of salience network processing, which in theory should predict reduced attention and encoding. By parsimony, these studies suggest that impoverished encoding is one neural pathway of amnesia for traumatic events.

Consistent with this interpretation, a recent study provided a striking experimental demonstration of the impairment of autobiographical memory by depersonalization, as evoked by a multisensory perceptual illusion during encoding. Study participants evidenced impoverished recall of scripted life events encoded in an “out-of-body” (depersonalized) condition. This was induced by altering subjects’ visual and somatosensory experience to give the false impression that their embodied frame of reference emanated from a place 2 m behind or beside their actual physical position. Participants rated events encoded from this depersonalized perspective as less vivid and recalled these events more poorly. Moreover, a neuroimaging study showed that impoverished recall was associated with reduced left posterior hippocampal activation in early rehearsal trials, with greater activation in later trials. This is a reversal of the observed and expected effect for encoding under natural conditions. The authors concluded that a dissociative out-of-body experience during an acutely stressful event could, by itself, impair the encoding mechanism and produce fragmented, spatiotemporally disorganized memories.

Neuroimaging has also been used to study laboratory paradigms of active memory suppression or repression. For example, an influential study conducted in healthy persons examined neural response during conditions in which participants were either instructed to think about or “not think” about (i.e., suppress memory of) the second member of a previously seen pair of words. Subsequently, cued recall of suppressed words was inferior to recall of baseline words and even generalized to novel test cues. Neural networks implicated in this suppression response involved bilateral prefrontal cortex, paralimbic, subcortical, and parietal integration areas and reduced activation bilaterally in hippocampal areas. Moreover, hippocampal activation patterns differed from trials involving ordinary forgetting. These were greater in response to suppression-induced forgetting compared to items where suppression failed: that is, items that were successfully recalled despite attempted suppression.

The authors concluded that activation of a broad neural network was involved in memory suppression, including hippocampus, DLPFC, anterior cingulate cortex, medial-temporal lobe, dorsal premotor cortex, presupplementary motor area, and intraparietal areas. The authors described a neurobiologic model for memory control in response to trauma, where, via encoding effects, these networks are involved in producing lasting amnesia in response to traumatic events.

Neurobiology of Dissociative Amnesia: Disturbed Retrieval. Although no neurobiologic studies of dissociative amnesia have employed large samples, case studies of patients with generalized dissociative amnesia or dissociative fugue subtype with loss of personal identity have shown unusual metabolic and activation patterns in PET scanning and SPECT studies. A PET study of 14 amnestic patients tested with PET in a resting state showed decreased metabolic rate within right inferolateral prefrontal cortex. These findings complemented those in a neuropsychological case series of persons with amnestic syndromes prompted by traumatic and/or stressful events demonstrating deficient response in right frontotemporal cortex. Other findings included, respectively, reversal of the usual patterns of right and left hemisphere activation during autobiographical and semantic recall. These were similar to findings in individuals with traumatic brain damage and related memory deficits, and those with disruptions or functional disconnections between major neural networks.

Replicated neurobiologic case studies of dissociative amnesia have shown deficits in activation of the hippocampus and medial temporal lobe, with possible inhibition by frontal systems. Reduced occipital involvement during episodic recall has also been documented. These findings are consistent with fMRI studies of posthypnotic amnesia in healthy subjects that showed reduced response in anterior temporal and occipital cortex, with increased response in left rostrolateral prefrontal cortex. These patterns normalized after discontinuation of the hypnotic suggestion for amnesia. Nonhypnotized participants exhibited the expected habituation effect to repeated presentation of previously encoded cues. Participants in the hypnotic amnesia condition had *decreased* neural response during early recognition trials, as compared to later trials following removal of the hypnotic suggestion for amnesia. These findings implicate deficits in

retrieval processes, rather than the deficient encoding in depersonalization and dissociative amnesia.

Hans J. Markowitsch has reported similarities between organic and psychogenic (i.e., dissociative) retrograde amnesia, both thought to be caused by a desynchronization or blockade in neural processing ("mnestic block syndrome") related to altered brain metabolism possibly including changes in various neurotransmitter and hormonal systems, such as GABA-agonists, glucocorticoids, and acetylcholine. Current neurobiologic theories of dissociation suggest a possible role for glutamate in at least some dissociative symptoms, warranting further pharmacologic investigation.

Markowitsch and his colleague Angela Staniloiu have studied several large samples of individuals with dissociative amnesia. In addition to the above, they posit that psychological trauma in early life induces a stress-hormone-related-and mediated neurotoxic cascade resulting in desynchronization between frontal lobe systems important for autonoetic consciousness (awareness of our self in past, present, future and related to development of sense of self and identity) and the temporal lobe/amygdalar systems that underlies emotional processing of memory. They view this desynchronization as precipitated by traumatic and adverse life experiences, particularly in childhood, adolescence, and early adulthood. These may be modulated by genetic, epigenetic, critical period, familial, and sociocultural factors as well as medical and psychiatric comorbidities. They hypothesize that glucocorticoid stress hormones bind to receptors in the amygdala and hippocampus leading to changes in morphology and/or function of these systems and impairment in encoding and/or retrieval of episodic-autobiographical memory. In case studies, they found support for this hypothesis with FDG-PET showing overall reduction in cerebral metabolism and in memory-sensitive areas of the temporal and diencephalic regions, as well as bilateral hippocampus. They view "mnestic block syndrome" as demonstrating that memories are encoded in brain, but full conscious access is blocked.

Michael C. Anderson and colleagues reviewed a large group of studies that attempt to show that memory can be actively suppressed, either at the point of memory encoding or by retrieval inhibition. Many of these studies utilize the laboratory paradigm of "Think, Not Think" (TNT) instructions: to study the variety of neurobiologic processes that may be involved subjects are instructed to recall or forget word pairs or whole lists

of words. In these studies, similar to the model of frontal systems suppressing amygdala and insula in the dissociative subtype of PTSD, DLPFC, and VLPFC appear to be involved directly in suppression of activity in hippocampus, the fusiform gyrus (perceptual awareness of objects), and occipital lobe (visual perceptual priming). Neural networks that account for the findings in the TNT studies are similar to those found in the fMRI study of posthypnotic amnesia. Also, as discussed below, in PET studies of dissociative identity disorder, similar findings of frontal activation and suppression of neural systems involved in autobiographical memory and self-referential processes occurred in self-states that did not experience personal trauma scripts as autobiographical memory.

Neurobiology of Self/Identity-State Dissociation

In contrast to the literature implicating dysregulation of specific neurochemical systems in the experience of depersonalization and derealization, it is unlikely that any single or simple combination of a few neurotransmitter systems could underlie the highly complex symptom picture of dissociative identity disorder. This picture includes symptoms found in each of the other dissociative disorders—depersonalization/derealization and dissociative amnesia—for past and current life experiences, as well as dissociative fugue experiences. In addition, individuals with dissociative identity disorder experience symptoms of identity confusion and identity alteration; symptoms of overlap, interference, and intrusion of identities; and spontaneous age regression, analgesia, multimodal hallucinations, and negative hallucinations (lack of perception of sensory stimuli) consistent with spontaneous dissociative, posttraumatic, and autohypnotic processes (also, see section on Diagnosis).

Historically, early medical models attempted to explain dissociative identity disorder by invoking phenomena such as sleep and dreams, hypnosis and somnambulism, epilepsy, and disconnections between the cerebral hemispheres to explain the multiplicity of identity and sense of self that characterizes this disorder. The scientific investigation of identity-state dissociation dates to the experiments of Prince in 1908, who, by way of a crude polygraph to measure GSR, demonstrated distinct responses to emotionally valenced words across alternative identity states in a dissociative identity disorder patient. This basic experimental paradigm, involving a comparison of biologic measures in different dissociative

identity disorder self-states, continues to dominate the literature to this day. Indeed, over the next century dozens of psychophysiological and cognitive performance studies were published along similar lines. Often, these lacked methodologic rigor either due to small sample sizes, single case study design, or deficiencies in experimental control. In contrast, the work of Frank W. Putnam and Antje A.T.S. Reinders stands out as a notable exception. Their studies included rigorous control groups as well as study of dissociative identity disorder subjects under a variety of conditions, including hypnotic trance and states of relaxation, among others.

Putnam's research group has demonstrated unique autonomic system (ANS) reactivity between alternative identity states in dissociative identity disorder patients and dysregulation of the EEG during transitions between identity states. Nevertheless, an important observation in these studies was the instability of both ANS and CNS measures not only across but also *within* different identity-state presentations, the magnitude of which was found to be greater than that observed in nonpsychiatric control groups. Rather than implicating a model of sustained differences between alternative identity states in persons with dissociative identity disorder, these studies found general disorganization in both temporal and spatial integration of ANS and CNS. Consistent with this, beyond the gross measures of amplitude of various bandwidths of the EEG typically employed in early studies, more recent literature is also turning to the investigation of functional connectivity and signal complexity as possible EEG markers of dissociative disorders and the general effects of complex trauma histories.

For example, an EEG study of α-wave coherence using five simulator controls and five dissociative identity disorder subjects found significant differences in the latter group between identity states in six brain regions, whereas there were no differences in the control group. A study comparing ERPs elicited by words learned in the same or in different identity states for four dissociative identity disorder patients found little support for the existence of amnesia between personality states when compared to controls from another study who deliberately concealed knowledge of previously learned words. However, given that the ERP is highly relevant to the early detection of salience and basic stimulus processing, the current authors think it unlikely that this very early indicator of cognitive processing would strongly distinguish identity states

in dissociative identity disorder. The latter are more likely to be distinguished during poststimulus phases typified by cognitive elaboration and higher-level cognition partially overlapping other EEG markers such as the phenomenon of pre- and poststimulus EEG alpha desynchronization (see subsection on Inter-Identity Amnesia in the section on Dissociative Identity Disorder). A Quantitative EEG (QEEG) study, found that EEG-β activity in frontal and temporal lobes varied between different identity states in dissociative identity disorder patients. Other studies also suggest putative roles for primary sensory and motor cortices, and frontal and prefrontal cortex and nucleus accumbens, during transitions between identity states.

General neural markers for dissociative identity disorder include Vedat Sar and colleagues' findings regarding decreased perfusion in the orbitofrontal region coupled with increased blood flow within medial and superior frontal regions, all associated with self-referential processing in controls; these researchers further identified increased perfusion in occipital cortex. Left temporal involvement in dissociative identity disorder also has been implicated in SPECT studies, which may partially underlie auditory hallucinations (voice hearing) frequently reported by such patients. Strikingly, hippocampal volume was also reported to be 19% smaller, and amygdalar volume 32% smaller, in patients with dissociative identity disorder compared to healthy controls. Reduced volumes in the parahippocampal gyrus were also reported and correlated with severity of both psychoform and somatoform dissociation symptoms.

Reinders' group has reported elevated heart rate, higher systolic blood pressure, and lower heart rate variability in persons with dissociative identity disorder in response to audio-recorded personal trauma narratives when individuals experienced the narrative as autobiographical in nature (in a Traumatic Identity State [TIS]). Their biologic indices differed when they experienced the event as non–self-referential in a different self-state (Neutral Identity State [NIS]); under those conditions, their autonomic responses and brain activation patterns were similar to those of individuals with the dissociative subtype of PTSD. These researchers have extended the alternative identity-state paradigm to fMRI neuroimaging. They found that response within regions of the brain previously associated with "self-referential processing" in controls (thinking about oneself and evaluating whether a stimulus such as a personality trait descriptor is self-referent) differed between TIS and NIS in

persons with dissociative identity disorder. These differences were noted most notably in the medial prefrontal cortex and midline posterior cortex (posterior cingulate, precuneus). Moreover, these effects cannot be simulated by trained nonpsychiatric controls. Differences from controls have also been observed in regions associated with emotional processing (amygdala, insula) and body representation (TPJ). Resting state metabolism and functional connectivity also differed between identity states in persons with dissociative identity disorder, indicating a level of internal (in)coherence and (de)stabilization that endures beyond the momentary, stimulus-reactive experimental design employed by most previous studies.

Reinders and colleagues have continued to expand the fMRI findings in response to the critics of the TM of dissociation. In studies comparing the two previously described types of dissociative identity disorder identity states (“traumatic” and “neutral”) in high and low “fantasy-prone” simulators, Reinders and colleagues replicated and extended the findings from the PET studies. Both types of patient states were significantly different from simulators on brain activation and autonomic variables, particularly from the high fantasy-prone group. TIS differed from simulators on autonomic activation and on activation of the insula and dorsal striatum. Replicating the findings from the prior studies, and similar to individuals with the dissociative PTSD subtype, NIS showed bilateral activation of the superior frontal gyrus, prefrontal cortex, cingulate, posterior association areas, and parahippocampal gyri. Brain deactivation patterns in individuals with dissociative identity disorder were independent of fantasy-proneness. Significantly differently from both control groups, in response to traumatic and neutral scripts, TIS showed activation of the striatum, particularly the caudate nucleus not the hippocampus. This was interpreted as processing of trauma memory and maintenance of state stability by the caudate, not the hippocampus, in dissociative identity disorder. In fact, dissociative identity disorder patients were more like *low* fantasy-prone than high fantasy-prone simulators, showing less reactivity in emotional brain areas. This is consistent with the psychological profile data that, in dissociative identity disorder, dissociation is an ideational, distancing defense recruited to attempt to downregulate emotional stimuli (see section on personality organization of Dissociative Identity Disorder).

Data on the neurobiologic basis of dissociative identity disorder are growing rapidly. However, a factor that has significantly impeded progress

in this domain is the (at least implicit) concern of many studies to use neurobiologic measures to cross-validate the existence of the disorder, as opposed to utilizing research methods to better understand the unique neurobiologic and psychophysiological profiles of this group of patients. Studies have frequently been designed to reveal biologic differences between personality states in dissociative identity disorder, often compared with simulator controls. As with attempts to demonstrate out-of-body states in depersonalization/derealization disorder, the focus of much research has been to replicate the finding that such psychological states are indeed real. This methodology would scarcely ever be expected for inclusion in biologic studies of other disorders, for example, depression, schizophrenia, PTSD, or borderline personality disorder. Instead, the veracity of that self-reported symptomatology is taken for granted, with biological studies then designed to interrogate its etiology rather than serving to discount concerns that the self-reported symptoms might be factitious. Also, studies of dissociative identity disorder rarely include male subjects, although epidemiologic data show that the male-to-female ratio in general population studies is about equal.

More recent neurobiologic studies have begun to address these issues. Sima Chalavi and colleagues found that, although both individuals with PTSD and those with dissociative identity disorder comorbid with PTSD had smaller hippocampal volume than healthy controls, the comorbid-disorder group differentiated from the PTSD group in the abnormal shape and significantly smaller volume of their CA2-3, CA4-DG and (pre)subiculum. This correlated with more severe histories of childhood trauma and dissociative symptoms. In a multi-center, case-control study, Reinders' group evaluated cortical morphology of women with dissociative identity disorder compared to healthy controls. The dissociative identity disorder group showed reduced cortical volume, thickness, and surface area relative to controls. There were significant, widespread, spatially dependent abnormalities in gray and white matter in numerous areas of the frontal cortex, anterior cingulate cortex, temporal, parietal, and occipital cortices and cerebellum. Women with dissociative identity disorder show extensive, significant volumetric reductions of regional gray matter in the insula, the cingulate cortex, the dorsolateral, superior, medial, and orbitofrontal prefrontal cortex, and the superior and inferior temporal lobe. Differences in cortical thickness and surface area were largely nonoverlapping and each contributed separately to cortical

volume. Pattern-recognition models of brain biomarkers differentiated patients with dissociative identity disorder from controls with a sensitivity of 71.88% and a specificity of 73.81%, like what has been found for other psychiatric disorders.

Lauren LeBois, Milissa Kaufman, and colleagues developed an ingenious paradigm to test the capacity of dissociative identity disorder patients to recognize their own faces. Phenomenologically, individuals with dissociative identity disorder report discomfort, detachment, alienation, and fear about their bodies and faces. Often, they are phobic of being seen, as well as of seeing themselves in the mirror, frequently describing lack of self-recognition and/or seeing shifting “other people” instead of themselves in mirrors (e.g., “a blonde little girl,” “a scary witch,” “a big, burly man”). A backward-masking study in which healthy controls and individuals with dissociative identity disorder were asked to rate familiarity of their own faces, a stranger’s face, and that of a famous person was conducted. Dissociative identity disorder patients showed a significant lack of self-bias effect across face types. However, patients who had progressed in treatment had recovered this capacity, possibly due to improved internal cooperation, coordination, cooperation, and awareness among self/identity states.

These investigators performed a novel, large-scale connectivity analysis using machine learning on patients with dissociative identity disorder. The goal was to develop brain-based measures that were sufficiently sensitive and robust to assess pathologic dissociation apart from self-reports. The models showed a moderate ability to estimate dissociation within individuals after controlling for childhood trauma and PTSD severity. Connections that contributed most to the model involved the default mode and frontoparietal control networks, the latter replicating findings from multiple studies of dissociation using differing methodologies (see above). This work represented a first step in developing functional brain biomarkers for dissociation in individual subjects.

The studies of Chalavi et al. and LeBois et al. begin to move away from the neurobiological studies of dissociation and dissociative disorders where the goal is to respond to critics and “prove” that these conditions are “real.” In a recent review, Constance Dalenberg and colleagues described the use of multiple rhetorical, not scientific, arguments in most critiques of the TM of dissociation, and the reality of dissociative disorders. These include—among others—“moving the goalposts,” asking

for a “super study,” and/or utilizing “motivated skepticism” to discount every study supporting the TM, always demanding some additional “proof.”

Rather, what the literature requires is a greater number of comparative studies, for example, between different dissociative disorders, and between dissociative and nondissociative trauma-related disorders. A dimensional perspective may also be useful in this regard. Frontal, limbic, temporal, and parietal cortices are nonspecifically implicated in both depersonalization/derealization disorder and dissociative identity disorder, and may relate to alterations in self-referential processing, emotional numbing, and felt disembodiment common to both disorders. However specific distinguishing clinical features (e.g., voice hearing in dissociative identity disorder) may require study of specific markers appropriate to differential diagnosis, for example, within auditory association cortex. Longitudinal and naturalistic studies utilizing biological measures will be needed, as well as neuroimaging studies of combined psychological and neurobiological interventions (e.g., neurofeedback, rTMS) to better appreciate the clinical significance of the biologic markers so far identified for the dissociative disorders, and to help develop more effective treatment for these patients.

ETIOLOGY OF DISSOCIATION AND DISSOCIATIVE DISORDERS

This section discusses etiologic theories about dissociation and dissociative disorders. A comprehensive etiologic model involves integrating components of several of these as well as cognitive and neurobiologic correlates (see Neurobiology).

Discrete Behavioral States (DBS) Model

The concept of *state of consciousness*—as a distinct unit of behavioral organization—has been part of the psychological vocabulary for several centuries. DBSs are defined as repeating patterns of mind, body, and brain variables/dimensions that for a finite period are correlated with and/or influence how a person thinks, feels, and acts. Each distinct DBS—combinations of states—uniquely (state-dependently) influences perception, cognition, memory, emotion, motivation, values, psychophysiology, and interpersonal interactions.

The DBS model, developed by Frank W. Putnam, Jr., is a transtheoretical, translational *theory of human consciousness*. DBS theory elucidates human experience and behavior across myriad normal and pathologic domains. Discrete states of being are so pervasive and ubiquitous in our moment-to-moment lives as to be essentially invisible unless they shift in dramatic, unexpected ways and, even then, we usually do not conceptualize these changes in terms of behavioral "states." In the "atheoretical" DSM-5, the term "state" occurs over 100 times. DBST is an organizing framework for a vast array of normal and pathologic human behavior and experience, individually, in relationships, and in groups. The power of DBST is based on substantial support from numerous domains of research, including trans-species chronobiology, child development, neurobiology, psychopathology, and many others—from subcellular to social systems.

The notion of DBSs is inherent in all theories of dissociation and the dissociative disorders. As such, DBST subsumes and is a superordinate, organizing framework for all other theoretical models discussed in this chapter. Transdiagnostically, DBST postulates that dissociative disorders belong to a large group of psychiatric conditions characterized by rapid—often environmentally triggered—discrete shifts in states of consciousness, “state-change disorders.” Others include mood disorders (e.g., bipolar disorder), panic disorder, periodic catatonia, substance use disorders, trauma- and stressor-related disorders, conversion disorder, sleep disorders, borderline personality disorder, impulse control disorders, delirium, paraphilias, most feeding and eating disorders, brief psychotic disorder, and many others. In state-change disorders, there are gradual or rapid switches or shifts between two or more distinct states of consciousness, at least one of which is pathological. Switches among dissociative identity disorder self-states, panic attacks, and PTSD flashbacks are examples of dysfunctional behavioral states, often triggered by specific stimuli or interactions that rapidly reorganize an individual’s emotions, thinking, and behavior.

The DBS model postulates three general levels of psychopathology inherent in all *state-change* disorders. The first is intrinsic to the nature of the pathologic states per se, for example, flashbacks, numbing, depression, mania, dissociative identity self-states, depersonalization/ derealization. The second results from the individual’s inability to self-modulate the expression of these dysfunctional states or to integrate them into their life, such as by becoming unable to work. The third level results from maladaptive attempts to block or minimize effects of painful, distressing, pathologic states, such as attempts to self-medicate mood disorder symptoms; self-injury to modulate intense emotional states like shame, anger, and sadness; and/or social withdrawal to avoid triggering PTSD reactivity. Transdiagnostically, the DBS model predicts that effective treatment should facilitate better self-modulation of intense or dysphoric states; address the state dependency of dysfunctional perceptions, cognitions, and

assumptions; and assist patients in finding recovery-oriented solutions to modulate symptomatic states.

Behavioral States as the Basic Unit of Human Development. In the 1960s, a group of child psychologists and psychiatrists formally operationalized the study of DBSs in normal human infants. Heinz Prechtl, Robert Emde, Robert Harmon, and Peter Wolff empirically validated a multidimensional, ethologic classification system used to study normal infants. By using four to five variables (e.g., heart and respiratory rate, extremity muscle tone, skin perfusion, vocalization, facial expression), researchers could delineate a basic set of DBSs shared by most full-term, newborn infants. Each state was time-limited, with a distinct switch between them. Caregiver interactions could evoke or suppress certain states to shape the infant's behavior. With maturation, additional behavioral states were added, and the pathways of connections among the distinct states become more complex, corresponding to the child's increased behavioral repertoire. Fundamental to healthy emotional regulation, the developing child increases the ability to self-modulate the expression of these DBSs and to integrate the many additional states related to normal development. More recent research characterizes the interplay of DBS between caregiver and child as essential to developing normal attachment, capacities for behavioral state regulation, brain executive functions, and other vital human capabilities.

Theories of Dissociation

In the literature, the term *dissociation* is conceptualized in over 25 different, and sometimes diametrically opposed, ways. Substantial imprecision can result in both clinical and scholarly discussions unless one is clear about which definition is being used (see Table 20–8 for a partial list of the often-contradictory ways dissociation has been defined in the literature). For example, dissociation has been hypothesized as a normal psychobiological capacity to filter perception to focus attention on salient information

(e.g., being unaware of the sensation of one's body while sitting in a chair). Most theories of dissociation conceptualize it as a *dimensional, adaptational process* (e.g., as a response to trauma) and subsequently as an intrapsychic defense to prevent full awareness of past traumatic experiences and their impact on the person. In the DSM and ICD systems, dissociation describes *categorical distinctions among psychopathological entities:* the dissociative *disorders.*

Discrete Behavioral State Model, Psychopathology, and Dissociation

The DBS model conceptualizes dissociative phenomena as distinct states of consciousness differing in terms of the individual's senses of self, identity, and physical being; access to explicit, implicit, and /or autobiographical memory; and accompanied by specific patterns of state-dependent psychobiological activation (e.g., in the ANS). Disturbances of self-organization are the nucleus around which dissociative states organize—just as distinct moods serve to organize the DBSs of bipolar patients. This is the case in dissociative amnesia, as autobiographical memory continuity and coherence is fundamental to sense of self.

Table 20–8.
Different Conceptualizations of Dissociation

1. Dissociation is described as a *normal* part of the perceptual filtering system of the brain/mind that allows for normal functioning by helping the mind focus on relevant stimuli and filtering out other stimuli.
2. A fundamental aspect of hypnotic experience, related to the capacity for divided consciousness/attention, and/or separation of cognitive and behavioral schemas (e.g., losing track of driving for several minutes).
3. Theories of mind that describe divided consciousness in normal, hypnotic, and pathologic states (e.g., Ernst Hilgard's *Neo-Dissociation Theory*).
4. Continuum Model: *A continuum from normal to pathologic,* with normal capacities for absorption, focused attention, and imaginal involvement at one and end, and dissociative disorders at the other.
5. Taxon Model (mixed dimensional /categorical): Two *different dimensional continua of dissociative phenomena* that are categorically different: *normal dissociation* and *pathologic dissociation.*
6. A *psychobiological process* that is involved in human response to acute and/or chronic trauma.
7. An intrapsychic defense that is understood in psychodynamic terms, e.g., protective against full recall of traumatic experiences and impacts, e.g., trauma-based intrapsychic conflict, caregiver betrayal.
8. In the DSM and ICD systems, dissociation is used to describe *categorical distinctions among psychopathological entities:* the dissociative *disorders.*

The DBS model conceptualizes dissociation as basic to the psychobiology of the human response to life-threatening danger: a protective activation of altered states of consciousness that change perception, pain sensation, time sense, access to memory, and

senses of self and identity. Trauma-related memories and affects are encoded during these altered states. Upon return to baseline, the person has less access to the dissociated information, with dissociative amnesia for at least some part of the traumatic events. However, the dissociated memories and affects can manifest themselves in nonverbal forms as posttraumatic nightmares, reenactments, intrusive imagery, and somatoform symptoms. Not only is there amnesia for the traumatic event but the person also frequently has dissociated basic assumptions about the self, relationships, other people, and the nature of the world that have been altered by the trauma.

In dissociative disorders related to childhood adversity, the DBS model postulates that early childhood trauma, disturbances in attachment, or both (see section on Type D attachment and betrayal trauma) disrupt the processes essential to self-modulation and the developmental integration of new behavioral states.

Taxon Model of Pathologic Dissociation

Recent interest in the *taxon model* resurrects a century-old debate about whether dissociation occurs along a continuum proceeding from normal to pathologic or whether pathologic dissociation, such as dissociative identity disorder, represents a distinct type (a taxon) of psychological organization. As data with dissociation measures accrued across clinical and community-based populations, it became apparent that there existed a distinct group of high-scoring individuals. These observations led to research on the possible existence of a dissociative type of individual differing significantly on dissociation measures from other individuals, irrespective of their psychiatric status. Using newly developed taxonometric approaches, researchers examined item-response data for manifestations of a latent class variable. They identified eight DES items (Table 20–9), composing the DES-T (Taxon) subscale, that robustly differentiate the most severely dissociative patients from other psychiatric patients and normal controls, who almost never endorse these items.

Table 20–9.
Dissociative Experiences Scale Items Comprising the Dissociative Experiences Scale Taxon

Subjects are asked to rate the percentage of time, from 0% to 100%, that they have the experience.

3. Some people have the experience of finding themselves in a place and having no idea how they got there.
5. Some people have the experience of finding new things among their belongings that they do not remember buying.
7. Some people sometimes have the experience of feeling as though they are standing next to themselves or watching themselves do something, and they actually see themselves as if they were looking at another person.
8. Some people are told that they sometimes do not recognize friends or family members.
12. Some people have the experience of feeling that other people, objects, and the world around them are not real.
13. Some people have the experience of feeling that their body does not seem to belong to them.
22. Some people sometimes find that, in one situation, they may act so differently compared to another situation that they feel almost as if they were two different people.
27. Some people sometimes find that they hear voices inside their head that tell them to do things or comment on things that they are doing.

Studies have subsequently affirmed that a taxonic approach is a clinically useful way to identify a subgroup of dissociative patients within any given diagnosis (e.g., the dissociative subtype of PTSD) who differ from the rest of the group on symptoms and features. In psychophysiological investigations of dissociation, simply dividing

samples into high and low scorers has identified different physiologic and cognitive responses to traumatic reminders. The taxon model implies a different developmental scenario than the continuum model as well as a different approach to treatment. The typologic differences between high dissociators and virtually everyone else supports a genetic predisposition (see section on Genetics) and/or a fundamentally different early developmental trajectory that has long-lasting effects on brain connectivity. Research linking dissociation with type D attachment disturbances (discussed later in this chapter) offers another potential environmental factor that may mediate the relationship between genetic diathesis and expression of pathologic dissociation. A large, prospective, general population study from Finland found a point prevalence for the dissociative taxon of 3.4%, consistent with retrospective re-analyses of DES data.

Dissociation as a Transdiagnostic Process

In a recent meta-analysis of 219 studies of dissociation measured by the DES, involving over 15,000 patients in 19 diagnostic categories, Lisa Lyssenko and colleagues concluded that dissociation is an important *transdiagnostic process* that often indicates poorer outcome to standard treatments and should routinely be assessed. The ACE Studies, the National Comorbidity Studies, and other research found that at least subgroups of many common psychiatric disorders are associated with higher rates of childhood trauma. Thus, intuitively, dissociative symptoms likely would be present among many diagnostic groups. Mean DES scores were highest, consistent with the pathologic dissociation taxon model, for dissociative identity disorder (48.7), followed by all dissociative disorders combined (38.9), PTSD (28.6), borderline personality disorder (27.9), functional neurologic symptom disorder (conversion disorder) (25.6), anorexia nervosa (24.1), and bulimia nervosa (22.0). Mean DES scores for nonclinical populations tend to cluster around 8 (see Table 20–10 for the full range of scores).

Table 20–10.
DES Mean Scores Across Diagnostic Groups

- *Dissociative identity disorder: 48.7
- *Dissociative disorders: 38.9
- *PTSD: 28.6
- *Borderline personality disorder: 27.9
- *Conversion disorder: 25.6
- *Anorexia nervosa: 24.1
- *Bulimia nervosa 22.0
- *Substance-related and addictive disorders, including gambling disorder: 19.9
- *Alcohol use disorder: 19.7
- *Non-conversion somatic symptom disorders: 18.8
- Schizophrenia: 17.8
- *Other substance-related disorders 17.7
- Panic disorder 15.6
- Depressive disorders: 15.3
- OCD 15.3
- *Anxiety disorders: 15.2
- Bipolar disorder 14.8

Disorders marked with an asterisk have at least subgroups with high rates of childhood maltreatment and neglect, as well as adult traumas.

Adapted with permission from the Lyssenko L, Schmahl C, Bockhacker L, Vonderlin R, Bohus M, Kleindienst N. Dissociation in psychiatric disorders: a meta-analysis of studies using the dissociative experiences scale. *Am J Psychiatry*. 2018;175(1):39.

DES sub-group factor scores could only be calculated for the cohorts of individuals with dissociative disorders, borderline personality disorder, and schizophrenia. Dissociative disorder patients had significantly higher mean scores on all DES factors: amnesia (12), absorption (12), and depersonalization/derealization (17). The mean scores for the other diagnostic groups were amnesia (4) absorption (4) and depersonalization/derealization (4,5); individuals with schizophrenia scored higher than borderline

personality disorder patients. These subgroup findings are consistent with studies using other measures (e.g., the SCID-D) that compared dissociative identity disorder and borderline personality disorder (see section on Differential Diagnosis of Dissociative Identity Disorder), showing overall lower scores and a different pattern of scores on standardized dissociation measures for individuals with borderline personality disorder. Apart from individuals with dissociative disorders, there are no data on the pathologic dissociation taxon in any diagnostic group other than PTSD. These findings suggest that elevated dissociation scores across diagnoses may, in part, represent different patterns than that of the dissociative taxon.

The Hierarchical Taxonomy of Psychopathology (HiTOP) model uses the observed covariation of symptoms to organize psychopathological syndromes dimensionally by grouping related symptoms and their components/subtypes. Comorbidity is assessed by combining co-occurring syndromes into spectra. In a prospective study of 486 community volunteers, Stephanie Ellickson-Larew and colleagues assessed dissociation based on the HiTOP model. Participants, approximately half of whom were African American, were evaluated at baseline with two 3-hour sessions for self-report measures and a diagnostic clinical interview, respectively. Three hundred participants returned an average of 9.5 months later to complete 3 hours of self-report measures. The authors derived three facets for dissociation: depersonalization/derealization, memory disturbances (amnesia), and fantasy, the latter related to absorption. Bivariate and multivariate analyses across both self-report and interview data showed that all the dissociation facets related broadly across psychopathology dimensions, including internalizing, externalizing, and psychoticism. When controlling for neuroticism, memory disturbances and depersonalization/derealization (the latter to a lesser degree) maintained these relationships. These patterns established the transdiagnostic nature of dissociation.

At follow-up, depersonalization/derealization and memory disturbances maintained strong predictive power across symptoms; fantasy was predictive of mania. After controlling for neuroticism, depersonalization/derealization maintained strong predictive power

for internalizing symptoms and had substantial predictive power for increases in psychopathology, particularly suicidality. The memory disturbances facet was the strongest correlate of current psychopathology. Fantasy was weaker in predictive power, more for externalizing symptoms.

This study strongly supported dissociation as an important transdiagnostic factor that was related to all diagnoses tested in this model, including PTSD, fear- and distress-based disorders such as anxiety and mood disorders, substance abuse, OCD, mania, and psychotic disorders. These authors argued that dissociative symptoms may be a cross-cutting indicator of the effect of trauma on psychopathology in general as well as associated with poorer treatment outcome. This group strongly recommended that dissociation be assessed systematically in all diagnostic assessments.

Dissociation: A Major Risk Factor for Suicide Attempts and Nonsuicidal Self-Injury

All studies that have evaluated the question have shown that dissociation and dissociative disorder diagnosis are independent risk factors for nonsuicidal self-injury and suicide attempts, particularly multiple suicide attempts. Clinical studies of dissociative identity disorder ascertain that 90% to 100% of these patients report a past or current history of suicidal ideation; 60% to 78% endorse prior, often multiple suicide attempts; 78% endorse current or past nonsuicidal self-injury. Clinical case series report that patients with generalized dissociative amnesia are at high risk for suicide attempts if the amnesia is too quickly broken down and there are inadequate safeguards to protect the patient.

Logistic regression analysis of dissociative disorder patients in an inner-city clinic found that dissociation was the only remaining significant relationship with multiple suicide attempts, after PTSD, substance abuse, trauma history, and borderline personality disorder were entered into the analysis. Meta-analyses of suicidality and nonsuicidal self-injury find that higher DES scores and dissociative

disorder diagnosis predict suicide attempts and nonsuicidal self-injury. Patients with a dissociative disorder diagnosis are more likely to report previous suicidal ideation and nonsuicidal self-injury compared to other patient groups. In studies using a DSM-based methodology to diagnose dissociative disorders, results remain highly significant for both outcomes. Accordingly, dissociation is an independent risk factor for dangerousness to self and should be assessed in all clinical evaluations for safety issues and in all research studies of suicide risk.

Dissociation as a Response to Trauma

As noted in the historical section, there is a longstanding debate about the relationship of dissociation to antecedent traumatic experiences. Since the 1980s, multiple lines of evidence have linked dissociative disorders with antecedent trauma, building a strong case for its role as a necessary antecedent to the development of pathologic dissociation. For each of the DSM-5-TR dissociative disorders, there now exist multiple independent case series, including non-Western samples, documenting unusually high rates of trauma in these patients, including case series where one or more traumatic events have been verified for most patients. Several hundred peer-reviewed studies have found significantly higher levels of dissociation, as measured by the DES and other well-validated instruments, in traumatized groups compared to nontraumatized clinical and general population samples.

Across multiple international, cross-cultural studies dissociative disorders are associated with more severe and chronic trauma, early-life trauma, and attachment disturbances with primary childhood caregivers. Early life adversities strongly associated with dissociative disorders include childhood sexual abuse and physical abuse, emotional abuse, and neglect and can include nonmaltreatment forms of childhood trauma such as multiple, painful medical procedures and wartime dislocation. Survivors of more severe and chronic adult trauma, including prisoners of war, torture survivors, women in prostitution and trafficking, and women

subjected to intimate partner violence, show elevated dissociation scores. Recently, Ruben Vonderlin and colleagues performed a meta-analysis of 65 DES studies with 7,532 individuals reporting abuse or neglect. A childhood history of abuse or neglect predicted significantly higher DES scores compared to nonabused subjects. Childhood sexual and physical abuse were associated with higher DES scores, compared to emotional abuse and neglect, although in these groups dissociation scores were significantly higher than in subjects without a childhood trauma history. The combination of physical and sexual abuse resulted in even higher mean DES scores. Higher DES scores were related to earlier onset of abuse, longer duration of abuse, and parental abuse. These were highly intercorrelated, consistent with other studies of intrafamilial maltreatment (e.g., in the second National Comorbidity Survey), finding in these highly pathologic families such strong intercorrelations between all abuse types and family dysfunction that these cannot be readily parceled out.

Dissociation is instrumental in shaping outcomes related to traumatic experience and psychophysiological responses to future stress and trauma. Peritraumatic dissociation—including symptoms of depersonalization/derealization, disorientation, time distortion, trance- /automaton-like behavior, and amnesia measured right after traumatic events (or described retrospectively)—predicts subsequent PTSD. This can help identify individuals at risk for PTSD after acute trauma. Dissociation has been shown to mediate the relationship between antecedent trauma and subsequent psychopathology, including PTSD. This means that—once the level of dissociation is statistically controlled—the strength of the relationship between trauma and psychopathology significantly decreases or disappears. High levels of dissociation also alter the psychophysiological responses of traumatized individuals to traumatic reminders. As noted above, multiple lines of evidence support the existence of a dissociative subtype of PTSD (see chapter on PTSD). This subtype is characterized by earlier and more severe trauma, more severe PTSD symptoms, specific autonomic and neurobiologic circuitry

patterns in response to trauma scripts, and possible SNPs associated with the subtype, among other differences.

Dissociation in Complex and Dissociative PTSD. In the ICD-11 field trials of complex PTSD, individuals with this ICD-11 diagnosis reported significantly more types of developmental and lifetime trauma—including neglect—as well as significantly higher overall dissociation scores, but not limited to depersonalization/derealization, when compared with traumatized controls and individuals with only ICD-11 PTSD. In a national U.S. study of over 3,000 treatment-seeking adolescents (ages 12 to 16; 60.5% female) a latent class analysis evaluated the relationship of PTSD to dissociation. Two models were selected; the first, the DSM-5 depersonalization/derealization model, had five classes. A second, expanded dissociation model identified an additional class characterized by dissociative amnesia and detached arousal. This second model significantly improved differentiation of the high-dissociation—high-PTSD group from the high-PTSD—low-dissociation group. The high-dissociation—high-PTSD group represented 14.7% of the sample, consistent with prior studies of the PTSD dissociative subtype. The high-dissociation PTSD and the PTSD groups did not differ significantly on number or types of maltreatment nor on most demographic variables.

Compared to the high-dissociation/high-PTSD group, the dissociative amnesia group reported decreased PTSD intrusion/reexperiencing symptoms, fewer trauma experiences, and more numbing, detachment, and amnesia. The former had high levels of intrusive PTSD symptoms as well as depersonalization/derealization. The authors hypothesized that the dissociative amnesia may lead to underreporting of trauma, as described in adult populations. These findings are consistent with clinical observations that breakdown in dissociative amnesia results in increased PTSD intrusive symptoms.

Studies in Diverse Cultural Settings. The relationship between traumatic exposure and dissociative disorders has been confirmed in

diverse cultural settings. Several studies in Africa have examined the association of traumatic exposure and dissociative pathology, especially in regions affected by civil war. In Uganda, for example, separate studies by two groups of investigators found a significant association between episodes of pathologic “spirit” possession and traumatic exposure. Frank Neuner and colleagues interviewed 1,113 youth ages 12 to 25 with pathologic dissociation attributed to spirit possession, most of whom had been abducted as child soldiers. In multivariable analysis, pathologic possession was associated with higher trauma exposure, such as being forced to kill someone, after adjusting for poverty, education, sex, and other factors; spirit possession was also associated with a greater number of traumatic event types. Dissociative possession symptoms were significantly correlated with symptoms of PTSD (Spearman’s rho = 0.36) and depression (rho = 0.37); in addition, 44.5% of individuals meeting a threshold criterion for dissociative possession met PTSD criteria, compared to 9.8% of those with low levels or no spirit possession.

In a second study in Uganda conducted in a relatively peaceful post-conflict zone, Marjolein van Duijl and colleagues compared 119 individuals reporting pathologic spirit possession with 71 residents of the same villages without pathologic possession experiences using the Harvard Trauma Questionnaire and the Traumatic Experiences Checklist. Mean scores on both trauma assessments were higher in individuals with pathologic possession and these scores were significantly correlated with the number of spirit possession symptoms and scores on the DES and the SDQ.

In a representative community-based sample of youths ages 11 to 17 in Puerto Rico, pathologic dissociative symptoms on the Adolescent DES were significantly higher among participants who reported severe physical abuse and/or were exposed to violence. Compared to individuals with conversion but without a dissociative disorder, individuals in Turkey who also met criteria for a dissociative disorder were more likely to endorse childhood trauma. Several studies conducted in clinical and nonclinical populations in Brazil found a correlation between DES scores and measures of traumatic exposure.

At the same time, international studies have noted that some forms of dissociation—pathologic possession, psychogenic nonepileptic seizures, conversion disorder with dissociative features, dissociative cultural idioms of distress such as *ataque de nervios* (attacks of nerves)—can be associated with significant but nontraumatic stressors. For example, these include school and family conflicts among youth, troubled romantic affairs, emotional neglect, unemployment, and insecure attachment. It is possible that some cultural characteristics—such as the avoidance of strong negative affectivity to maintain equanimity and/or the development of a more "porous" sense of self open to transpersonal spiritual experiences—may nurture dissociative capacity, which may develop into pathologic dissociation upon exposure to severe but nontraumatic stressors. However, only some of these studies systematically assessed for the presence of childhood trauma that could play a role in predisposing individuals to dissociative disorders once exposed to these nontraumatic stressors. This is similar to descriptions of precipitants to episodes of severe dissociation in the classic cases and case series on generalized dissociative amnesia and dissociative fugue. Here, extreme intrapsychic conflict and/or acute loses or stresses appeared to precipitate most of these events. In virtually every study, however, careful reading showed that these individuals had suffered from severe prior traumas such as wartime combat, experiences of violence or sexual assault, and/or childhood sexual abuse and/or physical abuse. Further research is necessary to clarify this issue.

Studies of Military Survival School Subjects. Remarkable research conducted by Morgan and colleagues with military Special Operations units under extremely stressful conditions are as close as one can ethically come to an experimental model of trauma-induced dissociation. Military Survival, Evasions, Resistance, and Escape (SERE) training is offered by all branches of the U.S. military and is based on American POW experiences during WWII, and the Korean and Vietnam wars. This involves days of inescapable stressors, including semi-starvation, exhaustion, sleep deprivation, lack of

control over hygiene and bodily functions, abusive interrogations, hooding, and lack of control over one's movements, social contact, and communication. Working with both U.S. and European units undergoing SERE and similar training, as well as the grueling Combat Diver Qualification Course, Morgan examined the neurobiologic and psychological effects of intense stress uniformly applied to drug-free, healthy, nonclinical subjects. The neuroendocrine stress effects measured in these soldiers were equal to or exceeded those reported for individuals subjected to life-threatening experiences. These stressful experiences were positively associated with dissociation measures. Significant differences were found between pre- and posttest scores with the greatest effects for depersonalization items (e.g., looking at the world through a fog, time slowing, "spacing out"). Life threat from prior trauma was significantly correlated with pre- and poststress dissociative symptoms. In general, the prestress pattern of elevated dissociation predicted poorer performance during these high-stress situations, including problems with attention, working memory, and problem-solving. Dissociation scores also accounted for 41% of the variance in health complaints after the stress experience. The significant relationship between the pre- and poststress change in dissociation score and somatic symptoms is congruent with many clinical studies reporting linkages between somatization and dissociation.

Morgan's systematic studies are consistent with observational reports of the high frequency of dissociation, especially depersonalization symptoms, in normal individuals exposed to life-threatening stress. The ubiquity of acutely high levels of dissociation during extreme stress indicates that other factors, perhaps prior life-threatening trauma, are operative in the peritraumatic dissociation–PTSD linkage discussed previously. The highest-dissociation scores were associated with intense subjective appraisal of life threat from past trauma. However, one highly traumatized subgroup, Special Forces soldiers, had *low life-threat appraisals of their past trauma* and, consequently, the *lowest pre- and poststress change in dissociation scores.* As described in the neurobiology section, after interrogation stress during survival training, Special Forces soldiers

showed significantly higher levels of Neuropeptide Y (NPY) compared with soldiers in the general forces, suggesting a role of NPY in regulation of anxiety and/or dissociation during high-stress situations. Clinically, such individuals report the capacity to remain calm and focused during extreme danger, even when suffering from PTSD that is disruptive in other contexts. They describe the ability to ramp down their stress response, achieving resolute, unemotional clarity evaluate and manage threat.

In summary, several independent lines of evidence point to a causal relationship between trauma and dissociation. This relationship is apparent for many forms of trauma and has been found across various cultural settings in which it has been investigated. Significant levels of dissociation in the immediate aftermath of traumatic events appear to predispose to developing PTSD and related psychopathology, although additional factors involving the psychological appraisal of prior trauma also appear to be involved. Dissociation appears to be a major mediating process between traumatic experiences and subsequent psychopathology and thus is an important target for prevention and early intervention efforts. Stress-resistant individuals can be characterized, in part, by their lack of dissociative responses to significant stressors and/or their ability to—consciously or unconsciously—modulate their stress response during threat.

Culture, Dissociative Disorders, and Sociocognitive Phenomena

Cultural and sociocognitive factors shape the presentation of all psychiatric disorders. Certain symptoms may be emphasized above others when experiencing or describing disorders (e.g., psychological vs. somatic aspects of depression) and specific experiences may be common in certain settings but rare in others due to societal-structural differences as well as diverse meaning traditions. For example, conversion-like dissociative symptoms are more common in India than in certain affluent settings in the United States. Attributions of pathologic experience also vary. Nineteenth-

century individuals with paranoid schizophrenia did not have delusions of being controlled over the internet.

The inclusion in the DSM-5 of the pathologic possession form of dissociative identity disorder was based on cross-cultural research that described sociocognitive differences in the structuring of the disorder between secularized (often Western) contexts and nonsecularized (often non-Western) ones. In the literature on dissociative identity disorder, various developmental, social, cultural, intrapsychic, interpersonal, and cognitive factors, including the impact of psychotherapy, are hypothesized to account for the *secondary structuring* of the dissociative process into the individualized identities characteristic of a given person in a specific cultural context. Influences may include family factors (e.g., contradictory parental demands for the child to be a boy or a girl); religious and other cultural and social influences (e.g., characters from books, films, television, or video games); the accepted existence of nonmaterial entities (e.g., gods, demons, possessing spirits); and specific traumatic experiences (e.g., being sexually trafficked in childhood and having to create identities to fit the fantasies of “purchasers”; being a child soldier); among others.

In clinical case series, developmental factors affect the presentation of the dissociative identity disorder self-states in important ways. Usually, children with the disorder manifest less overt switching and self-states are described more as elaborated and autonomous imaginary companions. During adolescence, the person may develop more complex, secondarily structured self-states that relate to many aspects of psychological life. Intelligence and creativity may lead to greater elaboration of identity states in some individuals with dissociative identity disorder, as does posttraumatic withdrawal from outside reality due to trauma and neglect; these may lead to the creation of more elaborate fantasy worlds in which to “live.” Cross-cultural research could help describe childhood forms of pathologic possession in cultures that support these belief systems. Future research may trace in greater detail how culture interacts with biology in a developmental timeframe and in the context of an individual’s exposure to experiences that shape

the expression of culturally diverse phenomenologies of dissociative psychopathology (see Developmental Models of Dissociation).

Type D Attachment

Attachment pathology in infancy has been linked with later dissociation in prospective studies. Disorganized (Type D) attachment in infancy as coded by the Strange Situation protocol (between 12 and 20 months) is manifest as conflicted, disoriented, and/or fearful behavior toward the parent. Disorganized attachment is most common in severely maltreated children but can occur with nonabusive traumas, losses, and unresolved parental trauma and loss. Frightened, frightening, or dissociative caregiver behavior is strongly implicated in the development of disorganized attachment; and in the case of the dissociative parent, may contribute to the multigenerational transmission of trauma and dissociation.

Two prospective, longitudinal research studies following families at high risk for maltreatment found that infants with disorganized attachment had significantly higher-dissociation scores in late adolescence and early adulthood compared with infants classified with other categories of attachment. In one study, Type D attachment accounted for almost half of the variance in dissociation scores 20 years later. Disorganized attachment in young adulthood partially mediates the relationship between the severity of childhood maltreatment and dissociation scores. A prospective, case-control study following sexually abused and nonabused comparison girls into adulthood found that increased maternal dissociation predicted harsh parenting of the type associated with the development of disorganized attachment in offspring. Consistent with these childhood studies, a study of 554 healthy adults found a large effect size (d = 1.43) for the combination of verbal/emotional abuse and witnessing domestic violence in childhood in predicting dissociation, comparable to the effect of familial sexual abuse.

Betrayal Trauma

Beyond the multiple associations among various types of traumatic experiences and dissociative sequelae, Jennifer Freyd has formulated a specific *Betrayal Trauma Theory* (BTT), derived from social psychological principles and developmental attachment theory (see section on History). BTT began as an attempt to explain childhood amnesia for trauma as related to the meaning of the negative event as a betrayal by a trusted, needed other, rather than simply related to the frequency and aversiveness of traumatic experiences. Betrayal influences how the event is processed and remembered. In this model, supported by data in clinical and nonclinical samples, a child is more likely to develop amnesia when subjected to abuse by a family member or another person whom the child trusts or on whom the child is dependent. The amnesia is protective of the child's developmentally mediated need for attachment, allowing for preservation of emotional and cognitive growth despite the abuse.

It is hypothesized that psychological schema about the abuse (i.e., the betrayal) are subjectively sequestered from mental mechanisms that control attachment and attachment behavior. BTT is consistent with the DBS model and the Type D attachment findings. It elucidates cognitive factors that may influence dissociation of state-related information. Traumas involving betrayal are processed differently at the cognitive level from other autobiographical experiences, leading to state-dependent memory deficits. BTT helps explain the lower prevalence of amnesia for wartime trauma, natural disasters, and the Nazi Holocaust, among others, as compared to intrafamilial childhood sexual or physical abuse. Difficulty in being able to "share" the traumatic experiences also may contribute to amnesia for trauma. In addition to the neurobiologic factors that inhibit verbal access to such events, they are less likely to be shared because of threats, shame, developmental inability to find words for the experience, reliance on adults to define childhood experience, and intense confusion and emotional arousal engendered by the abuse.

Compared with traumatized individuals not reporting betrayal, those reporting betrayal show higher levels of dissociation,

particularly dissociative amnesia, alexithymia, anxiety, depression, nonsuicidal self-injury, and physical health complaints. In a community study, “double betrayal” was defined as sexual abuse by a caregiver followed by a negative response to disclosure. This was associated with more severe dissociative amnesia and higher rates of revictimization.

Betrayal trauma and lack of integration of betrayal information—called *betrayal blindness*—have also been studied across diverse types of experience. These include personal betrayals, such as marital infidelity, as well as institutional betrayal (e.g., the Catholic Church in the clergy abuse cases) and cultural betrayal (e.g., a member of a cultural minority group feeling betrayed by another member of the same group). Betrayal blindness may be a common human response to these situations, with intense emotional reactions when awareness of the betrayal becomes less dissociated from the person’s awareness.

A unified information processing and betrayal model predicts the relative likelihood of amnesia under varying circumstances, such as high threat/low betrayal, high threat/high betrayal, and so forth. However, as described above, various factors may lead to disturbances of autobiographical memory for traumatic experiences, although betrayal trauma may be particularly salient as a factor in the lack of integration of trauma-related information. BTT may also help explain liability to revictimization in survivors of childhood trauma. When the survivor encounters potentially exploitative individuals, the “betrayal detection system” becomes relatively unavailable to consciousness. This, as well as the over-learned freeze response to threat developed in childhood (see section on Neurobiology), may explain how dissociation is a risk factor for revictimization.

Developmental Model of Dissociative Disorders

Modern interest in a developmental model of dissociative disorders, especially dissociative identity disorder, can be traced to pioneers who examined children with the condition, such as Cornelia Wilbur

and Richard Kluft. Long-forgotten case reports were later discovered in which 19th-century clinicians used phrases in Latin to hint at incest and unspeakable familial trauma. Small case series and reviews of childhood dissociative disorders appeared in the mid-to-late 1980s, with more systematic studies coming in the 2000s. As with the adult case series, histories of severe trauma were commonly noted (see section on Dissociative Identity Disorder).

The core phenomenology of dissociative disorders in children is largely like that in adults (see section on Culture, Dissociative Disorders, and Sociocognitive Phenomena). However, as with most childhood manifestations of lifelong psychiatric disorders, the day-to-day symptoms vary with the child's age. In general, older children and adolescents are more overtly symptomatic than younger children. In part, this may reflect the ability of older children to better report subjective distress as well as their greater opportunity to manifest psychopathology in a variety of settings.

In a pooled sample of 177 child and adolescent dissociative disorder cases, amnesias, identity disturbances, and auditory hallucinations increased with age, whereas trance-like and "spacey" behavior was ubiquitous across all age groups. Related psychopathology, such as suicidal ideation, self-mutilation, and somatization, increased with age in parallel with dissociative symptoms. Boys and girls did not differ on dissociative symptoms but girls were significantly more symptomatic for anxiety and phobic symptoms, PTSD, sleep disturbances, sexual acting out, and somatization. Boys showed more externalizing behaviors such as aggression and violence. These findings closely parallel the gender differences in adult clinical profiles. Here males with dissociative identity disorder report higher rates of violence, criminal involvement, and alcohol and substance use disorders. Children and adolescents diagnosed with dissociative identity disorder were the most symptomatic across all age groups, which is consonant with the clinical belief that dissociative identity disorder is the most severe of the dissociative disorders.

Validated child and adolescent dissociation measures have been administered to various clinical and nonclinical samples (see

Table 20–1). Scores were significantly higher for traumatized (typically child abuse) versus nontraumatized respondents across all age groups. As in the adult studies, levels of dissociation were also significantly associated with more general psychopathology. Among maltreated preschoolers, there were robust correlations with internalizing and externalizing behavior problems for girls and boys, respectively. A comparison of maltreated and nontraumatized preschoolers matched on family constellation and demographics found that the maltreated group had significantly increased levels of dissociation a year later, with the physically abused children accounting for the greatest increase in scores. The controls showed substantial decreases in their dissociation scores over the same period, in line with the often-reported decrease in dissociation scores with age in normal children.

Studies have explored the possible mediating role of dissociation in the development of psychopathology in sexually abused children and adolescents. Measuring psychopathology with a variety of standard measures, the main effect of sexual abuse on behavioral problems disappeared when levels of dissociation were controlled for, as measured by a self-report measure (A-DES) or by observer report (Child Dissociation Checklist [CDC]). The possibility that dissociation is a critical mediating variable for subsequent psychopathology has significant implications for early intervention with maltreated and traumatized children. Assessment of dissociation should be a standard part of the evaluation of traumatized children and adolescents and significant elevations should be addressed in the treatment plan. This would include diagnostic assessment for specific dissociative disorders, for example, dissociative identity disorder, and development of a treatment plan that specifically targets dissociative symptoms/disorders. The latter is critical as studies of adult trauma survivors show that, without specific attention to dissociation, standard trauma-informed treatments are likely to be partially effective at best.

Search for Developmental Precursors and Substrates of Dissociation

Imaginary Companionship. The focus on child dissociative identity disorder led clinical investigators to initially focus on childhood fantasy phenomena, such as imaginary companionship, as possible developmental precursors for dissociative disorders. Imaginary companions are reported in 20% to 60% of normal children depending on the age of the child and the definition used. Normal imaginary companionship is widely regarded as benign and is commonly considered to be a sign of creativity in young children but it becomes increasingly suspect in older children and adolescents and is thought to be always pathologic in adults. In dissociative children, the rates of imaginary companionship range from 42% to 84%, with the highest rates reported for children diagnosed with dissociative identity disorder.

Comparing the characteristics of imaginary companions in maltreated and non-maltreated boys showed that maltreated boys averaged 6.4 entities compared to 2.5 entities for the non-maltreated boys. The latter first appeared between 2 and 4 years of age and had all disappeared by 8 years of age. The imaginary companions reported by the boys in residential treatment, however, served other functions, including as (1) helpers and comforters, (2) powerful protectors, and (3) family members. In some cases, the boys reported feeling as if they had lost control and their imaginary companions took over their behavior. The maltreated boys reported that their imaginary companions were still present at a mean age of 10.6 years, well after they had disappeared in the nonmaltreated boys. The imaginary companions of the maltreated boys often had names such as *God, the devil,* and *guardian angel.* Authorities theorize that some of the imaginary companions found in maltreated children eventually represent the dissociative identity disorder self/identity states.

Developmental Mediation of Psychopathology by Dissociation

The negative effects of elevated dissociation on child development may operate by hindering the development of a sense of self, emotional regulation, impulse control, information processing, and coping with stressors. Children assemble and seek to integrate a complex, multidimensional sense of self over the course of development. Dissociative components, such as autobiographical amnesias, depersonalization, and passive influence experiences, interfere with the integration of self and the development of a unified sense of self-agency.

Dissociative amnesias also disrupt the child's understanding of cause-and-effect sequences, so that negative or risky behaviors may appear unconnected from their consequences, experienced as "coming out of the blue." This lack of connection can interfere with the ability of dissociative children to learn from experience. The impact of dissociation on the metacognitive function of self-monitoring behavior can disrupt integration of experiences across contexts, further complicating the child's ability to learn and to practice self-control, particularly in the context of stressors. Increased dissociation is well correlated with increased aggression, impulsivity, and poorer social skills in children and adolescents.

Prospective studies of sexually abused girls compared with carefully matched controls show that dissociation is negatively associated with competent learning and overall classroom performance and is strongly predictive of school avoidance. The combination of cognitive dysfunctions and negative school trajectories puts the dissociative child at an academic disadvantage that has profound implications for adult attainment.

Chronic depersonalization, closely associated with emotional numbing in PTSD patients, is thought to promote a sense of detachment from self that fosters risky and self-destructive behavior, such as nonsuicidal self-injury (see section on Dissociation and Dangerousness to Self). Dissociative patients often describe self-inflicting pain in attempts to break through profound states of depersonalization and numbness. At other times, they report feeling nothing as they cut or burn themselves. Alienation from self is also thought to play a role in the high rate of suicide attempts in

dissociative patients. As noted above, dissociation has been implicated in predisposing an individual to revictimization. In aggregate, these experiences expose dissociative individuals to further traumatization, which takes a cumulative toll over the individual's life. Identification of protective environmental factors may help stimulate intervention models that prevent the development of significant dissociation in acutely traumatized children.

4-D Model of Trauma-Related Dissociation. The "4-D Model of the Trauma-Related Dissociation" has been articulated by Paul Frewen and Ruth A. Lanius. This framework, based on work from philosophy and consciousness studies, elaborates the concept of trauma-related altered states of consciousness (TRASC) introduced by the DBS model. The 4-D model proposes a four-dimensional neurophenomenology as a means of describing specific experiential states: (1) time and memory, (2) verbal/thought, (3) embodiment, and (4) emotion. The neurophenomenologic approach is based on subjects' personal descriptions of experiences that are correlated with neurobiologic measures. Imaging studies of individuals with PTSD and in community samples have shown differences in fMRI patterns between individuals with and without dissociative symptoms, irrespective of diagnosis. Those without dissociative symptoms have shown patterns of distress associated with the neurobiologic normal waking state of consciousness (NWC) as opposed to TRASC, characteristic of distress in individuals with the dissociative subtype of PTSD and with dissociative experiences related to trauma. The 4-D model, consistent with the developmental DBS model, provides a testable way to link neurocircuitry patterns to abnormalities of emotion regulation and self-referential appraisal. These, along with other factors such as attachment disturbances (see sections on Betrayal Trauma and Type-D Attachment), may be important in development of dissociative disorders such dissociative identity disorder and depersonalization/derealization disorder.

Hypnotic Model. Recent reviews have revived the hypnotic model of dissociation as particularly etiologic for dissociative identity

disorder. This model hypothesizes that a traumatized child uses their innate hypnotic capacity to induce autohypnosis as a defense against overwhelming or repetitive traumatic experiences. In dissociative identity disorder, with continuous use, the autohypnotic state is personified into self-states. Support for this model includes that dissociative patients are the most highly hypnotizable group of individuals, especially those with dissociative identity disorder. Many clinical phenomena associated with pathologic dissociation—such as trance states, age regression, auditory hallucinations, and amnesias—can, in a hypnotic state, be transiently produced in highly hypnotizable, normal individuals. Finally, two studies suggested that childhood trauma might increase hypnotizability.

Among problems with this model, it reasons retrospectively from adult patients to hypothesized mechanisms in children. Hypnotic capacity is difficult to assess in children at least until early adolescence. More systematic research has dispelled the notion that childhood trauma generally increases hypnotizability. At least six studies found no differences between traumatized and nontraumatized adult and child samples. In clinical and general population samples, there are no discernible dose effects between measures of trauma severity and hypnotizability. However, a small group of individuals, termed *double dissociators,* score high on measures of dissociation and hypnotizability. These individuals generally have histories of earlier and more severe trauma. This observation is most compatible with the taxonic model of pathologic dissociation and may explain the greater hypnotizability of dissociative identity disorder patients. There may be different types of hypnotizability, with high dissociators making up a distinct type. However, other hypnotizability studies have found subgroups of highly hypnotizable people in nondissociative samples. In dissociative identity disorder, autohypnosis may be involved in secondary elaboration of self-states, in attempts to attenuate intrusive symptoms, and as a self-protective process during maltreatment. Autohypnosis is a core aspect of dissociative trance disorder (see section on Other Specified Dissociative Disorders).

Psychoanalytic Models. As described in the section on History of Dissociation, psychoanalytic theory has had difficulty with the concept of dissociation since the unfortunate schism of Freudian and Janetian ideas in the late 19th and early 20th centuries. In addition, in psychoanalytic writings, the term trauma was broadened to refer to almost any developmental stressor, a conceptual difficulty recognized by some psychoanalytic writers such as Anna Freud when she studied British children with wartime trauma caused by bombings of the United Kingdom by Germany during World War II. Also, psychoanalytic theory became focused on the intrapsychic appraisal and symbolization of events rather than on interplay between the severity of traumatic events and subjective appraisal.

Other than in the work of David Rappaport and his associates at the Menninger Clinic in the 1940s that attempted to integrate Freudian and Janetian concepts, as well as a few papers on "hypnoid states," until recently most psychoanalytic writing has centered on the concept of "splitting" as equivalent to dissociation. On the other hand, psychoanalyst Steven Marmer, based on his experience treating dissociative identity disorder patients, posited intrapsychic transitional object phenomena as a specific developmental aspect of the creation of dissociative identity disorder self-states. Some theorists of the relational school of psychoanalysis now view dissociation as a general psychological phenomenon that underlies all neurotic, personality disorder, and posttraumatic symptoms. However, in general, psychoanalytic theory appears to have difficulty viewing dissociation as a specific response to trauma, both developmentally and in adults, and as a specific intrapsychic defense against subsequent awareness of trauma and its impact on the person.

Structural Dissociation Theory. Onno van der Hart and Ellert Nijenhuis have attempted to develop a comprehensive theory, *Structural Dissociation Theory* (SDT), postulating that a basic dissociative "split" in personality accounts for posttraumatic manifestations and disorders. SDT is especially popular in Europe as an etiologic theory and treatment model. This theory proposes that

dissociative disorders, PTSD, somatoform disorders, and some cases of borderline personality disorder are fundamentally "dissociative" in that severe traumatic experiences led to a "split" between an *Apparently Normal Personality* (ANP) and an *Emotional Personality* (EP). The hypothesized ANP is constricted and avoidant, unaware of traumatic memories, externally focused on daily life, and phobic of internal experiences. The EP is filled with the pain and distress of unintegrated, unprocessed traumatic memory. SDT theorists have been the guiding force in the ICD-11 diagnostic criteria for dissociative identity disorder and partial dissociative identity disorder.

In this theory, PTSD results from a single EP and the ANP; more complex dissociative disorders involve "secondary" and "tertiary" structural dissociations with, respectively, multiple EPs and then multiple ANPs. "Tertiary structural dissociation" results in the development of dissociative identity disorder and secondary structural dissociation in "less complex" dissociative disorders. SDT follows DBST in conceptualizing dissociative identity disorder as resulting from an early developmental failure to consolidate a consistent sense of self across different emotional states, social contexts, and relationships. However, SDT postulates that the alternation of approach/avoidance behavior of infants and toddlers with Type D attachment patterns is an expression of an alternation of an "ANP" and an "EP," an adult-based construct not consistent with accepted models of the psychobiological development of human children,

Problems with SDT include its overly reified conception of the mind as a structure, with a concretized "personality" that is "split" and made up of "parts." Dissociative disorders are better conceptualized as disorders of self-organization, with development of complex dynamic self-state systems, not a lesion of the "personality." SDT is based on reasoning backward from adult dissociative identity disorder rather than forward from the developmental perspective of the DBST. It minimizes the complexity of child development by positing hypothesized adult psychological "structures" in infants and toddlers. In addition, meta-analyses of PTSD and dissociation are

consistent with the model that dissociation is either best understood as a subtype or a component of PTSD, not that dissociation underlies all forms of PTSD. Other problems include the unwieldy, reified, and difficult-to-operationalize conceptual language (e.g., “apparently,” “normal,” and “personality”) that minimizes the notion of dissociation as a process or set of processes in favor of metaphors for “structure.” The SDT model of dissociation posits universally rigid amnestic barriers between ANP and EP and sequential activation of differentiated states rather than the shifting, variable symptom presentation that characterizes most dissociative identity disorder individuals with overlap, interference, influence, and intrusion between states, as well as cooperation among self-states/systems.

Iatrogenic, Sociocognitive, Fantasy, and Sleep Models of Dissociation and the Dissociative Disorders. Despite research data on the relationship between trauma and dissociation, some authorities continue to question the existence of dissociation, the trauma–dissociation relationship, and/or the validity of the dissociative disorders, particularly dissociative identity disorder and dissociative amnesia (see section on History). This skepticism has taken for forms: *the iatrogenic model* (IM), the *sociocognitive model* (SCM), the *fantasy model* (FM*),* and, most recently, *the sleep-dissociation model* (SDM).

IATROGENIC AND SOCIOCOGNITIVE MODEL OF DISSOCIATION. The IM posits that dissociative identity disorder and dissociative amnesia are not authentic psychiatric disorders but instead the product of direct or indirect cuing and suggestion during psychotherapy by credulous therapists to highly “suggestible,” hypnotizable, and “fantasy-prone” patients. These are supposed to be characterized by dependent, borderline, and/or histrionic traits and to be desperate for acceptance and a sense of identity. The therapist, through an ideologic belief in dissociative identity disorder or “repressed memory,” engages in a “risky” “recovered memory therapy” (a nonexistent, pejorative “treatment” created as a forensic and public relations gimmick) that focuses only on retrieval of as many trauma memories as possible

using “suggestive techniques,” including hypnosis, and pharmacologically facilitated interviews. The therapist thereby implicitly and/or explicitly cues and encourages the patient to undertake the role of the trauma survivor with recovered repressed memories and/or dissociative identity disorder. The patient develops a real, albeit iatrogenic, factitious disorder, now truly believing in the roles that they enact. Advocates of these models posited that dissociative disorder cases were only found “in a few centers” run by “enthusiasts” who churned out an “epidemic” of dissociative identity disorder and recovered memory cases.

The SCM is similar to the IM, but adds a factor related to the broader cultural and social influence—often promulgated by the internet, mass and social media, self-help books, and/or victim support groups—in which people, primarily in North America, come to accept the possibility of *multiple identity enactments* or a history of forgotten childhood victimization, or both, as part of an established social role. In this view, therapy may not be a necessary factor in the development of a dissociative disorder; a susceptible person may develop the disorder simply through more general social influence. The SCM for dissociation is constructed as an analog to the Sociocognitive Model of Hypnosis, where hypnotizability is not related to an altered state of consciousness or discontinuities in experience but solely is a learned social role, that of “being hypnotized.”

Treatment requires removing the patient from the therapy, ignoring any reference to self-states or trauma memories, educating the patient about the factitious nature of these phenomena, and beginning “real” therapy for other issues. If the patient has become estranged from their family of origin due to belief in the false abuse history, reunification with the family is deemed important as well.

Recent comprehensive reviews of the IM/SCM for dissociative disorders find that virtually no empirical, scientific studies have been performed in clinical populations to examine this model. The original database supporting these constructs consists of a few heterogeneous studies from the 1940s and 1950s, mostly consisting of anecdotal case reports. These demonstrated that some degree of

role enactment of an alternative identity occurred with hypnosis, automatic writing, and strong repeated suggestion. Many subjects were the students of the researchers and knowledgeable of the goals of the experiments. The role enactments were limited to the experimental situation. One of the researchers, studying a traumatized soldier, concluded that hypnosis allowed access to authentic, previously dissociated self-states, not to artifacts of the procedure.

Research with thousands of subjects undergoing hypnosis over several decades has shown that a subgroup of highly hypnotizable individuals can exhibit limited, temporary apparent self-states after hypnotic suggestion. These states were phenomenologically dissimilar from clinical dissociative identity disorder and were limited to the experimental situation. The researchers noted that they could not determine whether these procedures uncovered previously existing dissociated aspects of the mind or created them de novo.

A few studies of college volunteers in various hypnotized and nonhypnotized conditions found that highly hypnotizable, “fantasy-prone” students would enact the role of a dissociative identity disorder murderer with amnesia when given a series of robustly explicit suggestions to do so. This research has been criticized on several grounds, including lack of diagnostic controls (e.g., enacting another psychiatric disorder, such as a murderer with schizophrenia); lack of equivalence of the research design with the clinical situation; conflation of dissociative identity disorder with role enactments, rather than the complex polysymptomatic picture described in the clinical and research literature; lack of attention to strong expectancies and demand characteristics of the research design; and failure to account for preexisting dissociated self-states and traumatic experiences.

Finally, the large, international, cross-cultural epidemiologic and phenomenologic studies of dissociative disorders cannot be accounted for by the IM/SCM postulates. Cases were ascertained by administering valid and reliable screening measures and structured interviews to a wide array of patients in myriad settings, hardly specialized “dissociative clinics,” including inpatient, outpatient,

partial hospital, state hospital, private psychiatric hospital, substance abuse treatment, and emergency departments in high-, middle-, and low-income countries (see section on Epidemiology).

The Fantasy Model (FM). The next iteration of this skepticism is the FM. In this model, dissociation is not a phenomenon that follows traumatic or overwhelming experiences. It is a personality trait consisting of a mild form of cognitive/executive function impairment that predisposes an individual to being suggestible and generally prone to fantasy and to have a specific liability to confabulated traumatic experiences. FM proponents aver that the relationship between trauma and dissociation is weak or nonexistent. Being fantasy prone was originally described in nonclinical samples, seen in individuals with high hypnotizability, vivid fantasy lives, and a capacity to spontaneously create intense perceptual, sensory, and imagery experiences, often more vivid than actual reality. Fantasizers also described vivid recall of childhood and multiple religious and paranormal experiences.

Systematic Comparison of the Trauma and Fantasy Model of Dissociation

A general critique of the literature on fantasy proneness posits that the basic psychometric inventories for fantasy proneness do not measure a specific construct but rather diverse factors apparently related to potential clinical and normative phenomena, most of which are unrelated to being fantasy prone. Second, fantasy proneness and dissociation measures have been found to overlap. Third, some studies have found a relationship between fantasy proneness and childhood trauma, potentially explaining the correlation between dissociation and fantasy proneness measures.

In 2012, Constance Dalenberg and colleagues published a comprehensive, rigorous meta-analysis that examined eight contrasting predictions from the TM and the FM of dissociation. These findings are summarized in Table 20–11.

This review only included studies with sufficient data to calculate effect sizes, sample sizes greater than 50, and whose design was unlikely to restrict the range of the trauma or dissociation variables. A particularly strong point was a review of the relationship between various suggestibility paradigms and dissociation. Major reviews of the term *suggestibility* cite the multiple definitions and explanations that have been used both for the phenomenon of *suggestion* and the hypothesized trait of *suggestibility.* These have included studies of hypnotic phenomena, unconsciously produced motor behaviors, dissociative possession states, false confessions, susceptibility to advertising, responses to psychotherapy, behavioral conditioning, and memory distortions, among many others. Also, one type of suggestibility may not correlate with other types.

Table 20–11.
Eight Predictions of the Trauma Model versus the Fantasy Model of Dissociation

In contrast to predictions associated with the Fantasy Model, The Trauma Model for Dissociation was confirmed on the following eight predictions:

1. The relationship between trauma and dissociation was consistent and moderate in strength across studies.
2. The relationship between trauma and dissociation remained significant when proven, well-supported, and/or objective measures of trauma were used, not just self-report.
3. Dissociation was temporally related to trauma and trauma treatment; symptoms tended to decrease with time, and were responsive to trauma treatment, rather than inflate and increase with treatment.
4. Dissociation was predictive of trauma history when fantasy-proneness was controlled, but not vice versa.
5. Dissociation was not reliably associated with suggestibility on a series of suggestibility paradigms.
    a. Event suggestibility
        i. For nonautobiographical events (post-event misinformation)
        ii. For autobiographical events (“false memory” creation)
    b. Interrogatory suggestibility (IS) (liability to false confessions)
    c. Imagination inflation
    d. Source monitoring errors
6. There was no relationship between dissociation and inaccuracy of documented memory with delayed recall (“recovered memory”); i.e., *both* continuous and delayed recall memories may be accurate, partially accurate, or confabulated.
7. Dissociation negatively related to general measures of narrative cohesion, indicating that dissociation led to difficulties in recall, not inflation of false trauma accounts.
8. Neurobiologic research supported the trauma theory of dissociation as a regulatory response to fear or other extreme emotion with measurable biologic correlates.

Data from Dalenberg CJ, Brand BL, Gleaves DH, et al. Evaluation of the evidence for the trauma and fantasy models of dissociation. *Psychol Bull*. 2012;138(3):550–

588. doi:10.1037/a0027447.

In the review by Dalenberg and colleagues—across various suggestibility paradigms, including those hypothesized to etiologically generate false trauma memories—*dissociation was not reliably related to suggestibility.* Indeed, the average *weighted effect sizes between all forms of suggestibility and dissociation accounted for only 1% to 3% of the variance.* Consistent with previous research, the review suggested that a subgroup of dissociative individuals may be more prone to generation of confabulated memory, although studies have not distinguished between false memory, false belief, and acquiescence to an authority figure in giving responses. In addition, studies have not tested *false nonbelief,* that is, subjects who come to deny actual memories (i.e., parallel to false trauma recantation) when suggested to do so by an authority figure. In response to the Dalenberg review, advocates of the IM/SCM/FM models, in a major concession, acknowledged for the first time that some delayed recall of trauma memories may be veridical.

Based on the evidence for the eight predictions of the TM of Dissociation, Dalenberg and colleagues concluded that there is *strong empirical support for the hypothesis that trauma causes dissociation* and that dissociation remains related to trauma history after adjusting for fantasy proneness. They found little empirical support that the dissociation–trauma relationship is due to confabulated memories of trauma, various types of suggestibility, and/or fantasy proneness.

A recent meta-analysis of 104 international studies of 31,905 college students by Mary-Anne Kate and colleagues tested several assumptions of the TM versus the FM. Findings included that the prevalence of dissociative disorders in this sample (11%) fit the predictions of the TM model, not the FM (4%). They concluded that rates of dissociative disorders and elevated dissociation better fit the international prevalence of traumatic experiences (12%), not media exposure rates. Prevalence rates of dissociation/dissociative disorders have remained stable over time, not fluctuant as would be consistent with the ebb and flow of a fad. Prevalence rates of

dissociative disorders were similar in college students to other populations, a finding contrary to FM postulates. Studies of dissociation by FM proponents found *higher-dissociation scores*, but did not use validated screening or diagnostic inventories, and may have primed subjects by prior administration of scales of fantasy proneness. Overall, this large meta-analysis supported the TM over the FM.

DISSOCIATION, DISSOCIATIVE IDENTITY DISORDER, AND INTERROGATORY SUGGESTIBILITY. The Gudjonsson Suggestibility Scale (GSS) is a robust measure of susceptibility to external pressure to produce confabulated narrative accounts, developed to assess *Interrogatory Suggestibility* (IS), the liability to false confessions. The GSS includes subscales assessing the respondent's liability to yield to leading questions and to shift (confabulate) responses under pressure from the examiner. Ninety-two adults recruited from the community were studied with measures of fantasy proneness, dissociation, trauma history, and the GSS. Participants' dissociation scores correlated significantly with trauma history and fantasy proneness, but not with GSS scores. Moreover, dissociation was negatively correlated in a sub-study with recall of the events of 9/11. In another study, hospitalized women with recovered childhood sexual abuse memories were significantly less suggestible on the GSS compared with general psychiatric controls from the same hospital.

These data are consistent with preliminary findings from studies of dissociative identity disorder that showed lower GSS scores compared with subjects with PTSD, trauma controls, and individuals with borderline personality disorder. Dissociative identity disorder subjects were *more* resistant than the other groups to interpersonal persuasion. A different study of SCID-D–diagnosed dissociative identity disorder patients failed to confirm the basic clinical profile posited by the SCM and replicated the finding that dissociative identity disorder patients did not show elevated interrogatory suggestibility. In particular, the dissociative identity disorder patients were highly introversive on the Eysenck personality inventory and

showed low histrionic personality features on the Million Multiaxial Clinical Inventory. Most dissociative identity disorder respondents were low or moderately high on fantasy proneness, with a subgroup showing high scores. This may indicate that there is a subgroup of dissociative identity disorder individuals with high fantasy-prone scores who may have more difficulty with reality testing and possibly greater liability to forms of suggestibility and production of factitious symptoms, self-states, and personal history.

THE DISSOCIATION/PATHOLOGIC SLEEP MODEL. After the refutation of the FM, the critics of trauma-dissociation theory have moved on to conceptualize dissociation as caused by sleep problems, specifically a subclinical form of narcolepsy characterized by sleep paralysis and hypnogogic and hypnopompic hallucinations. This view denies that sleep disruption is symptomatic of posttraumatic dissociation itself, together with common comorbidities (e.g., PTSD, major depressive disorder). Rather, sleep problems are thought to be *causative* of dissociation, which, possibly accompanied by childhood trauma, leads to cognitive errors, problems with source monitoring, and promulgation of false memories of trauma. These studies downplay the idea that sleep disorders are the result of dissociation, trauma, and comorbid disorders (e.g., PTSD) and may secondarily contribute to the level or intensity of symptoms and disability. One study compared 12 female dissociative identity disorder patients, with 27 PTSD patients, and 55 normal controls on retrospective sleep assessments, the DES, measures of fantasy-proneness, and "cognitive efficiency." Diagnoses of the dissociative identity disorder patients were ascertained with the SCID-D only, and the PTSD patients with the Clinician Administered PTSD Scale (CAPS) only. The authors concluded that intrusions of sleep phenomena into waking consciousness led to dissociative experiences. However, as 80% to 100% of dissociative identity disorder patients meet diagnostic criteria for PTSD, failure to assess dissociative identity disorder patients for PTSD makes the study uninterpretable. The authors did not explore the complex sleep pathology of dissociative identity disorder patients that includes severe PTSD intrusions,

nocturnal activation of self-states, and awakening in flashbacks with fugue behavior. Also, due to dissociation, PTSD, and autohypnosis, many waking dissociative symptoms naturalistically have an oneiroid quality.

The transdiagnostic prevalence of dissociation suggests that sleep problems are related to underlying psychopathology, possibly exacerbated by dissociation, not causative of dissociation. Improvement in sleep may have general ameliorative effect on all types of psychopathologies, including dissociation. Amelioration of sleep and dissociative symptoms does not indicate a causal role for sleep problems in dissociation. Finally, this theory focuses on symptoms that no longer are part of the diagnostic criteria for narcolepsy. General population studies have found that hypnogogic/hypnopompic hallucinations and sleep paralysis are far more common in the general population than the prevalence of narcolepsy. Thus, there is minimal empirical support for the role of disordered sleep as etiologic in the development of dissociation and dissociative disorders.

CONCLUSION. In a recent review, Constance Dalenberg and colleagues described the use of eight nonscientific rhetorical arguments found in most critiques of the TM of dissociation. These include (a) extraordinary claims = anything that you believe that I do not; (b) *ipse dixit* or the bare assertion fallacy; (c) false consensus; (d) the “ever-shifting” goalpost (e.g., non-trauma dissociation theories); (e) ad hominem arguments and accusations of these against those with whom we disagree; (f) motivated skepticism; (g) demand for a super-study; and (h) arguing from authority (*ad verecundiam*). In addition, as in the sleep studies, there is a basic failure to understand the phenomenology of dissociation and dissociative identity disorder and how these affect all domains of functioning. Motivated skepticism is shown by, even in studies involving dissociative identity disorder individuals, failure to assess them for PTSD, to assess for trauma history, and/or attempt to specifically replicate methodology from trauma-model-based studies of dissociation/dissociative disorders.

DISSOCIATIVE IDENTITY DISORDER

Dissociative identity disorder has been researched most extensively of all the dissociative disorders. It is the paradigmatic dissociative psychopathology in that the symptoms of all the other dissociative disorders are commonly found in patients with dissociative identity disorder: Amnesias, fugues, depersonalization, derealization, and similar symptoms. The DSM-5-TR diagnostic criteria for dissociative identity disorder are discussed in the section on Nosology and are listed in Table 20–3.

Etiology of Dissociative Identity Disorder—Trauma

In all studies that have systematically examined this question, non–possession-form dissociative identity disorder is strongly linked to extreme, chronic, and early childhood maltreatment. Across a wide variety of studies, in both men and women, the rates of reported severe childhood trauma for children and adults with non-possession dissociative identity disorder range from 85% to 97% of cases. Sexual and physical maltreatment, usually in combination, are the most frequently reported sources of childhood trauma, although other kinds of trauma have been reported, such as multiple painful medical and surgical procedures during childhood, and wartime trauma. Emotional abuse, neglect, and experiencing and/or witnessing family violence have also been cited as traumatic antecedents of dissociative identity disorder, usually in combination with physical and sexual violence. Studies in the National Comorbidity Study Replication (NCS-R) have found that sexual, physical, and emotional abuse, neglect, intimate partner violence, and severe family dysfunction covary together so extensively in abusive families that no one of these can easily be partialled out from any other in attempting to understand the impact of early life maltreatment. Across studies (e.g., the NCS-R and a large population sample of children and adolescents from the National Childhood Traumatic Stress Network [NCTSN]), childhood sexual

abuse is the most potent “synergistic” developmental adversity, combining with more ACEs than any other ACE.

Data on the role of trauma in possession-form dissociative identity disorder, although more limited, confirm the association between this presentation and traumatic exposure. Two epidemiologic community-based studies in Africa report the widespread attribution of pathologic dissociative possession to the restless spirits of individuals who perished in local civil wars, linking “spirit” possession and violent death. One study in Northern Uganda found that individuals with high likelihood of pathologic dissociation were significantly more likely to have suffered various forms of war-related trauma; 45% of individuals with this condition also met DSM-IV criteria for PTSD. Marjolein Van Duijl and colleagues conducted a systematic study of traumatic exposure among 119 possessed patients who visited traditional healers in Uganda. These individuals scored higher on the Harvard Trauma Questionnaire and the Traumatic Experiences Checklist than 71 randomly selected healthy inhabitants of the same villages, and scores on both trauma scales were strongly correlated with symptoms of dissociation (r = 0.64 to 0.69) and pathologic possession (r = 0.51 to 0.64).

Nontraumatic stressors, such as romantic disappointments and work or religious conflicts, have triggered other cases of pathologic dissociative possession. However, systematic assessment of childhood trauma is usually not conducted in these studies, precluding the exclusion of traumatic antecedents in the genesis of this condition. Other studies find a partial relationship with trauma; for example, one community-based epidemiologic study in Mozambique (N = 941) found only a trend-level association between pathologic dissociative possession states and the Harvard Trauma Questionnaire, although sufferers of this condition were more likely to have experienced the death of a child. Pathologic possession states may encompass presentations that do not meet criteria for dissociative identity disorder; those that do, however, appear more likely to be associated with traumatic etiologies.

The posttraumatic etiology of dissociative identity disorder is supported by data that many disorders, symptoms, life experiences,

and maladaptive behaviors typical of traumatized individuals are commonly found in dissociative identity disorder. For example, the National Comorbidity Study-1 (NCS-1) found that the most common outcomes of trauma included PTSD, depression, and substance/alcohol abuse. Studies of dissociative identity disorder have found comorbid PTSD in 79% to 100% of cases, current or past depression in 83% to 96%, and a past or current history of substance abuse in 83% to 96% of cases. High rates of childhood abuse and maltreatment characterize subsamples of individuals with somatic symptom and related disorders, especially functional neurologic symptom (conversion) disorder and somatic symptom disorder. Across studies, 40% to 92% of individuals with dissociative identity disorder report somatoform symptoms and 35% to 61% have a comorbid somatic symptom disorder. Data from Turkey suggest that pseudoneurologic conversion symptoms are the most common presenting symptom of persons with dissociative identity disorder; some of these Turkish patients attributed their self-states to possession, often combined with non–possession-form self-states. In one study by Vedat Sar and colleagues, nearly half of 38 consecutive psychiatric outpatients diagnosed with conversion disorder met DSM-IV criteria for a dissociative disorder, including 17% with dissociative identity disorder and nearly three-quarters with dissociative disorder NOS. A subgroup of North American/European dissociative identity disorder patients come to clinical attention for a primary functional neurologic symptom disorder, especially nonepileptic seizures and sensory–motor conversion symptoms.

Individuals with dissociative identity disorder frequently meet diagnostic criteria for somatic symptom disorder, often with predominant pain—particularly headaches, abdominal pain, and pelvic pain, but also migratory pain syndromes. Childhood sexual abuse survivors with psychophysiological disorders are more likely than controls to have a lower threshold for experiencing physiologic phenomena as noxious or painful. Conversely, repeated childhood abuse can lead to *anesthesia* for physical pain, such as during dental procedures. This can create the paradoxical situation that dissociative identity disorder patients may be highly sensitized to

chronic pain patterns associated with childhood sexual abuse (e.g., chronic pelvic pain, headaches, irritable bowel syndrome) and may have numerous, costly, unproductive workups for these symptoms, including exploratory surgery.

Dangerousness to Self and Others and Dissociative Identity Disorder

Suicidal, self-destructive, violent, and high-risk behaviors are also strongly associated with trauma and, particularly, with early life trauma and repeated traumatic experiences. Across studies, 66% to 80% of individuals with dissociative identity disorder reported a history of suicide attempts, and 92% to 100% reported current or past suicidal ideation. Individuals with dissociative identity disorder have higher rates of multiple suicide attempts than individuals with borderline personality disorder, PTSD, and substance abuse disorders who do not have a comorbid dissociative disorder. In a 30-month prospective, longitudinal treatment outcome study described in detail below, 2 patients—1.8% of the final sample of 119—died by suicide. This is likely an unrepresentatively low rate, based on participation in a treatment outcome study that demonstrated an overall decrease in suicidality among its participants. Case series also have described death by suicide in dissociative identity disorder patients, including in possession-form cases.

Studies with pre–DSM-5-TR criteria show that 78% of individuals with dissociative identity disorder have engaged in self-harm behaviors. These include severe forms of nonsuicidal self-injury such as major lacerations requiring sutures or surgical repair to limbs, genitals, and abdomen; severe burns including use of acids and caustic substances; ingestion of caustic compounds such as drain or oven cleaner; deliberate fracture of limbs; genital mutilation; and severe head-banging resulting in bruising, bleeding, and/or skull fractures, among many others.

Clinical case series document that a subgroup of individuals with dissociative identity disorder engage in violent behavior; some have been incarcerated for violent crimes including murder, severe

assaults, and rape. A case series of male patients with dissociative identity disorder revealed that 20% admitted to perpetrating homicide and 13% to rape. In this study, 10% of females with the disorder also reported perpetrating homicide. In a clinical study of mothers with dissociative identity disorder, 16% engaged in significant maltreatment of their own children and 45% were compromised or impaired as mothers. Abusive and/or neglectful mothers contribute the multigenerational transmission of trauma.

Table 20–12 enumerates many of the safety issues that occur in patients with dissociative identity disorder.

Like other victims of early life trauma, individuals with dissociative identity disorder have high rates of adult traumatization, in particular rape. In one study, 60% of women and 17% of men with dissociative identity disorder reported being raped as adults. Nearly 60% of women with dissociative identity disorder reported suffering intimate partner violence or other forms of violence in adulthood; 36% reported experiencing violence in the past year. These rates of rape and intimate partner violence are notably higher than those for the general U.S. population.

As described in the Epidemiology section, a subgroup of individuals with dissociative identity disorder report being trafficked, often beginning in childhood, including being sold as children to be raped by male or female adults, most commonly family members, and sometimes recorded on video or transmitted via live-streaming. Many of these individuals also report that they continue to be trafficked into adulthood, sometimes by the same perpetrators, often members of their families of origin. Recent clinical case series document that a subgroup of individuals with dissociative identity disorder continues, even into middle age, to be incestuously raped and/or trafficked by family members, typically male family members, but generally known about, condoned, and even participated in by female family members. This is consistent with recent international reviews of public criminal cases describing adults who, often for years, have been entrapped into emotional, physical, and sexual violence by family members. This phenomenon urgently requires

further study and antihuman trafficking legislation should take such dynamics into consideration.

Table 20–12.
Types of Dangerousness to Self and Others Typically Found in Dissociative Identity Disorder Patients

1. Dangerousness to self
   a. Self-destructive behavior
   b. Nonsuicidal self-injury
   c. Suicide attempts
   d. Death by suicide
2. Dangerousness to others
   a. Abuse of minor children of the patient and/or neglect leading to abuse of children by others, intra-famillialy and/or extra-famillialy
   b. Intimate partner violence
   c. Assault, sexual assault, arson, murder, serial murder, etc.
3. High-risk behaviors, e.g., repeated reckless driving, risky sexual behaviors
4. Substance-related and addictive disorders
5. Eating disorders
6. Enmeshment in/victim of abusive/traumatizing relationships
   a. Enmeshment with abusive family of origin
   b. Intimate partner violence
   c. Being trafficked into prostitution
7. Lack of food, clothing, and/or shelter
8. Lack of access to and/or avoidance of adequate medical care

Despite abundant evidence of the relationship between trauma and dissociative identity disorder, critics have raised questions about the validity of dissociative identity disorder patients' self-reports of childhood trauma. Recent studies, including large samples of maltreated children with dissociative disorders and intensively validated case studies, nevertheless have provided rigorous

independent corroboration of the patients' reports of maltreatment. These studies continue to strongly support a developmental linkage between childhood trauma and dissociative identity disorder. In general, studies involving adult self-reports of childhood trauma have not shown these reports to be any less valid than self-reports of other clinical phenomena, such as self-reports of a history of smoking.

Discrete Behavioral States and Dissociative Identity Disorder

The DBSs model, discussed in the prior section on Etiology, is a particularly helpful overarching construct for conceptualizing dissociative identity disorder. It is grounded in data on child development and on the alterations that maltreatment and/or severe early stress causes on the trajectory of development in the sense of self and identity, autobiographical memory, capacity for attachment, emotion regulation, cognitive schema, ability to maintain and/or modulate behavioral states, and beliefs about the perpetrators, the self, and the world.

According to the DBS model, *dissociative identity disorder is conceptualized as a childhood-onset posttraumatic developmental disorder* in which the traumatized child is unable to complete the normal developmental processes involved in consolidating a core and singular sense of self. Instead, repeated early trauma disrupts the usual unification of sense of self, resulting in the development of multiple independent or DBSs. In normal development, adults implicitly recognize state changes in children and attempt to assist the child in reducing distressing states (e.g., feeling hungry, wet, teething, tantrums, ill) and/or in returning to better states (e.g., feeling calm, interested, sleepy). Adult attunement to the child helps develop the child's capacities to recognize and self-modulate their own states, and, ultimately, to develop a singular and internally consistent sense of self across states, relationships, and contexts, including distressing ones.

In comparison, traumatic experiences—particularly repeated, unpredictable maltreatment perpetrated by caregivers—not only

produce extreme, overwhelming states, but also leave the child to attempt to recover from these states, typically by a global dissociative shut-down. Abusive parents usually provide little or highly inconsistent soothing experiences, especially after having just hurt the child. They may compound the difficulty by blaming, mocking, and humiliating the child for being distressed, and/or literally telling the child that the distress, as well as many other characteristics of the child, causes the parent's abusiveness.

Due to disturbed caretaker–child attachment and parenting, repeated early trauma disrupts the development of normal metacognitive processes involved in the consolidation of a unified sense of self across different relational (e.g., with parents, peers, others); social (e.g., at school, at home, with peers); and emotional states (e.g., terrified, humiliated, enraged, mixed). The models of Type D attachment and BTT fit observations of children and adults with dissociative identity disorder. Typically, among the psychodynamic underpinning of self-states, there is at least one group that denies trauma and reports strong attachment to at least some childhood caregivers, citing their positive qualities. These states are usually in profound conflict with other self-states reporting revulsion and hatred of the same caregivers, and who describe profound maltreatment-based betrayals.

The child who develops dissociative identity disorder often experiences marked discontinuities between the reality of a chronically abusive, violent home life and the presentation of the family as "perfect" in the outside world (e.g., at church, school, public events). The dissociative child may also experience other areas of life as additional disconnected realities: school, athletics, artistic endeavors, and so on. Thus, the developing self-states may be experienced as encompassing alternate, often contradictory realities, leading some to refer to the disorder as a *multiple reality disorder.*

Over time, the child's developing internal sense of self may come to reflect the disorganization and conflict evident across the various relationships and environments with which they are occupied. Different self-states can become subjectively personified and develop along independent developmental trajectories. In

adolescence, “separation and individuation,” including issues of sexuality and autonomy from family, are major developmental tasks. This is difficult to negotiate for dissociative adolescents, who may experience elaboration and secondary subjective structuring of self-states. This process can involve creation of states with different roles (e.g., “everyday life,” “school,” “home”); intrapsychic and emotional functions (e.g., “protector,” “angry one”); relationships to trauma (e.g., one who “knows,” one who has no memory), and creative secondary elaborations (e.g., names, accents, wardrobe, hair style, behaviors).

Making Sense of Self-States

In dissociative identity disorder *self-states are defined as discrete behavioral states, each organized around a prevailing affect, a sense of self (often including a distinct body image), a set of—usually limited—state-dependent autobiographical memories, and a discrete behavioral repertoire, with a capacity to affect the person’s behavior.* In other words, *dissociative identity disorder self-states are multiple, relatively separate centers of information processing in the mind, capable of relatively independent thought, emotion, sense of self, and memory, as well as the capacity to—directly or indirectly—control the person’s behavior.* Despite its current name referencing “identities,” developmental deficiencies in integration of the *self* and *self-systems* are the basic psychobiological process in dissociative identity disorder.

Usually, over developmental time, dissociative identity disorder self-states organize into multiple interacting *self-state systems.* The subjective experiences and behavior of the dissociative identity disorder individual can be best understood in terms of the model of *complex dynamic systems.* On a moment-to-moment basis, these “outputs” depend on the cooperation, collaboration, and communication among some self-states/systems that may be variably in conflict with other self-states/systems, typically resulting in symptoms of overlap, interference, influence, and intrusion. It is beyond the scope of this chapter to provide in-depth discussion of

the concepts of “self” (and self-systems), “identity,” and “personality.” In the literature, these are defined differently by different schools of psychology, philosophy, and anthropology. Sometimes the definitions are tautological, for example, “self” is defined as “identity.” These terms have “fuzzy boundaries” and are hard to define without reference to each other. These constructs also may be best conceptualized as interactions among complex, dynamic psychological systems. For simplicity, subjectively, self is “who” we are—and there may be many “whos” in different situations and contexts over the lifespan. Identity is “what” we are: a whole host of (usually) longer-term dispositions having to do with ethnicity, gender, age, sexual orientation, political affiliation, profession, etc. These can be *negatively* imposed from outside by bullying, racism, genocide, and, among others, the child abuse survivor being told abuse is their fault. “Personality” is defined differently by various schools of thought, including theoretical nonclinical domains, but is defined by long-term, relatively stable, psychobiological dispositions and patterns, within which self and identity states are shaped. Manifest personality symptoms can be state-dependent (e.g., a depressed individual appears to meet diagnostic criteria for a personality disorder). Often, both mood and apparent personality disorder symptoms remit with successful antidepressant treatment.

The DBS developmental model of dissociative identity disorder postulates that, contrary to typical conceptualizations, there is no “real” singular self, identity or “personality” from whom “alters split off,” even when a patient themselves endorses this view. The seemingly “real” self-state(s) are commonly conflated with those claiming the legal name of the human being. Rather, here, their mind is made up of a combination of all self-states, dissociative defenses, and nondissociative psychobiological processes. Developmentally, the individual with dissociative identity disorder is not a “shattered mirror” with a finite number of “fragments” or “parts.” The individual’s mind encompasses complex, dynamic, potentially imaginatively infinite systems of DBSs, more like a network of three-dimensional jigsaw puzzles. Different self-states often encompass painful psychological issues for the individual, frequently taking the form of

polarized pairs representing antithetical positions, although self-states embodying more neutral and conflict-free processes also commonly occur. In some individuals with dissociative identity disorder virtually every aspect of mental life is personified.

Individuals with the disorder show considerable variability in terms of the complexity and therapeutic tractability of their self-state systems. Most psychotherapeutic work is directed toward these self-state systems and toward the "whole human being." Much general information and many functions and abilities are shared across self-states, indicating the fundamental unity of the mental processes of the dissociative individual. This provides the foundation for therapeutic efforts directed at the development of a more consciously integrated sense of self.

Self-States in Possession-Form Dissociative Identity Disorder

Dissociative possession experience involves altered states; thus, DBS theory conceptualizes possession-form dissociative identity disorder in similar terms as the non–possession-form disorder. In societies where spiritual agents (e.g., deities, ghosts, animal spirits, demons, *jinn*) are considered ontologically "real," these agents represent alternative sources of identity-state construction. Individuals who are maltreated may engage these supra-individual self-states as figures that represent aversive or supportive elements in their lives. Even in societies where supernatural forces are not generally endorsed, intracultural variation may encourage the assumption of spiritual self-states within certain families and social groupings (e.g., highly religious groups). This process would give rise to possessing agents that have a collective existence. For example, in India the same spirit may possess different family members down the generations (or different villagers in the same generation). In societies where the cultural conception of the self is more porous to other self-states depending on context ("dividual"), including spiritual self-states, the development of DBS may proceed along less individualistic paths, resulting in differently organized self/identity states. Similarly, clinical data on Western families with

multigenerational dissociative identity disorder have found similar self-states across three generations of the same family.

The Four-Factor Theory of Dissociative Identity Disorder. Richard Kluft has proposed a Four-Factor Theory (FFT) of dissociative identity disorder that is a specific case of the DBS model. The first factor is the *capacity for dissociation,* likely due to a genetic diathesis (discussed in the section on Neurobiology). Per DBS theory, the next factor involves *experiences that overwhelm other nondissociative adaptive capacities of the child.* The child cannot fight or flee from perpetrators but freezes and flees inwardly into altered states of consciousness that provide encapsulation and relief from traumatic experiences. The third factor is the *lack of soothing and restorative experiences,* where the traumatized child must find solitary ways to calm and soothe themselves to attempt mitigation of traumatic experiences and attendant emotions.

The fourth and final factor of the FFT involves the many posttraumatic, psychodynamic, familial, social, and cultural factors leading to the *secondary structuring, subjective personification, and elaboration of the self-states into "identity states"* (also see section on Culture, Dissociative Disorders, and Sociocognitive Phenomena). These can include posttraumatic, attachment-based psychodynamic factors resulting in the first, very early psychological self-construction, the creation of an isomorphic state: one child who is betrayed through perpetration by attachment figures and one who is not. Further elaboration may include, for example, a female child thinking that, if she were a boy, sexual abuse would not be happening, leading to development of a subjectively male state. Other personified states may attempt to mitigate and sequester the impact of multiple ongoing traumas, leading to development of multiple traumatized self/identity-states that encapsulate traumatic memories or parts of one or more memories. Traumatic and/or overwhelming experiences in adolescence or adulthood may also lead to the development of additional traumatized self/identity-states. Other states may be experienced as without emotions or pain perception to mitigate the impact of traumatic memories and

experiences. These states may be experienced as biographical variants of the individual (e.g., a numb child identity)—as is typical in non–possession-form dissociative identity disorder. Alternatively, in possession-form presentations they may be experienced as supernatural, collectively validated states that transcend death (e.g., the ghost of the suffering child, out for revenge) or as mythical, insensible, invulnerable presences seeking redress (e.g., an avenging spirit).

Attempts to feel strong and safe may lead to subjective creation of a tough, powerful adult male state or a powerful spiritual ally, such as a deity. The desire to control and anticipate at least some aspect of continual, inevitable, unpredictable trauma may lead to the development of a state that is an internalized representation of the abusive, shaming perpetrator(s), often termed an *introject self-state;* alternatively, this could take the form of a demon or punishing animal spirit. By contrast, people who have been kind to the individual may also be represented as introject states. For example, if a supportive, kind relative dies, the person with dissociative identity disorder may have difficulty grieving the loss of this person. An introject state develops instead as an internal representation of the deceased individual, forestalling the need for grieving. In addition, later traumatic or overwhelming events may lead to development of additional self-states.

Mr. T, a divorced musician in his 30s, was admitted to a psychiatry unit. He was suicidal after repeatedly finding himself dressed in women's clothes. He denied recall of buying or putting on these clothes, or for the periods of time that he cross-dressed. He had become panicked, mortified, and intensely suicidal when family members discovered him dressed in female clothes. He had always viewed himself as "a tough, macho kind of guy." Mr. T had been in recovery from drugs and alcohol for a decade and vigorously denied any recent substance use. His family and AA sponsor corroborated Mr. T's having remained sober and screening for drugs and alcohol was negative. He reported gaps in his recall for many periods of his life. He ascribed the memory problems to substance use, although memory gaps were present for long periods of sobriety as well, which he attributed to "dry blackouts." He described sudden disconcerting lapses in his musical abilities, which had created job problems for him. At other times, he described finding that he could play other instruments proficiently without knowing how he had learned them. He reported that his head was "filled with opinions that don't belong to me." On more careful history taking, he described a chaotic early life, being sent to live with violent, abusive relatives. The only consistently positive figure in his development was his maternal grandmother, who had supported and protected him as much as she could. She had died suddenly—just before the episodes of cross-dressing began. As he discussed this, Mr. T reported hearing his grandmother's voice and broke down in tears stating that he could not bear the idea that she was dead. On sequential evaluation, several self-states were identified, including one based on his grandmother, reportedly created as a comforting protector in childhood, experienced as reactivated after her death. This self-state acknowledged buying and dressing in the female clothes, "So I could always be with him." Work on grieving for his grandmother resolved the acute episodes of amnesia and pressure to cross-dress. Mr. T was

referred to long-term outpatient psychotherapy for dissociative identity disorder.

Shame and Childhood Trauma. Feelings of shame are likely a concomitant of most, if not all, traumatic experiences. The intent of all perpetrations is power, control, and dominance over the victim. Humiliation is the delivery system through which these are created and enforced. Multiple early life traumas, often involving deliberate, sadistic humiliation and mocking of the victim, lead to an extreme burden of shame. Systematic focus on shame is critical in the treatment of all interpersonally traumatized people, as well as on other powerful emotions like anger, fear, anguish, disgust, and their combinations. The development of dissociative identity disorder in early childhood leaves emotions experienced either as entirely suppressed or overwhelmingly activated, often accompanied by alexithymia.

Richard Kluft, based on the work on affect theory by Donald Nathanson, pioneered the conceptualization of self-states as embodying specific shame "scripts" such as *self-attack* (i.e., repeated self-shaming); *avoidance of shame affect* and anything that might engender it (e.g., by drugs, alcohol, nonsuicidal self-injury); *withdrawal* from situations that engender shame (e.g., a student drops out of college because of shame about performance); and/or *attack the other* by humiliation. Also, for example the latter is almost universally experienced by victims of perpetration, wanting to "get back at" and make the bully experience humiliating retaliation.

Negatively valenced introject self-states may take the form of the humiliating perpetrator(s). These represent "paradoxical protection" to anticipate and gain some sense of control over unpredictable, *but inevitable*, mortifying childhood violence by attachment figures. The adult individual with dissociative identity disorder experiences profound relational mistrust, anticipating that all attachments will result in betrayal: abuse, abandonment, or both. These commonly misunderstood self-states represent a kind of early warning system —usually unheeded—about the dangers of attachment. Therapists

and other self-states often conceptually reify these self-states as “malevolent” or “bad,” as they may drive self-destructive behavior and/or “sabotage” gains in therapy. In general, it is far more effective to interpret the protective functions of these self-states, while insisting on maintaining safety to find recovery-oriented methods for protection from potential betrayal.

Other Substrates Shaping Self-states. In possession-form presentations, self-states are usually perceived to be “real” and external by members of the social group who share the sufferer’s perspective regarding the ontologic validity of spiritual beings. In non–possession-form dissociative identity disorder, however, the experience of self-states as literally separate, “outside” people is termed *delusional separateness.* This usually occurs when, early in development, repeated traumatic events have been experienced as so overwhelming, intolerable, damaging, shameful, disgusting, dissonant, and ego-dystonic that the person may attempt to subjectively extrude them altogether, as “not-me” events. In assessment of possible psychosis, it is important for clinicians to consider the prevailing range of cultural views of the person and their community as well as processes such as hallucinatory phenomena related to self-states and delusional separateness that are best explained by a dissociative and posttraumatic etiology.

Other factors that lead to secondary structuring of dissociative identity disorder identity states can include contradictory parental demands (i.e., father wants a son and dresses the child as a boy, even using a different name; mother wants a girl and does the converse). Sociocultural factors that lead to further elaboration of self/identity-states include all forms of media, as well as religious beliefs (e.g., in demons). The intelligence and creativity of the person can influence the complexity of the subjective elaboration of self-states. Some individuals with dissociative identity disorder may retreat into highly complex, elaborated inner worlds. This is most likely to occur when the experience of outer reality is perceived as too painful and especially when the person has not only undergone severe life traumas but also has experienced a limited positive

adaptation to the world in their adult life. This constellation may be associated with poorer treatment outcomes. Similarly, studies have shown that psychotic patients with grandiose delusions are less adherent to medications than those with non-grandiose delusions. In both these clinical situations, patients attempt to avoid experiencing their painfully limited lives by remaining lost in elaborate dissociative fantasy worlds or grandiose delusional beliefs, respectively.

Inappropriate psychotherapy can lead to the development of additional self-states, especially if the treatment is experienced as unsafe and/or overwhelming to the person. Therapists may unintentionally reinforce separateness by playing favorites among self-states; engaging in very different behavior with different states (e.g., playing with child self-states); viewing self-states as “good” or “bad” rather than psychological adaptations that need to be understood; refusing to speak to some self-states; and not encouraging a decrease in dissociative barriers by failing to promote internal communication, collaboration, and coordination among self-states—for example, by making ongoing, separate appointments with self-states as if with separate people. Sexual or other forms of exploitation by therapists are severe traumatic betrayals and, as all adult traumas, can also lead to the development of additional self-states.

Unfortunately, the *least important phenomena associated with Factor 4* are those that lead to the most fascination with the patient or the diagnosis and emphasized in media portrayals of dissociative identity disorder. These include the person’s highly elaborated, differing presentation of identity-states, or fantasies about the states (“12th century monk”; “Samurai Warrior”); in the media, even these factors are depicted in an exaggerated way compared to their clinical presentations. In patients, there may be elaboration of the presentational and subjective characteristics of the self-states with shifts in wardrobe, grooming, accents, gait, and so on. It is a poor prognostic sign when the patient has significant narcissistic investment in having dissociative identity disorder and/or in the extensive elaboration of marked presentational differences between self-states.

Personality Organization, Personality Disorders, and Dissociative Identity Disorder

Borderline personality disorder has been reported in 31% to 83% of patients with non–possession-form dissociative identity disorder. Some early explanatory theories characterized dissociative identity disorder as a variant of borderline personality disorder and/or within the psychoanalytic construct of borderline personality organization. However, several studies have shown substantial differences between persons with dissociative identity disorder and individuals with Cluster B personality disorders. Using the Structured Clinical Interview for the DSM-IV Dissociative Disorders (SCID-D; see Table 20–1), patients with dissociative identity disorder and those with Cluster B personality disorder (primarily borderline personality disorder) did not differ significantly on measures of depersonalization and derealization. However, patients with dissociative identity disorder reported significantly more amnesia, identity alteration, and identity confusion. Also, the dissociative patients had significantly earlier and more extensive histories of trauma.

Psychological assessment of large numbers of individuals with dissociative identity disorder using the Rorschach test, and other assessment instruments such as the Millon Clinical Multiaxial Inventory-III (MCMI-III), did not show a personality profile typical of borderline or histrionic personality types or of patients with psychosis studied with the same measures. On the Rorschach, individuals with dissociative identity disorder showed a unique personality structure characterized by marked traumatic reactivity, obsessional features, introversion, and high complexity of response—far more complex than individuals with personality disorders or psychosis, Also, contrasted with individuals with personality disorder or psychosis, those with dissociative identity disorder showed notable ability for self-reflection, as exhibited by good insight (Rorschach variable FD), reality testing, and capacity for logical as opposed to distorted thinking. These patients tended to try to distance from posttraumatic stimuli through auto-hypnotic and dissociative defenses.

The posttraumatic reactivity during testing led to the development of a specific Rorschach variable, the Trauma Content Score (TC), the sum of morbid, anatomy, sex, and blood special scores divided by total responses. Depending on the study, DID individuals show 50% to 150% TC responses on the Rorschach (i.e., sometimes more than one TC response per card), which are significantly higher than all other patient or nonclinical groups. During testing, when starting to experience PTSD symptoms, many individuals with dissociative identity disorder attempted to avoid these symptoms through hyperfocus on small features of the blot, autohypnotic trance symptoms, and depersonalization/derealization. This may parallel the findings among individuals with dissociative PTSD in a study of unconscious and conscious responses to fearful faces. The dissociative PTSD group showed rapid, marked unconscious arousal of fear circuitry to the threatening stimuli. With conscious processing, however, frontal brain systems that regulate emotional arousal in the amygdala were immediately activated, accompanied by increased dissociative symptoms. With failure of dissociative avoidance of intrusive PTSD symptoms, patients with dissociative identity disorder went into flashback. They increasingly lost capacities for reality testing and relationship to reality, switching to often regressed self-states, and even perceiving the Rorschach card itself as a malign object.

Consistent with the conceptualization of dissociative identity disorder as a posttraumatic developmental disorder, psychological profile studies of persons with dissociative identity disorder suggest *that early-life dissociation serves as a protective, resiliency-inducing function* for predisposed children growing up in violent, unpredictably malevolent environments. The dissociative “sequestration” of traumatic memories and emotions allows for more normal development in capacity for logical and reality-based thought, executive function, mentalization and insight, artistic and intellectual accomplishments, a sense of humor, hope, and willingness to engage in relationships with others. The latter may underlie a capacity for the therapeutic alliance, a transtheoretical predictor of response to psychotherapy.

Similarly, across studies on the MCMI-III, compared to other patient groups, individuals with dissociative identity disorder showed highest scores on depression, PTSD, and anxiety. They frequently endorsed negative personality traits—especially avoidant, self-defeating, passive-aggressive, and borderline traits—like patterns found in individuals with chronic PTSD. Consistent with the Rorschach findings of obsessional personality elements in dissociative identity disorder, on the MCMI-III they scored the *lowest* on histrionic traits, followed by low scores on narcissistic, antisocial, and sadistic traits.

DISSOCIATIVE DISORDERS, DISSOCIATION, AND BORDERLINE PERSONALITY DISORDER. Psychological profile differences between borderline and dissociative identity disorder patients have been delineated above. International studies of borderline personality disorder have identified dissociative and nondissociative subgroups. Consistent with the transdiagnostic studies of dissociation, the former had significantly poorer response to unmodified dialectical behavior therapy (DBT). International studies with the DES, A-DES, DES-T, SCID-D, MID, DDIS, and DSM-IV SCID-BPD, among other measures, assessed the relationship between dissociative identity disorder, other dissociative disorders, and borderline personality disorder. In meta-analyses of the DES, borderline personality disorder showed lower mean scores than the dissociative disorders and PTSD. Other studies using the DES described several borderline personality disorder subgroups, including about 25% without a dissociative disorder, 29% with mild dissociation, and 54% meeting DSM-IV criteria for either dissociative identity disorder or dissociative disorder NOS, both with more severe “borderline” symptoms. Studies of dissociation and borderline personality disorder using standardized diagnostic instruments, commonly find that substantial subgroups of the borderline group meet DSM diagnostic criteria for dissociative identity disorder.

Other studies suggest that individuals with dissociative identity disorder experience a self-image that is relatively stable within self-states, with instability manifesting due to shifting and

overlap/interference among states. In studies using the MID, “core” dissociative symptoms in dissociative identity disorder primarily were predicted by actions/interactions of self-states; in individuals with borderline personality disorder, dissociation was predicted by rapid, stress-driven disruptive state shifts affecting perceptual, affective, and neurocognitive functioning, often accompanied by depersonalization/derealization. Unlike patients with borderline personality disorder, the avoidant personality traits of individuals with dissociative identity disorder indicate that many of the latter *prefer* to be alone—as is common in other posttraumatic stress populations—and do not make desperate efforts to avoid being alone.

Several international studies found that, when individuals with dissociative identity disorder meet DSM (IV-TR, 5) diagnostic criteria for borderline personality disorder, it was a severity indicator of *decompensation*, not core personality disorder pathology. A DDIS diagnosis of borderline personality disorder significantly correlated with more extensive trauma histories, higher scores on the DES, more passive-influence symptoms, increased complex amnesia, and similar severe dissociative symptoms. After stabilization through appropriate treatment interventions, these “borderline” individuals mostly no longer meet diagnostic criteria for borderline personality disorder.

ANTISOCIAL PERSONALITY FEATURES AND DISSOCIATIVE IDENTITY DISORDER. Forensic case series and intensive forensic case studies document individuals with dissociative identity disorder who have pervasive antisocial, psychopathic, and/or manipulative personality features. This includes a group of imprisoned murderers, none of whom had used their dissociative diagnosis as a legal defense. An intensive clinical case study of an arsonist with dissociative identity disorder suggested that she used the adaptive psychological capacities described in prior sections in the service of criminal behavior. This included malingering more severe dissociative symptoms to manipulate others and to attempt to avoid being adjudged by clinicians and the courts as responsible for her behavior. This subgroup of patients may be relatively infrequent in

clinical settings but may be found in the social service or law enforcement systems. As noted earlier, a subgroup of individuals with the disorder is involved in criminal activities, including the severe neglect, abuse, and/or trafficking of their own children, perpetuating the multigenerational transmission of family violence and trauma. Paranoid personality traits, well beyond the typical posttraumatic suspiciousness of the complex trauma survivor, may be found among this subgroup. Some individuals with dissociative identity disorder may engage in sporadic antisocial behavior or manipulation of others. The differential diagnostic issue is whether there are global antisocial/psychopathic personality features, rather than problematic behavior related to specific circumstances, decompensation, and/or experienced as driven only by specific self-states.

Forensically and clinically, individuals with dissociative identity disorder should be held responsible for all behavior, whether ascribed to self-states, amnesia, or passive influence. Human beings engage in behavior, not self-states. The personality profile of individuals with dissociative identity disorder indicates that as "a whole human being," typically, they have the capacity to plan, to delay, and they know the difference between right and wrong behavior.

Table 20–13.
Amnesia and Memory Symptoms in Dissociative Identity Disorder

Blackouts or time loss
Disremembered behavior
Dissociative fugues
Unexplained possessions
Inexplicable changes in relationships
Perplexing fluctuations in skills, habits, and knowledge
Fragmentary recall of entire life history
Chronic mistaken identity experiences
Microdissociations (brief interruptions of awareness with amnesia)

Mental status examination questions for dissociative amnesia

If answers are positive, ask the patient to describe the event.

Make sure to specify that the symptom does not occur during an episode of intoxication.

1. Do you ever have blackouts? Blank spells? Memory lapses?
2. Do you “lose” time? Have gaps in your experience of time?
3. Have you ever traveled a considerable distance without recollection of how you did this or where you went exactly? Find yourself somewhere else without knowing how you got there?
4. Do people tell you of things you have said and done that you do not recall?
5. Do you find objects in your possession (such as clothes, personal items, groceries in your grocery cart, books, tools, equipment, jewelry, vehicles, weapons, etc.) that you do not remember acquiring? Out-of-character items? Items that a child might have? Toys? Stuffed animals?
6. Have you ever been told or found evidence that you have talents and abilities that you did not know that you had? For example, vocational, musical, artistic, mechanical, culinary, literary, athletic, etc.? Do your tastes seem to fluctuate inexplicably? For example, food preferences, personal habits, taste in music or clothes, use of tobacco products, alcohol, drugs, etc.?
7. Have you ever found or been told that at times you cannot access well-learned skills, For example, vocational, musical, artistic, culinary, mechanical, literary, athletic, or other talents or

abilities? This is not the same as “having a bad day” at work, doing athletics, etc.

8. Do you have gaps in your memory of your life? Are you missing parts of your memory for your life history? Are you missing memories of some important events in your life? For example, weddings, birthdays, graduations, pregnancies, birth of children, etc.?
9. Do you lose track of or tune out conversations or therapy sessions as they are occurring? Do you find that, while you are listening to someone talk, you did not hear all or part of what was just said?
10. What is the longest time period that you have lost? Minutes? Hours? Days? Weeks? Months? Years? Describe.

Adapted from Loewenstein RJ. An office mental status examination for chronic complex dissociative symptoms and multiple personality disorder. *Psychiatr Clin North Am.* 1991;14(3):567. Copyright © 1991, with permission from Elsevier. doi:10.1016/S0193-953X(18)30290-9.

Diagnosis and Clinical Features

Tables 20–13 through 20–16 describe the symptom clusters that are commonly found in individuals with dissociative identity disorder and some of the mental status questions that may elicit these symptoms.

Memory and Amnesia Symptoms. Since the descriptions of dissociative identity disorder in the early 19th century, memory deficits have been a hallmark of the disorder (see Table 20–13). Studies of large cohorts of patients with dissociative identity disorder assessed with the MID found that the experience of amnesia in these individuals manifests both as an ongoing symptom as well as clinically significant lacunae in retrospective autobiographical memory. In contrast, amnesia in individuals with dissociative amnesia disorder is characterized only by retrospective autobiographical memory deficits.

As part of the general mental status examination, clinicians should routinely inquire about current or past experiences of “losing time,” black-out spells, and major gaps in the continuity of recall for

personal information. Patients rarely spontaneously report these, requiring active inquiry by the interviewer. Positive responses should be documented with specific examples provided by the patient. In some instances, patients report “coming to” amid an activity with little or no recall of how they began doing so. Frequently, patients find evidence of having done or acquired things for which they have no recall (see DID Case 1). Friends and family members may tell them about significant things that they have said or done that they cannot remember. Patients may find that they have unknowingly traveled some distance (a fugue episode) or that days or even weeks have passed for which they cannot account. Dissociative experiences of time loss are too extensive to be explained by normal failures of episodic/autobiographical memory. The former typically are characterized by either sharply demarcated onsets and offsets and/or a jumble of memory “fragments,” often with impaired sequencing and temporal awareness. Interviewers should establish that time-loss experiences occur in the absence of intoxication or substance abuse, although high rates of drug and alcohol abuse in dissociative patients may complicate this determination and some severely dissociative patients would prefer to ascribe their memory problems to substance use (see DID Case 1).

Commonly, patients with dissociative identity disorder report perplexing fluctuations in skills, habits, or well-learned abilities, such as how to do one’s job, fluency in a foreign language, and/or athletic or artistic abilities. Patients may report drawing a complete blank for skills or knowledge at times whereas, at other times, they easily and reliably access the information in question. Conversely, combining different types of dissociative amnesia, they may be told of abilities or capacities of which they are unaware (e.g., artistic, academic, athletic). Uncannily, they find that “somehow” an ability appears and then disappears; for example, a failing student suddenly finds themselves inexplicably knowing the correct answers on an important test. These patients may describe perplexing handwriting fluctuations, vision changes, and/or oscillation of interest in and tolerance for alcohol, drugs, and/or medications.

At the same time, the quotidian amnesia in dissociative identity disorder is relative. All the symptoms of ongoing amnesia are explicable by the actions, interactions, and/or conflicts among self-states. The “everyday” self-states may have no recall of a lengthy episode of dissociative fugue. Self-states that take responsibility for the fugue can recall it as detailed first-hand autobiographical memory. Variability in skills, habits, and knowledge can be deconstructed by asking to communicate with self-states experienced as responsible for these, such as a self-state that reports, “that was me who gave him the answers to the test. I didn’t want him to fail another time.”

Just as for ongoing dissociative amnesia, individuals with dissociative identity disorder report significant difficulties with retrospective autobiographical memory. Memory deficits are commonly experienced as sharply demarcated gaps and/or fragmentary, jumbled recall, typically more densely for childhood and adolescence. Neither pattern is consistent with research on normal autobiographical memory, which describes a graded recall declension with more distant life epochs recalled in less detail than more recent ones. Notwithstanding methodologic limitations, individual case studies using autobiographical memory paradigms have found marked alterations in retrospective autobiographical memory in dissociative identity disorder. This includes reports of no available life memories before early adolescence and/or gaps in memory for specific periods, such as between 8 and 12 years old.

Table 20–14.
Dissociative Identity Disorder Process Symptoms

- Presence of dissociative identity disorder self-states
- Switching behaviors (identity alteration)
- Identity confusion
- Passive influence symptoms/interference phenomena between self-states
  - Made feelings from self-states
  - Made impulses from self-states
  - Made actions by self-states
  - Thought insertion from self-states
  - Thought withdrawal by self-states
  - Self-states' voices commenting on behavior
  - Self-states' voices arguing
- Multimodal hallucinations or pseudohallucinations (may occur in a flashback)
  - Visual
  - Auditory
  - Tactile
  - Olfactory
  - Gustatory
  - Somatic

Mental status examination questions for dissociative identity disorder process symptoms

If answers are positive, ask the patient to describe the event.

Make sure to specify that the symptom does not occur during an episode of intoxication.

1. Do you act so differently in one situation compared to another situation that you feel almost like you were two different people?
2. Do you ever feel that there is more than one of you? More than one part/side/aspect of you? Side of you? Do they seem to be in conflict or in a struggle?
3. Does that part(s)/side(s)/aspect(s) of you have its (their) own independent way(s) of thinking, perceiving, and relating to the world and the self? Have its (their) own memories, thoughts, and feelings?
4. Does more than one of these entities take control of your behavior?
5. Do you ever have thoughts or feelings, or both, that come from inside you (outside you) that you cannot explain? That do not feel like thoughts or feelings that you would have? That seem like thoughts or feelings that are not under your control (passive influence)?
6. Have you ever felt that your body was engaged in behavior that did not

- Dissociative or posttraumatic thought disorder
- Posttraumatic stress disorder–based cognitive distortions
- Trance logic (toleration/rationalization of logical inconsistency in the hypnotized and/or dissociated state)
- Other thought process abnormalities
- Disorganization due to switching, passive influence
- Posttraumatic suspiciousness
- Literal and concrete alternating with abstract
- Linguistic usage: Refers to self as we, they, us, him, her, etc.
- Depersonalization and derealization symptoms
  - Depersonalization
  - Out-of-body experiences (In DID, sometimes experienced as observing oneself from “inside” oneself.)
  - Body parts changing in size

seem to be under your control? For example, saying things, going places, buying things, writing things, drawing, or creating things, hurting yourself or others, etc.?

That your body does not seem to belong to you?

7. Do you ever feel you have to struggle against another part/side/aspect of you that seems to want to do or to say something that you do not wish to do or to say?
8. Do you ever feel that there is a force (pressure, part) inside you that tries to stop you from doing or saying something? That you struggle with?
9. Do you ever hear voices, sounds, or conversations in your mind? That seem to be discussing you? Commenting on what you do? Telling you to do or not do certain things? To hurt yourself or others? That seem to be warning you or trying to protect you? That try to comfort, support, or soothe you? That provide important information about things to you. That argue or say things that have nothing to do with you. That have names. Men? Women? Children?
10. I would like to talk with that part (side, aspect, facet) of you (of the mind) that is called the “angry one” (the Little Girl, Janie, that went to Atlantic City last weekend and spent

(metamorphopsia)
Emotional numbing
Loss of connection to the body
Loss of connection to one's own memories
Derealization
Déjà vu
Jamais vu
Déjà vécu
Dream-like states

lots of money, etc.). Can that one come forward now, please? If that feels too distressing, can you listen inwardly and let that aspect of the mind speak to you, and you tell me what is said?

11. Do you frequently have the experience of feeling like you are outside yourself, inside yourself? Beside yourself, watching yourself as if you were another person?
12. Do you ever feel disconnected from yourself, your thoughts, or your body as if you (your body) were not real? Like a robot? Mechanical?
13. Do you frequently experience the world around you as unreal? As if you are in a fog or a daze? As if it were painted? Two-dimensional? Flat?
14. Do you ever look in the mirror and not recognize yourself? See someone else there?
15. Do you feel like you have lost the capacity for feeling? For emotions? For affection toward others? For hunger? Thirst? Pain?

Autobiographical memories may have a depersonalized or derealized quality where recalled events seem to be memories of a dream; as if the patient had seen them happen to someone else; as if they had read about the events; or heard about the events from

someone else. Some dissociative patients report that they only know about major parts of their past from discussions with friends or relatives or from looking at photographs of themselves in past activities. Other individuals may describe systematized amnesias with lack of memory for certain categories of experience, such as recall of school events, but normal memory for home events; inability to recall a specific family member; and/or failure to recall some everyday experiences (e.g., failure to recall snow despite growing up in a New England state).

Ms. B was seen in consultation in a hospital after becoming confused at work, unable to recall how to do her job, at which she was highly proficient. She reported lack of recall of other recent events, such as coming to the hospital. An extensive work-up for medical causes of memory pathology was entirely normal and the neurologic consultant opined that this was a case of “hysterical” memory loss. On closer questioning about memory, Ms. B noted that she had “always had a lousy memory.” For example, she reported that “my memory is like Swiss cheese.” She described gaps in her memory for years in grammar school, high school, and college. She could not recall her wedding, but “knew” it happened from pictures. She could not recall her school or teachers in first to fourth grades but recalled school and teachers in fourth to seventh grades. Despite many yearbook pages devoted to her accomplishments in high school, she was perplexed at her limited recall of those years. Her memory was reportedly more continuous once she left home for college. She stated, “I have no memory for my older brother, not at all. They [family members] said he was a holy terror, violent, out of control, using drugs. He’s in prison now for rape.” She attempted to be “perfect” but would have puzzling lapses of recall in school, for events friends reported to her, and embarrassing sexual situations that went against her moral values. These problems continue into the present with her being told of excellent presentations she has made at work, for which she denied any recall. She reported lack of any artistic ability but at times she can paint brilliantly (“I do it, I can just do it”), moving her hand in an elegant depiction of a brush stroke. Old friends make fun of her difficulties with recall of vacations and other events, even when there are photos of the events. She reported feeling “different ages at different times, sometimes more than one at the same time.” She frequently found herself having driven somewhere without recall of the drive. She discovered many items in her closet that she cannot recall purchasing. She has been approached by people she does not know, but insist

that they have done things with her, gone places with her, and so on. She rationalizes this, and many other memory problems, as “well, isn’t this just normal, to have a lousy memory? Maybe I just have a face that’s familiar.” After beginning psychotherapy, Ms. B identified self-states that accounted for many of these unrecalled situations. She also began to remember continual violence and chaos in her family as well as repeated rape beginning as a small child by her now imprisoned brother and his friends—reportedly ignored by her parents, despite finding evidence of the assaults (e.g., bloody underpants that her mother complained required repeated washing).

Table 20–15. Autohypnotic Symptoms in Dissociative Identity Disorder

Spontaneous trance
Deep enthrallment
Spontaneous age regression
Negative hallucinations (not perceiving aspects of the self or environment that are present)
Hidden observer phenomenon (awareness of what is occurring when in the hypnotized state—e.g., experiencing pain in a study of hypnotic analgesia)
Trance logic (tolerance of logical inconsistency during a trance state)
Voluntary analgesia/anesthesia
Eye roll, eye blinking, etc., with switching

Mental status examination questions for spontaneous autohypnotic symptoms

1. Do you frequently space out, trance out, block out, or withdraw from the world around you? Perhaps by putting yourself in a pleasant scene or place in your mind? By focusing your attention on something inside or outside of you? (spontaneous trance)
2. Do you get so wrapped up in a book or a movie that you can completely block out everything else around you? As if the world could end, and you would still be completely engrossed in that activity? (enthrallment)
3. Do you feel that you are different ages at different times? Do you ever feel like you get little? Like you become a child or an adolescent again? When this happens, does it feel like your body changes in size? Do you experience it in your mind only, or does your whole perception of yourself and the world change also? (spontaneous age regression)
4. Do you ever feel like you are more than one age simultaneously? Child and adult? Teenager and adult? Older than your age and your age? Other combinations? More than two ages at once?

5. Do you ever *not* see or hear what is going on around you? Do you or can you block out people and things altogether? (negative hallucinations)
6. Are you able to block out (ignore) physical pain if you want to? Wholly? Partly? Always? Sometimes? (voluntary analgesia)
7. Is there a part of the mind that appears to be observing: aware of and recalls what is occurring when other parts do not? (hidden observer)

INTER-IDENTITY AMNESIA. Since the 19th century, inter-identity amnesia has been studied as a paradigm for amnesia in dissociative identity disorder. Here, it is hypothesized that two specific self-states reliably and repeatedly report complete amnesia between themselves. The notion of relatively stable, fixed “two-way” amnestic states is based on the classical notion of dissociative identity disorder as made up of unchanging, structured “personalities” whose characteristics are reliably reproduced on repeated assessment. This contrasts with the current understanding of dissociative identity disorder as a posttraumatic developmental disorder involving dynamic self-state systems based on a variety of intrapsychic, interpersonal, and psychosocial needs over developmental time in a sociocultural context and a phenomenology based on overlap, interference, and intrusion as well as distinct state switching. As in the psychobiological studies, attempts to replicate the classic studies at the NIMH in the 1980s found that, compared to simulating controls, participants with dissociative identity disorder often could not maintain a stable state throughout testing and/or were disrupted by subtle switching and overlap/interference.

Table 20–16.
Comparison of Non–Possession-Form and Possession-Form Presentations of Dissociative Identity Disorder

Characteristic	Non–Possession-Form	Possession-Form
	Internal aspects of the person, usually representing idiosyncratic ages, genders, and functions related to the person's life and intrapsychic needs (e.g., early childhood, adolescence, protector)	External agents usually of supernatural or spiritual origin following collectively defined identities (e.g., the spirit of a dead person or demons, deities, spiritual beings, animals, or mythical figures)
Behavior of alternative identity	Patterned by characteristics of identity: childlike, aggressive, fearful, sexual	Patterned by collective representations of identity: deity, demon, ghost
Elaborateness of presentation	Typically reticent, inhibited, obsessional	May be dramatic (e.g., shrieking, thrashing) or reticent
Relationship with trauma	Linked systematically to extreme, repeated, and	Associated with traumatic events and nontraumatic stressors (e.g., romantic disappointments). However,

	early childhood maltreatment	systematic studies of childhood trauma are lacking
Onset and presentation to others	Typically gradual and hidden, upon accumulation of traumatic exposures	Gradual and nonspecific (e.g., diverse somatic complaints) or abrupt and specific (e.g., sudden transition to altered identity)
Course	Chronic; in relapsing and remitting pattern	May be transient and episodic, although chronic, relapsing course has been observed
Extent of misdiagnosis	In high-income countries, an average of 3.9 incorrect diagnoses and 7–12 years in care before correct diagnosis	Unknown
Treatment	Multiphasic treatment like that for other complex posttraumatic dissociative disorders	Often exorcism, initiation into spirit devotion cult, and/or specialized role in healing practice, typically supervised by indigenous healer. However, exorcism may fail, and may be experienced as traumatic to the person, with alienation from religion and spiritual life. Then, may respond to phasic treatment as per the non–possession-form,

and may experience self-state system phenomena more typical of non–possession-form.

Despite this, Rafaele Huntjens and her colleagues as well as other cognitive researchers have carried out a series of comparisons of simulators with individuals with dissociative identity disorder who report mutually amnestic self-states. Studies included tests of neutral episodic information, perceptual and conceptual priming, procedural memory, transfer of trauma-related words, and stimulus valence as shown by affective priming. They found no objective evidence of inter-identity amnesia on any of these tests and concluded that dissociative amnesia in dissociative identity disorder might have more to do with subjective appraisal and "metamemory" than with actual lack of accessibility of memory between self-states. Paradoxically, in another study based on implicit and explicit memory tasks, different researchers found that individuals with reported *co-consciousness* (i.e., the ability to completely share memory and information) *did* have inter-identity amnesia on memory tasks between self-states.

Using the same paradigm of purportedly mutually amnestic self-states, Huntjens and colleagues also studied autobiographical memory in dissociative identity disorder. Here, using constructs from structural dissociation theory, the mutually amnestic self-states were conceptualized as "traumatic" and "normal" identity states, with the former reporting recall of traumatic memories as first-hand autobiographical memory and the latter claiming complete amnesia for these. In two standard autobiographical memory paradigms, these researchers could not document inter-identity amnesia for autobiographical memory between the pairs of self-states. To perform these types of studies, as well as neurobiology studies using a similar paradigm based on structural dissociation theory, dissociative identity disorder individuals need to be stabilized in treatment sufficiently that they can more reliably switch among "traumatic" and "normal/neutral" self-states and, even with difficulty,

are more able to maintain state stability during testing. As treatment outcome studies show, successful treatment response leads to significant decreases in dissociative amnesia barriers among self-states and could contribute to the findings.

In an additional study by Huntjens' group, individuals with dissociative identity disorder were compared with several control groups, including participants with PTSD resulting from multiple episodes of childhood sexual abuse and maltreatment but without dissociative identity disorder. The groups with PTSD and dissociative identity disorder both showed patterns of *overgeneral autobiographical memory* with difficulty retrieving a specific event from memory. This pattern may be related to avoidance of recalling specific information about traumatic memories to attenuate intrusive symptoms. This study concluded that overgeneral memory processes may maintain dissociated memory in traumatized individuals, especially those with severe, multiple early life traumas.

In a directed-forgetting paradigm between subjectively amnestic dissociative identity disorder self-states, findings by another group of researchers supported partial and state-dependent explicit memory difficulties, indicating possible encoding problems as well as retrieval inhibition between self-states. Amnesia between states was not rigidly compartmentalized, consistent with the view that, in dissociative identity disorder, access to memory between self-states may vary in complex ways depending on various factors. In this study, retrieval inhibition began to break down with more emotionally charged stimulus words. This confirmed the observations of both the psychological profile and fMRI studies, where subjects attempted to dissociate to attenuate posttraumatic intrusions but, when unable to do so, devolved into experiencing severe intrusive symptoms.

The latter two studies are consistent with the current view of dissociative identity disorder. More definitive, if more difficult, future studies of dissociative amnesia in dissociative identity disorder could be based on real-time experiential sampling methodology with assessment of psychobiological variables that may affect autobiographical memory accessibility (e.g., interpersonal stress, increased PTSD symptoms, etc.).

Process Symptoms. Dissociative process symptoms include depersonalization and derealization, dissociative hallucinations, passive influence and interference experiences, and dissociative cognition (see Table 20–14). Some authorities include dissociative alterations in self-state (shifting/switching) under this category. Depersonalization and derealization are commonly reported in dissociative identity disorder and may include profound out-of-body experiences as well as observing oneself from *within* one's mind. Patients frequently report feeling spaced out or disconnected from themselves and others. The world is perceived as distant or unreal, with a hazy or foggy quality. Patients may report feeling at times as if they exist in a waking dream state. Out-of-body experiences commonly take the form of watching oneself from a distance (inner, as well as outer), as if observing another person, with little or no ability to affect one's actions.

Dissociative Hallucinations. Based on data from the MID, dissociative hallucinations are reported by close to 100% of individuals with dissociative identity disorder; they are common in both possession-form and non–possession-form presentations. In non–possession-form states, they are typically experienced as voices originating from within the mind, as opposed to coming from the outside. Individual-hallucinated voices often represent a distinctive age and gender, and in possession-form presentations a type of agent, such as a demon or deity. These voices may comment negatively about the patient, argue with each other, command the patient to perform certain acts, discuss neutral topics, or sometimes provide useful information or comfort. The voices may be indistinct but described with a personified quality, such as being at a party but not being able to make out all the conversations around one.

Patients with non–possession-form dissociative identity disorder generally recognize that the voices are hallucinations and may be reluctant to reveal their existence for fear of being considered psychotic or "crazy." Possession-form patients may share the same fear, but usually attribute the voices to culturally accepted spiritual agents. Ultimately, dissociative voices often are identified with

specific self-states or possessing agents. Visual hallucinations often take the form of detailed images with traumatic or frightening content. Other visual hallucinations may be understood as depicting self-states or may even have a complex artistic quality. Tactile, somatosensory, gustatory, and olfactory hallucinations may also occur, leading to misdiagnoses of seizure disorder or other brain disorders. Intrusive posttraumatic flashbacks and images may also be experienced as complex multimodal hallucinations. Musical hallucinations also may occur.

Studies using the MID found that, compared to SCID-diagnosed individuals with a psychotic disorder, those with dissociative identity disorder experience hallucinations as ego-alien and do not have delusional explanations for them or passive-influence experiences. Compared to individuals with psychosis, persons with dissociative identity disorder scored significantly higher on scales measuring child voices, angry voices, persecutory voices, and voices arguing and commenting on the individual's thoughts and behavior. Hallucinations in dissociative identity disorder, but not in psychosis, are related to posttraumatic responding.

Individuals with dissociative identity disorder also report *negative hallucinations*—in which external percepts and stimuli are not consciously registered. This can occur in any sensory modality: auditory, visual, tactile, gustatory, and olfactory, as well as pain perception. Most positive and negative hallucinations in individuals with dissociative identity disorder are not a manifestation of a psychotic process. They are similar to phenomena experienced in deep trance states among highly hypnotizable individuals who can experience hallucinations in all sensory modalities. As dissociative flashbacks in PTSD often involve multi-sensory hallucinosis, posttraumatic factors likely also contribute to multimodal hallucinations in dissociative identity disorder. Unfortunately, in current practice, hallucinatory phenomena of any kind, but especially voices commenting or arguing, are *automatically* diagnosed as psychotic, without considering their differential diagnosis and/or exploring the phenomenology more deeply. This ignores a large literature on nonpsychotic hallucinations in the general population

and “hysterical hallucinations” commonly described in the older psychiatric literature.

Passive Influence Symptoms and Symptoms of Overlap, Intrusion, and Interference among Self-States. Passive influence and interference symptoms include many apparent “first-rank” Schneiderian symptoms (FRS), such as audible thoughts, voices arguing with each other, influences playing on the body, thought withdrawal and insertion, and “made” feelings, impulses, and actions. These symptoms were once considered pathognomonic of schizophrenia but they can also be found in patients with affective and other psychotic disorders. As noted in the section on Nosology, studies of passive influence symptoms in dissociative identity disorder find them more prevalent than in studies of psychotic disorders. As with hallucinations, individuals with dissociative identity disorder may feel confused, puzzled, or ashamed of these “crazy” symptoms. Typically, these individuals have evocative, often personified descriptions of passive influence, such as, “I feel like someone else wants to cry with my eyes”; “I keep getting these “ghost” feelings….” Unless suffering from actual comorbid psychosis, persons with dissociative identity disorder almost never endorse symptoms of thought broadcasting, audible thoughts, and delusional perception. As with hallucinations, studies comparing passive-influence symptoms in dissociative identity disorder and psychotic disorders found that a salient differential diagnostic factor was lack of delusional explanations by individuals with dissociative identity disorder. Patients may report strong affects or impulses that they experience without a sense of personal ownership but with a peremptory sense of intrusion and control. Complicating their differentiation from psychotic conditions, possession-form presentations of passive-influence are usually experienced as external and “real.”

Dissociative Thought Disorder. Distinctive responses to standardized projective testing can often be helpful in distinguishing dissociative patients from other diagnostic groups, such as patients

with affective disorders, nondissociative forms of PTSD, personality disorders, psychotic disorders, and factitious disorders. Research using projective testing finds distinctive cognitive process markers, including evidence of confusing and contradictory responses to the same stimulus. Other forms of dissociative identity disorder thought abnormalities include profound trauma-based cognitive distortions, such as pervasive self-blame for abusive trauma. These posttraumatic and dissociative cognitive distortions may seem so intense as to be virtually delusional at times. However, in most cases, one or more self-states will report understanding that these attributions are incorrect or that they would be incorrect if someone else believed them. Individuals with dissociative identity disorder may also appear to have derailment and loosening of associations caused by rapid, dysfunctional shifting of states that overlap and interfere with each other.

Dissociative Alterations in Identity

NON–POSSESSION-FORM PRESENTATIONS. Clinically, *non–possession-form* dissociative alterations in identity may first manifest through odd first-person plural or third-person singular or plural self-references. Patients may refer to themselves using their own first names or make depersonalized self-references, such as “the body,” when describing themselves and others; for example, “The father hurt the body, so she was upset. We tried to protect her, but it didn’t work.” Patients often describe a profound sense of concretized internal division or personified internal conflicts between self-aspects. In some instances, these self-states may have proper names or may be designated by their predominant affect or function: for example, “the angry one” or “the wife.” Patients may suddenly change the way in which they refer to others: for example, “the son” instead of “my son.”

Clinicians may observe a group of behaviors collectively referred to as *state shifting or switching behaviors*. These may be accompanied by intra-interview amnesias, where the patient does not seem to recall or is confused about the process and content of

an assessment or therapy session. These *microdissociative episodes* may manifest via abrupt shifts in train of thought or sudden inexplicable changes in affect or in rapport and may then quickly shift back again. A variety of physical signs, including pronounced upward eye rolls or bursts of rapid blinking and eyelid fluttering, may occur in conjunction with microdissociative episodes. The patient's tone of voice and manner of speaking, posture, and demeanor may show subtle to marked alteration. When clinicians encounter evidence of possible microdissociative episodes, using nondirective, open-ended questions, they should seek to clarify what the patient is experiencing and can recall. Dissociative amnesia is a common concomitant of these episodes; sometimes they may extend for a few minutes or even the entire psychotherapy session. These cognitive, behavioral, and physical shifts are manifestations of personality state shifting/switching or overlap and interference between states, or both.

POSSESSION-FORM PRESENTATIONS. *Possession-form* presentations of state switching may be subtle or dramatic. Onset can be gradual and nonspecific (e.g., diverse somatic complaints) or sudden and specific, in the form of an abrupt transition to the identity state. If the presentation is gradual and nonspecific, transition to the identity may occur spontaneously or after contact with an indigenous healer specializing in the treatment of pathologic possession. Dramatic onsets may be characterized by semi-purposeful movements (e.g., thrashing, falling to the ground, shrieking); aggressive or violent actions directed at self or others accompanied by derogatory verbalizations; and/or specific gestures, comments or requests denoting the appearance of a known possessing agent by (1) reference to standard attributes of culturally recognizable figures or (2) the name and degree of relation of deceased family members or acquaintances. At times the possessed individual "acts out" some narrative aspect of the possessing agent's story to communicate to their social network the suffering inflicted by the spiritual being or the desires of the possessing agent. For example, a young woman, experiencing herself as afflicted by the spirit of a dead adolescent

girl who committed suicide by jumping in a well, engaged in suicidal behaviors that evoke these past events. Alternatively, individuals possessed by high-status spirits may demand deference from family members.

Possession by the spiritual agent is frequently episodic, resulting in alternation between the usual identity of the subject and the altered state. The subject in their usual identity appears dazed, exhausted, distressed, or confused about the situation. They may report visual or auditory hallucinations regarding the possessing agent, as well as “unconsciousness” and partial or total amnesia for the altered state. States of consciousness may alternate continuously within one episode over hours to weeks, with each state lasting minutes to hours. This pattern may persist intermittently over months or years.

Ms. C is a 23-year-old bilingual woman (Spanish-English) of Latinx Caribbean descent who was born and raised in a large eastern city of the United States. Her family was active in an Afro-Catholic religious cult involving normative dissociative possession states until, when Ms. B was 5 years old, all members converted to Evangelical Protestantism. Since early childhood, she was thought to have spiritual abilities allowing her to predict the future in her dreams and to identify other co-religionists suffering from demonic possession (by seeing "shadows" around them). These were considered spiritual gifts and were highly prized by her family and congregation. Since age 4, Ms. B was the victim of sexual abuse in the form of touching her genitals without penetration by older individuals outside the family. She also received physical abuse as "punishment' by her parents, reportedly resulting in severe bruising but no fractures. Conflicts with her family led to a potentially lethal suicide attempt at age 15 (medicine cabinet overdose). This led to a 3-week inpatient hospitalization and outpatient follow-up with antidepressants for a diagnosis of major depression with panic attacks. However, after 3 months, she self-discontinued treatment. At age 21, Ms. B began to question her faith and to ask God in prayer whether he and the demons she was seeing were "real." In this context, she experienced a prolonged possession episode that was involuntary and extremely distressing. Onset came during sleep, when she felt a demon attempt to enter her body but not fully succeed. This occurred for several consecutive nights and was followed during the day by the onset of voices mumbling and calling her name. Several days later, she felt "many spirits coming inside of me" and taking over control of her actions. Daily for 3 months, these "demons" spoke through her mouth in a deep and "not human" voice— "like a monster or several voices at once"—and communicated with her family and other church members who came to pray around her. During most of these episodes, Ms. B was aware of the surrounding events but was unable to control

her speech or actions. She reported amnesia for some of the possession episodes but reported recall of most of them. She had no visual hallucinations of the main possessing demon. However, she heard him speaking to her, saying that he would "drive her crazy." At those times, Ms. B felt that God sent her a message of reassurance. Once, she felt evil spirits were pulling her soul out of her body. She saw an angel standing at the foot of the bed, that she believed was sent by God to protect her, described as "invisibly white, see-through white" with wings and no face. This helped calm her. Multiple attempts at exorcism conducted by local church leaders were unsuccessful. A prominent pastor was called in from abroad to assist. The demon claimed to recognize the pastor and alluded to their past encounters during other cases of possession. His exorcisms were also unsuccessful. After 3 months, while she was participating in a religious retreat, she felt God sent her a message, "today is the day." At that point, "the demon trembled and left." Since this event, two years prior, she did not suffer another possession state. However, she remains intensely phobic of the dark. She reports auditory and visual illusions when hearing background noises in an otherwise silent room ("sound like voices") or if sees herself in a mirror from a distance ("my face is scary, as if I had a demon inside again"). One year ago, she had an episode of conversion hemiparalysis that came on gradually over the course of a day and then disappeared. She continued to suffer from major depression and panic attacks.

Table 20–16 compares possession-form and non–possession-form presentations of dissociative identity disorder.

Symptoms Related to Spontaneous Autohypnotic Phenomena. Individuals with dissociative identity disorder commonly exhibit or describe symptoms of involuntary autohypnotic phenomena, consistent with their high scores on standardized hypnotizability scales (see Table 20–15). These include spontaneous

trance states that can be clinically disabling; spontaneous or voluntary anesthesia and analgesia; negative hallucinations; spontaneous age regressions; and *trance logic*. The latter is defined as tolerance or rationalization of logical contradiction in the hypnotic state but with ongoing reality orientation. For example, an individual with dissociative identity disorder reported disorientation to time, stating that it was 15 years before the interview. When told the actual year, she said, “Oh. Wow! We’re in the future!” Other autohypnotic symptoms overlap with dissociative process symptoms (e.g., hallucinations, thought disorder, child self-states, passive influence) and PTSD symptoms (e.g., behavioral re-experiencing episodes with multimodal hallucinations and age regression to the time of the trauma).

Other Associated Symptoms. As noted above, non–possession-form dissociative identity disorder is conceptualized as a paradigmatic posttraumatic disorder, with most patients meeting DSM-5-TR diagnostic criteria for PTSD, major depression, current or past substance use disorders, and somatic symptom disorders, as well as commonly engaging in self-destructive and suicidal behavior. Table 20–17 enumerates associated symptoms of dissociative identity disorder.

Table 20–18 lists the most important differential diagnostic considerations for dissociative identity disorder. One must differentiate disorders that are comorbid with dissociative identity disorder from those that must be differentiated from dissociative identity disorder. For example, depression, PTSD, substance abuse, and somatic (previously somatoform) symptoms are very common comorbidities with dissociative identity disorder.

Numerous recent studies have shown a robust relationship between mood disorders and an antecedent history of trauma, particularly childhood sexual abuse. Major depression is increasingly understood as one of the outcomes following traumatic experiences. Most individuals with dissociative identity disorder meet criteria for a depressive disorder, typically characterized as “treatment resistant,” with little or no response to multiple adequate trials of

antidepressants with augmentation strategies, mood stabilizers, ECT, and transcranial magnetic stimulation. Careful assessment of the affective state of the individual commonly finds a variety of emotions and cognitions as part of the “depression.” These may include intense shame, profound grief, posttraumatic dysphoria, demoralization, survivor guilt, and distress at one’s life situation (see section on Target Symptoms for Medications in the Treatment of Dissociative Identity Disorder-Mood Disorder Symptoms).

Frequent rapid “mood swings” are common, usually experienced as occurring within minutes or hours. These are usually due to posttraumatic and dissociative state alterations and are much more rapid than even the most rapid cycling documented in bipolar disorder. There may be considerable overlap between PTSD symptoms and those of depressive disorders. These include problems with attention and concentration, disturbed sleep, anxiety (fear in PTSD), and dysphoria/anhedonia. Unlike individuals with mood disorders, those with dissociative identity disorder typically describe a sleep disturbance dominated by nightmares and posttraumatic reactivity with specific phobias of night, bed, and sleep based on childhood nocturnal sexual assaults. Trauma-based sleep symptoms must be specifically inquired about as patients generally will not disclose them when asked generic questions about problems falling asleep, staying asleep, early morning awakening, and/or bipolar hypo/hypersomnia. Under the sway of some self-states, individuals with dissociative identity disorder may describe even several days of hyperactive behavior. However, this is not experienced “across the whole mind,” is not accompanied by typical bipolar sleep symptoms, and typically is not accompanied by manic grandiosity, although an apparent mixed state presentation may be harder to separate from bipolar disorder.

Table 20–17.
Associated Symptoms Commonly Found in Dissociative Identity Disorder

- Posttraumatic stress disorder symptoms
  - Intrusive symptoms
  - Severe dissociative flashbacks and nightmares
  - Avoidance and numbing symptoms
- Persistent and exaggerated negative beliefs/expectations and cognitions about self/world
- Persistent negative emotional state (especially shame/guilt, fear, sadness, anger)
- Detachment/estrangement
- Hypervigilance
- Reckless/self-destructive behavior
- Problems with sleep and concentration
- Symptoms of somatic symptom disorders
  - Conversion and pseudoneurologic symptoms, especially, seizure-like episodes
  - Somatic symptom disorder
  - With predominant pain symptoms such as:
    - Headache, abdominal, musculoskeletal, pelvic pain
    - Psychological factors affecting other medical conditions
    - Medical disorders associated with adverse childhood experiences (see Table 20–7)
    - Perimenstrual disorders (sexual abuse)
    - Irritable bowel syndrome (sexual abuse)
    - Gastroesophageal reflux disease (sexual abuse)
    - Morbid obesity (sexual abuse)
- Affective symptoms
  - Depressed mood, dysphoria, or anhedonia (typically, “depressed all my life”)
  - Brief mood swings or mood lability (within minutes/hours)
  - Suicidal thoughts, plans, intent, and behavior
  - Guilt and survivor guilt
  - Profound shame
  - Helpless and hopeless feelings

Obsessive-compulsive symptoms
- Ruminations about trauma and its impact on the person
- Obsessive counting, singing
- Arranging
- Washing
- Checking

Compulsive body movements

Table 20–18.
Differential Diagnosis of Dissociative Identity Disorder

Comorbidity vs. differential diagnosis (see discussion in text of outcomes of childhood trauma and Table 20–7)
Affective disorders
Psychotic disorders
Anxiety disorders
Posttraumatic stress disorder
Personality disorders
Neurocognitive disorders
Neurologic and seizure disorders (e.g., multiple sclerosis, tic disorders, movement disorders)
Somatic symptom disorders
Other dissociative disorders
Factitious disorders
Malingering

OCD symptoms are also commonly found in individuals with PTSD. Obsessive-compulsive personality traits are common in dissociative identity disorder and intercurrent OCD symptoms are regularly found in individuals with the disorder, with a subgroup manifesting severe OCD symptoms. OCD symptoms commonly have a posttraumatic quality, for example, checking repeatedly to be sure that no one can enter the house or the bedroom, compulsive washing to relieve a feeling of being dirty because of abuse, and

repetitive counting or singing in the mind to distract from anxiety over being abused.

Child and Adolescent Presentations (also, see section on Developmental Model of Dissociative Disorders). A growing clinical research literature documents the diagnosis and treatment of child and adolescent dissociative disorders, including dissociative identity disorder. In many respects, children and adolescents manifest similar core dissociative symptoms and secondary clinical phenomena as adults. Age-related differences in autonomy and lifestyle, however, may significantly influence the clinical expression of dissociative symptoms in youth. For example, dissociative amnesias and perplexing forgetfulness may be more apparent in school situations than in work or family life. Younger children have a less linear and continuous sense of time and are often unable to self-identify dissociative discontinuities in their behavior. Informants, such as teachers and relatives, may be useful in documenting dissociative behaviors.

Several normal childhood phenomena, such as imaginary companionship, elaborated daydreams, or participation in normal dissociative possession experiences as part of religious rituals, must be carefully differentiated from pathologic dissociation in younger children. For example, preadolescent children with dissociative identity disorder may manifest fewer obvious switching behaviors than adolescents or adults. The clinical presentation may be that of elaborated or autonomous imaginary companions, with these companions taking control of the child's behavior. This is often experienced as passive influences or voices in the child's mind commanding the child to behave in certain ways.

Ms. D had been in treatment for dissociative identity disorder for several months when she voiced concern that her 8-year-old daughter was “depressed.” One day, to her psychiatrist’s surprise, she brought her daughter to therapy. During the session, the child began to fidget, then got up and began to walk around the room. The mother suddenly appeared to shift in demeanor, appearance, and voice tone, shouted at the girl in a harsh and angry voice, grabbed the daughter’s arm tightly, and began to angrily slap the child. The little girl attempted to curl up in a fetal position, wailing like a much younger child, while the psychiatrist jumped into the fray, and literally physically separated the mother from beating the child. As he pulled the mother away, the little girl crawled under a table, and said, “I hate you! I hate you!” Both then appeared dazed, the mother wandered back to her chair, the little girl emerged from under the table, looking confused, but appearing more her actual age. When queried about what had happened, both claimed no recall of the events, even when the psychiatrist detailed for them what had just happened. The psychiatrist then arranged for another family member to pick up the little girl and stay with her. He probed the mother until an angry self-state emerged spitting, “the little s–t isn’t mine, it’s *hers*!” and took responsibility for the events in the office and admitted to beating her daughter on numerous occasions. The psychiatrist insisted that the patient report herself to the Department of Social Services (DSS) to investigate her ability to care for her daughter. He made the safety of the child the central part of the patient’s treatment and assisted with the DSS investigation, resulting in additional supervision for the mother and child but placement remaining in the home. He also interviewed the father, a passive man, whose work often took him away from home and who had abdicated child rearing to his wife. A colleague evaluated the daughter, who reported “people in my head,” whom she said talked to her and “told [her] what to do.” The little girl described “two ladies who are twins” in her mind; “one is a nice mommy, and the other is mean,

and you cannot tell them apart, so you never know when one or the other is around." The child said that "a lot of the people in my head are twins, one does it one way, the other the opposite. When that mean lady is around, my twin littler ones are there." The psychiatrist learned that the mother's self-state system also was based on many groups of subjectively experienced twin self-states, including the maternal and abusive ones, that reportedly called themselves by the same names as the little girl's twin mother and abusive self-states. The mother told the psychiatrist that *her* mother also likely shares the diagnosis of dissociative identity disorder and was born with a twin sister who died shortly after birth. Work with the abuser self-states—actually based on the grandmother—led to cessation of violence toward the child. Another group of self-states acknowledged bringing the child to the mother's therapy to expose the maltreatment they felt was impossible to stop without outside assistance. Careful monitoring over many years continued in both the mother's and child's psychotherapies.

Pathology and Laboratory Examination

A clinical mental status examination (Office Mental Status Examination) based on the various symptom clusters described in Tables 20-13 through 20-15 can be helpful in the diagnosis of dissociative identity disorder. Questioning about amnesic, depersonalization/derealization, autohypnotic, PTSD, mood, passive-influence, and somatic symptoms usually precedes detailed inquiry about symptoms related to the self-states. Careful in-depth questioning about these phenomena may readily bring forth information related to actions/interactions of self-states. For example, discussion of complex amnesia experiences may readily lead to questions about how purposive behaviors can occur without apparent memory. Discussion of PTSD symptoms may lead to manifestations of self-states related to traumatic experiences.

The development and increasing use of screening instruments and standardized diagnostic interviews (see Table 20–2) has contributed

to the rising number of identified cases of dissociative identity disorder over the last decade. Before the development of these assessment tools, hypnotic or amobarbital interviews were used primarily for diagnosis of the disorder. Due to the current academic and forensic controversies surrounding dissociative disorders and trauma memory, as well as most clinicians' lack of familiarity with these modalities, it is prudent to reserve these interventions for emergency situations when other methods of assessment have failed; for example, in a female patient who is emergently hospitalized after engaging in repeated, dangerous nocturnal fugues and who cannot account for these behaviors despite intensive interviewing. These interventions should optimally be conducted by a clinician experienced in their use and in the differential diagnosis of dissociative disorders. Clear, informed consent should be obtained for use of these interventions for diagnosis of dissociative identity disorder and recall of traumatic experiences. Informed consent should include education that memory material reported under hypnotic or pharmacologic conditions should not be considered any more or less valid than memories recalled under other conditions. Pharmacologically facilitated interviews (e.g., amobarbital interviews) are now considered conscious sedation by The Joint Commission and can only be performed with the assistance of an anesthesiologist.

Differential Diagnosis

On average, more than 6 to 12 years pass in high-income countries between first psychiatric contact and the diagnosis of dissociative identity disorder. The time lag between symptom onset and referral for treatment in possession-form presentations may vary, depending on the dramatic or gradual nature of the symptoms. Treatment failure and apparent "treatment resistance" may be an important differential diagnostic indicator of dissociative identity disorder, especially after multiple, at best only partially successful, psychotherapy (e.g., CBT, DBT, psychoanalytic), medication, ECT, and rTMS trials with adequate dosages for appropriate time frames. Rather than displaying histrionic flamboyance, it is estimated that over 95% of individuals with non–possession-form dissociative identity disorder are reticent about revealing their dissociative symptoms, especially hallucinations, amnesia, and self/identity divisions. They most commonly present as being relatively inhibited and obsessional, with mood and somatic complaints, and typically receive an average of three or more psychiatric diagnoses before their dissociative identity disorder is recognized. Symptom patterns distinguishing dissociative identity disorder from mood disorders, psychotic disorders, and personality disorders have been discussed earlier in this section.

Table 20–18 lists the most common disorders that must be differentiated from dissociative identity disorder.

However, because many of these disorders can coexist with dissociative identity disorder, as well as be mimicked by dissociative identity disorder, differential diagnosis may be complex. A small subgroup of individuals with dissociative identity disorder has an intercurrent psychotic disorder with a mixture of psychotic thought derailment, both psychotic and dissociative hallucinations, and at times tangential, bizarre associations and persecutory delusions that may imbricate with posttraumatic mistrust and interpersonal hypersensitivity. Often, they can distinguish between psychotic hallucinations and those of the internalized voices of the self-states although this can be harder to differentiate in possession-form cases. Individuals with dissociative identity disorder with comorbid psychosis may describe thought broadcasting, audible thoughts, ideas of influence and reference, and delusional explanations for these phenomena. Even so, some of these patients may preserve insight that psychotic symptoms are different from posttraumatic and dissociative

symptoms. Some of these patients may have a mixture of delusional beliefs that amplify posttraumatic hypersensitivity which can be difficult to entangle (e.g., “they all can see the shame that’s on my face,” as opposed to “everywhere I go, the victim people follow me. I hear them whispering about my bad face”).

Individuals with actual intercurrent bipolar disorder may experience sustained hypomanic or manic episodes—different in duration and quality from dissociative mood shifts—and more typical bipolar depression symptoms that are superimposed on the patient’s baseline chronic complex posttraumatic mood state. Stabilization of the actual intercurrent bipolar disorder symptoms with mood-stabilizing medication or ECT is necessary to allow the patient to participate fully in phasic trauma treatment for dissociative identity disorder. However, depressive symptoms usually are only returned to the patient’s more usual chronically dysphoric baseline.

Factitious, Imitative, and Malingered Dissociative Identity Disorder

Concerns about factitious and malingered dissociative identity disorder are common. Recently, reports are increasing of individuals claiming to have dissociative identity disorder who do not meet diagnostic criteria for the disorder when carefully assessed clinically or with structured interviews, such as the SCID-D-R. There may be a mixture of factors leading to this presentation, including misdiagnosis, factitiousness, and assumption of a social role by an abuse victim. Dutch researchers have named this *imitative dissociative identity disorder* when there does not appear to be conscious simulation. Patients may build their lives around their diagnosis and are commonly supported in so doing by concerned others and by their therapists.

Clinical indicators of falsified or imitative dissociative identity disorder may include those typical of other factitious or malingering presentations, such as symptom exaggeration, lies, use of symptoms to excuse antisocial behavior (e.g., amnesia only for bad behavior), amplification of symptoms when under observation, refusal to allow collateral contacts, legal problems, and *pseudologia fantastica.* In contrast, individuals with genuine dissociative identity disorder usually are reticent to endorse symptoms and appear confused, conflicted, ashamed, and distressed by symptoms and trauma history, alternating between endorsing then denying them. In forensic settings, genuine individuals with dissociative identity disorder

may refuse to use an insanity defense, much as many paranoid patients do. The feigning patients frequently show little dysphoria about their disorder and posttraumatic triggers and appear to be gratified by having the diagnosis. These imitative and factitious patients fit the socio-cognitive model of dissociative identity disorder, with one exception: rigorous diagnostic efforts show that they do not meet diagnostic criteria for the disorder.

The SCID-D-R has been used to help distinguish genuine from feigned/imitative dissociative identity disorder in clinical and forensic contexts. On the SCID-D-R, individuals with fabricated dissociative identity disorder tend not to describe the typical comorbid conditions and symptoms associated with the disorder—such as amnesia, identity confusion, and identity alteration—although they may report high levels of depersonalization and derealization. Instead, they often describe symptoms in a jargon-filled way ("I'm dissociating" or "I'm switching") and cannot readily explain their subjective experience on follow-up questions on the SCID-D-R or in clinical interviews. Most frequently, they show personality disorder traits on structured diagnostic interviews but do not meet diagnostic criteria for a dissociative disorder.

There are no absolute clinical indicators to differentiate imitative, factitious, or malingered dissociative identity disorder from the actual disorder. Some persons with the bona fide disorder become invested as their main social role in a dissociative identity disorder identity or that of being a trauma survivor. Some patients with possession-form presentations use or exaggerate symptoms for overt external gain. For example, a late adolescent newlywed had recently moved in with her husband and his family of origin. She reported being treated "badly" by her mother-in-law; this allowed her to return home for prolonged periods to "treat" her possession state. Just as individuals with non–possession-form presentations can be reticent and secretive about their illness, this may also be the case for many possession-form individuals. In some instances of the latter, possessing self-states may remain undisclosed until a specialist healer exposes them.

There are also patients with the actual disorder who report factitious histories, produce factitious crises, and create factitious self-states. Some patients report that their only happy childhood experiences were when they were hospitalized medically. Like more typical patients with factitious disorder, they seek out and try to remain hospitalized in psychiatric and medical settings. Münchhausen syndrome and Münchhausen syndrome-

by-proxy have also been reported in patients with dissociative identity disorder and their first-degree relatives. In forensic contexts, individuals with dissociative identity disorder seeking exculpation have malingered greater severity of dissociative and posttraumatic symptoms.

Ms. F, a 48-year-old divorced mother of three, was referred to a trauma disorder inpatient unit by her managed care company for consultation about diagnosis and treatment. She had been diagnosed with dissociative identity disorder after doing “inner-child work” with her outpatient therapist, as well as during her outpatient therapist’s group for sexually abused women. Ms. F reported an extensive history of childhood neglect, as well as physical and sexual abuse outside her family from ages 8 to 12. She had numerous hospitalizations for suicidal ideation and nonsuicidal self-injury. She was on disability and had been investigated several times by her state division of child welfare, which had recently placed her children in foster care. On arrival in the trauma unit, Ms. F proclaimed to patients and staff that, “I have dissociative identity disorder. I was sexually abused.” She did not seem distressed by either of these ideas. She repeatedly stated, “I’m switching, I’m switching,” although staff members experienced with dissociative identity disorder patients did not observe any of the typical signs of dissociative identity disorder switches nor had they observed a patient with dissociative identity disorder announce switches in this way. Ms. F became irritable when staff attempted to dissuade her from speaking about this in the milieu. She was evaluated clinically, observed by nursing staff in the ward milieu, and given a battery of psychological tests, including the DES, the SCID-D, PTSD assessments, the Rorschach, and personality assessments. On the clinical evaluation, Ms. F did not endorse complex chronic amnesia symptoms, amnesia for her life history, autohypnotic or passive influence symptoms, or inner voices. She endorsed episodes of depersonalization and derealization and reported only “child and baby alters” but could describe little about them when questioned. She would say things like, “See, now I’m like a child. Can’t you tell? That’s one of my littles.” She did not endorse any sense of fear, shame, conflict, or inner struggle around “switching” nor were any of the typical phenomena of switching noted at these times. Ms. F became vague when discussing reported childhood sexual abuse. She became angry when confronted about contradictions in her accounts, the dramatic nature of her presentation, and discrepancies between her history and her emotional reactions. She appeared uninterested in individual or group psychotherapy that sought to teach her more effective ways to manage symptoms and increase coping. On psychological and

diagnostic testing, Ms. F did not endorse most items consistent with clinical dissociation other than depersonalization and derealization. She did not display typical PTSD or dissociative reactivity to inquiries about the abuse history nor did she meet diagnostic criteria for PTSD. She did not show behaviors typical of individuals with dissociative identity disorder during a serendipitous event while being tested, remaining unaffected when another patient suddenly required aggression management on the ward near the testing room, whereas other patients reacted with severe PTSD and dissociative symptoms. Ms. F was diagnosed with DSM-IV-TR factitious disorder with psychological symptoms, mood disorder NOS, and personality disorder NOS with histrionic, borderline, and dependent features. However, she did not appear to be consciously feigning and seemed to believe in her self-reports of switching, self-states, and a history of childhood sexual abuse. Both Ms. F and her outpatient provider were resistant to the new diagnostic formulation.

Recently, a group of researchers has explored the standard inventories used in forensic settings for detection of malingering, such as the Structured Interview for Reported Symptoms (SIRS), developed by Richard Rogers. They found that the SIRS misclassified individuals with SCID-D-R–diagnosed dissociative identity disorder as feigning. Rogers replicated this finding and modified the SIRS, now as the SIRS-II, to classify dissociative trauma survivors more accurately. At this time, assessment of possible factitious or malingered dissociative identity disorder presentations—or factitious or malingered amplification of symptoms in persons with actual dissociative identity disorder—requires a complete clinical and psychometric evaluation, in addition to a review of old records, data from collateral informants, and other forms of assessment. Psychometric instruments, which usually must be administered by a psychologist familiar with how symptoms of dissociation present on standard measures, generally include the DES, MID, SCID-D-R, Rorschach, Thematic Apperception Test (TAT), Trauma Symptom Inventory (TSI), Minnesota Multiphasic Personality Inventory (MMPI)—although this also may misclassify dissociative individuals—Personality Assessment Inventory (PAI), SIRS-II, and additional assessment measures of malingering, and assessment measures for depression and PTSD, among others.

Course and Prognosis

Little is known about the natural history of untreated dissociative identity disorder. Small studies of patients with dissociative identity disorder diagnosed in middle age and in geriatric populations have shown that severe dissociative identity disorder symptoms can persist or can appear in older-age patients. A relapsing and remitting course is common and appears to be the modal pattern in possession-form cases. Also, patients can mask or suppress symptoms for periods of time. Both phenomena may be mistaken for complete spontaneous remission of the disorder. Possession-form presentations tend to be described in case series as more transient and episodic than non–possession-form cases. It is possible that the emergence of the possession-form type is facilitated by the same porosity of the self that patterns the external attribution of alternate self-states, leading to more transient states after a wider range of stressors. However, it is also possible that possession-form cases only seem transient and episodic, but that this is the overt presentation of phenomena that persist in more subtle form over time. Support for this possibility comes from data on relapse of possession-form presentations. In India, for example, relapse within 15 years was not infrequent, and was also recorded after two to three decades. Four of 15 subjects in one study were found to have suffered previous episodes, and one subject in another series reported three consecutive postpartum attacks. In China, individuals with chronic possession-form illness may be hospitalized after a history of recurrent episodes. Systematic research with larger samples over time is required to clarify this issue.

Some individuals with untreated dissociative identity disorder remain involved in abusive relationships or violent subcultures, resulting in their retraumatization and likely that of their children, with the potential for multigenerational transmission of trauma and the disorder (see Case 4). Experience with many dissociative identity disorder cases suggests that there are diverse subgroups of afflicted individuals. Some function very well for long periods while others have severely impaired and dysfunctional life trajectories often beginning early in development. The former may only show symptoms when severely stressed or overwhelmed; the latter may be continuously and severely symptomatic and come to clinical attention as children or adolescents. As described in the section on Nosology, there are high rates of disability in individuals with dissociative identity disorder in the community and in partial hospital and inpatient settings.

Patient presentations and prognosis vary somewhat across the life span. Children with non–possession-form dissociative identity disorder show many dissociative symptoms and behaviors but typically have fewer and less-crystallized self-states that are less invested in their individuality. If diagnosed early, and removed from abusive or neglectful environments, childhood dissociative identity disorder may resolve relatively rapidly with appropriate treatment. In adolescence, self-states become more distinct and more invested in their autonomy. Additional self-states may appear that are associated with life stresses, such as academic, athletic, social, or sexual challenges, and the self-sate system dynamics may become more complicated and polarized. In general, adolescents have a poorer prognosis than children or adults in part because, like other adolescents, they are often not invested in their treatment and are reticent to open up to adults. Better outcome has been reported in adolescents with dissociative identity disorder when their families were successfully engaged in treatment. Young adults typically present in crisis and have a layering of affective, somatic, posttraumatic, and personality disorder symptoms in addition to their core dissociative pathology.

First presentations of dissociative identity disorder in older patients frequently involve a life event, such as the loss of a job, death of a parent, or revictimization, such as a rape, that reactivates earlier conflicts and destabilizes the self-state system. Achieving sobriety in a substance-abusing patient with dissociative identity disorder may precipitate overt symptoms of the disorder and of PTSD. In adult patients, there appear to be treatment-responsive and treatment-refractory subgroups of individuals. Time course of improvement also may vary, with some patients improving relatively quickly and others requiring intensive treatment over long periods. Some healing traditions for possession-form presentations reformulate the person's suffering into beneficent individual and communal practice via initiation into a spirit devotion cult—such as the Siri cult of South India—or education into the roles of oracle (diviner), exorcist, or, rarely, avatar (divine incarnation).

Prognosis is poorer in patients with comorbid organic mental disorders, psychotic disorders, and severe medical illnesses. Refractory substance abuse and eating disorders also suggest a poorer prognosis. Other factors that usually indicate a poorer outcome include significant antisocial personality features, current criminal activity, ongoing perpetration of abuse, and current victimization—including being trafficked, with refusal to leave abusive relationships or situations, whether out of fear or for other

reasons. Repeated adult traumas with recurrent episodes of ASD may severely complicate the clinical course. Boundary violations and abuse by a prior treating therapist may prolong the treatment course because the treatment setting now feels unsafe and precipitates posttraumatic reactivity. Severe personality disorders are also generally associated with a poorer prognosis characterized by narcissistic overinvestment in multiplicity as a way of life, in having the disorder and/or the elaborate secondary structuring of self-states; engagement in psychotherapy primarily to seek gratification; and a refusal to take responsibility for behavior, behavior change, and/or symptom management. Number of self-states, however, has only a moderate effect on treatment course.

Treatment of Dissociative Identity Disorder

Current treatment approaches to non–possession-form dissociative identity disorder have evolved considerably. By contrast, the treatment of possession-form presentations remains largely unexplored except in anthropologically oriented observation studies. Available data suggest broad similarities between the treatment of both possession-form and non–possession-form presentations, including direct negotiation with the possessing self-states, allowing them to “give voice” to their concerns and assisting them to identify and redress their problems. Specialized indigenous practitioners and ritual therapies are generally available and widely utilized in many low-and-middle-income countries, but psychiatric treatment is typically avoided. Indigenous treatments include neutralization of the conflict or stress via the communal rituals involved in exorcism and/or other longer-term activities, such as integration into a healing community with a specialized function. The evolution of the self-states over time, and their eventual change to a more adaptive configuration, constitute one major basis of improvement that is common to both possession-form and non–possession-form presentations. Unlike non–possession-form cases, however, possession-form presentations typically do not resolve by unification into a subjectively singular self, given the supernatural attribution of most possessing agents.

The rest of the section on Treatment addresses the care of non–possession-form cases. An in-depth discussion of these current treatment approaches can be found in the *Guidelines for the Treatment of Dissociative Identity Disorder in Adults 3rd Revision* (2011) from the ISSTD (http://www.isst-d.org). In 2004, the ISSTD promulgated *Guidelines for the*

Evaluation and Treatment of Dissociative Symptoms in Children and Adolescents that can also be found on the ISSTD website. Both guidelines are in revision.

The current model of treatment of the individual with dissociative identity disorder follows a phasic model that is the current standard of care for complex posttraumatic disorders. The phases include (1) development of safety and symptom stabilization; (2) (optionally) focused, in-depth attention to traumatic material; and (3) integration or reintegration, in which the individual moves away from a life adaptation based on chronic traumatization and victimization. These phases are relatively heuristic, and aspects of each may be part of the others.

Treatment Outcome Studies in Complex PTSD and Dissociative PTSD. Convergent data from treatment outcome studies of patients with complex PTSD, the dissociative subtype of PTSD, and dissociative identity disorder have shown lack of response, or even clinical deterioration, if standard, unmodified Progressive Exposure/Cognitive Behavioral Treatment (PE/CBT) models for PTSD are used to treat these populations. Studies have shown better outcome in individuals with complex and dissociative PTSD from treatment paradigms that give attention to stabilization of dissociation, emotional dysregulation, and safety issues before, or even instead of, intensive processing of trauma memories. In some studies, highly modified exposure protocols—to “fractionate” the intensity of memories—were required for trauma memory processing in individuals with multiple early life traumas to prevent flooding by trauma memories.

Other studies report significantly higher-than-expected discontinuation rates and lower rates of abstinence after treatment for individuals with dissociative disorders who received standard substance abuse treatment. They also show lack of response to standard treatment for anxiety disorders and higher rates of non-retention in group therapy among sexual abuse survivors. In addition, elevated dissociative symptoms in patients with borderline personality disorder predict limited response to standard DBT.

A Norwegian study evaluated the response of dissociation and other symptoms among consecutive admissions to an inpatient program that provided stabilization treatment based on a phasic trauma treatment model for complex trauma survivors. Treatment primarily consisted of group and individual therapy, with adjunctive pharmacotherapy. Patients who met

DSM-IV-TR diagnostic criteria for dissociative identity disorder or dissociative disorder NOS (Example 1) only substantially improved when dissociative symptoms were directly addressed in treatment. None of their patients had previously been assessed or treated for a dissociative disorder and, at the time of this study, the program did not specifically target dissociative disorders in childhood trauma survivors.

Treatment Outcome Studies of Dissociative Identity Disorder

Single-case descriptions of successful treatments for dissociative identity disorder date back more than a century. Systematic outcome studies of non–possession-form cases, however, have only appeared recently. Reviews of clinical case series generally agree that patients with dissociative identity disorder improve with the phasic trauma treatment model. A meta-analysis of eight treatment outcome studies for dissociative identity disorder, including inpatient and outpatient treatments—with treatment provided by both nonexpert and expert clinicians—showed that the phasic model of dissociative identity disorder treatment was associated with improvement across a range of symptoms and comorbidities. These included fewer DSM-IV-TR diagnoses of comorbid axis I and II disorders; decreased dissociation, depression, anxiety, suicidality, and substance abuse symptoms; and reduced general distress. In studies from an inpatient specialty trauma disorder program, gains persisted at 2-year follow-up. Limitations of these studies include data from only a single clinician in some studies, small samples sizes, nonrandom inclusion of patients, high discontinuation rates, failure to account for nonspecific effects such as regression to the mean, and lack of control groups.

Cost Efficacy Studies of Dissociative Identity Disorder Treatment. As described above, individuals with dissociative identity disorder may spend years of unproductive treatment in the mental health system. Costs of their treatment have been hypothesized to be unnecessarily inflated due to lack of treatment response for incorrect diagnoses, frequent utilization of more restrictive levels of care (e.g., inpatient, residential, partial hospital, and intensive outpatient treatment), as well as costs for unnecessary medical procedures and work ups (e.g., repeated MRIs, EEG telemetry). Although costs were not estimated, a general population study in New York State found, compared to other diagnoses, the highest rate of disability in individuals with dissociative identity disorder. An international, naturalistic, longitudinal treatment outcome study of DSM-IV-TR dissociative identity

disorder and dissociative disorder NOS (see next section) found significant reductions in inpatient utilization at 30 months, consistent with clinical improvement and reduction in treatment costs.

Data from 55,000 Massachusetts Medicaid patients from 1993 to 1996 showed that inpatient treatment for dissociative identity disorder cost over $3 million during the study period—33.5% of the total Medicaid inpatient costs—although patients with dissociative identity disorder made up only 2.6% of the sample. Cost of treatment for patients with dissociative identity disorder was higher than for patients with panic disorder, major depressive disorder, and bipolar disorder. In a large study of health care utilization, although less than 1% of the sample, wives of active-duty military personnel with a dissociative disorder had more outpatient visits than wives seeking treatment for any other psychiatric disorder. Individual case studies and small case series document substantial cost savings (e.g., ~50% to 67% reduction in costs) after correct diagnosis of dissociative identity disorder and initiation of phasic trauma treatment. Cost savings included both decreased utilization of more restrictive levels of care and reductions in medical costs.

A recent qualitative, systematic review of cost-efficacy studies for dissociative disorders demonstrated that these patients were costly to treat and a reduction in service utilization and associated costs with correct diagnosis and trauma/dissociation-focused treatment. However, studies varied in how costs were estimated and in other variables, making a meta-analysis impossible. The study authors suggested that better data are needed to rigorously assess treatment cost and cost savings in diagnosis and treatment of individuals with dissociative identity disorder.

Longitudinal Treatment Outcome Studies

Bethany Brand and colleagues developed the *Treatment of Patients with Dissociative Disorders Study* (TOPDD Study; http://www.towson.edu/topddstudy/index.asp) that included several treatment outcome study initiatives. The first was an international, prospective, longitudinal outcome study of 280 patients diagnosed with DSM-IV-TR dissociative identity disorder or Dissociative Disorder NOS Example 1 treated by 292 therapists from 19 countries. Treatment progress was assessed prospectively at study entry and at 6, 18, 30, and 72 months of treatment. Outcome measures were assessed using a five-stage model where stages 1, 3, and 5 corresponded to the three stages in

the clinical Phasic Trauma Treatment model: establishing stability and safety (stage 1); processing of trauma memories (stage 2); and integration and reconnection within self and with others (stage 3).

At each time point, therapists completed a data sheet on the patient's stage of treatment (1 to 5), Global Assessment of Functioning (GAF), and incidence of self-harm, suicide attempts, and hospitalizations. Also at each time point, clinicians completed the Progress in Treatment Questionnaire (PITQ) that assesses management of impulse control; emotion regulation; capacity to use skills for symptom management; decreases in posttraumatic cognitive distortions and misperceptions; increased internal communication and cooperation between self-states; capacity to work on, and full awareness of, posttraumatic memories; integration of self-states; and increasing capacity to see oneself and others in a realistic, integrated way.

Patient measures were the DES, the Posttraumatic Check List-Civilian version (PCL-C), and the Symptom Checklist-90 (SCL-90-R). Patients also completed a behavioral checklist to assess the frequency over the last 30 days of self-injurious behavior, suicide attempts, "very impulsive" behaviors, alcohol and drug consumption, and high-risk behaviors that could have resulted in death. Also, patients reported the frequency of positive experiences and adaptive behaviors in the last 30 days including: volunteering or attending school, working for pay, using symptom management techniques, socializing, and feeling good "even if for a brief period." Patients also reported the days in inpatient and day treatment programs in the month prior to assessment.

Results from the 30-month follow-up are shown in Table 20–19.

The initial cross-sectional TOPDD results showed that patients in treatment stage 1 had higher levels of dissociation and PTSD, more hospitalizations, higher overall distress, and less adaptive functioning than patients in stage 5. As reported by both patients and therapists, at the 30-month follow-up there was decreased dissociation, PTSD, general distress, depression, suicide attempts, self-harm, dangerous behaviors, drug use, physical pain, and hospitalizations, as well as improved functioning as indicated by higher GAF scores. At the 30-month assessment, more patients were involved in positive activities in volunteer jobs and/or attending school and socializing and reported feeling well. Consistent with the phasic treatment model, more patients progressed from early stages of treatment to more advanced stages than those that moved in the opposite direction.

At 30-month follow-up, patients with the highest levels of dissociation, and with the most severe depression, also showed significant improvements in these symptoms. More patients showed “sudden improvement” than “sudden worsening” (i.e., 20% increase or decrease in symptoms) at one or more time point(s). Rates of revictimization showed a decreasing trend during the study. Therapists reported less frequent revictimization events and stressors among the patients who improved suddenly relative to those who worsened. Consistent with clinical experience, revictimization and/or severe external stressors were most likely to contribute to worsening in treatment. Only 1.1% of patients showed worsening over more than one data collection point, less than overall rates of worsening in treatment outcome studies of general psychiatric patients. As noted above, there were two deaths by suicide among study patients.

Younger patients, despite having elevated symptoms at baseline, were more likely to show improvement, indicating that early treatment of severely dissociative patients may lead to a more positive life trajectory. Patients reported a significant decrease in feeling like “different people” and hearing voices. A trend decrease in reports of dissociative amnesia supports the view that the phasic trauma treatment model helps to improve core dissociative process symptoms, not to increase them as critics of this model have suggested. At 72 months, 61 therapists from the original study provided data on their patients’ progress. These included continuing significant improvement in GAF, decline in inpatient utilization, decreased stressors, and fewer episodes of sexual revictimization. Patients maintained prior gains in decreased rates of nonsuicidal self-injury and suicidal behavior.

In summary, the TOPDD study documented that the phasic trauma treatment model improves a wide range of symptoms and adaptive functioning indices in patients with pathologic dissociative disorders and documented decreased utilization of more restrictive levels of care. Limitations of this study included the lack of a randomized control group, of fidelity compliance assessments for therapists, and of a specified psychotherapy protocol.

The TOPDD Network Study

The TOPDD Network Study is an ongoing study that assesses the impact of web-based interventions on a group of international patient–therapist

dyads. Patients were clinically diagnosed with either DSM-IV-TR or DSM-5 dissociative identity disorder (76.5%) or dissociative disorder NOS/other specified dissociative disorder (20.6%/2.9%). (The study spanned the transition from DSM-IV-TR to DSM-5). Unlike most treatment outcome studies, patients were *not* excluded for current suicidality, nonsuicidal self-injury, recent hospitalization, comorbid disorders, substance abuse, social isolation, current stressors, and/or clinical instability. Evaluations at baseline and at 6, 12, 18 and 24 months included the PITQ (therapist and patient versions), DES, PCL-C, and the Difficulties in Emotional Regulation scale (DERS). Therapists reported on numbers of episodes of nonsuicidal self-injury, suicide attempts, and days of hospitalization for the 6 months prior to the study. Published data from the first 24 months of the study are described here (N = 111).

Patient–therapist dyads were provided 45 web-based psychoeducational videos, each 5 to 15 minutes in length, with additional written and behavioral practice exercises. These focused on establishing safety and reducing suicidal and high-risk behaviors as well as nonsuicidal self-injury. Other videos focused on symptom management (e.g., emotional dysregulation, uncontrolled PTSD and dissociative symptoms). The authors tracked how often videos were used, both in and outside of therapy. New videos could only be accessed 1 week after the previous one.

Table 20–19.
Findings at 30 Months from the Treatment of Patients with Dissociative Disorders Study (TOPDD Study)

Completion of Treatment, Drop out, and Termination Rates			
Variable	**Patients**	**Therapists**	**# Countries**
Baseline	226	295	19 North America, Latin America, Europe, UK, Australia, New Zealand, China, Singapore, Israel, Slovakia, South Africa
N at 30-month follow-up	119	135	
% Drop out of study (of those who were still in treatment)	36%	48%	–
Successful treatment completers	3% of baseline sample (*n* = 6)	–	–
Terminate treatment for any reason	18% of baseline sample (*n* = 40)	–	–

Summary of significant treatment outcomes (Note: All variables changed in the hypothesized direction, so all significant linear changes indicate improvement over time. If the curvilinear term was significant, it means that the change in that variable flattened out over time; i.e., improvement slowed over time.)

Continuous Variables	**Direction of Change**	**Significant Improvement over Time (Linear Change Significant)**	**Change Flattens over Time (Curvilinear Variable was Significant)**
Patient Reported			

Dissociation	Decrease	X	
PTSD	Decrease	X	X
Distress overall	Decrease	X	X
Depression	Decrease	X	X
Therapist Reported			
GAF	Increase	X	
Adaptive Functioning (PITQ)	Increase	X	X

One Item Dichotomous Variables	Direction of Change	Significant Improvement Over Time (Linear Change Significant)	Change Flattens over Time (Curvilinear Variable was Significant)
Patient Reported: Symptoms			
Self-injurious behavior	Decrease	X	
Dangerous behavior	Decrease	X	
Getting high	Decrease	X	X
Impulsive behavior	Decrease	X	
Inpatient hospitalizations	Decrease		X (hospitalizations went up in the second follow-ups, but decreased by third and fourth follow-ups)
Patient Reported: Adaptive Functioning			
Volunteering/Attending School	Increase	X	
Socializing	Increase	X	
Feeling good	Increase	X	
Therapist Reported:			

Symptoms		
Self-injurious behavior	Decrease	X
Inpatient hospitalizations	Decrease	X

Not significant:

- Only single-item variables
- Patient reported: suicide attempts, drinking alcohol, using symptom management skills
- Therapist reported: day program attendance

Data from Brand BL, McNary SW, Classen CC, et al. A longitudinal naturalistic study of patients with dissociative disorders treated by community clinicians. *Psychological Trauma.* 2013;5(4):301–308. doi:10.1037/a0027654; and a paper presented as part of a symposium at the annual convention of the International Society for Traumatic Stress Studies, Montreal, Canada.

White female patients predominated; the sample was 10% male, 1.5% transgender; 5.6% Latinx, 2.8% Asian, 1.4% Black, and 7% other ethno-racial background. At baseline the patient sample was divided into a high-DES group (average = 59.89) and a low-DES group (average = 18.21). The former had significantly higher baseline PCL-C and DERS scores. At study completion, effect sizes showed large improvements in patients' adaptive functioning (PITQ) and emotion regulation (DERS); medium improvement in PTSD symptoms (PCL-C); and smaller improvement in DES scores. The high-dissociation group improved more than the low-dissociation group, with large effect sizes for improvement in adaptive capacities, emotion regulation, PTSD symptoms, and dissociation. The low-DES group demonstrated medium-to-large effect size improvements in postintervention adaptive capacities and emotion regulation but only small improvements in PTSD and dissociation. The effect sizes for change in therapist-rated adaptive function were of medium and low magnitude in the high and low-dissociation groups, respectively. The DES decrements were significantly related to time in the study. Over 24 months, the high-DES group showed a steeper slope of reduction in PCL-C and DERS scores. Over the 24 months, improvement in emotional regulation predicted improvement in dissociation scores.

Despite study limitations (e.g., clinical diagnoses instead of structured interview diagnoses, possible selection effects of patient–therapist dyads), the inclusion of a high proportion of patients with nonsuicidal self-injury, suicidality, and hospitalizations is a particular strength. The frequency of

nonsuicidal self-injury substantially decreased over the 2 years of the study. Therapist reports of patient self-injury behavior in the 6 months prior to the study were not normally distributed in the sample, with 60.4% engaging in these behaviors (average = 13.75 episodes for those engaging in nonsuicidal self-injury; overall sample range 0 to 150 episodes). At study conclusion, for the group with nonsuicidal self-injury, about 70% showed steady reduction in this symptom (average = 1.74 episodes), about 25% increased, and the remainder stayed the same or increased and then decreased. The three patients with the highest number of episodes of nonsuicidal self-injury (100, 125, 150 events in the prior 6 months) showed reduction to 0, 10, 10 times, respectively, in the last 6 months of the study. There was a trend for a decreasing number of suicide attempts and hospitalization days.

In a subsequent analysis, greater difficulty with emotional awareness, clarity, and acceptance predicted nonsuicidal self-injury, as did impulsivity and struggle with goal-directed behavior. This finding confirms the expert consensus that it is essential to educate individuals with dissociative identity disorder that dangerousness to self is a maladaptive, trauma-based attempt at self-regulation. Interventions focused on the patient "stopping bad behavior" are doomed to failure. The authors' clinical experience is that the latter stance—basically shaming the individual for something experienced as uncontrollable—increases dangerousness to self, as shame is one of the main dysregulated emotions that drives these behaviors. Individuals with dissociative identity disorder can markedly decrease dangerousness to self when they can make sense of these behaviors as attempts at self-regulation. Reduction in these behaviors accompanies improvements in emotional regulation skills, challenges to trauma-based cognitive distortions about the necessity of self-destruction, and the increasing capacity to delay self-destructive actions and replace them with recovery-oriented symptom management and emotional regulation skills.

Expert Consensus Guidelines for Phasic Treatment of Dissociative Identity Disorder

Central to development of the TOP-DD studies, 36 international dissociative identity disorder experts were surveyed to identify treatment phases and evidence-based interventions. The experts rated 28 interventions on a 0 (never) to 4 (very often) scale across the stages of the

phasic trauma treatment construct. They agreed upon a core set of beneficial interventions. The most frequently recommended interventions for each treatment stage are shown in Table 20–20.

Even in the stage where work on trauma memories is most predominant, the expert treatment recommendations still focus on safety, stabilization, the therapeutic alliance, cognitive work, and symptom management. In the final phase, the therapeutic work is directed toward “reintegration,” living well in the present, and relegating traumatic memories to the status of “bad memories”—as opposed to flashbacks, behavioral re-experiencing, and/or intense posttraumatic reactivity to current situations. These stages are heuristic since trauma memory may need to be addressed—if only in a more cognitive and distanced manner—in stage 1 and worked through again from a more integrated perspective in stage 3. Safety may be an issue at all stages of trauma treatment. Finally, the entirety of trauma treatment is directed toward helping patients adapt better to their current circumstances.

Table 20–20.
Expert Recommendations for Treatment of Dissociative Identity Disorder—Stages 1–5

Stage	1	2	3	4	5
Establish safety	✓	✓	✓		
Establish/repair alliance	✓	✓	✓	✓	✓
Teaching/practicing grounding	✓	✓	✓		
Educate about disorders and treatment options	✓	✓			
Diagnose/rule out comorbid psychiatric illnesses	✓				
Teaching/practicing self-care	✓	✓		✓	✓
Developing healthy relationships	✓			✓	
Affect tolerance and impulse control	✓	✓	✓	✓	
Stabilizing from current day stressors/crises	✓	✓	✓	✓	✓
Teaching/practicing containment	✓	✓	✓		
Developing healthy relationships		✓			✓
Cooperation with self-states		✓	✓	✓	
CBT focus on cognition distortions			✓		
Identify/work with self-states			✓		
Awareness of body sensation			✓	✓	✓
Discussing therapeutic relationship				✓	✓
Processing patient's reactions to therapy				✓	✓
Ego strengthening activities				✓	✓
Awareness of emotion					✓
Stabilizing following intrusions from reported perpetrators					✓

Note: Phasic Trauma Treatment Model has three Stages, corresponding to TOPDD stages 1, 3, 5—see text for discussion.
Data from Brand BL, Myrick AC, Loewenstein RJ, Classen CC, et al. A survey of practices and recommended treatment interventions among expert therapists treating patients with dissociative identity disorder and dissociative disorder not otherwise specified. *Psychol Res Pract Policy.* 2012;4(5):490–500.

The experts recommended interventions around safety most frequently in all but the last stage of treatment. Safety is a consistent focus because each stage can bring about emotionally dysregulated crises that patients may feel compelled to manage via unsafe behaviors. Developing and repairing the therapeutic alliance was recommended as a top intervention in every stage of treatment, indicating the centrality of the therapeutic alliance in successful treatment of dissociative identity disorder. Recent

research suggests that the therapeutic alliance is important in predicting improvement across a range of symptoms as it is in most successful psychotherapies. Individuals with dissociative identity disorder have suffered betrayal and maltreatment in the context of early dependent relationships (see sections on Betrayal Trauma and Type D attachment). On the other hand, an aspect of their resiliency is belief in the possibility of a positive attachment, despite the cruel betrayals. This may underlie their capacity to develop the therapeutic alliance that, along with ability to use insight, may be crucial in their recovery. As individuals with dissociative identity disorder suffer maltreatment almost universally in the context of attachment, experts recommended ongoing attention to transference issues, particularly traumatic transference reactions, that are endemic to this population.

Other core interventions recommended across all stages of treatment include differential diagnosis to identify symptoms better conceptualized as aspects of the complex posttraumatic dissociative processes, as opposed to genuine comorbid disorders; psychoeducation about the role of medications in dissociative identity disorder treatment; strategies for improved awareness of emotions and development of emotional regulation skills and impulse control; management of daily functioning and current relationships; and help coping better with stressful life situations, losses, and additional trauma. The treatment recommendations in this chapter are based on these expert recommendations, the ISSTD Treatment Guidelines, and the interventions documented in the TOPDD studies that have demonstrated efficacy in these patients' improvement.

Stage 1 Phasic Trauma Treatment: Stabilization and Safety

Successful treatment of dissociative identity disorder *requires* development of safety from all aspects of dangerousness to self/others and stabilization of dyscontrolled dissociative, PTSD, and other comorbid symptoms. Before establishing safety, the patient actually and/or symbolically lives in a world of ongoing trauma, whether perpetrated by others and/or by the patient on themselves due to ongoing dangerousness to self/others. The clinician must logically prioritize basic life and health over other interventions. The clinician may need to resort to many different levels and types of interventions to protect the patient, including hospitalization, specialized substance use or eating disorders programs, police assistance and shelter for victims of intimate partner violence, social service interventions to

protect minor children, and assistance with housing and access to medical care. To achieve safety, stability, and overall treatment progress, effective stabilization in patients with dissociative identity disorder requires psychotherapeutic work with self-states/self-state systems.

Direct Therapeutic Engagement with Self-States

Clinicians new to dissociative identity disorder are frequently uncomfortable or perplexed by the need to work directly with self-states and how to do this without producing a chaotic regression or reinforcing the patient's sense of separateness among self-states.

The model of dissociative identity disorder as a childhood failure of unification of self/identity across states, relationships, and contexts frames the psychotherapeutic approach to working with self-states. No self-state is any more or less "real" or better or worse than another. All are aspects of a single human being and have adaptive psychological importance that needs to be heard and respected. The clinician should not engage in interactions that reinforce notions of self-states as separate people. These can include "playing favorites," supporting the notion that some self-states are fundamentally "good" and others "bad," refusing to communicate with certain self-states, and giving ongoing, separate appointments to self-states as one would with individual patients. However, this does not mean that the clinician condones self-destructive, dangerous, suicidal, violent, or other high-risk behaviors. To help stop these behaviors and develop the person's repertoire of recovery skills; it is critical to understand the self-states that drive these self-regulatory behaviors and the trauma-based cognitive distortions that underlie them.

All self-states must be held accountable and responsible for the behavior of any other state, even if experienced with amnesia or lack of subjective ownership. Human beings engage in behavior, not self-states. One can attempt to understand the mental state of the person who does the behavior, but *explanations are not excuses*. Expert consensus and clinical experience postulates that to do otherwise is an invitation for the patient to regress. Because patients with dissociative identity disorder have both psychological strengths and liabilities, over time they improve when held to a standard that underscores their strengths. As described above, self-states can be understood as developmentally concretized forms of organizing, symbolizing, and mobilizing mental contents around psychological survival from repeated, unpredictable, attachment-based

maltreatment. The fullest engagement of all mental symbols and sources of knowledge, skills, and adaptations is likely to produce the best outcome in any psychotherapy. This approach also forms the recommended basis for forensic standards around competence and not-guilty-by-reason-of-insanity (NGRI) judgments. It uses the psychological-structure findings of preservation of logical thinking and reality testing and the notion that patients with dissociative identity disorder can inhibit and conform behavior in many contexts.

Concerns about "iatrogenesis" are often raised in these circumstances. Understanding the self-states fundamentally as forms of intrapsychic symbolization reduces this concern to a more routine psychotherapeutic task of understanding the meaning of mental contents, rather than a suppression of some mental states as less authentic than others. At the same time, the clinician must also be able to appreciate the patient's subjective reality in which the self-states are experienced as distinct selves or even as separate persons. The therapist must be able to tolerate engaging with the self-states *as if* they were separate entities, while simultaneously maintaining the understanding that the self-states represent the structuring of psychological processes in personified form within a mind.

The continuity, stability, and respectful impartiality of the therapist toward the different self-states provides an important therapeutic experience that helps the patient experience, examine, and integrate these dissociated aspects of self. The processing of negative life events, often from the multiple perspectives of different self-states, is an important part of the narrative reorganization of the patient's divided self/identity into a more coherent whole. The therapist usually is actively involved in negotiating between and among the various self-states to achieve therapeutic goals. The therapist works to assist the self-states/system with improved communication, coordination, cooperation, and internal empathy. This stance helps with development of emotional regulatory skills and adaptive functioning. As shown by the TOPDD studies, rather than reinforcing dissociation, working in this way gradually diminishes dissociative barriers among self-states. This is associated with decreased dissociative amnesia, dissociative hallucinosis, passive-influence symptoms, and dysregulated state-switching/shifting, as well as better ability to manage PTSD symptoms and maintain safety from dangerousness to self/others.

Practical Management of Safety Issues

As described in the TOPDD network study data, patients with dissociative identity disorder use unsafe and high-risk behaviors as attempts to regulate, manage, and modulate severe dissociative, PTSD, emotional, somatic, and cognitive dysregulation. Work on safety generally includes discussion of the antecedents to, and functions of, these behaviors as well as safety agreements and crisis management plans. There is usually a logic behind the patient's self-destructive behavior. For example, there is a highly prevalent cognitive distortion in this population that, "I'm going to get hurt no matter what I do, so control of the timing and intensity of harm is all the control I get." These beliefs can be reframed as an attempt to achieve a sense of control to survive the helplessness and unpredictability of repeated maltreatment throughout development. The therapeutic goal then becomes to change this "survival skill" to a "recovery skill": developing adult, non–trauma-based strategies for appraising one's current life situation and level of external danger, gaining a repertoire of skills to keep oneself safe in the present, and creating overall safety and self-protection in one's current life.

Usually, in this patient group, self-destructive behavior has an addictive component and many of these patients have current or past problems with substance misuse. Using addiction metaphors can be helpful: "sobriety" from dangerousness to self involves a commitment to safety, the realization that symptoms likely will *worsen* once the behavior stops, and intensive work to find alternatives to help manage intolerable, often unnamable, affective states such as extreme shame, humiliation, rage, horror, helplessness, and disgust/revulsion. At times, self-injury is experienced as an attempt to "feel something" when in a numb state and/or to "put the pain on the outside" where it seems more real, or where (the patient believes) others may take it more seriously.

Safety Agreements. Safety agreements may be a useful clinical tool to assist the individual with dissociative identity disorder manage safety issues and to support the person's ambivalence about being unsafe. Safety agreements are no substitute for the clinician's judgment about the patient's safety from dangerousness to self or others. The clinician must continually assess the patient's safety and, based on clinical judgment, act to protect the patient or others, including initiating involuntary hospitalization, despite the patient's protestations that they will maintain the agreement.

It is useful to think of safety agreements as *delaying* agreements, where the patient has access to a hierarchy of interventions to use instead of self-destruction, up to and including going to the emergency department for stabilization. Individuals in recover from addiction/substance abuse are taught to think in “one-day-at-a-time” approaches to sobriety. In trauma recovery, patients with dissociative identity disorder may be unable to commit to safety “forever,” but may be able to commit to a safety plan for a more manageable period (e.g., from therapy session to therapy session). Some clinicians prefer that the patient write down and sign this type of agreement. The authors’ experience is that the crucial factor is the patient’s honesty about safety and the ability to maintain themselves as a safe outpatient, following the safety plan. Many signed safety agreements are not honest and many verbal commitments are. Some patients feel that writing and signing an agreement reinforces the seriousness of and concretizes the commitment to it. It is not necessary for “all” self-states to sign the safety agreement. Instead, the clinician can ask all states, “known or unknown,” if there is any objection to the agreement and to indicate so by a physical signal, such as a head nod or verbally. If there is an objection, the clinician can ask for some sort of communication in the patient’s mind about the concern. Often, the issues that emerge are quite helpful to the patient in the process of working honestly on safety. It may help the patient to realize that the clinician must trust the *patient’s* honesty regarding safety agreements and that the patient is not the only one in the therapy who has concerns about trust. If a signed agreement is created, the patient may sign several names and add that “and all [other] known or unknown” self-states agree as well. Occasionally, the patient with dissociative identity disorder will have an idiosyncratic posttraumatic reaction to the words, “safety” or “agreement.” In this case, the patient may be asked to provide a reasonable alternative, such as the “no-immediate-action pact.”

EDUCATION AND INFORMED CONSENT. It is important to educate the individual with dissociative identity disorder about the disorder, its actual and apparent comorbidities, and the course of treatment. Educative interventions help decrease anxiety about symptoms that are often frightening and overwhelming, build a therapeutic alliance, and provide information that is the basis for a meaningful consent for treatment. Furthermore, it is necessary to educate the patient about the contentious

and divisive debates that surround the diagnosis and treatment of dissociative identity disorder in contemporary psychiatry and psychology.

Other major issues in informed consent include advising the patient of potential risks and benefits of the treatment and the current evidence base for the treatment model. In addition, patients should be informed about approaches that differ from the phasic trauma treatment model, such as the iatrogenic/sociocognitive/FM that advocates ignoring the self-states and the history of trauma, and the evidence base and potential risks and benefits of these alternatives.

The patient should also be informed about current controversies concerning traumatic memory and its retrieval and explication in therapy. Additional informed consent should be obtained for formal hypnosis and pharmacotherapy. The patient should be counseled that symptomatic worsening may occur temporarily during treatment, particularly during phases in which memory material is worked with in depth. Simultaneously, however, subjective amelioration of other symptoms may occur, with the patient achieving a better sense of control, mastery, and self-coherence as they successfully work through painful material.

Similarly, like many obsessional individuals, patients with dissociative identity disorder often respond positively to learning that their dissociative and PTSD symptoms have a name and an organizing framework. There is often relief at a diagnosis that fits the patient's subjective life experience, especially if there has been a long prior history of unsuccessful psychiatric treatment for other disorders. At the same time, patients may respond with distress at the dissociative identity disorder diagnosis due to media and popular stereotypes, because it brings into sharper relief the meaning of painful symptoms, due to shame reactions such as feeling like a freak, and/or because it brings more focus to the distressing history of early trauma and problematic relationships with family members.

Individuals with dissociative identity disorder often need to be counseled that the purpose of treatment is not to suppress or destroy self-states but rather to allow therapeutic engagement with them as vital aspects of the mind. Self-states may express strong wishes to "get rid" of others and are simultaneously terrified that the therapist will attempt to do so. Most experienced clinicians educate patients that treatment is geared toward optimal function and adaptation and that there are usually too many variables at the beginning of treatment to predict whether it will necessarily ultimately result in unification of all self-divisions, a concept that the patient usually cannot really comprehend at the beginning of treatment. At the

same time, most experienced clinicians see unification of all self-states as usually providing the best long-term outcome in dissociative identity disorder.

The education and informed consent process should be ongoing throughout treatment. Many of these issues need to be revisited as treatment proceeds and the patient changes in therapy. As with the safety agreement, if a signed informed consent is used, it is not necessary for "all" self-states to sign the agreement and self-states that are experienced as newly emerging later in treatment may report amnesia for prior psychoeducation. An overly rigid concern about how many states sign the agreement may reinforce subjective separateness by treating the self-states more as separate people than subjectively structured personified mental processes.

Boundaries and Treatment Frame

Most patients with dissociative identity disorder report that their traumatic life experiences occur over long periods of time in the context of close personal relationships with those who have hurt them. These patients often report boundary violations in subsequent relationships with teachers, therapists, medical professionals, and social service workers, among others. For these patients, the role description of significant others does not necessarily predict their behavior, and relationships are often seen as "up for grabs." The patient expects and fears that the clinician will violate boundaries. There may be a subtle (or not so subtle) pull in the transference for the therapist to change the frame of treatment. Patients may experience this as trying to make the inevitable happen, so that they do not have to endure the agony of waiting for things to go wrong. Accordingly, clinicians working with these patients must pay careful attention to issues of the treatment frame and appropriate and consistent boundaries. These include firm limits on the length of therapy sessions; acceptable behavior during sessions (e.g., the therapy space is "not a hurting place," it is one of safety for therapist and patient alike to talk about important issues); the extent of extra-session contacts; and payment of fees; among many others. Dissociative identity disorder individuals may express relief at the predictability of the treatment frame and boundaries, even as they may have other traumatic-transference based reactions to them. Calm, educative, non-blaming interpretation of the patient's fears

over the perceived inevitability of boundary violations is preferable to enacting them.

The ISSTD Guidelines, the expert survey, and the TOPDD study all converge to discourage boundary-crossing activities, even if the patient insists that only these interventions will help, and/or particularly help specific self-states, such as child states that are portrayed as needing concrete demonstration of love from someone. Particularly, the therapist may be asked to hold or hug the patient, hold the patient's hand, or other types of physical contact. Rather than acting on this, the clinician should inquire if some self-states are distressed at the idea of this physical contact, as "nice" touching may have evolved into traumatic abuse in the patient's reported history. Then, the issue is a therapeutic discussion of the meaning of the request and the patient's profound conflict about it.

It is not recommended that the clinician accept more than a token gift such as a card or a small piece of artwork; give the patient gifts; routinely contact the patient while on vacation; engage in out-of-office contact with the patient, such as going for walks and/or going out for coffee; and screen the patient's voice mailbox for calls from reported perpetrators, among many other potentially boundary-crossing behaviors. Clinicians who feel overwhelmed by the treatment of these patients are more likely to accede to the patient's insistence on these sorts of actions. It is important to recognize that the patient's reported history of abuse often involved being special to the abuser in some way. Thus, these boundary transgressions recreate this double-edged situation for the patient. Once again, education of the patient about boundaries is the most helpful clinical strategy.

Many of the clinical and conceptual issues that help make treatment workable with these patients are not taught in standard training programs for mental health professionals. The ISSTD has a series of courses on diagnosis and treatment of dissociative disorders that can be accessed at www.isst-d.org. Consultation with experienced clinicians should be considered by clinicians who are new to working with this patient population, and/or if stalemates or seemingly unsolvable predicaments develop in treatment.

Interventions for Safety and Stability: Containment, Grounding, and Imagery Techniques

The expert consensus recommends that use and teaching of grounding techniques begin in stage 1 and continue through subsequent stages.

Grounding may include a variety of interventions that begin in therapy but are practiced independently by the patient outside of sessions. Grounding may include having the patient change positions, open their eyes, use their five senses to become more aware of current circumstances: touch an object, such as the arms of the chair, keep their feet on the floor, and look around the room. If the patient enters a severe dissociative flashback, the therapist may literally have to orient the patient to the date, place, and circumstances, including the name and profession of the clinician. Grounding can also assist the patient with the confusion, fear, and dysphoria that occurs with overlap and interference among self-states as well as help the patient maintain state stability to prevent dysfunctional switching.

In all but the last stage of treatment, expert consensus suggests that the patient develop containment skills for traumatic material. These interventions help the patient use dissociative defenses more adaptively. Patients may oscillate from feeling “all shut down” to overwhelming intrusion of trauma material. The patient can be taught that containment is different than shutting down. It involves a voluntary psychological sequestration of trauma memories or overwhelmed self-states until these can be worked with in a gradual way later.

With the onset of treatment, most expert therapists rapidly introduce grounding and containment skills for symptom management. This necessitates active structuring of sessions to work on containment of severe symptoms and skills-building. Containment techniques include teaching self-hypnosis (only if the clinician is credentialed in the use of hypnosis) and imagery to control the intrusiveness of traumatic material (see discussion on hypnosis). These techniques use patients’ high dissociative and hypnotic capacity to assist their dissociative defenses to become more flexible and adaptive. This may involve imagery techniques to attenuate the intensity of PTSD, somatoform, and dissociative symptoms; successful stabilization of self-states that embody or are experienced as creating symptoms; and encouragement of collaboration, communication, and empathy among self-states. Experienced clinicians work to attenuate the impact of PTSD intrusions rather than opening this material prematurely. Imagery interventions also may include ego-strengthening (i.e., interventions to promote better overall functioning); calming imagery such as safe-place imagery; imagery for sequestration and/or attenuation of difficult material such as flashbacks; reaffirming

statements; relaxation training; and cognitive-behavioral work to change trauma-based cognitions.

Given the consistency of strategies recommended by experts, the authors of the expert survey concluded that these interventions make up the core treatment processes and structure for treating dissociative identity disorder. The consistency of the recommendations in the expert survey and the ISSTD Treatment Guidelines, as well as results of the TOPDD studies, indicates that there is now an evidence-based standard of care for the treatment of dissociative identity disorder.

Responsibility for Recovery. The clinician should be clear that the ultimate responsibility for symptom and behavioral management outside of sessions lies with the patient, who is viewed as an active partner in the treatment. In general, if not immediately, patients with dissociative identity disorder respond well to taking more active responsibility for safety or behavioral control between sessions. The therapist may prescribe homework for the patient to work on symptom management and internal communication between sessions. These strategies are usually essential in countering the patient's tendency toward regression and demoralization. Patients often use journal writing as a helpful adjunctive treatment strategy that allows more controlled expression and communication among self-states, fulfillment of homework assignments, and a more attenuated and distanced way of handling overwhelming subjective experiences.

Trauma-Focused Cognitive-Behavioral Interventions. Individuals with dissociative identity disorder may experience many cognitive errors and distortions based on traumatic life experiences and the ability of dissociation to interfere with reality testing. These include basic misattribution of causality: "I caused my father to abuse me"; de-catastrophizing (minimizing violent physical discipline as appropriate), and catastrophizing (a minor disappointment becomes a matter of survival); trauma-based doublethink (e.g., "sex is love," "anger is violence," "self-assertion is mean," "hurting myself makes me safe," and many others).

Other cognitive distortions include the insistence on delusional separateness and delusional disorientation to time and place (i.e., self-states insist that they do not inhabit the same body and are unaffected by harm that comes to it; and that self-states literally exist in a different time or place, respectively); that the patient is helpless to control themselves and requires the clinician to manage all difficulties; that the clinician is

completely untrustworthy and must not be allowed any access to the patient's mind; since love and sex are the same, and because trauma and abuse are inevitable, it is best to invite them or enact them oneself, so that at least their timing, intensity, and shamefulness can be better controlled.

Many cognitive distortions are only slowly responsive to cognitive therapy techniques, and successful cognitive interventions may lead to additional dysphoria and sometimes explosive, intrusive PTSD symptoms. Behind these cognitive distortions frequently lie exceptionally painful realizations and recollections. For example, if the patient gives up the idea of blameworthiness for childhood maltreatment, the reality must be faced that beloved relatives have done the patient grievous harm—have treated the patient as a hated object, not a person. This may lead to flood of flashbacks embodying this reality.

Transference and Countertransference. Individuals with dissociative identity disorder manifest a complex multilayered transference, as "whole human beings," system(s) of self-states, and individual self-states. Transference is dominated by themes of trauma and abuse, with the therapist seen as (in alternation) perpetrator, rescuer, victim (with the patient as a—typically disguised—perpetrator), or unconcerned bystander/witness. Individuals with dissociative identity disorder commonly suffer from the deep-seated, betrayal-based assumption that there are only three outcomes of attachment: exploitation, abandonment (if the person is not abusive), and/or both. Interactions may subtly recreate themes from the patient's history of attachment-based maltreatment. Individuals with dissociative identity disorder in a *flashback transference* may literally envision the clinician as the embodiment of an abusive figure from the past, requiring active interventions to help the patient separate the past from the present. Interactions in therapy may unconsciously reenact themes from the patient's experiences with malevolent, often sadistic, attachment figures.

Countertransference responses typically involve similar posttraumatic and dissociative responses with, at times, almost uncanny symbolic repetition of past interactions the patient describes with people from childhood. Classically, the inexperienced clinician may begin as an over-involved rescuer for the patient. When this inevitably fails, the clinician may feel exasperated, overwhelmed, de-skilled, and ashamed. The therapist may then develop a detached, hostile skepticism, and/or (often abrupt) discontinuation of treatment. In the best case, the clinician seeks expert

consultation, training, and education about diagnosis and treatment of dissociative identity disorder. The therapist learns that these dynamics—reminiscent of intrusion and numbing in PTSD—are represented by self-states in conflict about these issues, and are best worked with by exploration of these conflicts.

Clinicians may experience countertransferential autohypnotic and dissociative phenomena during dissociative identity disorder treatment that need to be recognized and managed. Education about hypnosis may help the clinician identify and manage these experiences. Secondary PTSD and burnout have been reported for therapists and treatment teams working with patients with dissociative identity disorder unless adequate attention is paid to limit-setting, boundaries, and assistance to clinicians adversely experiencing reports of extreme abusive trauma or being overwhelmed by work with these patients.

Affect Regulation/Shame. As described above, innate affect theory is a helpful framework for viewing the experience of the individual with dissociative identity disorder as well as the structure of the inner world of the self-states. The four components of a “compass of shame” include “attack self,” “attack other,” “avoidance,” and “withdrawal.” Shame affects and “shame scripts” may dominate the psychic life of patients with dissociative identity disorder. As noted above, Richard Kluft has developed a typology of dissociative identity disorder self-states that links their characteristics to one or more of the poles of the shame compass. Kluft suggests that avoidance of difficult material in dissociative identity disorder is frequently related to hidden shame scripts. In many instances, the dissociative patient is not amnestic, but profoundly inhibited by shame avoidance from discussing important material. Expert consensus agrees that systematic attention to shame allows for improved negotiation of many difficulties and potential impasses in the treatment of dissociative identity disorder.

Stage 2 Phasic Trauma Treatment: Work on Traumatic Memories. For patients who stabilize and form a reasonable working alliance in treatment, longer-term treatment goals involve the detailed, affectively intense, psychotherapeutic processing of life experiences, especially traumatic experiences, and the transformation of the meaning of these experiences for the individual. Authorities emphasize that, in most cases, intensive, detailed psychotherapeutic work with traumatic memories should

only be initiated after the patient has demonstrated the ability to consistently maintain safety, to use symptom management skills independently, that the self-state system can work together in a reasonably cooperative way, and after a solid therapeutic relationship has been established.

The patient should be able to give informed consent and have a realistic understanding of the potential risks and benefits of intensive focus on traumatic material. Potential risks may include temporary, acute worsening of PTSD; affective, somatoform, and self-destructive symptoms; and short-term interference with daily activities. Long-term benefits may include significant amelioration of dissociative and PTSD symptoms, decreases in subjective self-division, fusion of self-states, and freeing of psychological energy for daily life. The patient must be able to understand that the goal is integration of dissociated thoughts, feelings, recollections, and perceptions, not the exhumation or expulsion of memories per se. As with other traumatized patients, particularly during this treatment phase, grieving becomes a major issue. Grieving may focus on the necessity of viewing early relationships differently but also on the losses engendered by the individual's life trajectory. These include losses of a normal childhood and adolescent development; loss of potential educational, work, and family life precluded by the posttraumatic/dissociative life trajectory; loss of relationships with important others; and a sense of "wasted" years seeking and undergoing the rigors of this type of treatment.

Furthermore, the patient should not be in the midst of an acute life crisis or major life change, comorbid medical and psychiatric disorders should be stabilized, they must have the ego-strength and psychosocial resources to withstand the rigors of the process, and there must be adequate resources, such as support by significant others and, potentially, support for additional sessions. Many of these are listed in Table 20–21 (see also Table 20–22. Contraindications to Stage 2 Work). The clinician must also have the skills to work in this phase of treatment, and have the time, availability and resources for more intensive work and need for possible emergency contacts (e.g., not about to leave on a long vacation; not in a particularly stressful life-space, etc.).

Table 20–21.
Therapeutic Considerations for Stage 2 Phasic Trauma Treatment in Dissociative Identity Disorder (See also Table 20–22 on Contraindications for Stage 2 Memory Integration Work)

Patient has achieved the goals of earlier stages, including
- Basic acceptance of diagnoses, trauma issues
- Ability to maintain safety despite stress
- Basic understanding of the importance of safety
- Reasonable level of empathy, internal communication, coordination, collaboration/noninterference among self-states
- Demonstrated ability to independently use symptom management/containment strategies
- Mapping of self-state system gives basic view of major self-state groups/types
- Basic stabilization of paradoxically protective angry, “persecutory” self-states
- Adequate therapeutic alliance
- Severe dysregulated PTSD controlled
- Uncontrolled, dysfunctional switching absent, infrequent, or reasonably easily contained
- Rational motivation for engaging in the process
- Reasonably stabilized life circumstances
- Presence of interpersonal supports (and how to manage if limited or nonexistent)
- Stable comorbidities, both psychiatric and medical
- Adequate ego strength to undergo this process without major decompensation
- The therapist is prepared in both availability, skills, and ego strength to work with/tolerate the material

Data from Kluft RP, Loewenstein RJ. Dissociative Disorders and Depersonalization. In: Gabbard GO, ed. *Gabbard’s Treatment of Psychiatric Disorders*. 4th ed. American Psychiatric Press; 2007.

Table 20–22.
Contraindications to the Memory—Integration Phase of Amnesia Treatment (see also Table 20–21)

Has not achieved stable safety from nonsuicidal self-injury, suicidality, high-risk behaviors; eating disorders; lack of adequate food, clothing, shelter, medical care, etc.
Current substance use disorders or dependence
Has not achieved symptom stabilization
Severe, uncontrolled, intrusive posttraumatic stress disorder symptoms
Extreme PTSD avoidance symptoms
Severe, uncontrolled dissociative symptoms (dysfunctional switching, intractable internal conflict, fugue episodes, etc.)
Dysregulated mood symptoms (e.g., mania, bipolar depression)
Self-state systems do not engage in adequate internal communication, cooperation, coordination; severe lack of internal empathy
Inadequate therapeutic alliance
Current abusive relationship
Acute life crisis or times of life transition (divorce, job change, completing Ph.D., etc.)
Other potentially problematic life circumstances (e.g., has small children at home, limited child care, etc.)
Severe physical illness or infirmity
Severe personality disorder symptoms (e.g., antisocial features)
Comorbid psychosis, severe regression
Unrealistic idea of purpose of Stage 2 work (e.g., “Then I’ll know the truth”; “So I can sue my parents”; “I’ll get rid of all the memories,” etc.)
Current involvement in litigation
Impending absence of therapist

Adapted with permission from the *Treatment of Psychiatric Disorders*. 3rd ed. Vol 2. American Psychiatric Association; 2001.

Experienced clinicians attempt to carefully structure affectively intense sessions focused on traumatic material, with attention being given to affect modulation, re-stabilization of the patient before concluding the session, and reasonable availability to assist the patient supportively between sessions. In addition, many sessions may be needed to explicate fully the cognitive and emotional meaning of traumatic events so they become

integrated into a nondissociative, non-flashback autobiographical memory narrative.

TRAUMATIC MEMORIES. Media attention and legal cases have led to concerns over the authenticity of traumatic recollections of patients with dissociative identity disorder. Recent rigorous case series have supported the experience of clinicians, who have found corollary information to corroborate these patients' recollections or who have even unearthed data about traumas that the patient does not recall. Based on corollary information, however, some individuals with dissociative identity disorder can misinterpret and misrepresent contemporary information or confabulate aspects of their history. In addition, dissociative patients are hardly immune to ordinary human emotions, such as greed, envy, wishes for revenge, wishes to evade consequences for misbehavior, and desires to placate significant others. All of these may complicate the patient's veracity, especially in situations of potential financial gain, media attention, legal cases, and possible loss of family contacts, among others. Collateral informants, such as family members, may be subject to the same sources of unreliability as the index patient and their input should be weighed accordingly. The concern about "false" trauma memories does not extend to concern about "false" *non-trauma* memories, as perpetrators typically threaten victims to remain silent and/or, after an episode of rape, may tell them that "nothing happened… You won't remember what happened," and so on.

Typically, individuals with dissociative identity disorder oscillate from regarding their recollections as all true or all false. Self-states may take opposing positions. In the absence of reliable collateral information, the clinician is best served by maintaining a neutral stance toward the patient's recollections of their life by neither "believing" nor "disbelieving" a given memory report, other than questioning recollection of clearly impossible events (e.g., alien abduction). It is generally most helpful for the clinician to identify for the patient their internal conflicts over the veracity of recollections and to invite an open airing of all points of view. Repeated discussion of the complex factors that may impact autobiographical recall typically is part of an ongoing informed consent process as treatment progresses.

The therapist should respond respectfully and thoughtfully to all clinical material brought by the patient. Patients can be helped not to come to premature closure about their views of past events. Some individuals with

dissociative identity disorder come to understand life events differently as they become less dissociative over the course of treatment. This is another reason that clinicians must avoid validating memories for the patient or dismissing them out of hand. Therapy is most successful for the patient if the clinician maintains the role of therapist to help the patient make sense of their autobiography, not personal advocate, detective, or derisive skeptic.

Stage 3 Phasic Trauma Treatment: Fusion, Integration, Resolution, and Recovery. Over the course of treatment, significant unification of dissociated mental processes may be observed. Self-states lose distinctness and decrease compartmentalization of thoughts, memories, and affects. The patient develops a more unified sense of self. Transference is modified consistent with these changes. Amnesia and switching become less apparent. Fusion of states results in psychological merging of two or more entities at a point in time, with a subjective experience of loss of all separateness. The term *integration* is sometimes used synonymously with *fusion* but is more generally defined as the process of undoing all forms of dissociative division during treatment. Some patients proceed to what appears to be a complete fusion of all states, with a shift in self-representation from that of an individual with dissociative identity disorder to one with a consistent and continuous sense of self across all behavioral states. Many patients never attain a complete fusion of their personalities but achieve a therapeutic *resolution:* improved communication, collaboration, and cooperation among self-states leading to relative stability and adequate function.

As this integrative process occurs, PTSD symptoms usually improve significantly. Patients often experience a freeing of energy toward everyday life and away from trauma-focused ways of living. Cognitive distortions frequently substantially subside. At the same time, nondissociative and integrative coping strategies must be identified and substituted for dissociative responses to life stressors. The patient must be helped to connect and cope with the larger world in a more functional manner.

Hypnosis. Hypnosis is a set of techniques that facilitate treatment, not a treatment in and of itself. Because of the high hypnotizability and autohypnotic states of the patient with dissociative identity disorder, all treatment of this disorder involves hypnotic phenomena. Clinicians working with this population should obtain training in hypnosis, if only to recognize

spontaneous, autohypnotic processes that may be readily observable during treatment, as well as specialized training in hypnosis for traumatized and dissociative individuals. Hypnotherapeutic interventions can often alleviate self-destructive crises or reduce symptoms, such as flashbacks, dissociative hallucinations, and passive-influence experiences. These interventions usually act far more robustly and rapidly than medications, particularly as crisis interventions. It is important that patients be taught to use these techniques independently of the therapist, often by having several self-states become “internal” hypnotherapists. In addition, teaching patients self-hypnosis usually gives them a sense of control over lifelong autohypnotic experiences that have bewildered and overwhelmed them. Hypnosis is also used to create relaxed mental states in which negative life events can be examined without overwhelming the patient’s “window of tolerance.” Clinicians should be aware of current controversies over the impact of hypnosis on accurate reporting of recollections and should use appropriate informed consent for its use. Expert consensus on hypnotherapy for trauma disorders opines that the patient should receive psychoeducation that any memory material emerging during hypnotic interventions should not be viewed differently than any others that emerge during treatment: they may be essentially veridical, partially accurate, or completely confabulated.

Psychopharmacological Interventions. Guidelines for the use of medications with dissociative patients emphasize the need to identify specific treatment-responsive symptoms rather than attempting to treat symptoms of pathologic dissociation per se, as no medication(s) have been shown to be effective for this indication. Medications may be helpful in attenuating symptoms to assist the patient in stabilizing during treatment. Patients should be advised that medication response is likely to be partial, devising the best “shock-absorber” system for the patient at a given time. In general, success is more likely if the target symptoms for the medication are present across most or all self-states rather than confined to one or a few. Because many individuals with dissociative identity disorder lead stressful lives, and psychotherapy for the disorder may also be stressful, rapid symptom oscillations are common. In general, it is not advisable to chase each symptom shift with a medication change. Expert consensus states that it is preferable to change medications in response to shifts in the psychological “climate,” not the day-to-day alterations in the

psychological "weather." Medications and medication targets are listed in Table 20–23.

INFORMED CONSENT FOR PSYCHOPHARMACOLOGICAL INTERVENTIONS. Individuals with dissociative identity disorder require psychoeducation about which symptoms are likely to be medication responsive, the partial nature of medication effects for most comorbid disorders, and that even relatively robust medication effects may appear to be overwhelmed by severe stress—although without the medications, the patient may fare considerably worse during a crisis. These patients respond best if treated like a partner in evaluating the use of medications and medication response, with the physician as expert consultant, rather than in a more authoritarian stance.

Some individuals with dissociative identity disorder have an addiction-like affinity for medication that they use to attempt anesthesia for all psychological distress. These patients may be reluctant to accept the shock-absorber model of psychopharmacology and struggle against the psychiatrist's attempt to keep the medication regimen as rational and simple as possible. They may come to treatment on complex, extensive polypharmacy regimens that may include a plethora of psychoactive medications including medications for psychiatric disorders, sleep, pain, and medical disorders. Much effort may be required to simplify these regimens, especially as the patient learns more effective psychotherapeutic and symptom-management interventions.

On the other hand, some individuals with dissociative identity disorder report being drugged during abuse and have self-states that are phobic of taking medications. Considerable effort may then be required to educate the patient that medications are tools that potentially could be used for either good or malign purposes; it is how and why they are used that is important to assess. The patient can be asked to risk taking medications as prescribed, and to report honestly about medication effects, so that medication response and adverse effects may be better distinguished from posttraumatic reactivity. Without this process, the psychiatrist may later come to learn that the patient has been partially or fully nonadherent. Individuals with dissociative identity disorder often fear that medications may be used coercively; now that the psychiatrist controls something the individual depends on the psychiatrist can now demand "something" in return. In addition, the "need" for medications may symbolize the patient's sense of need and attachment as inherently humiliating and dangerous.

Psychoeducation may help alleviate the individual's concern about the psychiatrist exerting "control" through medications. The psychiatrist only writes a prescription, they do not control all the next steps involved in the patient getting the medication from the pharmacy, taking it home, taking it as prescribed, and honestly reporting back to the psychiatrist.

If the psychiatrist is working as a medication manager alongside a nonphysician psychotherapist, it is important to maintain communication about the patient. The therapist should let the psychiatrist know about issues that may be affecting symptoms, such as an acute loss or life crisis. In turn, the psychiatrist should inform the therapist about medication changes that may have an impact on the psychotherapy and that the therapist can assist in assessing. Education of the therapist about the role of medications in dissociative identity disorder is important as well. It is key for the medicating psychiatrist to attend to issues of boundaries and treatment frame. It is vital that the patient have only *one* primary therapist and that the psychiatrist not become an additional therapist who sees the patient frequently (e.g., once weekly) unless major medication changes require more intensive contact. In addition, the psychiatrist should be clear that they are only available for medication/medical emergencies and not be seen as the designated emergency back-up if the patient cannot reach the therapist during a psychotherapy or safety crisis. Also, the medicating psychiatrist should be clear about their availability for back-up during the therapist's absences, and only assume this role after specific agreement.

Table 20–23.
Medications for Associated Symptoms in Dissociative Identity Disorder

Medications and somatic treatments for PTSD, affective disorders, OCD, etc.

Alpha-Adrenergic Blocking Agents

Prazosin (Minipress) helpful for PTSD nightmares, and flashbacks, if patient can tolerate BP symptoms. Patients may require up to 20–25 mg daily for maximal effect with divided daily dosing for daytime flashbacks/intrusive symptoms. Time of administration can be adjusted, e.g., patient has a period with severe intrusive symptoms in the afternoon.

Doxazosin (Cardura) also useful for this indication and may help with daytime symptoms with single daily dosing—may require 10–16 mg daily.

Clonidine (Catapres) Less consistently helpful than prazosin/doxazosin.

β-Blockers (for PTSD hyperarousal symptoms; if giving both β-blockers and α-blockers, give α-blocker first to prevent reflex tachycardia)

- Selective Serotonin/Selective Serotonin/Norepinephrine Reuptake Inhibitors (no preferred agent, except for OCD symptoms); these medications mostly provide a partial, "shock-absorber" anti-depressant response; rarely effective for PTSD in this population. There are no data on antidepressant augmentation strategies in this population. The authors' experience is that this patient population rarely responds to this; other experts disagree. Response likely to be small.
- Fluvoxamine (Luvox) (for OCD presentations)
- Clomipramine (Anafranil) (for OCD, if patient is safe enough to take a TCA)
- Other tricyclic antidepressants
- Monoamine oxidase inhibitors (if patient can reliably maintain diet safely)
- Mood stabilizers (*more useful for PTSD and anxiety than mood symptoms*)
  - Lamotrigine (Lamictal) (may help with depressive symptoms more than others)
  - Carbamazepine (Tegretol)
  - Divalproex (Depakote)
- Benzodiazepines
  - Clonazepam (Klonopin) and lorazepam (Ativan) have best track records

- Atypical neuroleptics
  - Ziprasidone least likely to cause weight gain: a major issue for many dissociative patients.
  - Clozapine for patients with mixture of psychotic and dissociative symptoms; very severe almost delusional cognitive distortions
  - Typical Neuroleptics, e.g., Perphenazine
- Medications for acute dyscontrol
  - Oral or intramuscular neuroleptics
  - Oral or intramuscular benzodiazepines
- Medications for sleep problems
  - Trazodone (Desyrel) (high margin of safety; rareantidepressant effect at antidepressant doses, i.e., 1,000–1,500 mg. daily)
  - Low-dose mirtazapine (Remeron)
  - Low-dose tricyclic antidepressants
  - Low-dose neuroleptics
  - Benzodiazepines, Zolpidem (Ambien) (often less helpful for sleep problems in this population)
  - Anticholinergic agents (diphenhydramine [Benadryl], hydroxyzine [Vistaril])
  - Melatonin and congeners sometimes effective
- Medications for nonsuicidal self-injury, addictions
  - Naltrexone (ReVia)

Limited data on electroconvulsive treatment (ECT); best for “double depression” presentation, not for baseline, long-term “mood” issues (see text). No data on other brain stimulation techniques, ketamine infusion, etc.

OCD, obsessive-compulsive disorder; PTSD, posttraumatic stress disorder.

Target Symptoms for Medications in the Treatment of Dissociative Identity Disorder-PTSD Symptoms. The most robust medication treatment effect in this patient population is the response of nightmares to α_1-adrenergic antagonists, most commonly prazosin (Minipress) in a wide dose range, as documented in many studies, primarily of patients with combat-related PTSD. Clinical experience suggests that these medications are more effective in patients with more severe PTSD symptoms. If the patient tolerates the blood pressure effects, research in combat-related PTSD finds that dosages of prazosin as high as 18 to 25 mg daily (in

women and men, respectively), in single or twice-daily doses, are effective for this indication. Daytime dosing may also be helpful for control of flashbacks and intrusive symptoms. Recent studies show that doxazosin (Cardura), a longer-acting α_1-adrenergic antagonist, may also be effective for nightmares and intrusive symptoms in PTSD. In addition to prazosin/doxazosin, a variety of medications are helpful as adjunctive agents to help with sleep problems. These are listed in Table 20–23.

Nocturnal PTSD symptoms in this population, and in other patients with complex trauma disorders, may be complicated by posttraumatic reactivity related to reported nocturnal physical and sexual abuse; then, nighttime, the bedroom, being in bed, and even sleep itself may be experienced as posttraumatic triggers. Patients may report being drugged during these attacks, compounding the phobia of bedtime medications in some self-states, while other self-states describe desperation to find an anodyne for sleep problems). Also, patients may report that some self-states “stay up” to protect the patient from possible abuse and/or emerge nocturnally, often in the early morning hours, as this was the only time the patient felt safe enough to allow awareness of internal experience. Because of these issues, some self-states may attempt, usually successfully, to psychologically override the beneficial effects of medications or to refuse to take medications at all. These issues require psychoeducation about nocturnal PTSD triggers; cognitive behavioral interventions (e.g., attempts to decrease posttraumatic responses to these phobic stimuli and to help the patient separate past from the present); internal communication around conflicts between self-state groups about medication; and symptom-management techniques (e.g., finding a “safe place” to sleep for traumatized self-states before the patient attempts go to bed; finding a more adaptive way for self-states to “guard” against feared nocturnal attack, etc.). Patients should begin work on these issues several hours before bedtime.

Other medications have shown to be efficacious for PTSD symptoms in double-blind studies of PTSD patients. These include the selective serotonin reuptake inhibitors (SSRIs) sertraline (Zoloft) and paroxetine (Paxil), the tricyclic antidepressant (TCA) desipramine (Norpramin), and the monoamine oxidase inhibitor (MAOI) phenelzine (Nardil). Unfortunately, most medication studies of PTSD do not include patients with suicidal ideation, multiple comorbid disorders, and substance abuse and thus may have limited ecologic validity for complex trauma patients.

Experts in psychopharmacology for this population have not found robust efficacy for the antidepressant medications for comorbid PTSD symptoms although, as discussed below, these medications may help ameliorate some mood disorder symptoms in these patients.

Other medications for PTSD symptoms that can have efficacy in reducing intrusive symptoms, hyperarousal, and anxiety in patients with dissociative identity disorder include β-blockers such as propranolol (Inderal), other α_1-adrenergic antagonists like clonidine (Catapres), anticonvulsants such as lamotrigine (Lamictal) and carbamazepine (Tegretol), and typical and atypical neuroleptics. One small study showed that risperidone was efficacious for intrusive PTSD symptoms in complex PTSD patients. However, since the response of PTSD, anxiety, and panic symptoms to these medications is usually relatively limited in patients with dissociative identity disorder, the psychiatrist and patient together should carefully balance the potential risks (e.g., metabolic syndrome) against the potential benefits of these medications.

Many patients with dissociative identity disorder report some response to benzodiazepines such as lorazepam (Ativan) or clonazepam (Klonopin) for posttraumatic fear, panic, anxiety, and sleep problems. These patients may tolerate higher doses of these medications than many nondissociative patients. The clinician should educate the patient that severe PTSD involves states of terror, not anxiety. Thus, limited response to anti-anxiety medications is the rule. Careful monitoring of patients on benzodiazepines is necessary to assess tolerance and compulsive drug-seeking behaviors. Gradual tapering of these medications is essential to prevent withdrawal symptoms.

Target Symptoms for Medications in the Treatment of Dissociative Identity Disorder-Mood Disorder Symptoms. As described above, patients with dissociative identity disorder commonly have a complex negative mood state, often described as depression, but with elements of many other negative affective states (e.g., profound shame, grief, distress over ongoing stressful life events, the severely dysphoric impact of PTSD). These patients commonly describe themselves as having been depressed for their “whole life.” Nonetheless, antidepressant medications, including SSRIs, selective serotonin/norepinephrine reuptake inhibitors (SNRIs), TCAs, and MAOIs are often important in the partial reduction of depression and stabilization of mood. The psychiatrist should take a careful history of the mood symptoms and question the patient about other affects such as

shame, sadness, and grieving; in addition, the psychiatrist should educate the patient that complete remission of the depressive symptoms is unlikely and about the shock-absorber nature of medications. In general, expert consensus has shown that no antidepressant is likely to be any more effective than any other in this population. Somatic treatments for mood disorder symptoms in dissociative identity disorder patients may be most effective in a "double depression" clinical picture although somatic treatments typically return the depressed mood back to the patient's usual chronic negative mood state.

A subgroup of patients with dissociative identity disorder experiences marked obsessive-compulsive symptoms (OCD) and may preferentially respond to antidepressants such as fluvoxamine (Luvox) and clomipramine (Anafranil). During the clinical evaluation, clinicians should always assess patients for the presence of OCD symptoms.

In general, unless the patients describe more clear-cut, sustained, hypomanic or manic episodes, they infrequently respond to mood stabilizers, especially lithium. If they describe more typical bipolar depression symptoms, usually these too will follow the double depression pattern of treatment response.

OTHER TARGET SYMPTOMS FOR MEDICATIONS IN THE TREATMENT OF DISSOCIATIVE IDENTITY DISORDER. Case reports suggest that aggression may respond to carbamazepine in some individuals with dissociative identity disorder if EEG abnormalities are present. Open-label studies suggest that naltrexone (ReVia) may be helpful to ameliorate recurrent self-injurious behaviors and other compulsive, quasi-addictive high-risk behaviors in a subset of traumatized patients. This medication may be helpful in reducing relapse in patients with dissociative identity disorder who have significant substance abuse issues.

Questions are often raised about the efficacy of neuroleptic medications, particularly for symptoms such as hallucinations. Expert consensus is that the hallucinations in patients with dissociative identity disorder almost never respond robustly to antipsychotics, as they are hypothesized to originate in dissociative, posttraumatic, and autohypnotic processes, not psychosis. Patients with dissociative identity disorder with a true comorbid psychotic disorder can sometimes distinguish between neuroleptic response to the "outside" psychotic voices and report lack of effect on the voices of the self-states. Occasionally, thought-disorganized, overwhelmed, chronically ill patients with dissociative identity disorder who

have not responded to trials of other neuroleptics respond favorably to a trial of clozapine (Clozaril).

Electroconvulsive Therapy, Repetitive Transcranial Magnetic Stimulation, and Ketamine Treatment. During their long psychiatric careers of misdiagnosis and treatment failure, many patients with dissociative identity disorder receive unsuccessful trials of ECT. This led to the view that ECT was not an effective treatment in this patient population. One small clinical study of severely depressed dissociative disorder patients, primarily with DSM-III-R dissociative disorder NOS, suggested that, for some patients, ECT was helpful in ameliorating refractory mood disorders and did not worsen dissociative memory problems as measured by the DES. Clinical experience in tertiary care settings for severely ill individuals with dissociative identity disorder suggests that a clinical picture of major depression with persistent, refractory melancholic features across all states may predict a positive response to ECT. As with medications, response to ECT is more likely in a double depression clinical presentation where melancholic symptoms develop as a distinct change from the patient's chronically depressed baseline. ECT response is usually only partial, as is typical for most successful somatic treatments in patients with dissociative identity disorder and returns the patient to their more usual mood state.

There are no data in this population on response to transcranial magnetic stimulation, ketamine infusion, or Esketamine treatment. The authors' clinical experience in a few cases is that none of these treatments were effective for refractory depression or suicidality in dissociative identity disorder individuals. A severely depressed, highly suicidal individual with dissociative identity disorder—who had failed trials of appropriate staged psychotherapy, multiple antidepressants and/or mood stabilizers, and multiple courses of ECT—died by suicide during a trial of ketamine infusions. However, the suicide could have been related, not to ketamine, but to the patient's despair over lack of response to this "last-resort" treatment, as well as ongoing, severe psychosocial stress. As in other cases, ketamine treatment was not associated with worsening of dissociative symptoms.

Inpatient Treatment. As with patients with other psychiatric diagnoses, inpatient hospitalization is most used for treatment of acute worsening of baseline unsafety, typically accompanying a major destabilization. Most

dissociative identity disorder individuals experience self-destructive and suicidal ideation/impulses at baseline. Thus, hospitalization returns the patient to their usual outpatient safety status and should not be expected to definitively resolve all safety issues.

Less commonly, in the age of managed care, hospitalization provides a safe environment for intensive work with painful affects and memories that cannot be safely managed on an outpatient basis despite intensive efforts. For several reasons, patients with overt dissociative identity disorder can have disruptive effects on the milieu of general psychiatric units and often stimulate division and conflict among staff about the best way to relate to the patient and the self-states. Typically, the split is between the believers and the skeptics, often paralleling larger societal debates, as well as the subjective conflict within the patient about belief in the dissociative identity disorder diagnosis and the authenticity of traumatic memories. Inpatient treatment on general hospital units is most successful if there is an attempt to bridge different opinions about dissociative identity disorder to focus on a unified approach for ameliorating specific target symptoms and restabilizing the patient to allow safe resumption of outpatient treatment.

Inpatient programs specializing in the treatment of dissociative and PTSD patients are more successful. They provide a unified treatment with a consistent approach to the patient's symptoms, prioritizing safety issues, often by resolution of internal conflicts and providing a safe environment to work with dangerous self-states; rigorous boundaries and firm limit setting, especially around responsibility for safety and behavioral dyscontrol; specific, active treatment interventions to assist with dissociative and PTSD symptoms; and an emphasis on helping the patient become proficient in symptom management skills, including skills for improved internal communication, cooperation, coordination, and empathy among self-states.

In both specialty and general hospital units, the patient should be expected to respond to their legal name, or at least one specific name, in the hospital milieu and in all therapeutic interactions, except individual psychotherapy/psychiatric rounds or individual interactions with designated hospital staff. The patient should be expected to be able to present in a reasonably functional adult mode in the hospital, with regressed, dysfunctional, or child states restricted to designated one-on-one encounters or private time in the patient's room. The patient is urged to seek their "inner adult" in this regard. The patient's activities in the hospital

(e.g., group therapy) should be limited to those in which the patient can participate while following these guidelines.

Trauma-Informed Inpatient Care. The concept of trauma-informed care has led to initiatives to reduce to zero the use of inpatient seclusion and restraint. Evidence shows that use of seclusion and restraint engenders heightened risk of injury to both patients and staff; alternatives to these improve the safety of psychiatric inpatient units. Seclusion and restraints can be psychologically traumatizing to patients (and sometimes to staff) as well as retraumatizing to traumatized patients by revivifying—often uncannily—prior traumatic experiences, including those in psychiatric hospitals. Trauma-informed care concepts involve attempts to understand symptoms—particularly those of dyscontrol/unsafety in the hospital—as logically related to prior traumatic events where the patient (and staff) is unaware of the connection between trauma and symptoms. Thus, interventions directed at these issues may provide a safe resolution to the situation, as well as the patient and treatment team gaining a comprehensible, nonpejorative framework for working on many problematic behaviors.

For example, a dissociative identity disorder inpatient repeatedly became dyscontrolled and engaged in nonsuicidal self-injury around the 3 PM shift change on a psychiatric unit, typically resulting in manual and physical restraint. On inquiry about whether there were any trauma reminders about the 3 PM shift change, she responded, “Yes, when I was 16, they put me in a state hospital for 6 months. Most days at 3 PM shift change, some orderlies would tie me up and rape in the quiet room.” This understanding allowed for work with self-states on “separation of past/present,” and symptom management skills around shift change, as well as other hospital-based trauma reminders. The dyscontrol episodes rapidly decreased to zero.

Hospital staff working in the trauma-informed model can educate patients about these initiatives and the importance for patients and staff of reducing use of restraint. Staff and patients can work to identify trauma-reminders and triggers, and anticipate these with development of safe, recovery-oriented methods to manage anticipated dyscontrol. Unfortunately, dissociative identity disorder inpatients may still become so unsafe that, when less restrictive alternatives have failed, hospital staff may be required to use these restraints to prevent escalating dangerous behavior. If restraints are needed, they should be used for the minimum

time needed to restore safety. After a restraint episode, processing the event is crucial (e.g., by using the DBT behavioral chain analysis or similar) to focus on making sense of these episodes, noticing early warning signs, and finding earlier interventions (e.g., relaxation techniques, “dialing down” and/or safe-place imagery, and oral prn medication, among others) to prevent symptom escalation.

Specialty units for dissociative identity disorder and related disorders use restraint much less frequently than general hospital units. Specialty unit staff is trained to help patients use symptom management and containment strategies to anticipate and manage potential crises. Inpatients with dissociative identity disorder in behavioral dyscontrol may also respond to as-needed oral dosages of atypical or typical neuroleptics with or without benzodiazepines.

If the dissociative inpatient shows a limited or transitory response to psychosocial interventions, and remains dangerously agitated and unsafe, oral and/or intramuscular prn medications may help decrease these symptoms and avoid more restrictive interventions. Single doses of oral or intramuscular neuroleptics may help manage acute dyscontrol by allowing a change in behavioral state. Options include 2 to 5 mg of haloperidol (Haldol) oral or intramuscular; 5 to 10 mg of oral, sublingual, or intramuscular olanzapine (Zyprexa); or 20 mg of oral or intramuscular ziprasidone (Geodon); with or without 1 to 2 mg of oral/intramuscular lorazepam (Ativan).

Discharge from hospital usually occurs when the patient with dissociative identity disorder has negotiated the acute crisis; has a realistic structure for outpatient safety consistent with discharge to the next level of care; has made adequate gains in symptom management skills and internal communication to handle problems more adaptively; medications have been adjusted to provide better treatment of comorbid disorders; and/or the outpatient psychosocial environment has restabilized sufficiently.

Partial Hospitalization. Partial hospital treatment can be an effective modality for the dissociative patient if clinical interventions target trauma-based issues and adaptations. Specialized partial hospital trauma programs with groups emphasizing symptom containment, cognitive and behavioral interventions, development of life skills, and psychoeducation can effectively help stabilize more severely and persistently ill dissociative patients as well as provide an intensive stabilization experience for higher-

functioning individuals. Patients with dissociative identity disorder frequently do not respond positively to more usual partial hospital programs developed for patients with psychotic and/or mood disorders.

Adjunctive Treatments

GROUP THERAPY. Authorities agree that, in therapy groups including general psychiatric patients, the emergence of self-states can be disruptive to the group process by eliciting excess fascination or by frightening other patients. Therapy groups composed only of patients with dissociative identity disorder are more successful, although the groups must be carefully structured, must provide firm limits, and should generally focus only on here-and-now issues of coping and adaptation. Some stabilized patients may be able to work effectively in process-oriented psychotherapy groups. Even so, it is important that there are firm boundaries and limits on group structure and contacts by patients outside of sessions; the intensity of trauma material that the patients can discuss be monitored; and that patients who become destabilized and unsafe may need to return to a group that focuses on symptom management and stability.

FAMILY THERAPY. Family or couples therapy is often important for long-term stabilization and to address pathologic family and marital processes that are common in individuals with dissociative identity disorder and their family members. Education of family and concerned others about the disorder and its treatment may help family members cope more effectively with dissociative identity disorder and PTSD symptoms in their loved ones. Group interventions for education and support of family members have also been found helpful. Family members should be discouraged from interacting with individual self-states, calling them out, and relating to them as separate individuals. Family members should be helped to support the patient's goal of becoming a functional adult in adult relationships and a functional parent to children. Sex therapy may be an important part of couples' treatment when the patient is more stabilized, as the patient may be triggered into flashback by sexual interactions and thus intensely phobic of intimate contact. Clinicians who work with these patients and their spouses on sexual issues should be trained to work with survivors of childhood sexual abuse and on the specific complexities of these issues for patients with dissociative identity disorder, including the patient's difficulty in excluding traumatized self-states from intimate interactions.

Family therapy with the individual's family of origin is often extremely distressing to patients with dissociative identity disorder. Some interactions with these family members may lead to an acute decompensation in the patient. Contacts should be carefully structured for defined therapeutic purposes, and the patient should be well prepared for potential adverse reactions. At the same time, such meetings may help clarify or resolve the conflictual emotions that patients frequently experience toward family members. "Confrontation" of family members about past traumas in an accusatory manner almost invariably has a disastrous outcome for the patient and the relatives. Before any such meeting, it is most helpful for the patient with dissociative identity disorder to clarify hidden fantasies about these interactions (e.g., "they're going to say they are sorry"), and how these are typically unlikely to occur.

Despite the description of intrafamilial maltreatment, some individuals with dissociative identity disorder maintain ongoing contact with members of the family of origin, including financial dependence. Clinical case series document ongoing incestuous abuse into adulthood—even middle age—by family members of individuals with dissociative identity disorder. Thus, the clinician should help identify possible lack of safety during these contacts and make this a major focus of treatment to help protect the patient. Typically, specific self-states are activated in this situation and other self-states are "off-line" and/or are unable to interfere. Apart from this or other lack of safety in contact with the family of origin, the clinician should focus on the individual's conflicts about the family and contact with them, also typically parceled out among self-states. If the individual with dissociative identity disorder is a victim of intimate partner violence, the clinician needs to take a similar approach. In both these situations, clinicians must be patient as there is usually intense, fear-based attachment to perpetrators.

DIALECTICAL BEHAVIOR THERAPY. DBT is a treatment developed by the psychologist Marsha Linehan for borderline personality disorder. Its concepts and techniques may be helpful to structure aspects of stabilization throughout dissociative identity disorder treatment since many patients with borderline personality disorder report significant trauma histories and fit the complex trauma construct. Helpfully for the patient with dissociative identity disorder, DBT focuses on the primacy of safety, therapy-interfering behaviors, affect regulation strategies, distress tolerance, and radical acceptance.

However, DBT also may have notable limitations for the patient with dissociative identity disorder. Many individuals with dissociative identity disorder report—often repeated—failed trials of DBT, as DBT treatment outcome studies show that dissociative individuals do not respond to unmodified DBT. DBT does not focus on stabilization and management of dissociative symptoms such as depersonalization/derealization and dissociative amnesia, flashbacks, and unconscious reenactments, traumatic transference, and related trauma-based symptoms. DBT does not address stabilization of the self-states' contribution to symptoms since resolution of many symptoms in dissociative identity disorder treatment can only occur in the context of work with the patient's self-state system.

EYE MOVEMENT DESENSITIZATION AND REPROCESSING. Eye movement desensitization and reprocessing (EMDR) is a treatment for posttraumatic disorders developed by the psychologist Francine Shapiro. In treatment outcome studies for PTSD, EMDR has similar efficacy to cognitive-behavioral therapy. However, patients with suicidality, substance abuse, and multiple comorbidities have generally been excluded from EMDR outcome studies, as in other treatment studies of cognitive-behavioral therapy and medications for PTSD. Dismantling studies have shown that the eye movements that distinguish EMDR from other therapies do not add to its therapeutic effect, although EMDR practitioners dispute this.

There are no systematic studies of EMDR in patients with dissociative identity disorder, although some case reports have been published. Experts in both EMDR and phasic trauma treatment of dissociative identity disorder have written an appendix to the standard text on EMDR and a section of the ISSTD treatment guidelines cautioning use of this modality in dissociative identity disorder treatment unless the patient is stabilized in stage 1 treatment.

Because EMDR has the significant exposure and free association components, in unmodified form this modality can cause significant harm to individuals with dissociative identity disorder. The lead author has considerable experience with adverse outcomes of EMDR when used in these patients during stage 1 of treatment or before even beginning stabilization in treatment. These outcomes have included severe posttraumatic and dissociative crises, suicide attempts, self-destructive behavior, and acute worsening of PTSD, dissociative, and mood disorder symptoms, often resulting in emergency hospitalization as well as long-term impairment.

The ISSTD Treatment Guidelines, clinical case series, and the EMDR text appendix state that clinicians may choose EMDR as an *adjunctive* treatment in some cases to allow the patient to process memories during stage 2 treatment. Specifically, for the clinician to practice EMDR with patients with dissociative identity disorder, the clinician must be knowledgeable and skilled in phasic trauma treatment, have completed advanced training in EMDR, and have received supervision in this modality for the treatment of dissociative identity disorder.

SELF-HELP GROUPS. Individuals with dissociative identity disorder usually have a negative outcome to self-help groups or 12-step groups for incest survivors, now often moved online. Most experienced clinicians, as well as the ISSTD guidelines, strongly discourage these patients from participating in these modalities. Complications include intensification of PTSD symptoms due to discussion of trauma material without clinical safeguards, exploitation of the patient with dissociative identity disorder by predatory group members, contamination of the patient's recall by group discussions of trauma, and a feeling of alienation even from these other reputed sufferers of trauma and dissociation. Negative outcomes for individuals with dissociative identity disorder using social media have been described in the section on History.

EXPRESSIVE AND OCCUPATIONAL THERAPIES. Expressive and occupational therapies, such as art and movement therapy, have proven particularly helpful in treatment of patients with dissociative identity disorder. Art therapy may help patients contain and structure severe dissociative identity disorder and PTSD symptoms, as well as allow for safer expression of thoughts, feelings, mental images, and conflicts that may be difficult to verbalize. Movement therapy may facilitate normalization of body sense and body image for these severely traumatized patients. Occupational therapy may help the patient with focused, structured activities that can be completed successfully and may help with grounding and symptom management.

Ms. V was a 33-year-old married woman who presented to psychiatric attention after discovering her 5-year-old daughter “playing doctor” with several neighborhood children. The patient began to become fearful that her daughter would be molested. She became increasingly obsessed with this idea, much to the bafflement of her husband. The patient was seen by her internist and treated with antianxiety agents and antidepressants, but with little improvement. Ms. V became increasingly anxious, phobic, depressed, and preoccupied. She sought psychiatric consultation from several clinicians but repeated, adequate trials of antidepressants, antianxiety agents, and supportive psychotherapy resulted in limited improvement. After the death of her father from complications of alcohol use disorder, the patient became more symptomatic. He had been estranged from the family since the patient was approximately 12 years of age, owing to his drinking and associated antisocial behavior. Ms. A developed a variety of somatic complaints, including headaches, abdominal pain, menstrual and gastrointestinal problems, back pain, and sleep difficulties. Repeated medical workup was unrevealing, leading to diagnoses of fibromyalgia, irritable bowel syndrome, and premenstrual tension. Family and marital difficulties increased, and work function deteriorated. Psychiatric hospitalization was precipitated by the patient’s arrest for disorderly conduct in a nearby city. She was found in a hotel, in revealing clothing, engaged in an altercation with a man. She denied knowledge of how she had come to the hotel although the man insisted that she had come there under a different name for a voluntary sexual encounter. On psychiatric examination, the patient described dense amnesia for the first 12 years of her life with the feeling that her “life started at 12 years old.” She reported that, for as long as she could remember, she had an imaginary companion, an older adult African American woman, who advised her and kept her company. She reported hearing other voices in her head: several women and children as well as her father’s voice repeatedly speaking to her in a derogatory way. She reported that much of her life since age 12 was also punctuated by episodes of amnesia: for work, for her marriage, for the birth of her children, and for her sex life with her husband. She also reported perplexing changes in skills and repeated experiences of sudden “blasts” of emotion that would appear and suddenly disappear, primarily anger, fear, and sadness. She described feeling that her thoughts were being removed

from her mind, especially when attempting to recall difficult issues in life. She reported experiencing saying things that felt out of her control: “My mouth has a mind of its’ own; my mind has a mouth of its’ own; my mind has a mind of its’ own!” At times, she reported automatic writing, as if her “hand is possessed” and different handwritings appeared without her control. Her husband noted that, at times, she would speak like a child; sometimes she would adopt a southern accent; and, at other times, she would be angry and provocative. She frequently had little recall of these episodes. Questioned more closely about her early life, the patient appeared to enter a trance and stated, “I just don’t want to be locked in the closet” in a child-like voice. Inquiry about this produced rapid shifts in state between self-states that differed in manifest age, facial expression, voice tone, and knowledge of the patient’s history. Gradually, with more communication from self-states, the patient recalled a history of family chaos, brutality, and neglect during the first 12 years of her life, until her mother, also alcoholic, achieved sobriety and fled her husband, taking her children with her. The patient began to recall episodes of physical abuse, sexual abuse, and emotional torment by the father, her siblings, and her mother. The self-states reported “piggy-backing” emotions, thoughts, impulses, and actions, leading to the experiences of passive-influence. This also explained “taking thoughts out of her head, that she isn’t supposed to know,” when the patient suddenly blanked on what was being discussed. The patient improved significantly with psychotherapy directed at stabilization of dissociative identity disorder and PTSD. She responded well to clomipramine (Anafranil) with a significant reduction in obsessive-compulsive and depressive symptoms. Family sessions with the patient’s mother and siblings confirmed much of the history, with the family recalling episodes of maltreatment that the patient did not recollect. The patient’s mother had bid the family never to speak of the earlier difficulties, hoping that everyone would “just forget the whole thing.” An older sister, who also had been severely abused, met diagnostic criteria for dissociative identity disorder. Other siblings had histories of substance use disorders, mood disorders, PTSD, and dyscontrol episodes. Family therapy was helpful in stabilizing the patient’s marriage and helping her husband with the aftermath of the hospitalization and its precipitants. The patient found adjunctive art therapy particularly effective. At 3-year follow-up, the patient reported fusion of most self-states and marked diminution in dissociative,

somatoform, and PTSD symptoms, although she still required clomipramine for stabilization of mood and OCD symptoms.

Dissociative Amnesia

The DSM-5-TR diagnostic criteria for dissociative amnesia emphasize that the disorder represents a recall deficit in *autobiographical memory* (some authorities [e.g., Staniloiu and Markowitsch—see below], using Tulving's model, prefer the term episodic-autobiographical memory [EAM]), particularly for traumatic and stressful experiences. As described in the prior sections, cumulative adverse experiences during childhood, particularly the extent and severity of childhood sexual and/or physical maltreatment, lead to increased deficits in autobiographical memory before age 18. To qualify for a diagnosis of dissociative amnesia, the amnesia cannot be better explained by medical, neurological, or substance use disorders, including a seizure disorder, transient global amnesia, head injury, or another neurocognitive disorder. The amnesia also cannot be better explained by dissociative identity disorder, ASD, PTSD, somatic symptom disorder, a psychotic or cyclic mood disorder, or acute intoxication. Dissociative fugue is conceptualized as a specifier of dissociative amnesia, not a separate dissociative disorder. Typically, in the dissociative fugue presentation the individual comes to clinical attention because of apparently purposeful travel or bewildered wandering that is accompanied by dissociative amnesia for identity and/or other important autobiographical information, including details of the travel the person has engaged in.

Studies with the MID find that the symptom of amnesia in the dissociative amnesia *disorder* is experienced as retrospective gaps and/or fragmentary memory of the individual's history that is too extensive to be explained by normal changes in autobiographical memory over the lifespan. Conversely, in dissociative identity disorder, amnesia includes *both* retrospective autobiographical memory disturbances and ongoing dissociative amnesia for current life. These include perplexing acquisition (or disappearance) of possessions (e.g., clothes, tools, weapons, items in one's grocery cart); inexplicable fluctuations in well-learned skills, habits, and knowledge (e.g., including finding evidence or being told of skills or habits about which the individual has no awareness); description of disremembered behavior; and/or ongoing episodes of dissociative fugue, among others.

What Is Dissociative Amnesia?

Dissociative amnesia can be broadly defined as a reversible autobiographical memory impairment in which groups of memories for personal experience that would ordinarily be available for conscious recall cannot be retrieved or retained in autobiographical memory (or, if temporarily retrieved, cannot be wholly retained in consciousness). This disturbance may be based on neurobiologic changes in the brain caused by traumatic stress. However, the disorder manifests as a potentially reversible form of psychological inhibition or retrieval deficit. Amnesia due to brain injury or cognitive disorders usually cannot be reversed, as is the case with most episodes of amnesia due to substance intoxication. On the other hand, a variety of clinical and experimental studies have shown state-dependent effects for some forms of memory retrieval with a variety of types of intoxicants (e.g., alcohol, barbiturates, amphetamines, marijuana) and with some mood state shifts (e.g., mania vs. depression). In these state-dependent/mood-state–dependent memory studies, reinstatement of context is important in demonstrating the phenomenon. Reinstatement of context, as well as cued retrieval, may be a factor in the recall of memories that have been subject to dissociative amnesia although, as described below, this usually comes in the form of PTSD intrusive symptoms and flashbacks, or highly emotion-filled recollections, not normal autobiographical recall.

Discrete Behavioral States Theory and Dissociative Amnesia

From the perspective of DBSs theory, dissociative amnesia represents complex examples of state-dependent/mood-dependent learning, memory storage, and retrieval. As discussed previously research shows that childhood autobiographical memory deficits (CAMD) involve memories of trauma as well as recall deficits for major aspects of everyday life whilst growing up with chronic interpersonal trauma. Autobiographical memory is fundamental for developing coherent, adaptive sense of self and identity. Accordingly, a major concomitant of dissociative amnesia is disordered, often limited, constricted self-states/systems. Metacognitive, autonoetic functions are also disrupted, as individuals with dissociative amnesia typically are impaired in making sense of themselves and their behavior. Missing, jumbled, and/or fragmentary memory impairs the ability to connect current thoughts, emotions, and behavior with past experiences. Because of dissociative amnesia, there may be unconscious reenactments. For

example, these individuals may be unable to recognize threat and terminate involvement with dangerous attachment figures, both from the childhood and/or adulthood. Individuals with dissociative amnesia often minimize the importance of their memory deficits (see case examples below) and avoid attempts to connect current life difficulties with their early life development.

During the "memory wars" of the 1990s and early 2000s, the debate polarized between a group that posited that "trauma memory is not forgotten, it is remembered all too well," and those who insisted that delayed recall for trauma occurred, often for years of an individual's life. Some of the debate can be understood as disagreement about the *mechanism* for delayed recall of traumatic experiences (e.g., repression, dissociation, ordinary forgetting, conscious withholding of information due to shame, or some or all of these). The DBS model, supported by a variety of clinical and experimental studies posits that *both* models contribute to the understanding of trauma memory. Overwhelming trauma can be encoded in memory, and recall can be inhibited/impaired by state-dependency. Trauma survivors commonly describe deliberate attempts to avoid thinking about trauma, and/or reluctance to share memories due to shame, attachment to perpetrators, failure to appreciate the abusiveness of interpersonal violence during childhood, etc. All these factors may be relevant for an individual growing up with ongoing intrafamilial violence. As one individual explained his improved recall as an adult of growing up with unpredictable, sadistic maltreatment, "I had to live there."

Conceptualizing Dissociative Amnesia

Conceptualizing dissociative amnesia generally involves four factors. First, relatively large groups of memories and associated affects have become unavailable, not only single memories, feelings, or thoughts. Second, the unavailable memories usually relate to day-to-day autobiographical information that would ordinarily be a routine part of conscious awareness: who a person is, what they did, where they went, what happened, with whom they interacted, what was said, what they thought and felt at the time, and so on. Third, the ability to remember new information, general cognitive functioning, and language capacity are usually intact, although in some cases the dissociative process can interfere with retrieval of perceptual, semantic, and procedural information (e.g., what did I see?, what is a contact lens?, what do I do with it?) and registration of new

memories (anterograde or continuous dissociative amnesia). Finally, the dissociated memories often indirectly reveal their presence in variably disguised form, such as intrusive visual images, flashbacks, somatoform symptoms, nightmares, conversion symptoms, and behavioral reenactments, with the individual impaired in ability to conceptualize their behavior as a reenactment. Dissociative amnesia states may alternate with states of hyperamnesia, flashbacks and/or derealized awareness in which the person experiences detachment or estrangement from autobiographical memory.

Clinical Presentation of Dissociative Amnesia

There are two basic presentations of dissociative amnesia. First, the "classical presentation" is generalized dissociative amnesia, a sudden disturbance in which extensive aspects of autobiographical memory are unavailable to conscious verbal recall, often including loss of awareness of personal identity. These patients are frequently seen in emergency departments or general medical or neurologic services because the sudden development of memory loss requires medical assessment. In addition, during an acute amnestic state, some individuals demonstrate symptoms that are best conceptualized as symptoms of peritraumatic dissociation and/or ASD. These include disorientation, perplexity, alteration in consciousness, somatoform symptoms, purposeless or fugue-type wandering, or a combination of these.

The clinical consensus of dissociative disorder experts is that generalized dissociative amnesia is most commonly a manifestation of dissociative identity disorder; an amnestic self-state is created or activated to resolve seemingly irreconcilable stress and conflict, often in the context of acute trauma, and may also represent a symbolic suicide. Multiple episodes of generalized dissociative amnesia are strongly indicative of underlying dissociative identity disorder.

The classic disorder is an overt, sometimes dramatic presentation that frequently results in the patient being brought quickly to medical attention because of amnesia. The paradigmatic case is that of the individual who is found without memory for identity or life history, with or without a dissociative fugue, sometimes leading to media reporting of the case. This presentation of amnesia is frequently found in individuals who have experienced extreme acute trauma such as combat or rape. It also commonly develops in the context of profound intrapsychic conflict or

emotional stress; for example, a terrified soldier in combat who experiences excruciating conflict over their urge to flee despite believing that “all cowards should be shot.” However, in the latter cases, there is almost always an antecedent history of severe traumatic experiences in childhood and/or adulthood. An illustrative case involves a World War II naval petty officer who presented with generalized dissociative amnesia. After his ship in the Pacific was hit, he was adrift for some days in a life raft with several other sailors. One was horribly wounded, screaming in agony, again and again begging them to kill him. Eventually, as he knew the man would die from his wounds, the petty officer shot him and pushed his body into the sea. All in the boat agreed to keep what happened secret. Generalized dissociative amnesia developed a year later when he was to be remobilized for the invasion of Normandy.

The second and far more prevalent form of dissociative amnesia is a deletion of significant portions of autobiographical memory and/or fragmentary experience of it. Ordinarily, patients do not complain of this and it is usually only discovered in taking a careful life history. Dissociative amnesia often has a clear-cut onset and offset, so that the person is subjectively aware of gaps in autobiographical memory. For example, a patient reports that she does not remember being in third grade despite having a clear memory of other school years. Individuals with dissociative amnesia also may report confused, jumbled, fragmentary autobiographical memory. Some may report both patterns for different segments of their history. Usually, such symptoms are associated with traumatic circumstances: for example, the patient reports being told that in third grade she was kidnapped by her estranged father during a contentious custody dispute, held hostage for months, and repeatedly raped by him. In some cases, the patient may deny recall for their entire childhood or other major life epochs. Unlike generalized dissociative amnesia, here there is no loss of personal identity or impairments in procedural and/or semantic memory.

A 45-year-old, married, left-handed, male bus dispatcher was seen in psychiatric consultation on a medical unit. He had been admitted with an episode of chest discomfort, light-headedness, and left-arm weakness. He had a history of hypertension and ischemic chest pain, without myocardial infarction. Psychiatric consultation was called, as the patient demonstrated memory loss for the previous 12 years, behaving and responding to the environment as if it were 12 years previously. He insisted that he was unmarried, denied he had a son, did not recall his current job, and denied recollection of current events (e.g., current president) but correctly recalled historical events from 12 years before (e.g., president 12 years earlier). Physical and laboratory examinations were unchanged from the patient's usual baseline. Imaging studies of the brain were normal. The patient displayed intact intellectual function other than the 12-year amnesia. He was perplexed by the contradiction between his memory and current circumstances. The patient described a childhood history of brutal beatings and physical discipline by his father, beginning when he was 3 years old. He was a decorated Vietnam-era combat veteran and described amnesia alternating with fragmentary memory for his combat experiences. In the military, he had been a left-handed golden gloves champion. He described amnesia for several of his boxing matches and, to his dismay, at one time "found" himself ferociously beating another soldier who had attempted to bully one of his friends. He was educated about his disorder and given the suggestion that his memory could return as he could tolerate it, perhaps overnight during sleep or perhaps over a longer time. If this strategy was unsuccessful, hypnosis or an amobarbital interview was proposed.

At the next examination, the patient reported that his memory had spontaneously returned. Before the amnestic episode, he described being stunned when his beloved wife said she wanted a separation and asked *him* to discuss this with his son. In addition, due to a variety of other family and work problems, he had come to feel completely responsible for his coworkers and for the care of his relatives. He was panicked, overwhelmed, and enraged. He had felt violently angry with his wife but had vowed in the past that he would "beat to death anybody who tried to hurt her." He stated that he would have attempted suicide but he "couldn't" because he had too many people relying on him. The amnesia developed after he felt a kind of "paralysis" in his left

arm while talking with his wife about the separation. Insightfully, he reported that, “I went back to the time, 12 years ago, before I met my wife, had this job and all this family stress. Back then, none of these problems existed.”

Diagnosis and Clinical Features

As noted above, there are two major clinical presentations of dissociative amnesia.

Classic Presentation. The primary data base for this form of dissociative amnesia are clinical case series and case reports going back to World War I. For example, a systematic neuropsychological study assessed memory function in 10 patients with severe retrograde dissociative amnesia with a median duration of 14 months. They were assessed on tests of retrograde and anterograde amnesia as well as of autobiographical memory. One respondent admitted to malingering and two acknowledged symptoms consistent with dissociative identity disorder, with the acute dissociative amnesia a manifestation of an amnestic self-state. Other than the malingerer, every patient had a long psychiatric history; dissociative respondents evidenced symptoms that were not feigned and improved or remitted with treatment. All subjects reported difficulty recalling specific autobiographical memories. In addition, tests of famous faces and past public events revealed that individual patients showed unique but internally consistent, memory difficulties for this material. These were not thought to represent factitious processes but rather the patients’ commonsense, individualized notions of how memory works that informed the phenomenology of their presentations.

For many years, Angelica Staniloiu and Hans J. Markowitsch have studied cases and case series of individuals with generalized dissociative amnesia, with and without fugue. As discussed in the section on Neurobiology, they have proposed a neurobiologic model of “mnestic block syndrome” to describe the phenomenology and neurobiology of the retrieval deficits characterizing the complex memory disturbances in these individuals. Recently, they published an extensive evaluation of one of the largest modern case series of 28 dissociative amnesia/dissociative fugue individuals, ranging from ages 11 to 54 (average = 35.6 years), all with the chronic form of dissociative amnesia. Staniloiu and Markowitsch emphasize the prevalence of this chronic course and do not include cases

of the sometimes spontaneous, rapid resolution of amnesia found in the older civilian and military literatures.

Staniloiu and Markowitsch performed an extensive neuropsychological test battery, including the DES and the DES-T, personality inventories, and forensic tests (e.g., the Test of Memory Malingering [TOMM]) to assess issues of feigning. Four cases involved criminal legal involvement, including embezzlement, reckless driving, and attempted blackmail in a foreign country. The latter individual developed dissociative fugue and generalized dissociative amnesia reportedly in response to the blackmail victim hiring someone to kill him. However, patients were not studied with lifetime trauma inventories, PTSD scales, or diagnostic assessments for dissociation like the MID or the SCID-D. Because of the individuals' amnesia for life history, an inventory of traumatic exposures was obtained via clinical interviews and collateral sources. A newspaper reporter acquired corroboration of some of the childhood trauma sustained by the blackmailer. As in prior studies, the researchers did not find a specific personality profile associated with generalized dissociative amnesia. They found extensive deficits in executive function, attention/concentration, and emotional processing, the latter characterized by emotional blunting and "*la belle indifference,"* as found in many classic cases from the 19th and 20th centuries. Confirming findings in prior studies, there were documented deficits in episodic, autobiographical, semantic, and procedural memory, as well as the rare form of anterograde (continuous).

Dissociative Amnesia

Staniliou and Markowitsch found no evidence supporting the sociocognitive/fantasy models of dissociation. Confirming the TM of dissociation they found evidence of childhood maltreatment in seven cases despite the fact that childhood history was often unavailable due to amnesia. Antecedent trauma history included childhood sexual, physical, and emotional abuse; placement in an orphanage; bullying by peers; unexpected severe illness or death of a loved one; death threats; surviving a terrorist bombing and witnessing numerous dead maimed bodies after the attack, etc.

Documented events that precipitated amnesia were either psychological stress or a mixture of psychological and physical stress (e.g., several cases with mild head injuries). As these authors have reported previously, a history of highly stressful/traumatic migration experiences was a factor in

six generalized dissociative amnesia/fugue cases. Stresses included refugee status; lack of ability to speak the language across several migrations; social dislocation and marginalization in their new countries; being orphaned and sexually abused in a foreign country as a child, and other stressors. They documented three cases of child/adolescent dissociative amnesia, one with a 2-year chronic course. As with the adult cases, these children had documented stressful/traumatic events as precipitant and/or distal etiology of the amnesia.

Other studies and case series report that these patients may present with comorbid somatic and/or classical conversion symptoms, as in the bus dispatcher case described above. They also may display alterations in consciousness, depersonalization, derealization, trance states, spontaneous age regression, dissociative fugue, and ongoing anterograde dissociative amnesia. Depression and suicidal ideation are reported in many, but not all, cases. A personal past and/or family history of somatoform or dissociative symptoms predisposes individuals to develop acute amnesia during traumatic circumstances. As has been found in studies of Vietnam-era veterans, the World War II studies of amnesia during combat show that the severity, intensity, and frequency of combat are the most important factors in the development of combat-related posttraumatic disorders, including dissociative amnesia. In a study of British soldiers after the battle of Dunkirk, the point prevalence of dissociative amnesia for the battle was 14% to 35% in those on the front lines. Six percent developed dissociative amnesia with “trifling stress” (e.g., they were in training camp or waiting for deployment). Almost all in the latter group were described with the dissociative fugue subtype and one with generalized dissociative amnesia. Most had family histories of “neurosis, psychosis… [and] amnesic attacks,” as well as dissociative fugue.

Generalized dissociative amnesia/fugue may occur in individuals where avoidance of responsibility plays a role. Sexual indiscretions, legal difficulties, financial problems, or fear of anticipated combat may be part of the clinical matrix that surrounds the amnesia. There is a possible association in some cases with an antecedent history of head trauma with or without loss of consciousness. Most case series of combat-related dissociative amnesia/fugue, with or without conversion symptoms, specifically ruled out head trauma as a significant factor in development of these disorders.

If carefully questioned, some of these patients give a history of recurrent episodes of amnesia or fugue, typical of dissociative identity disorder. In the dissociative identity disorder cases, the amnesia occurs when—to cope with overwhelming or traumatic circumstances and/or profound intrapsychic conflict—the person begins to experience themselves as a new—or newly reactivated—self-state who is unaware of some or all their past.

In some acute dissociative amnesia cases, the amnesia resolves within hours to months, spontaneously or through psychotherapy, hypnotherapy, pharmacologically facilitated interviews, or combinations of these modalities. However, as described above, recent case series show that a subset of these patients develop a chronic, disabling course. Chronic dissociative amnesia may be severely impairing and associated with limited ability to return to family, social, or occupational roles, even when patient “learns” about the missing autobiographical information. This acute presentation should be regarded as a psychiatric emergency, as clinical experience suggests that the more time passes before resolution of the amnesia the more likely that a chronic course will occur.

Ms. M is a 55-year-old woman was seen in psychiatric consultation because of sudden, complete loss of memory for her identity and entire life history. She had been found by her family after participation with a female friend in a “new age” therapy workshop where, in a session involving picturing oneself going back in time and being reborn, the patient appeared to enter a deep trance state in a fetal position with difficulty awakening. When she did, she could not identify who she was, where she was, or anything else about herself or her situation. Several days later, when found by her family, she was dazed, confused, and disoriented, unable to recognize them or provide any history of recent events. She had difficulty learning new information, seemingly forgetting it as it was provided. She was panicked and complained of not “feeling in my body.” She had difficulty recalling how to dress herself, what were and how to use her contact lenses, tampons, and so on. She underwent a complete neurologic, neuropsychiatric, and neuropsychological evaluation with the conclusion that she was not suffering from a cognitive disorder. When referred for consultation, she had “relearned” information about her identity, family, and her life, but fundamentally had no available autobiographical memory to contextualize this information. She complained of ongoing amnesia, spontaneous trances, and periods of intense depersonalization and derealization. She was impaired in performing most daily functions, having no recall of these skills. She had been depressed, and this improved with antidepressant medication, but her memory remained unchanged. Her memory did not return with hypnotic interventions or after an amobarbital interview. In psychotherapy, she gradually was able to recall events around the loss of memory. The “friend” who had accompanied her to the conference had pressured her sexually and, with great distress, she finally acceded. This event, experienced with profound shame, had uncanny parallels to episodes of childhood sexual abuse that the patient had described in a prior psychotherapy. After this disclosure, the patient began to have gradual return of her autobiographical memory. She described and was observed to shift among several self-states, including bewildered, amnestic child states, and several “new” Ms. M states without memory of the past. She reported that her previously functional states had all “gone away,” refusing to return, citing how “devastated”—that is, ashamed—she felt about the events that precipitated the amnesia. She received a

diagnosis of dissociative identity disorder. Gradually, she was more able to access her “functional” self-states and become better able to manage life issues. Still, the amnestic self-states denied recall of the sexual assault. These self-states “knew about” her history prior to the amnesia but denied first-hand memory of these. On reflection, she thought that, during several very stressful times in her life, she suffered at least two prior episodes of dissociative amnesia and conversion symptoms, albeit recalled without a sense of first-hand experience.

DISSOCIATIVE AMNESIA FOR VIOLENT/HOMICIDAL BEHAVIOR. Several international case series document dissociative amnesia for violent or homicidal behavior. These violent individuals described acute onset of extreme emotions, especially violent rage, precipitated by major interpersonal stress, such as unexpectedly finding evidence that a spouse had been unfaithful. Typically, they “came to” recognizing that they had savagely assaulted or killed someone. In general, these individuals did not attempt to use memory loss for exculpation. They called law enforcement and/or emergency services for assistance themselves after realizing what they had done, and accepted responsibility and legal consequences for the violent episodes. Unfortunately, none of the case series systematically studied these individuals with self-report or diagnostic inventories for dissociation, PTSD, other comorbid psychopathology (e.g., substance use disorders, mood disorders), history of trauma, history of violence, etc.

DISSOCIATIVE FUGUE SPECIFIER. The dissociative fugue specifier of dissociative amnesia is usually associated with generalized memory loss typical of the classic presentations of dissociative amnesia. Expert consensus views dissociative fugue as usually a manifestation of dissociative identity disorder, with amnestic, peripatetic self-states, either newly created or activated under stress, that flee from the individual’s current life, sometimes in an unconscious reenactment of a childhood attempts to escape from a violent family. The classic fugue cases with change in identify (e.g., Ansel Bourne) were considered by contemporaneous experts (e.g., William James) to be “double consciousness/dual personality.” During dissociative amnesia/fugue, individuals may engage in complex, purposive behavior, sometimes over weeks or months. Recurrent dissociative fugue states likely only occur in dissociative identity disorder.

In his case studies, Janet described that a single idea that symbolizes or condenses (or both) several important ideas and emotions frequently dominates the patient's thinking when in the fugue state. At some point, the individual becomes aware of the amnesia and/or loss of personal identity, resulting in their being brought for clinical evaluation. Sometimes, at this point, the individual returns to their baseline state, usually with amnesia for the fugue and identity alteration. As in case Example 1 in this section, there may be an age-regression to a chronologically earlier life period.

In some severe cases of PTSD, commonly comorbid with dissociative identity disorder, nightmares may be terminated by a waking fugue during which the patient hides in a closet, goes to another part of the house, or runs outside. Dissociative children and adolescents may be more limited than adults in their ability to travel. Thus, fugues in this population may be brief and involve short distances. Some cases of children or adolescents who precipitously run away actually may be instances of dissociative fugue, with the child escaping from an abusive or violent home situation. No systematic research exists on this point. All children and adults with the dissociative fugue subtype should be assessed for dissociative identity disorder.

During a fugue, patients often seem "normal" and tend not to attract attention. Some individuals, however, display overtly bizarre, disorganized, or dangerous behavior, such as a soldier who, during battle, began a fugue episode by standing up, exposing himself to intense enemy fire, and then dazedly walked away from the front lines. After the termination of a fugue, in addition to amnesia, the patient may experience perplexity, confusion, trance-like behaviors, depersonalization, derealization, and conversion symptoms. As the patient with dissociative fugue begins to become less dissociated, they may display mood, anxiety or PTSD symptoms, and/or intense suicidal ideation.

Nonclassic Presentation. Individuals with nonclassic dissociative amnesia can be said to have a *covert* dissociative syndrome, because their primary complaint infrequently relates directly to amnesia. Commonly, patients with the nonclassic presentations of amnesia do not reveal the presence of dissociative symptoms unless directly asked about them. These patients are often uncomfortable when amnesia is inquired about and may minimize the presence or rationalize the importance of the symptom.

In nonclassic presentations, the amnesia consists of a circumscribed memory gap or series of memory gaps for the life history, and/or fragmentary recall of the life history; often for times when traumatic events occurred, such as childhood or wartime. However, as described in prior sections, more extensive dissociative amnesia for life history also may occur, with the person describing large gaps in recall and/or fragmentary recall of years of early life. Like other traumatized individuals, these patients frequently come to treatment for other symptoms and disorders, such as depression, mood swings, substance abuse, sleep disturbances, somatoform symptoms, anxiety, panic, suicidal behavior, nonsuicidal self-injury, violent outbursts, eating disorder symptoms, and/or interpersonal problems. Amnesia may also occur for flashbacks or behavioral re-experiencing episodes related to trauma.

Ms. G is a 35-year-old, unmarried psychologist who was admitted to hospital because of increasingly severe nonsuicidal self-injury, a behavior she had engage in for years. She reported chronic depressed mood, anxiety, and interpersonal problems with inability to form intimate relations. Medications and intensive outpatient psychotherapy had helped moderate some of her symptoms but she had become increasingly demoralized by her overall failure to improve in treatment. She described virtually no recall for her life between ages 7 and 13 including family holidays, school events, and vacation trips. Her father had abused alcohol throughout her childhood, only achieving sobriety in her early adolescence. When she was 13, her older sister disclosed sexual abuse by the father to their minister, who “did a church intervention,” but there was no social service or police referral. Her father acknowledged the abuse at the time and received treatment by church counselors for alcohol abuse and “sex addiction.” He denied any other episodes of sexual abuse toward his children. Ms. G denied any feelings about these episodes stating that, “he took care of the problem. Now, he’s a great support. I have no reason to be mad at him.” She explained her amnesia by saying that “maybe nothing important happened and that’s why I don’t remember.” Treatment focused on establishing safety from self-injury. Self-harm impulses increased after phone conversations with her parents. Also, she began to have nightmares, highly disturbing bodily sensations in her genitals and rectum, and would wake up vomiting. Realizing that these were symptoms of PTSD, she found this uncanny, stating, “Nothing bad ever happened to me.” Finally, she began to have discrete flashbacks of sexual assaults by her father, together with her sister at times. In an emotional family meeting without the father present, the sister, long estranged from the family, confirmed that these events had occurred. She said, “I had hoped you would never remember, so I never told you.”

Subsequently, Ms. G’s father was arrested and pled guilty to federal charges of possession of videos of children being raped. At the state level, he pled guilty to charges of sexual abuse over many years of girls in the church, and was sentenced to a lengthy concurrent sentence in federal prison. The state investigated and found systematic child sexual abuse within the patient’s family church, including ministers, prominent church members like her father, and individuals in the church hierarchy.

Several of these men were charged and convicted of child sexual abuse. The state obtained a conviction of a church elder for conspiracy to conceal child abuse in the church. The long-term psychotherapy of Ms. G and her sister were complex and difficult, resulting in estrangement from their mother. Ms. G stopped engaging in any form of self-destruction or high-risk behavior. She described grieving over many lost years of her life but reported freedom to enjoy her life now, with renewed energy in her work and her personal life.

Only a few studies have examined the clinical characteristics of nonclassic dissociative amnesia patients. In a small, highly selected sample referred for consultation at a specialty clinic for dissociative disorders, most dissociative amnesia patients were women. As in the data from the ACE study, almost all had a prior history of childhood or adult physical, sexual, or emotional abuse and neglect, or a combination of these. The trauma history was less severe than has been reported in patients with dissociative identity disorder. Duration of dissociative amnesia ranged from relatively brief recurrent episodes to years of the life history. Traumatic precipitants of the amnesia were most common, although in 30% of cases amnesia was present for problematic behaviors such as sexual indiscretions and nonsuicidal self-injury. The most common comorbid conditions were mood disorders, PTSD, and personality disorder symptoms. Patients differed from individuals with dissociative identity disorder in having lower rates of substance abuse, nonsuicidal self-injury, hallucinations, fugues, sexual dysfunction, and somatoform symptoms. Mean DES scores were lower on average than in cases of dissociative identity disorder. Family history was characterized by alcohol abuse and mood disorders.

A random community sample of 1,301 university students in Sivas, Turkey was assessed for dissociative disorders and borderline personality disorder. The authors validated and used a self-report inventory for dissociative amnesia, the Steinberg Dissociative Amnesia questionnaire (SDAQ) developed as a screening measure based on the SCID-D dissociative amnesia scale. Eighty respondents (6% of the sample) met DSM-IV-TR criteria for borderline personality disorder, 78 of whom (98%) also met DSM-IV-TR criteria for a dissociative disorder. Of these, 15 participants (18.8% of the subsample with borderline personality disorder, 1.2% of the total sample) met diagnostic criteria for DSM-IV-TR

dissociative amnesia. As in all other studies, in dissociative identity disorder a diagnosis of borderline personality disorder was a severity measure, indicating a higher level of childhood trauma exposure and more severe, acute dissociative and PTSD symptoms.

Pathology and Laboratory Examination

Dissociative amnesia can be diagnosed with the DDIS, SCID-D-R, and/or MID. The DES and the SDAQ can be used as screening measures. Patients with dissociative amnesia have been reported to have high hypnotizability, as measured with standardized hypnosis scales.

Differential Diagnosis

Autobiographical Memory, Nonpathologic Amnesia, and Dissociative Amnesia. Nonpathologic forms of amnesia have been described, such as infantile and childhood amnesia, amnesia for sleep and dreaming, and hypnotic amnesia. Most forms of dissociative amnesia are thought primarily to involve difficulties with autobiographical memory—rather than implicit or general semantic memory—although rarely, as illustrated above, semantic and/or procedural memory may be disrupted. Autobiographical memory may have episodic and semantic components (e.g., “last year I bought a new car” vs. “every 5 years I buy a new car,” respectively).

Studies of autobiographical memory support the notion that infantile and childhood amnesia can be experimentally documented. However, data on preverbal learning and memory in young children suggest that later amnesia may result from difficulty translating preverbal memory into verbal form. Experiments in preverbal children designed to overcome this factor show that children can later report preverbal memories accurately in verbal form under suitable experimental conditions.

Studies demonstrate that normal adult autobiographical memory has a retention gradient for the last 20 to 30 years of the subject’s life, often with a subjective sense of wearing away of memories for the past, in contrast to the subjective gaps/fragmentation of memory typical of dissociative amnesia. Older adult patients in autobiographical memory studies have a relative decrease in recent autobiographical memories and a *reminiscence component* for the events of their youth. Older adults have more semantic autobiographical memories and fewer episodic autobiographical memories, anchored in specific time points. Consistent with this, there may be a shift

from the first person (field) to the third person (observer) form of autobiographical memory.

Autobiographical memory has several complex aspects, including emotion, mood, and state-based differentials in memory. For example, negative events may be preferentially recalled in depressed mood states. Schema memory effects may result in the inclusion of a memory of something one has not experienced into memories of a sequence of experienced events. Due to a variety of factors, individuals may develop “pseudomemories” for events that did not occur. This can include false confessions, experimentally induced “false memories,” and failures to recall events that *did* happen (omissions or “false nonmemory”). It may be difficult to differentiate actual memory alteration in these situations from the *belief* that something did or did not occur.

Autobiographical memory for repeated routine events, such as going to work or school every day, may not be encoded as discrete memories for each day but rather as broad memory categories for the events that repeatedly reoccur (*regeneric memory*). This is also thought to occur with some traumatic experiences, such as repeated episodes of childhood sexual abuse that occur frequently during many years (e.g., a child being incestuously raped most weekends of every year from age 5 to 15).

Clinically, patients with dissociative amnesia may have a variety of autobiographical memory deficits. For example, an individual case study of a rape survivor with subsequent generalized dissociative amnesia was evaluated with cognitive testing while amnesic and after memory recovery. As compared to a control with a cognitive disorder, the dissociative amnesia patient was able to recall memories from various points in the life history without the temporal gradient that characterized the retrograde amnesia of the cognitive disorder patient. Recall of autobiographical information during dissociative amnesia seemed related to positive life events that were unconnected with the traumatic events precipitating the amnesia. In this patient, implicit autobiographical memory phenomena were also documented. Similar phenomena have been described in posthypnotic amnesia, with implicit demonstration that the memories for which amnesia has been suggested have been encoded and stored but without being directly accessible for retrieval. Amnesic patients may also have intense reactions to stimuli that are emotionally significant without being aware of the reason for the reaction or the significance of the stimulus, such as when a patient with PTSD has a flashback without

consciously knowing what triggered it and often without clear recall later of the memory being evoked.

Several studies have confirmed the clinical observation that individuals with dissociative amnesia for their life history can demonstrate implicit autobiographical memory while amnesic. When asked to free associate, to imagine, or to make up a story, on projective tests, even with ectodermal responses, patients with dissociative amnesia include elements of autobiographical information without necessarily being consciously aware of this.

There is no single test or examination that can establish absolutely whether a memory disorder has a dissociative, neurocognitive, factitious, malingered, or mixed etiology. The clinician evaluating the amnesic patient must have a reasonable index of suspicion about any of these. In ambiguous cases, thorough reassessment on an ongoing basis of the clinical situation is helpful. However, most patients with dissociative amnesia present differently from other disorders with memory impairment (Table 20–24). The evaluation of acute dissociative amnesias is described in Table 20–25.

Cognitive Disorders. In patients with dementia, amnestic disorders, and delirium, the memory loss for personal information is embedded in a far more extensive set of cognitive, linguistic, attentional, behavioral, and memory problems. Loss of memory for personal identity is usually not found without evidence of marked disturbance in many domains of cognitive function. Confabulation may be present to various degrees and is usually implausible or bizarre. Causes of neurocognitive amnestic disorders include thiamine deficiency (Korsakoff psychosis), cerebral vascular accident (CVA), postoperative syndrome, infection, anoxia, and transient global amnesia. Electroconvulsive therapy (ECT) may also cause a marked temporary amnesia and, occasionally, persistent memory problems. In ECT-related amnesia, however, memory loss for autobiographical experience is unrelated to traumatic or overwhelming experiences and seems to involve multiple types of personal experience, most commonly those occurring just before or during the ECT treatments.

Table 20–24.
Differential Diagnosis of Dissociative Amnesia

Normal Autobiographical Memory Difficulties
Age-related cognitive decline
Nonpathologic forms of amnesia
Infantile and childhood amnesia
Amnesia for sleep and dreaming
Hypnotic amnesia
Dementia
Delirium
Amnestic disorders

Neurologic disorders with discrete memory loss episodes
Posttraumatic amnesia
Transient global amnesia
Amnesia related to seizure disorders

Substance-related amnesia
Alcohol
Sedative-hypnotics
Anticholinergic agents
Steroids
Marijuana
Narcotic analgesics
Psychedelics
Phencyclidine
Methyldopa (Aldomet)
Hypoglycemic agents
β-Blockers
Lithium carbonate
Many others

Other dissociative disorders
Dissociative fugue subtype
Dissociative identity disorder
Other dissociative disorders
Acute stress disorder
Posttraumatic stress disorder
Somatic symptom disorder

Psychotic episode/disorders

Lack of memory for psychotic episode when returns to nonpsychotic state

May be difficult to differentiate from thought disordered recall in schizophrenia

Mood disorder episode

Lack of memory for aspects of episode of mania when depressed and vice versa or when euthymic

Factitious disorder

Malingering

Table 20–25.
Evaluation of Acute Amnesia

Complete history (to the extent that this can be gathered)
Medical history
Psychiatric history
Trauma history (combat, violence, childhood maltreatment, etc.)
Developmental history
Collateral informants (if available)
Family and concerned others
Medical, military, police, and social service records
Sequential clinical observation
Physical and neurologic examination
Baseline physical and laboratory examination
Full mental status examination
Mini-mental state examination
Dementia workup
Electrocardiogram
Electroencephalogram
Telemetry in unusual cases
Brain imaging
Neuropsychological assessment

Posttraumatic Amnesia. In posttraumatic amnesia due to brain injury, there is usually a clear-cut physical trauma, a period of unconsciousness or amnesia—or both—and often objective clinical evidence of brain injury. In general, the length of the posttraumatic amnesia is a reasonable

predictor of cognitive outcome. Retrograde amnesia may also occur. An extensive retrograde amnesia out of proportion to the head injury may warrant an investigation for dissociative factors. Head trauma may cause an anterograde amnesia in some cases.

Seizure Disorders. In most cases of epileptic seizures, the clinical presentation is different from that of dissociative amnesia, with clear-cut ictal events and sequelae. Patients with nonepileptic seizures, however, may resemble epileptic patients in some ways but may also have dissociative symptoms, such as amnesia, elevated scores on dissociation measures like the DES, and an antecedent history of psychological trauma. Both epileptic and nonepileptic seizures can worsen with stress. Rarely, patients with recurrent focal-onset impaired-awareness seizures (previously complex partial seizures) may present with ongoing bizarre behavior, memory problems, irritability, or violence, making them hard to distinguish from patients with dissociative amnesia. Some patients with epilepsy have exhibited wandering or semi-purposeful behavior, or both, during seizures and in postictal states, for which there is subsequent amnesia. However, seizure patients in an epileptic (as opposed to dissociative) fugue often exhibit abnormal behavior, including confusion, perseveration, and abnormal or repetitive movements as well as experiencing an aura, motor abnormalities, stereotyped behavior, perceptual alterations, incontinence, and a postictal state. Stressful life events may be associated with an increase in seizure frequency in some susceptible epileptic patients and thus this factor alone is insufficient for differential diagnosis. Serial or telemetric EEGs, or both, usually show abnormalities associated with epilepsy accompanying behavioral changes whereas the EEG is normal in nonepileptic seizures. However, both may occur in the same individual.

Substance-Related Amnesia. Several substances and intoxicants have been implicated in the production of amnesia. Common offending agents are listed in Table 20–24. In most cases, a careful history from the patient and ancillary sources, sequential clinical observation, and objective testing clarifies the substance-related nature of the amnesia. In some instances of pathologic intoxication, in which a small amount of alcohol or of another substance produces a major behavioral disinhibition, the alcohol may be producing its effect by facilitating the onset of a dissociative episode in a susceptible individual, possibly suffering from dissociative identity disorder.

This may be analogous to the disinhibition that occurs in a pharmacologically facilitated clinical interview. Individuals may report amnesia for violent or other out-of-character behavior during such an episode.

The most difficult differential diagnostic problem usually involves patients with a history of both substance-induced and dissociative memory problems. Some of these patients may minimize dissociative amnesia and vice versa. Clinically, the relative contribution of the substance abuse and the dissociation may only be fully clarified by sequential clinical observation once the patient has achieved sobriety.

WANDERING BEHAVIOR. Individuals with dissociative amnesia may engage in confused wandering. To qualify for the dissociative fugue subtype, the individual must exhibit *purposeful* travel away from home or a customary place of daily activities and is usually preoccupied by a single idea that is accompanied by the wish to escape.

Wandering behavior during a variety of general medical conditions, toxic and substance-related disorders, delirium, dementia, and amnestic syndromes could theoretically be confused with the dissociative fugue subtype of dissociative amnesia. However, in most cases, the somatic, toxic, neurologic, or substance-related disorder can be ruled in by the clinical history, physical examination, laboratory tests, or toxicologic and drug screening. Use of alcohol or other substances may be involved in precipitating an episode of dissociative fugue. Wandering and purposeful travel may occur during the manic states of bipolar disorder or schizoaffective disorder, with difficulty recalling behavior that occurred after return to the euthymic or depressed state. In purposeful travel due to mania, the patient is typically preoccupied with grandiose ideas and often calls attention to themselves owing to inappropriate behavior. Assumption of an alternative identity does not occur, although the subjective differences in sense of self, emotions, and behavior may lead the person to feel like “different people” during the various mood states. Similarly, peripatetic behavior may occur in some patients with psychotic disorders. Memory for events during wandering episodes in such patients may be difficult to ascertain owing to the patient’s thought disorder. However, in general, dissociative fugue patients do not demonstrate a psychotic thought disorder or other symptoms of psychosis.

Transient Global Amnesia. Transient global amnesia may be mistaken for dissociative amnesia, especially since stressful life events may precede either disorder. However, in transient global amnesia there is a sudden onset of complete anterograde amnesia and learning abilities; pronounced retrograde amnesia; preservation of memory for personal identity; anxious awareness of memory loss with repeated, often perseverative, questioning; overall normal behavior; lack of gross neurologic abnormalities in most cases; and rapid return of baseline cognitive function, with a persistent short retrograde amnesia. The patient is usually over 50 and shows risk factors for cerebrovascular disease, although epilepsy and migraine have been etiologically implicated in some cases.

Dissociative Disorders. As noted previously, individuals with dissociative identity disorder or dissociative amnesia experience autobiographical memory deficits for past experiences. Most patients with dissociative identity disorder report multiple forms of complex amnesia, including recurrent blackouts, disremembered behavior, unexplained objects in their possession, and fluctuations in skills, habits, and knowledge. Some patients with other dissociative disorders, particularly acute dissociative reactions to stressful events, may develop amnesia in the context of other dissociative symptoms (e.g., perceptual disturbances). Individuals with more extensive amnestic episodes may qualify for a dissociative amnesia diagnosis (see section on Other Dissociative Disorders).

Acute Stress Disorder and Posttraumatic Stress Disorder. Many individuals with dissociative amnesia meet partial or full diagnostic criteria for ASD or PTSD. The DSM-5-TR stipulates that, to be diagnosed, the dissociative amnesia must be distinct from the course of ASD or PTSD. In practice, clinical judgment usually determines whether the extent of the amnesia warrants a separate dissociative diagnosis. As described in the section on etiology, a large-scale, latent class analysis study of traumatized adolescents found that the best model fit for PTSD dissociative subtype included dissociative amnesia in addition to depersonalization and derealization symptoms.

Other Psychiatric Disorders. State-related memory problems that are observed in individuals with cyclic mood disorders and psychosis may be understood, following the DBST framework, as state-change disorders or

exacerbations with state change (e.g., acute psychosis or exacerbation of psychotic disorder). Upon resolution of an acute psychotic episode, many individuals report lack of recall of their symptoms, behavior, or life events while psychotic. This lack of recall may also be observed in many individuals who recover from an episode of delirium. In contrast, a minority of individuals may fully recall their symptoms of psychosis or delirium and become tormented with confusion, fear, and shame regarding these experiences. State-related transitions between mania, depression, and euthymia may be accompanied by an autobiographical memory deficit for mood, behavior, perceptions, and sense of self during the different states. Manic individuals may deny recall of depressive episodes and vice versa. During euthymic states, the individual may have difficulty recalling details of being in the other mood states.

Malingering and Factitious Amnesia. There is no definitive test, battery of tests, or set of procedures that invariably distinguishes true dissociative symptoms from feigning. Malingerers/individuals with factitious disorders have been noted to continue their deception even during hypnotically or barbiturate-facilitated interviews. As noted previously, many of the classical dissociative amnesia cases occur in a context of financial, sexual, and legal problems or in soldiers who wished to escape from combat. Feigned amnesia is more common in individuals presenting with the acute, classic forms of dissociative amnesia. However, in one forensic case, an adult attempting to sue an admitted abuser using the delayed discovery rule was shown to have falsified delayed recall for trauma to overcome the statute of limitations. Investigations showed that the patient had discussed the abuse with others on many occasions before the purported delayed recall. On the other hand, some patients may have re-dissociated, and deny recalling and discussing traumatic experiences in the past.

Also, the legal theory of delayed discovery for trauma due to dissociative amnesia unrealistically requires complete amnesia (i.e., “repressed memory”) for childhood sexual abuse, with de novo recollection many years later. Although this does occur, most dissociative amnesia individuals experience variable recollection of childhood abuse in adulthood with fragmentary recall, derealized recall, emotionless recall, PTSD intrusive symptoms, and recall then re-dissociating memory. This can include often partial recollection of some abuse experiences but not others, even those corroborated by witnesses, and/or documented in

social service or medical records. Some individuals display dissociative disconnection of the seriousness of maltreatment. For example, a man reported that, after lighting a fire in a wastebasket at age 4, his father burned his fingers with a lighter. When the clinician cited that as abusive, the man insisted it was legitimate discipline.

As some U.S. states have done, a more realistic legal standard to expand the statute of limitations for childhood abuse is that the individual was unable to appreciate the *impact* of trauma until later life, whether dissociative amnesia is present or not. For example, maltreated individuals may not connect or comprehend the damage done to them until later life; after failed marriages, damaging substance use disorders, loss of employment, psychiatric hospitalizations, nonsuicidal self-injury, suicide attempts, and other difficulties.

Malingering of general dissociative amnesia with/without fugue may occur in individuals who are attempting to avoid consequences of legal, financial, or personal difficulties and in soldiers attempting to avoid combat or unpleasant military duties. These precipitating factors may be present as well in bona fide dissociative amnesia/fugue (see above). In the forensic context, the examiner should always consider the diagnosis of malingering when dissociative amnesia/fugue is claimed. On the other hand, factitious forms of dissociative amnesia often resemble the CAMD clinical picture. This may be related to wishing to seem a more interesting patient and/or adopting the imitative role of a childhood trauma survivor, or that of a more severely harmed trauma survivor. In some complex cases both genuine and exaggerated amnesia/fugue may be reported. For example, a woman with dissociative identity disorder feigned experiencing a several-day dissociative fugue after reported revictimization by a childhood abuser. As discrepancies in her story emerged, she admitted that she had spent the weekend with a new lover, betraying her long-term partner and frightening her outpatient therapist.

On the other hand, in clinical case reports, many malingerers have quickly confessed their deceptions spontaneously or when confronted by an examiner. In these nonforensic reports, the malingered amnesiacs were frequently pathetic individuals whose deception was transparent. Nevertheless, it can often be unclear where the conscious deception began and the unconscious defenses ended. In forensic contexts, feigned dissociative amnesia often is conveniently located for events related to criminal behavior but not to other areas of life. Feigners may become angry and resistant when their memory issues are challenged. They may

claim amnesia for some circumstances where their responsibility is at issue yet appear to have detailed recall of events and people with whom they are displeased and from whom they wish to extract some form of gain.

Bethany Brand and colleagues have developed psychological assessment batteries to attempt to discriminate feigned from genuine dissociative disorders and from dissociative disorders with factitious/malingered exaggeration. These may include standard screening and diagnostic inventories for dissociative disorders, personality assessment, MMPI, Rorschach, other measures to assess trauma history, PTSD, and complex trauma, as well measures used in forensic assessment of feigning (e.g., SIRS-II, TOMM). She and her colleagues have demonstrated that patients with actual dissociative disorder may be misclassified on some forensic measures for feigning. Interpretation of findings may require a psychologist with extensive clinical and assessment experience with dissociative disorders.

A patient who presents to psychiatric attention asking to “recover repressed memories” as a chief complaint is most likely to have a factitious disorder, and may display factitious or the imitative form of dissociative identity disorder described in prior sections. Most of these individuals do not describe bona fide amnesia when carefully questioned but they are often insistent that they must have been abused—or more extensively abused—in childhood to explain their unhappiness or life dysfunction. Unlike feigners, most dissociative individuals are fearful, ashamed, and avoidant of recall of traumatic memories and minimize and deny the dissociative amnesia and trauma history, even when corroborated. Memory recall in dissociative amnesia does not present as typical episodic, autobiographical memory recall. Rather, these usually are experienced as disturbing intrusive flashbacks with alarming and vivid perceptual, somatoform, and emotional experiences. They may display freezing or agitation, often with defensive dissociative symptoms like depersonalization/derealization, trance states, and attempts to “re-dissociate” the material.

Clinical Course and Prognosis

Little is known about the clinical course of dissociative amnesia. Acute dissociative amnesia can resolve spontaneously once the person is removed to safety from traumatic or overwhelming circumstances. At the other extreme, many patients develop chronic forms of generalized,

continuous, or severe localized amnesia who may be so profoundly disabled to require social support, such as nursing home placement or intensive family caretaking.

Individuals with nonclassic dissociative amnesia may have a persistent form of the disorder that does not cause them overt distress and thus may not seek clinical attention. Some of these individuals can be understood as being in an episode of PTSD characterized primarily by avoidant symptoms. In some cases, a later traumatic event or stress—even a relatively minor one—precipitates a florid episode of PTSD with alternations of re-experiencing and avoidant or amnestic symptoms.

Studies have shown that recall of previously dissociated memory frequently occurs outside of therapeutic settings, triggered by a variety of stimuli, including the person's children reaching a specific age at which the individual was abused, abuse of their own children, media accounts of trauma or abuse, death of an abusive parent, a variety of sensory cues, and feeling safe enough from danger in one's life situation, among others. Meta-analytic studies show that there is no difference in accuracy of trauma memory with delayed recall compared with "continuous" trauma memory.

Treatment

The diagnosis and treatment of dissociative amnesia became controversial in the 1990s due to disputes, often in the media and the courts, over delayed recall of childhood sexual abuse (see section on History of Dissociation). Prior to this, dissociative (psychogenic) amnesia and delayed recall for combat or other forms of trauma had not been considered controversial, even written about by clinician/researchers who later claimed it could not occur. Authors from the World War I and II eras opined that some of these wartime cases were malingered. In this regard, particularly during and after World War I, punitive treatments such as electric shock were devised for wartime amnesia and conversion symptoms. Also, controversy exists not only for the existence of dissociative amnesia but also for how to treat it.

Critics of the dissociative amnesia construct invented a false, nonexistent treatment: *recovered memory therapy* (RMT) to characterize a procedure in which clinicians supposedly make aggressive efforts and pressure patients to recall reported hidden, long-forgotten traumas as the central focus of treatment. RMT does not represent a known school of

therapy or of scholarly research. It may more accurately describe individual fringe practitioners and/or media or layperson views of trauma treatment.

The controversy over delayed recall of childhood sexual abuse is often discussed as if the clinical situation involves forensic determination of the "truth" of "accusations." Episodic, autobiographical memory is adaptive, not forensic. The gist of trauma memory is more likely accurate than peripheral details. In most circumstances, clinicians do not "validate" information patients report in treatment (e.g., where they were born, who was in their family, where they live, etc.) Barring extensive documentation that may include perpetrator admissions, documented physical injuries, etc., the clinician must realize that they "were not there" to determine the "truth" of maltreatment reports. Traumatized patients often vacillate between recalling childhood maltreatment (e.g., "I know this happened to me") and discounting their recollections (e.g., "I'm a liar, I made it all up"). As discussed in the section on dissociative identity disorder, just as in any other psychotherapy, the clinician's role is to assist the patient in making sense of their autobiography, not to make a forensic determination. This allows patients to explore issues like screen memories, viewing events differently from a more integrated perspective, and/or becoming increasingly clear that they accurately recall experiencing maltreatment during childhood. Clinicians find that it is more common that traumatized patients struggle, not with trauma "accusations," but with attachment to abusive caregivers, associated with dogged rationalization of or self-blame for maltreatment. Thus, reviews of the literature on trauma treatment emphasize that the predominant model for work on traumatic memories involves a focus on symptom stabilization and safety, integration of posttraumatic memories, beliefs, cognitions, affects, somatic representations, and object relations, not on memory recall as an end in itself.

Phase-Oriented Treatment. As for dissociative identity disorder, phase-oriented treatment is the current standard of care for the treatment of dissociative amnesia, although there are no systematic studies with large cohorts of patients. Treatment of the patient with acute, classic dissociative amnesia follows a similar phasic model. However, here, memory recall is a central issue, because loss of memory for personal identity and/or dense deletions in autobiographical memory is disabling and requires rapid intervention. On the other hand, case series of patients with generalized dissociative amnesia document serious suicide attempts and even death

by suicide when amnestic barriers are removed precipitously without adequate preparation and patient stabilization. Clinicians should make sure that they and the patient are both prepared for the abreaction of extreme emotions (e.g., terror, rage, extreme shame), that accompany recollection of devastating traumatic experiences and/or extreme psychological conflict.

Safety in Acute Stress Disorder with Dissociative Amnesia. Studies of psychiatric combat casualties with acute dissociative amnesia—with or without fugue—provide useful practical principles for treating ASD with dissociative amnesia. Acute generalized dissociative amnesia/fugue may occur in civilian settings during natural disasters, mass casualty events, refugees exposed to terrorism, torture, and civilians affected by war with/without refugee status. Unfortunately, in many of the latter circumstances, resources for medical, let alone psychiatric, care are minimal. In refugee populations, individuals may suffer from additional physical and sexual violence and exploitation, be grieving over the violent deaths of relatives, and lack basic provision of food, water, clothing, housing, or sanitation.

To the extent possible, establishing the person's physical safety is the first concern. This involves removing the individual from the traumatizing environment (e.g., acute combat), evaluating and treating medical problems, and providing shelter, food, and the ability to sleep. The paradigm of *psychological first aid* may be helpful in the initial stabilization of the acutely traumatized, amnesic individual. Sedative medications, such as the benzodiazepines, may be indicated to assist the patient with sleep. Case series suggest that, in this acute context, many patients with acute amnesia may have a relatively rapid spontaneous remission of symptoms once brought to the safety of the hospital or other protected environment (e.g., removal from the battlefield, provision of sleep). If immediate spontaneous remission does not occur after removal from traumatic environments, symptoms may abate later simply during the clinician's taking a psychiatric history or merely with suggestions and reassurance.

Phasic Treatment. As described in the section on dissociative identity disorder, three basic phases are recognized for treatment of both types of dissociative amnesia. This structure is heuristic to some extent because aspects of each phase may be worked on during another. First, there is a stabilization phase, with a focus on safety, symptom control, containment

of affects and impulses, and education about trauma treatment. Once adequate personal safety and clinical stability are established, if indicated, the individual may engage in a second phase that focuses on the integration of traumatic material in greater depth. This processing may involve attempts to gently interpret the fear that may underlie ongoing amnesia and to resolve material that is not dissociated or less completely dissociated. Finally, there is a third phase of *resolution* or *reintegration* in which the traumatized person is reconnected to ordinary life. In this phase, the focus is less on the trauma per se and more on the development of a renewed, reinvigorated life that overcomes the lack of freedom imposed by symptoms of the trauma disorder and the dominance of the person's psychology by issues related to traumatization.

In general, studies of treatment outcome in survivors of rape and childhood sexual abuse have shown better outcome when patients directly discuss dissociated trauma material in the context of a carefully designed, physically structured individual or group psychotherapy. International studies of individuals in specialized treatment for childhood sexual abuse show that dissociative trauma survivors do not improve without a direct focus on dissociation.

Safety in Nonclassic Dissociative Amnesia. Patients with nonclassic amnesia presentations generally should be managed within the framework of a longer-term psychotherapy directed at resolving the complex psychological sequelae of severe traumatization due to childhood maltreatment, combat, rape, intimate partner violence, trafficking, and/or other forms of adult victimization. Here, too, the first tasks of treatment are restoration of the patient's physical well-being and safety and establishment of a therapeutic alliance. The clinician must be prepared to intervene actively if the patient is acutely dangerous to self or others. Typically, these patients' difficulties involve suicide attempts, nonsuicidal self-injury, eating disorders, high-risk behaviors (e.g., reckless driving), alcohol or substance abuse, involvement in abusive or destructive relationships, episodes of rage or violence, abuse of the individual's own children or family members, and lack of adequate food, clothing, or shelter. Hospitalization may be necessary for stabilization, as may referral to specialty resources such as treatment for substance abuse or eating disorders.

In individuals with severe intrusive PTSD symptoms alternating with amnesia, containment, and management of intrusive recollections rather

than detailed processing of the traumatic material are usually the main goals of the stabilization phase of treatment. This may be accomplished with supportive psychotherapy, pharmacotherapy, imagery or hypnotic techniques for containment and symptom control, and/or dialectical behavioral and cognitive therapy techniques, or a combination of these. Although there is no pharmacologic agent that specifically targets dissociative amnesia, specific psychopharmacological treatment of the patient's PTSD, mood, impulsive, psychotic, obsessive-compulsive, or anxiety symptoms may help stabilize severe symptoms that prevent the patient's meaningful participation in psychotherapy.

Long-term treatment for these patients is focused on the manifold dimensions of dysfunction that chronic trauma engenders. These include problems with emotional, mood, anxiety, and impulse regulation; disordered attachment schemas engendering troubled relationships and problems with interpersonal boundaries; spontaneous altered states of consciousness and dissociation; memory problems; cognitive distortions and disordered meaning systems; perceptual abnormalities; problems with the sense of self and body image; somatoform symptoms; and self-destructiveness.

Treatment of Amnesia. Treatment of patients with nonclassic forms of dissociative amnesia necessitates that, to provide ongoing informed consent, the clinician should familiarize themselves with the controversies about trauma and memory, as well as the standard of care for phasic treatment. Factors that usually contraindicate intensive memory integration work are listed in Table 20–22 (see also Table 20–23 in the section on Dissociative Identity Disorder).

Free Recall. Patients with both forms of dissociative amnesia may respond well to free-recall strategies in which they allow memory material to enter consciousness. The clinician is supportive and nondirective but focuses on conflict, psychological defenses, and/or conscious reluctance to free recall to take place. Classic free-association suggestions are often the most helpful in understanding factors that interfere with recall and in allowing recall to occur at a pace that the patient can tolerate. Authorities recommend that in all trauma processing work, to the extent possible, the clinician not ask leading questions, whether in a free-recall situation or with methods that facilitate memory recall (see below). This includes statements like, "what happened then?," "what happened next?," or "what

did you think/feel at the time?" When exploring posttraumatic cognitive distortions like unwarranted self-blame and shame for aspects of the traumatic experiences, the clinician can inquire about what led to these beliefs, what would the person think if someone else described similar reactions in a traumatic context, and so on. These strategies gently challenge posttraumatic cognitive distortions. In general, it is most helpful to recontextualize these beliefs by locating them within the emerging history, as the patient may experience the all-too-common posttraumatic schema that self-blame is preferable to the experience of utter helplessness at the core of most traumatic experiences. Distress at recall may be titrated by techniques for distancing and fractioning emotion. For example, the patient may be asked to give a brief "headline" or two, as if reading a newspaper, but not to go into more detail (e.g., reading the newspaper article in full) until better able to do so.

Transference Interpretations. Studies of transference in patients with combat-related PTSD and severe dissociative disorders indicate that a traumatic transference is usually the predominant transference theme in these individuals. This is a set of unconscious perceptions of the clinician based on relationships formed under traumatic circumstances. For instance, the therapist becomes the buddy who was killed next to the patient in battle, the persecutory abusive parent, the incompetent officer who sent the patient into battlefield disaster, the neglectful relative unconcerned about the patient's abuse, or the patient themselves who is subject to the sadistic, abusive behaviors of an implacable other. Identification of the overt patterns of traumatic transference observed by the therapist may be another route to undoing amnesia. A recent study of corroborated trauma memory found that transference-based recall was more accurate than other forms of facilitated recall.

Cognitive Therapy. Cognitive therapy may have specific benefits for individuals with trauma disorders. Identifying the specific cognitive distortions that are based in the trauma may also provide an entrée into autobiographical memory for which the patient experiences amnesia. As the patient is more able to correct cognitive distortions, particularly about the meaning of prior trauma, more detailed recall of traumatic events may occur, although the potential for flooding is a significant concern. Educating patients about the concept of hindsight bias may be helpful. Here, later information biases understanding of events as they unfolded in real time

(e.g., the “Monday morning quarterback”). In posttraumatic disorders, hindsight bias is invariably *negative*, with shame, self-blame, and survivor guilt for what occurred.

Facilitated Recall of Trauma Material. A hierarchy of techniques to facilitate recall has been described for dissociative amnesia. The techniques include: (1) context reinstatement (i.e., attempts to focus the patient on time periods for surrounding the amnesia); (2) state-dependent recall (i.e., intensification and focus on affects or somatic sensations that appear to be related to trauma, such as terror, horror, confusion, rage, or sudden nausea or dizziness); and (3) specialized adjunctive techniques (e.g., hypnosis, relaxation, imagery, pharmacologically assisted interviews). Each of these techniques may facilitate recall of dissociated memories, particularly in classic forms of dissociative amnesia. It is particularly important that, when implementing these techniques, to the extent possible, the clinician use nonleading, nonsuggestive questions to minimize concern about inaccurate or confabulated recall. Some nonclinical research studies suggest that techniques for facilitation of recall may increase inaccurate recall. This remains a complex topic in terms of the ecologic validity of this research to treatment of traumatized individuals; what aspects of recall may be inaccurate (e.g., peripheral details vs. central aspects of the narrative), and what factors induce the inaccuracy (e.g., the techniques themselves or more general expectations and demand characteristics, such as hypnosis is somehow “special” in evoking accurate memories). The clinician’s overall stance about trauma treatment and approach to trauma memory is most important in managing these issues.

Hypnosis for Amnesia. Hypnosis has frequently played an important adjunctive role in the treatment of individuals with dissociative amnesia and dissociative fugue. Hypnosis is not a treatment in itself; rather, it is a set of adjunctive techniques that facilitate certain psychotherapeutic goals. The construct of hypnosis encompasses a wide and complex domain of phenomena and responses that have been applied to many therapies and diverse individuals. Concern about inaccuracies in hypnotically facilitated recall is based on research on memory for nontraumatic information showing that hypnosis increases a person’s confidence in what is recalled, even if it is erroneous. However, critical reviews have noted the complexity of this research problem, the inconsistency of findings among studies, and

the many variables related to hypnosis and nonhypnotic factors that appear to influence this and related phenomena. These reviews have emphasized that memory confabulation is related to techniques of social influence on suggestible subjects rather than to hypnosis per se.

The use of hypnosis for memory recall in no way ensures the veracity, or lack of veracity, of the information produced. The clinician should be aware of the reconstructive nature of memory and should avoid suggestions to the contrary. Thus, in addition to obtaining the patient's informed consent for the use of hypnosis, it is currently considered prudent to also obtain informed consent concerning the reliability or possible lack thereof for autobiographical information revealed during hypnosis. Studies show that educating patients about the controversies regarding hypnosis and memory and informing them of the need to critically evaluate any memory material that they recall during hypnosis, or at any other time in treatment, reduces the likelihood of credulous acceptance of potentially inaccurate information.

Also, clinicians should be aware that, in some states of the United States, individuals who have been exposed to therapeutic hypnosis might be enjoined from giving testimony as a witness in court. This may be so even if the hypnosis had little relationship to the events at legal issue. The clinician should attempt to discuss fully these issues with the patient and their legal counsel.

Hypnosis can be used in several different ways in the treatment of dissociative amnesia. Hypnotic interventions can contain, modulate, and titrate the intensity of symptoms; facilitate controlled recall of dissociated memories; provide support and ego strengthening for the patient; and, finally, promote working through and integration of dissociated material. In addition, the patient can be taught self-hypnosis to apply containment and calming techniques in their everyday life. Successful use of containment techniques, whether hypnotically facilitated or not, also increases the patient's sense that they can more effectively be in control of alternations between intrusive symptoms and amnesia.

In the acutely amnestic patient, a few sessions to help the patient experience trance successfully and to explore containment and distancing techniques may be sufficient to allow focused hypnotic work on the material for which the patient is amnestic. Clinicians since World War I have recognized how valuable it is for patients to process dissociated material repeatedly over several sessions, often at different levels of affective intensity, to complete the process of integrating the material. In

cases of acute amnesia, the first session for memory processing may necessarily be explorative. Here, again, the initial goal is to gain an overview of the information for which the patient is amnesic. As in cases of chronic amnesia, subsequent sessions then focus on reworking the material in greater detail. However, in nonclassic cases of severe, longstanding, posttraumatic disorders, the amnesia itself should be addressed only gradually in the context of a longer-term psychotherapy in which life stability and function are the basic foci.

It is useful to try to account systematically for different dimensions of the traumatic experience—sensory, affective, cognitive, and behavioral—to ensure that all key components have been identified and reconstructed. It is also useful to attempt to account systematically for a variety of painful affects that are commonly experienced during traumatic experiences such as despair, sorrow, grief, horror, shame, helplessness, rage, guilt, confusion, and anguish. Not all of these may be present in each patient; however, it is useful for the clinician to keep track of which affects the patient most readily describes and which seem less available. Inquiry about these other affects may be quite helpful in resolving the amnesia. Shame, horror, helplessness, and overwhelming confusion are emotions that patients may have the most trouble identifying without assistance from the therapist.

The treatment process is similar when the acute amnesia results not from traumatic experiences but from aspects of the person's current behavior that conflict with deeply held moral values or behavioral standards. In these instances, treatment initially seeks to help the patient tolerate these affects and conflicts without resorting to dissociative defenses. Frequently, these patients describe a developmental history characterized by a rigid family moral code enforced with harsh physical discipline. These experiences often appear to be the traumatic underpinning of the dissociative diathesis. Psychotherapy and hypnotherapy in these patients are directed in part at reducing the patient's brutally unreasonable, and often conflicting, expectations of themselves and the guilt and shame that so often accompany acute dissociation. Furthermore, these patients may have great difficulty tolerating anger or violent impulses because such affects tend to trigger recall of earlier experiences with physical abuse or similar traumas, often as a flashback experience. Thus, psychotherapy may serve not only to focus on the conflicts that led to the acute amnesia but also to explicate and work

through the patient's thoughts, feelings, and self-perceptions related to the antecedent traumatic events.

Somatic Therapies. There is no known pharmacotherapy for dissociative amnesia other than pharmacologically facilitated interviews. A variety of agents have been used for this purpose, including sodium amobarbital, thiopental (Pentothal), oral benzodiazepines, and amphetamines. To date, no controlled studies have assessed the efficacy of any of these agents in comparison with one another or with other treatment methods. A single placebo-controlled study of a barbiturate-facilitated interview did not find superiority of sodium amobarbital over placebo in producing more clinically useful information. In more systematic World War II studies of barbiturate-facilitated interviews for amnesia and conversion disorder, this treatment was described as producing more rapid recovery, especially for amnesia, although little overall difference was found in recovery in comparison to subjects treated with psychotherapy alone or with hypnotherapy.

Amobarbital narcosynthesis is a term devised to underscore the need for the patient to process material uncovered in a pharmacologically facilitated interview in their usual conscious state. Pharmacologically facilitated interviews are used primarily with acute amnesias and conversion disorder, among other indications, in general hospital medical and psychiatric services. This procedure is also occasionally useful in refractory cases of chronic dissociative amnesia when patients are unresponsive to other interventions. The Joint Commission now considers pharmacologically facilitated interviews to be conscious sedation, requiring the presence of an anesthesiologist. This procedure must be performed in settings where resuscitation equipment is available in case of respiratory arrest, a possible, albeit rare, complication. The interview usually is audiotaped or videotaped to replay for the patient, because amnesia generally is present for the material produced. Although in some cases repeated procedures may be helpful, in others, repeated procedures have led to the patient's dependence on pharmacologically facilitated interviews.

The current controversies over delayed recall for trauma have also focused on the use of pharmacologically facilitated interviews for patients with reported amnesia for childhood maltreatment. No modern systematic data exist on memory fallibility or accuracy in individuals undergoing pharmacologically facilitated interviews. As discussed previously, pharmacologically facilitated interviews were used extensively in World

War II for the treatment of combat-related dissociation. Although wartime memories recovered with pharmacologically facilitated interviews were generally considered to be accurate, some subjects were reported to dissemble completely or withhold crucial information, or both, despite barbiturate treatment.

Given the current controversies, the clinician should obtain informed consent focusing on the nature of memory for pharmacologically facilitated interviews for amnesia as for patients considering hypnosis. The clinician should emphasize that these drugs are not a truth serum; whatever apparently new information emerges under the drug condition should be regarded no differently with respect to accuracy than any other material that emerges over the course of treatment.

Group Psychotherapy for Amnesia. During World War II, group psychotherapy and group hypnotherapy were among the treatments used to promote recovery in traumatic war-related amnesia. Highly supportive, structured, reassuring, and re-educative approaches were often used by therapists in such cases to accomplish return of the patient to functional status and to prevent chronic disability.

Time-limited and longer-term group psychotherapies have been reported to be helpful for combat veterans with PTSD and for survivors of childhood abuse. During group sessions, some authors report that patients recall memories for which they have had amnesia. Supportive interventions by the group members or the group therapist, or both, may facilitate integration and mastery of the dissociated material. On the other hand, concern has been raised about memory contamination in such group therapy settings, as it has for patients' involvement in 12-step or self-help groups for trauma survivors.

TREATMENT OF DISSOCIATIVE FUGUE SUBTYPE. Treatment for dissociative fugue follows the basic structure described above for treatment of dissociative amnesia. Once stabilization is achieved, subsequent therapy is focused on helping the patient regain memory for identity, life circumstances, and personal history. Some patients with dissociative fugue may resist uncovering their actual identity even with hypnosis or pharmacologically assisted interviews. Appeals through the local (sometimes regional, national, or international) media may not alert the patient's concerned others. In one case, a patient was asked to randomly select numbers on a phone keypad. The patient tapped a phone number—

apparently outside of conscious awareness—that allowed the treating clinician to find the patient's family hundreds of miles away.

Family, sexual, occupational, or legal problems that were part of the original matrix that generated the fugue episode may be substantially exacerbated by the time the patient's original identity and life situation are detected. Thus, family treatment, legal, and social service assistance may be necessary to help resolve such complex difficulties. Also, the patient may display other extreme or bizarre dissociative symptoms, such as the Ganser symptom of approximate answers, or attempt to engage in another fugue to escape the situation.

DEPERSONALIZATION/DEREALIZATION DISORDER

As described in the section on Nosology, the DSM-IV-TR diagnosis of depersonalization disorder was renamed depersonalization/derealization disorder in DSM-5. This was based on a review that found no differences between patients with predominant depersonalization and those with predominant derealization, confirming the ICD-10/11 conceptualization of either symptom as characteristic of the disorder.

For many years, the ubiquity of depersonalization/derealization as a psychiatric symptom obscured its broader recognition as a disorder. Consequently, patients with chronic and primary depersonalization/derealization are commonly misdiagnosed as having solely mood or anxiety disorders. These disorders may be comorbid with chronic depersonalization/derealization and/or may develop in response to untreated depersonalization/derealization disorder symptoms. Recent systematic research by Daphne Simeon and Anthony David on two large cohorts of well-characterized patients with depersonalization/derealization disorder yielded strikingly consistent findings in the United States and Europe. Clinical features, course, prognosis, and cognitive and neurobiologic correlates clearly distinguish this disorder from other psychiatric disorders in which depersonalization/derealization symptoms occur. Also, valid and reliable instruments exist for screening and diagnosis, such as the Cambridge Depersonalization/Derealization Scale developed by Mauricio Sierra and Germán Berrios (see section on Nosology and Table 20–2).

Etiology

Discrete Behavioral States Theory and Depersonalization/Derealization Disorder. Individuals with depersonalization/derealization disorder describe highly distressing, continuous or relapsing/remitting DBSs characterized by alienation

from somatic, perceptual, cognitive, and affective processes. Unlike individuals with psychotic or delusional disorders, reality testing remains intact: for example, when queried these individuals acknowledge that they "feel" terrifyingly dead but they do not literally believe that they are dead. Individuals with the disorder usually have limited ability to modulate or moderate these states. Some describe states characterized by numbness and detachment. Typically, these individuals' emotionless, robotic outward presentation belies their substantial subjective distress at experiencing chronically anhedonic states of being. Conversely, many individuals with depersonalization/derealization disorder present with states of overt agitation and desperation about experiencing disconnection from themselves and/or the world.

FIGURE 20–2. Schematic integration of proposed models to explain depersonalization disorder.

Several models have been proposed to explain this disorder. A schematic integration is presented in Figure 20–2.

Psychodynamic. Traditional psychodynamic formulations have viewed depersonalization/derealization as a disintegration of the ego or as an response in defense of the ego. These explanations stress the role of overwhelming painful experiences or conflictual impulses as triggering events. The high rates of depersonalization/derealization symptoms in normal adolescents and in patients conceptualized as having borderline or narcissistic personality organizations are cited as evidence that ego immaturity, ego deficits, and/or self-self-system lability and/or deficits predispose to these conditions. More recently, attention has been drawn to the similarities between depersonalization/derealization and obsessive-compulsive symptoms. Patients with depersonalization/derealization disorder often display obsessive-like behaviors with respect to their symptoms. The split between an observing and a participating self is likened to the division between intellect and emotion in obsessive patients. Both groups respond to serotonin reuptake inhibitors, although the therapeutic response for patients with depersonalization/derealization disorder is usually much less robust.

Traumatic Stress. As described in prior sections, acute peritraumatic depersonalization/derealization states are common in accident victims and military recruits undergoing high-stress training, permitting peritraumatic, survival-based downregulation of autonomic functions (e.g., heart rate, blood pressure, rate of respiration, and of the HPA axis). In depersonalization/derealization disorder these states can be conceptualized as disconnecting from their earlier survival function and becoming persistently autonomous, activated by later stressful and/or traumatic experiences (e.g., financial, social, medical, psychopharmacological, and/or other stresses).

Other antecedent experiences to the development of depersonalization/derealization disorder include the unexpected, sudden death of a family member or close friend; sexual orientation struggles in adolescence; and major family/work stresses. In some cases of severe and/or prolonged mood or anxiety disorders with comorbid DSM-5-diagnosed depersonalization/derealization

disorder, this latter disorder becomes chronic after remission of the other disorders.

A controlled clinical study found significantly more childhood trauma, especially emotional abuse perpetrated by parents, in well-diagnosed patients with depersonalization/derealization disorder compared with healthy controls. Unlike the control group, separation or loss of parents appeared protective of development of depersonalization/derealization symptoms. Overall dissociation scores were related to sexual and emotional abuse in the control group, but emotional abuse alone predicted depersonalization/derealization scores.

In support of the power of emotional abuse as a traumatic stressor and of its link to dissociation, Martin H. Teicher and colleagues have shown that parental verbal/emotional abuse was “a potent form of maltreatment” in a community sample of 554 young adults. In this study, verbal/emotional abuse experiences resulted in moderate to large increases in measures of dissociation, anxiety, depression, anger-hostility, somatoform symptoms, and symptoms of “limbic irritability,” such as paroxysmal somatic disturbances, brief hallucinatory events, automatisms, and dissociative experiences.

In a recent report, a Puerto Rican convenience sample of 40 women with a history of interpersonal trauma was compared with 40 control women without such history. Subjects completed Spanish versions of the DES, a factor-analytic derived depersonalization/derealization subscale of the DES (DES-D), the CDS, the Patient Health Questionnaire (PHQ-9), and a validated measure of types and severity of prior physical, sexual, and/or emotional abuse. Half the trauma sample reported a history of sexual abuse. Participants reporting more frequent abuse experiences also had significantly higher mean depersonalization/derealization scores on the DES, DES-D, and CDS. The largest effect sizes were for CDS and depression scores. One-quarter of the trauma group scored above the CDs cutoff score of ≥70, indicating high likelihood of a depersonalization/derealization disorder diagnosis. As in other studies (see section on Epidemiology), there was a significant correlation between PHQ-9

depressive and depersonalization/derealization scores. The authors concluded that, despite limitations of this convenience-sample study, the findings provide evidence of a significant linkage between antecedent trauma and dissociative symptoms in a Latin American cultural context.

In a recent study of 106 women with PTSD (80% PTSD dissociative subtype) in a specialized partial hospital trauma program were studied using a multivariate linear regression model of multiple childhood adversities. These included physical abuse, emotional abuse, sexual abuse, emotional neglect, and physical neglect. In this sample, emotional abuse was significantly associated with higher depersonalization/derealization scores and physical abuse was associated with lower dissociation scores. There was no interactive effect of multiple types of abuse.

However, some studies have not shown significantly higher rates of childhood interpersonal trauma in individuals with depersonalization/derealization disorder compared to control groups (e.g., with depressive disorders). Some of these studies have found significantly higher rates of a first-degree relative with severe psychiatric illness (e.g., psychotic disorder or bipolar disorder). One hypothesis is that the chronic fear engendered by the relationship with the psychotic relative was etiologic in the development of the depersonalization/derealization disorder. For example, one patient reported that throughout her childhood her father and older brother left her to manage on her own her mother's psychotic and violent episodes. Despite intense terror and dread about her own safety, the patient feared more for her mother's safety. She followed her mother through the house while the mother typically brandished a large kitchen knife, loudly verbigerating at invisible persecutors.

As in the case of individuals with dissociative amnesia, an earlier history of trauma and/or severe stress may be present but is not the initiating factor in the onset of depersonalization/ derealization. Symptom exacerbations are commonly related to negative emotions, high levels of sensory input, and threatening, stressful, and/or unfamiliar situations. Traumatic or stressful events may precipitate or exacerbate depersonalization/derealization disorder symptoms.

Many individuals with depersonalization/derealization disorder do not identify an immediate traumatic antecedent and do not report a clear precipitant to disorder onset. On the other hand, nontraumatic stressors—such as severe interpersonal, financial, or occupational losses—have been associated with the onset or exacerbation of the disorder. Psychopharmacological stressors, most commonly marijuana and hallucinogens, can sometimes precipitate chronic depersonalization/derealization. These individuals can be conceptualized as having a neurobiologic or genetic vulnerability to chronic depersonalization/derealization after drug use, although early life trauma can also play a role.

Mr. A, a successful 42-year-old actor, was referred for psychiatric evaluation. Since his late teens, he had abused alcohol and a variety of drugs, usually in binges lasting several weeks. After one of his brothers died of a heroin overdose, he engaged in a several-week binge on alcohol, marijuana, and inhaled and smoked cocaine. At the conclusion of the binge, after his first sober night "crash," he awakened with intense, highly distressing depersonalization/derealization experiences. He reported feeling completely alien and disconnected from himself, his emotions, and his awareness of the environment. He reported estrangement from his body, not experiencing it as connected to him, feeling as if his limbs were either too far away from him or too close. He reported that the world seemed flat and unreal, almost as if it were a painting. He tried to read scripts that he had been given to prepare for auditions but the words seemed disconnected from him. When he tried reading scripts aloud, his voice sounded alien, "tinny," far away, and unfamiliar. He denied being fully out of his body, observing himself as if he were another person. However, he reported being "just beside myself, not really in myself, like to one side. It's terrible; I can't get back to me. I don't feel connected to who I am. I know I am feeling things, but I don't know what they are. All I feel is desperate to get back to how I used to be."

He described his father as a dictatorial alcoholic who berated him throughout his youth, calling him names, humiliating, and mocking him. He denied a history of childhood sexual abuse but said that both parents would hit him "randomly, with whatever they got their hands on." The father terrorized the family, including repeatedly insulting and hitting the patient's mother in front of the patient and his younger brother. Substance abuse began in adolescence to numb himself from feeling terrified, impotently enraged, and humiliated. He described substance abuse, depression, and suicide attempts in first-degree relatives, including his deceased brother, no family members had sought mental health treatment and it was stigmatized in his family. A

complete physical, laboratory, and neurologic work-up were all were within normal limits. Due to the symptoms, he stopped using alcohol and drugs completely, literally becoming phobic of drug use. However, several years later, he remained chronically depersonalized and only able to work in a very limited way. He reported distress that he cannot experience emotions about his brother's death or the family violence and dysfunction that led both of them to abuse substances with such adverse outcomes. He had little response to trials of antidepressants, mood stabilizers, and naltrexone. He reported mild improvement in mood and ruminations about his symptoms on fluvoxamine 300 mg daily and naltrexone 100 mg daily. Primarily, he was managed in a supportive psychotherapy, having had limited response to trials of cognitive-behavioral, dialectical behavioral, and psychodynamic psychotherapy.

Cognitive Theories. In the last decade, increasing attention has been paid to cognitive and behavioral aspects of chronic depersonalization/derealization, essentially positing that an initial, relatively benign, and possibly transient dissociative response is reinforced, maintained, and exacerbated by a vicious cycle of dysfunctional cognitions and behaviors. E.C.M. Hunter and colleagues in the United Kingdom have put forth such a cognitive-behavioral model, proposing that an initial trigger (e.g., trauma, anxiety, depression, stress, fatigue, intoxication) can induce transient symptoms of depersonalization/derealization which are subsequently cognitively processed by an individual as either situational or catastrophic. If the attributions are situational, and therefore more benign, the depersonalization/derealization symptoms will tend to fade as the situational factors alleviate. However, if the attributions are catastrophic, they may evoke overwhelming fears such as going mad, losing control, becoming invisible, or having a permanent brain dysfunction. In turn, these fears may lead to increased anxiety coupled with paradoxically decreased arousal, resulting in increased intensity of the depersonalization/derealization symptoms as the

individual enters the maintenance phase. During this phase, individuals may start to avoid situations that they associate with symptom provocation; become preoccupied with safety behaviors (such as acting “normal”); develop cognitive biases resulting in symptom over-monitoring; and experience a reduced threshold for the perception of threat. Over time, these maintenance factors are thought to perpetuate or exacerbate the symptoms.

Diagnosis and Clinical Features

In clinical samples, the disorder is equally common in men and women but is often missed. Under-diagnosis is facilitated by several aspects of the disorder. Patients experiencing depersonalization/derealization symptoms have difficulty putting their ineffable experiences into words and may have problems with alexithymia. They often fear that they may be seen as “crazy” if they **do** describe their symptoms and may be reluctant to speak about them. They may describe their severe suffering in ways that do not adequately convey their distress to an examiner; for example, repeatedly stating that, “I feel dead,” “Nothing seems real,” or “I’m standing outside of myself.” Individuals with depersonalization/derealization disorder typically endure an intensely unpleasant, and often disabling, subjective experience. Many say that they would gladly exchange the depersonalization/derealization for physical pain that would at least reconnect them with their body. Others say they do not contemplate dying because they already are dead. Some patients may appear remarkably detached and unemotional, due to profound dissociation of affects. As the patient’s complaints do not match their affective presentation, clinicians may not take the severity of this disorder as seriously as they should.

There are several distinct components to experiences of depersonalization and derealization. Individuals may be reluctant or have difficulty describing their symptoms, and clinicians should familiarize themselves with the range of depersonalization/derealization symptoms for direct inquiry. *Depersonalization* may include a sense of bodily changes, duality of

self as observer and actor, being cut off from others, and being cut off from one's own emotions. These individuals may suffer from teleopsia (objects appear further away), pelopsia (objects appear nearer than they are), metamorphopsia, micropsia, and/or macropsia. They may experience their body changing in size and shape; disintegration of time sense with little ability to assess how recently or remotely events occurred; *déjà vu*, *déjà vécu*, and *jamais vu*; numbing of emotions and perceptions, including the inability to perceive hunger or thirst; and feeling robotic, detached, and/or without thoughts or feelings. The individual may report out-of-body experiences or, as in the case example above, a highly dysphoric feeling of partial disconnection from oneself. On the other hand, in *derealization,* the world appears strange, foreign, or dreamlike. Objects may appear as if viewed from a great distance and as if they were two-dimensional, without depth or substance, or as if observed through a fog, mist, or hazy, frosted glass. Sounds come from a distance, muffled and distorted. Objects feel strange to the touch. Colors dim and lose their vitality. The faces of others change, becoming unfamiliar and frightening.

Two factor analytic studies of core symptoms of the disorder found convergent results. There were five discrete symptom clusters: unreality of self, defined as feeling detached from one's physical body, mind, and thoughts; perceptual alterations, encompassing visual, tactile, and somatosensory distortions; emotional numbing, characterized by blunted affect, detachment from pain, and abulia; anomalous subjective recall, consisting of disrupted experiences of memory and time; and alienation from surroundings, comprising symptoms of derealization.

A latent profile analysis of 303 individuals (57.4% male) with depersonalization/ derealization disorder at a British clinic for the disorder were assessed with the DES, CDS, Beck Anxiety Inventory (BAI), and questionnaires for past medical and psychiatric history, symptoms of depersonalization and derealization, triggers of episodes, and other aspects of the disorder.

The latent profile analysis resulted in five subgroups: three varied on low, moderate, or high symptom severity across measures. Two

other subgroups diverged on dissociative symptoms: a high DES dissociation group with amnesia, absorption, and depersonalization/derealization; and a high depersonalization/derealization group with higher CDS scores, but lower DES scores, particularly amnesia and absorption. The authors did not assess trauma history or conduct diagnostic assessments for other dissociative disorders (e.g., MID, SCID-D, MDI) or for comorbid diagnoses (e.g., SCID-5 to rule out schizophrenia). They suggested that the high-dissociation group may be better characterized by a diagnosis of dissociative identity disorder or of dissociative amnesia as conditions "comorbid" with depersonalization/derealization disorder. They speculated that the high-severity group may include subjects with schizophrenia. The elevated DES absorption factor in the high-dissociation group suggests the high hypnotizability found in dissociative identity disorder and dissociative amnesia. Preliminary studies of hypnotizability in depersonalization/derealization disorder do not show elevated hypnotic capacity on standardized measures. Also, in terms of DSM-5-TR diagnostic rules, diagnoses of dissociative identity disorder or schizophrenia would supersede that of depersonalization/derealization disorder (see below in section on Differential Diagnosis).

Cross-Cultural Aspects of Depersonalization/Derealization Disorder

In the 1990s, anthropologist Richard Castillo described a set of depersonalization/derealization symptoms derived from research in multi-cultural populations that was intended to broaden the cross-cultural validity of depersonalization/derealization disorder. Castillo's cluster of symptoms is similar to the more recent data-derived factor analytic models in Western samples, suggesting that the original "Western" descriptions may have been based on a limited sample of individuals. Components of Castillo's description that coincide with these contemporary descriptions include: persistent or recurrent experiences of depersonalization and/or derealization in which familiar experiences of the self and environment become distorted,

potentially resulting in physical and emotional numbing; alterations in body image; experiences of being an outside observer of one's mental processes or body; feeling like an automaton; time disturbances; feeling as if one's body or environment is "unreal" or dreamlike; and visual distortions (e.g., macropsia).

Relevant to diagnosis, the depersonalization/derealization experience must not occur exclusively during a culturally approved religious, spiritual, or ritual activity (e.g., meditative practice) and is not considered normal by the cultural standards of the patient's own social group(s). However, some individuals may initially induce these experiences intentionally but over time lose control over them and develop fear and aversion for related practices.

Differential Diagnosis

The variety of conditions comorbid with depersonalization/derealization disorder complicates the differential diagnosis. These include major depressive disorder (73%); any anxiety disorder (64%); obsessive-compulsive disorder (21%); avoidant personality disorder (23%); and borderline personality disorder (21%). Symptoms of depersonalization/derealization may be associated with PTSD, ASD, bipolar disorder, schizophrenia, dissociative identity disorder, and dissociative amnesia, among others. Depersonalization/derealization symptoms may also result from a medical or neurologic condition, particularly seizure disorders, intoxication or withdrawal from illicit drugs, or as a side effect of medications (e.g., over-the-counter cold medications containing dextromethorphan; prescription or over-the-counter medications with anticholinergic potency). A thorough medical and neurologic assessment is not routinely needed, except for patients whose symptoms or course appear atypical, or if there is reasonable suspicion or evidence of medical or neurologic disorders or toxicity. Expert consensus suggests consideration of medical, neurological, and toxicologic evaluation when the depersonalization/derealization begins after age 40; there are focal neurologic findings; symptoms of numbness or tingling in extremities or sudden onset of symptoms of
