
FIGURE 27.3–4. A highly schematic representation of the gut–brain axis. Exteroceptive or interoceptive stressors may activate a complex neuroendocrine response, which may influence the stress responsive systems, thereby influence GI tract motility and sensory sensitivity. This response feeds back into the central nervous system giving to the concept of bidirectional communication.

GENERAL PSYCHIATRIC APPROACH AND MANAGEMENT FOR FUNCTIONAL GI DISORDERS

Therapeutic Relationship

This can be developed when the psychiatrist (a) elicits and acknowledges the patient's beliefs, concerns, and expectations; (b) offers empathy when needed; (c) clarifies misunderstandings; (d) provides education; and (e) negotiates a plan of treatment with the patient. Some patients are initially

unwilling to accept the role of psychosocial factors in the illness and the need for psychiatric intervention; this difficulty is commonly seen in patients who have suffered severe developmental trauma such as sexual abuse.

Associating Bowel Symptoms with Psychosocial Factors

In order to adequately assess the link between bowel symptoms and psychosocial factors, the authors advocate that the patient is asked to keep a daily record of their symptoms along with the frequency and consistency of bowel movements and the timing of menstruation. Such a diary can be usefully complemented with records concerning dietary and lifestyle changes and psychosocial stressors. This information can provide the opportunity for psychoeducation and laying the basis for cognitive behavioral strategies. The psychiatrist's role in reinforcing the medical condition, namely, an FGID, is also essential since the naming of the disease, alongside explaining the development, pathophysiology, prognosis, and various treatment options, further build rapport with the patient.

Reassurance

Reassurance can only be achieved after the referring physician fully understands the patient's particular concerns, and it is here where the psychiatrist can act as a mediator, especially with emotionally complicated or aroused patients. The overall favorable prognosis for the functional GI disorder can then be stressed.

FIGURE 27.3–5. A number of physiologic factors such as hormones, injury, infection, and diet can alter and enhance visceral afferent nerve signaling. Chronic life stress, poor coping, a psychiatric history, or abuse can cause long-term dysregulation or disinhibition of visceral afferent nerve leading to hyperexcitability. (Data from Drossman DA, Chang L, Bellamy N, et al. Severity in irritable bowel syndrome: a Rome Foundation Working Team report. *Am J Gastroenterol.* 2011;106(10):1749–1759. doi:10.1038/ajg.2011.201.)

Accept the Adaptations of Chronic Illness

When the symptoms are chronic, the patient should be educated as to the nature of the illness as a troublesome cluster of symptoms rather than as an indication of an undiagnosed underlying pathology. In some patients, chronic illness may provide attention from others, release from usual responsibilities, and social and financial compensation. In these situations, appreciable clinical improvement may take a long time but can be advanced if the physician places more focus on improving the patient's function in the presence of illness rather than attempting to "cure." The psychiatrist must help to minimize diagnostic studies and symptomatic

treatments and work toward reinforcing health-promoting behavior in the patient.

SPECIFIC PSYCHIATRIC APPROACH AND MANAGEMENT FOR FUNCTIONAL GI DISORDERS

The specific psychiatric approach consists primarily of the diagnosis and treatment of psychiatric comorbidity and includes (1) psychiatric disorders (e.g., major depression and panic disorder) that require specific treatments (e.g., antidepressants, CBT, or other psychotherapy); (2) a history of abuse that comes to light during the consultation and may be interfering with adjustment to the current illness; (3) serious impairment in the daily function that requires specific treatment to improve coping skills; and (4) somatization, where multiple symptoms lead to numerous consultations across specialties. In order for the gastroenterologist to refer a patient to a mental health professional, they must acknowledge the relevance of the psychosocial aspects to the patient's presenting problem. Otherwise, the patient may resist the referral because of perceived stigma or a rejection ("the workup is negative, it must be in your head") by the gastroenterologist. Continuing care by the gastroenterologist may also be necessary.

PSYCHOPHARMACOLOGICAL PRINCIPLES AND MANAGEMENT FOR FUNCTIONAL GI DISORDERS

It is particularly with the use and clinical management of psychotropic medication that the role of the psychiatrist becomes crucial as part of the multidisciplinary team in the treatment of FGIDs. The rationale for using psychotropic agents lies in the high comorbidity: roughly half of the patients with FGIDs also suffer from depression and/or anxiety disorders, which may respond to psychopharmacological intervention. In addition, data continues to support both the efficacy of antidepressants in the relief of chronic pain and FGIDs: Empirical supports exist for efficacy in FGIDs independent of a change in mood.

Antidepressants

The most commonly used psychotropic medications in FGIDs are antidepressants. Specifically, TCAs are commonly used for their dual

central and peripheral pain-controlling effects, as well as being well tolerated and, for some, effective at low doses. TCAs additionally slow GI transit, of value for IBS-C patients. Numerous reviews and meta-analyses indicate the potential benefits of antidepressants in FGIDs, producing both a reduction in pain and global improvements in quality of life. They also indicate that the treatment with antidepressants is associated with a significantly decreased relative risk of persistent IBS symptoms. An odds ratio of between 2.6 and 4.2 has been estimated for overall improvement in IBS, translating into a number needed to treat (NNT) for antidepressants of 3.2.

In an open-label physician-rated study, up to 80% of patients with IBS showed improvement in antidepressants, and adherence to treatment was higher than for any other treatments. However, the therapeutic effects of antidepressants on visceral hypersensitivity remain unclear as study results to date have been mixed, although it appears that the peripheral effects on the gut may be of secondary importance as most of these patients responding to antidepressants have failed treatment with conventional gut-acting agents. TCAs and SSRIs may improve global measures of well-being without having a direct correlation with pain ratings. Especially with the use of SSRIs, it seems that improvements in global measures of well-being have the most benefit to patients, as opposed to the direct effect on pain ratings. The antidepressant and anxiolytic effects of SSRIs are mediated by a reduction in the sensitivity of 5HT-1A autoreceptors and heteroceceptors. SSRIs can also stimulate GI motility, thereby assisting with constipation-predominant IBS. Because morbidity associated with FGIDs is linked to the global distress of the patient, as seen with the impairment in social interaction, work absenteeism, and functional limitations, the improvements brought about by SSRIs are still deemed therapeutic, and their use in this context is seen as good practice. Furthermore, the classes of antidepressants have added differential benefits in the treatment of FGIDs. A generally accepted guideline is that the TCAs and SNRIs are used for pain regulation, particularly where diarrhea is the predominant bowel habit, while the SSRIs should be used for somatization associated with anxiety and phobias where constipation predominates. Furthermore, mirtazapine is often helpful in the context of nausea and for boosting appetite.

Antipsychotics and Mood Stabilizers

Antipsychotics like risperidone, olanzapine, and quetiapine have been found to be useful at low doses for visceral pain conditions associated with high arousal states and agitation, for instance, in conditions such as globus, aerophagia, regurgitation, and postprandial distress syndrome. Mood stabilizers such as carbamazepine, sodium valproate, pregabalin, and gabapentin have been found to be helpful in chronic visceral pain disorders. On the whole, the general approach is to first use monotherapies at doses that can be tolerated by the patient. Should this be unsuccessful to remediate symptoms, combinations of the same or different classes could be used. It has been reported that a combination at lower doses could have a better side-effect profile than, for instance, monotherapy at a higher dose.

For patients with more severe symptoms refractory to antidepressants, low doses of quetiapine mitigate anxiety and sleep disturbances, augment the effect of antidepressants, and provide an independent analgesic effect.

Anxiolytics

Anxiolytic agents are effective for reducing anxiety in the short term, but their CNS depressant effect, including mild transient cognitive dysfunction and the risk of addiction with long-term benzodiazepines, limits their use in FGIDs as they are mostly chronic in nature. Prescribing benzodiazepines beyond initial short-term stabilization should therefore only be considered after persistent refractory responses to other pharmacologic options (e.g., psychotropic or mood stabilizers). Alternative strategies for the treatment of anxiety should be adopted.

The antihypertensive clonidine, often employed in treating anxiety disorders, increases colonic compliance and has been found to be effective for symptoms of diarrhea. Patients should be monitored closely for orthostatic hypotension and drops in blood pressure.

Psychotropic Drugs and Neuroregeneration

The rationale for the use of centrally acting treatments in recent years is rooted in the concept of neuroplasticity. This regards the observed loss of cortical neurons following psychiatric trauma, but subsequent neurogenesis (i.e., the regrowth of neurons) following treatment with antidepressants and possibly psychotherapy. Functional neuroimaging studies have shown reduced neuronal density in cortical brain regions

involved in emotion and pain regulation in patients with pain disorders and IBS, just as with major depression and PTSD. Therefore, pain and psychological trauma (and especially their combination) can be neurodegenerative, much like Alzheimer or Parkinson disease. It is in these psychological and pain conditions that the use of antidepressants and other centrally targeted agents and methods might offer some remedy by stimulating an increase in the levels of brain-derived neurotrophic factor (BDNF) following treatment. BDNF stimulates neurogenesis, and this is observed with prolonged periods of treatment that correlate with the degree of recovery from depression. Finally, it is observed that the duration of antidepressant treatment correlates with a decreased frequency of relapse and recurrence in depression. These findings provide insight into neuronal growth regulation in key areas of the central pain matrix and provide new and important opportunities for research and patient care using antidepressants for the treatment of FGIDs.

PSYCHOLOGICAL THERAPIES FOR FUNCTIONAL GI DISORDER

Concerning the use of psychological therapies, experience and empirical research suggests that no single particular treatment is superior for treating FGIDs. The most important aspect of treatment is the patient's acceptance of the need for treatment and their motivation to engage in it. This can be enhanced if the gastroenterologist and psychiatrist (psychologist/therapist) help the patient accept the treatment as a necessary part of an overall plan of care. These range in their depth and ambition, from a limited attempt to control symptoms with simple behavior therapy to hypnosis or insight-oriented psychotherapy. It should be recognized that the availability of the more time-consuming techniques is limited in the public health sector, and their use should therefore be restricted to only the most difficult cases.

Relaxation Therapy

Relaxation therapy is the simplest form of "psychotherapy" that can easily be taught to patients. This is usually accessed on a self-help basis through a number of apps, audio recordings, or classes at local community centers or gyms. It is thought that if stress causes FGIDs, reducing autonomic arousal by relaxation may reduce symptoms and

induce a sense of well-being, allowing the patient to feel more confident and greatening their autonomy. Patients are taught to exclude sources of tension and to increase the degree of relaxation. Arousal reduction training includes a variety of different methods to teach patients to counteract the physiologic sequelae of stress or anxiety. The most widely used arousal reduction techniques include (1) progressive muscle relaxation training; (2) biofeedback for striated muscle tension; (3) autogenic training; (4) mindfulness-based stress reduction (MBSR); and (5) Tai-Chi, transcendental, or Yogic meditation. Such therapies have been shown to have an NNT of 6, however, with a broad range (95% CI 3–60). Unfortunately, to date, there are few well-designed controlled studies concerning short- and long-term efficacy.

Cognitive Behavioral Therapy

CBT is based on the assumption that FGIDs in some patients are behavioral diseases generated by responses to life events. In addition, patients who may benefit from this type of treatment may have (a) a high prevalence of anxiety, depression, and assertion difficulties; (b) a high need for social approval; and (c) perfectionistic attitudes. CBT consists of a wide range of strategies and procedures designed to bring about alterations in patients' perceptions of their situation. It facilitates their ability to control GI symptoms by learning new ways of thinking and behaving through personal experience and practice. The treatment essentially involves helping the patient to recognize maladaptive patterns of thinking and behavior, which produces a greater sense of control and autonomy in the patient. It insists that the patient takes some responsibility for the illness and helps them find a more healthy way of dealing with the underlying problem. Empirically, CBT has been demonstrated to produce good results. For instance, one meta-analysis which examined nine RCTs compared to control groups (n = 610) found that in 145 of 349 (41.5%) patients undergoing CBT, the symptoms did not improve, compared to 166 of 261 (63.6%) patients in the control groups. Despite the impact of CBT, access can be problematic, and the expertise of providers varies. Given this, internet-based CBT may be an opportunity for psychiatrists to consider for their patients, especially in light of empirical outcomes from small studies showing promise for such treatments.

One adjunctive therapy to CBT is mindfulness-based cognitive therapy (MBCT), which adds elements of CBT to stress reduction. Studies evaluating outcomes have demonstrated substantial improvements in symptom severity and quality of life as compared to a control group following an 8-week trial of mindfulness-based therapy. Moreover, MBCT has been demonstrated to impact visceral sensitivity.

Interpersonal Therapy

Interpersonal therapy focuses on resolving difficulties in interpersonal relationships that underlie or exacerbate abdominal symptoms in FGIDs. It consists of the identification and mental processing of key problem areas that include unresolved grief or loss, role transitions, and relationship discord. The initial focus is on the patient's abdominal symptoms, which are explored in detail. Emotional distress and abnormal feeling states arising from or linked to physical symptoms are then identified. Key problem areas in relationships and their link to physical and psychological symptoms are understood. This leads to the targeting of maladaptive relationship patterns, which may have developed after key childhood experiences such as trauma or sexual abuse. Solutions to these interpersonal difficulties are first tested out in therapy before subsequently being implemented outside of the therapy environment. Treatment is essentially an exercise in identifying and solving interpersonal problems, which facilitates a greater sense of control and autonomy and therefore reduces the overall degree of sustained arousal in interpersonal difficulties, producing an improvement in symptoms.

Psychodynamic Therapy

Psychodynamic psychotherapy is similar to interpersonal psychotherapy and requires a close relationship between the patient and the therapist, in which difficulties in interpersonal relationships can be highlighted. As the patient understands these problems, they may act upon these insights that may lead to a reduction in symptoms. Analytical psychotherapy attempts to provide the patient with an insight into why particular symptoms have developed and what they might mean or represent in the light of changes in key relationships. There is an implicit assumption that this insight will cause long-lasting changes in attitude and behavior. Symptoms often seem to stem from significant life changes (often a loss of a relationship) set against the background of a fragile personality and

difficulty coping with separation. The patient works through their interpersonal difficulties through a safe and contained relationship with the therapist. Psychodynamic psychotherapy has been demonstrated to have an NNT of 4 (95% CI 2–20), and in fact, the world gastroenterology organization has recommended it as a form of therapy for patients.

Hypnotherapy

Hypnosis is used to induce a state of relaxation with heightened suggestibility, in which the hypnotherapist uses progressive muscular relaxation with suggestions of relaxation to reduce striated muscle tension and to relax GI smooth muscle. This then alters the underlying abnormalities of gut motility or sensation and impacts the patient's perception of their symptoms. This is firstly initiated in the presence of the therapist, with the ultimate aim of enabling patients to control symptoms on their own. Patients are asked to practice autohypnosis at home using an audiotape, with the goal of being able to self-administer suggestions of relaxation. Unfortunately, the success of therapy can be dependent on the enthusiasm and skill of the therapist and is both time-consuming and expensive to provide. Studies, however, confirm that long-term efficacy is cost-effective in severe refractory cases and suggest that treatment is more likely to be successful with younger patients and those without serious psychopathology.

Biofeedback Therapy

Biofeedback is a therapeutic approach that depends on feedback as a measure of visceral function to show the patient a disturbance in physiology so that they themselves can learn to correct it. Heart rate variability feedback in relaxation and stress reduction is a growing application in FGIDs, but the most common use of biofeedback is in the treatment of incontinence and constipation. The therapy aims to make the patient more sensitive to rectal sensation and avoid inappropriate straining. It also provides a detailed explanation of normal physiology and a reeducation concerning the optimum defecatory patterns. A supportive relationship that the therapist can offer such patients undoubtedly contributes to the overall positive effect.

CONCLUDING REMARKS

The gut and the brain are intimately linked, and any disorder in one can manifest in the other. Therefore, psychiatry can play a pivotal therapeutic role in the management of patients with GI disorders.

ACKNOWLEDGMENTS

This chapter represents an update and revision of previous chapters in this series, most recently by Drs. Claude Andrew Botha, James K. Ruffle, and Adam D. Farmer from the last edition. We are indebted to Drs. Botha, Ruffle, and Farmer for their work and retain much of their prose in this current edition.

27.4 Psychosomatic Medicine: Obesity

Megan E. Lavery, Psy.D., and Ninoska D. Peterson, Ph.D.

DEFINITION, NOSOLOGY, AND EPIDEMIOLOGY

Obesity is a global epidemic with physical, economic, and psychological costs. The prevalence of obesity in the United States continues to rise, with 42.4% of U.S. adults meeting the criteria for obesity according to the 2017 to 2018 National Health and Nutrition Examination Survey (NHANES) (Table 27.4–1). In the United States, approximately 18.5% of children ages 2 to 19 have obesity. In both adults and children, there is a higher rate of obesity among minority groups, including Hispanics and African Americans. Rates of obesity have shown an alarming trend upward since the 1980s, with rates in the United States leveling off over the past decade. However, unlike the flattening of the obesity curve overall, severe obesity continues to increase.

Obesity is defined primarily by the body mass index (BMI). BMI is measured as weight in kilograms divided by height in meters squared (kg/m^2). A normal BMI is 18.5 to 24.5, and individuals are considered overweight with BMIs from 25 to 30. BMIs above 30 are in the obesity range, with a BMI above 40 considered to have severe obesity (Table 27.4–2).

Obesity raises the risk of morbidity from hypertension, dyslipidemia, type 2 diabetes, coronary heart disease (CHD), stroke, gallbladder disease, osteoarthritis, sleep apnea and respiratory problems, and some cancers. Obesity is also associated with increased risk in all-cause and cardiovascular disease mortality. In addition, obesity has a negative impact on quality of life, mobility, mental health, and stress level.

The economic costs of obesity and its associated health problems place a heavy burden on the US healthcare system. The costs of preventing, diagnosing, and treating obesity are directly observable, whereas the indirect costs may include loss of income, decreased productivity,

restricted activity, and absenteeism. Costs may also include the value of future income lost by premature death. According to the Centers for Disease Control, the estimated medical cost of obesity in the United States is $147 billion yearly in 2008 U.S. dollars.

DIAGNOSIS, CLINICAL FEATURES

BMI, as described above, has been the most widely used measure of obesity. While it is useful for population-level measurements and has utility as an estimate of health risk, BMI has also been criticized for failing to account for bone density, muscle mass versus fat mass, fitness, and other biometric measures of health. Another indicator of obesity is the measurement of waist circumference. Waist circumference greater than 35 inches for women or greater than 40 inches for men is considered obesity. High-waist circumference, or a hip-to-waist ratio, may elevate risks for obesity-related disease as well. Obesity was recognized by the American Medical Association as a disease in 2013. While obesity is not included as a diagnosis in the Diagnostic and Statistical Manual-5 (DSM-5), binge eating disorder (BED) has been formally accepted as a diagnosis, as discussed later.

Obesity in childhood is diagnosed using an age- and sex-specific percentile for BMI due to the variations in body composition with age and gender during childhood. Children with a BMI between the 85th and 95th percentile for children of the same age and gender are considered overweight, and children with a BMI above the 95th percentile are considered to have obesity.

Table 27.4–1.
Prevalence of Obesity and Severe Obesity Among U.S. Adults, Age 20 Years and Over, NHANES 2017–2018

	Total	Non-Hispanic White	Non-Hispanic Black	Non-Hispanic Asian	Hispanic
Obesity (BMI greater than or equal to 30)					
All	42.4	42.2	49.6	17.4	44.8
Men	43.0	44.7	41.1	17.5	45.7
Women	41.9	39.8	56.9	17.2	43.7
Severe Obesity (BMI greater than 40)					
All	9.2	9.3	13.8	2.0	7.9
Men	6.9				
Women	11.5				

NHANES, National Health and Nutrition Examination Surveys 2017–2018; BMI, body mass index

Table 27.4–2.
Classification of Obesity and Recommended Treatment

	Obesity Class	Body Mass Index (kg/m^2)	Recommended Treatment
Underweight		<18.5	Nutrition/eating disorder treatment
Normal		18.5–24.9	Maintenance
Overweight		25–29.9	BWM
Obese	I Mild	30–34.9	BWM + MWM
	II Moderate	35–39.9 (plus comorbidities)	BWM + MWM or BWM + WLS
	III Severe	>40	BWM + WLS

BWM, behavioral weight management; MWM, medical weight management; WLS, weight loss surgery.

COURSE AND PROGNOSIS

Childhood obesity is a risk factor for adult obesity and is related to the severity of adult obesity. Children with obesity are more likely to develop cardiovascular risk factors such as high-blood pressure and high-cholesterol; impaired glucose tolerance, insulin resistance, and type 2 diabetes; breathing problems such as sleep apnea and asthma; joint and pain problems; fatty liver disease, gallstones, and gastroesophageal reflux; and social and psychological problems, such as stigma and poor self-esteem (Fig. 27.4–1).

In adults, associated medical comorbidities of obesity include congestive heart failure, coronary artery disease, venous state ulcers, insulin resistance, polycystic ovarian syndrome, diabetes mellitus, hypertension, abdominal hernia, gall stones, gastroesophageal reflux disease, nonalcoholic fatty liver disease, stress urinary incontinence, deep venous thrombosis, pulmonary embolism, gout, plantar fasciitis, depression, anxiety, pseudotumor cerebri, stroke, infertility, asthma, obstructive sleep apnea, hypercholesterolemia, osteoarthritis, cancers, and others (Fig. 27.4–2). The risk of mortality and morbidity increases with a BMI above 35 and rises exponentially with the severity of BMI. Together, obesity and overweight are the second leading cause of preventable

death in the United States. An estimated 300,000 deaths per year are due to the obesity epidemic.

FIGURE 27.4–1. Medical comorbidities of obesity in adults. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2006–2015. All Rights Reserved.)

Behavioral and lifestyle interventions can effectively result in modest weight loss, which has a positive effect on comorbidities. However, the rate of recidivism is high, and weight loss is difficult to maintain for a variety of reasons. For patients with severe obesity, weight loss surgery appears to be an effective long-term intervention that results in significant weight loss and resolution of comorbidities.

PATHOLOGY AND LABORATORY CONSIDERATIONS

When working with patients with obesity, clinicians may want to consider the following adjunctive information: routine blood work for hyperlipidemia, hypertension, hypothyroid function, and hyperglucosemia; sleep studies to identify obstructive sleep apnea, and vitamin level panel to identify vitamin deficiencies.

ETIOLOGY

Fundamentally, obesity is the result of an imbalance between energy intake and expenditure. However, the development of obesity is far more complex than this simplified view portrays. Given the alarming rise in obesity rates, researchers have increasingly sought to elucidate the multifaceted causes of obesity in hopes of finding strategies to combat this epidemic.

Genetics, Biology, and Obesity

From an evolutionary perspective, the ability to store energy as adipose tissue would have yielded a selective advantage for survival and reproduction. Using this concept, Neel (1962) proposed the notion of thrifty genotypes. This theory hypothesizes that thrifty genotypes code for effective energy storage. Through natural selection, genes with the ability to save and store energy likely overrode other genes, resulting in many thrifty genes undergoing such selection. In fact, researchers have found over 600 single-gene mutations and genomic and chromosomal regions potentially related to obesity. Thus, due to natural selection, many individuals may be genetically susceptible to developing obesity.

In addition, twin and adoption studies have underscored the role of genes in obesity. This body of literature suggests that heritable genetic differences account for 55% to 85% of weight variance. Interestingly,

several twin and adoption studies also highlight how most of the nongenetic factors influencing weight may stem from nonshared environmental contexts unique to a given person (e.g., school environment and peer relationships). Contrary to common assumptions, the evidence suggests that the shared family environment may have a minimal effect on BMI. Therefore, genes and individual nonshared experiences may have a more significant impact on weight than the family environment.

FIGURE 27.4–2. Medical comorbidities of obesity in adolescents. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2006–2015. All Rights Reserved.)

Increasingly, adipose tissue and hormones have also been implicated as biologic contributors to obesity. More specifically, there is growing evidence that enlarged adipocytes in individuals with obesity create inflammation and result in the dysregulation of metabolic homeostasis, impacting levels of leptin, insulin, and adiponectin, thus creating metabolic syndrome. Researchers have just begun to understand how such changes can impact weight, as well as exercise, food intake, and overall

hormonal control. In particular, the role of the gut microbiome in weight gain and weight loss has been the target of increasing investigations. A body of evidence suggests that the gastrointestinal microbiota can impact dietary energy utilization and influences genes that regulate energy expenditure and storage.

Environment and Obesity

However, genetics in and of themselves do not explain the rising rates of obesity globally. A large body of research has underscored the importance of global environmental influences on eating behavior. For most of history, humans have struggled to combat food shortage, disease, and hostile surroundings. However, the modern industrialized environment stands in stark contrast to this type of setting. Instead, the current environment is overflowing with calorically dense foods, along with energy-saving devices. To capture these changes, Swinburn developed the term “obesogenic environment.” Researchers contend that the environments of most industrialized nations promote a positive energy balance through the availability and affordability of highly palatable, energy-dense foods, as well as numerous opportunities for inactivity (e.g., car ownership, television, sedentary job environments, and the supermarket system). In the current environment, expending an ample amount of energy typically requires individuals to engage in deliberate, consistent healthy lifestyle choices. Unfortunately, making a purposeful choice to be active is at odds with humans’ biologic propensity to conserve energy. Therefore, humans’ biologic predisposition makes them extremely vulnerable to overeating and inactivity, particularly in an environment with endless food and inactivity cues. The obesogenic environment has thus created an ideal setting for the growth of obesity. Many researchers and lobbyists have argued for national and global food reform, including taxation on sugary foods and drinks, as a primary means of combating obesity.

Food Addiction and Obesity

Despite a common food environment, research indicates that the susceptibility to food cues varies across individuals and serves as a predictor of BMI, the ability to resist cravings, and dietary compliance. Within this framework, researchers contend that food can become an addiction akin to other substance use disorders. More specifically, studies suggest that recurrent exposures to highly palatable foods result in

diminished dopamine levels in response to eating. As a result, individuals must consume larger amounts of food to feel satisfied, resulting in a cycle of overeating. The term *food addiction* (FA) has been used to capture the resulting pattern of excessive consumption. It is thought that FA to highly palatable, processed foods could be a key contributor to the development of obesity. Therefore, the availability of calorically dense foods, combined with a potential for physiologic addiction to these foods, may play a central role in the increasing rates of obesity.

The Yale Food Addiction Scale (YFAS) was specifically developed to measure FA by applying DSM-IV criteria for substance dependence to eating behaviors. A 2014 systematic metanalysis examined studies using the YFAST to assess for FA. The researchers found that the weighted mean prevalence of FA was 19.9% across adult samples. Higher BMI was associated with higher rates of FA diagnosis and number of symptoms. In fact, rates of FA were doubled in populations with overweight or obesity compared to healthy controls (24.9% vs. 11.1%, respectively). Additionally, in disordered eating samples, the mean prevalence of FA was extremely high (57.6%) compared to samples with no eating disorder diagnoses (16.2%). These results highlight the relationships between FA, weight, and disordered eating.

Behaviors, Cognitions, and Obesity

Many individuals report eating in response to negative emotions. Certain internal experiences, such as anxiety, sadness, negative thoughts, and cravings, are frequently felt to be unpleasant. Individuals vary in their ability to tolerate such internal distress. Some individuals may make a great effort to escape these experiences via psychological (i.e., suppression) or behavioral (i.e., isolation) avoidance. It is common for individuals to use food as a means of temporarily suppressing emotional distress. In fact, a significant number of patients report regularly eating in response to stress, boredom, fatigue, anxiety, and depression. For many, this pattern may begin in childhood and sustain throughout adulthood. Eating can become a learned response to emotional distress and, for some, may become a means of coping. Research suggests emotional eating is positively associated with weight and BMI. Thus, emotional eating can develop into a primary maladaptive affect regulation tool, resulting in weight gain.

Dimensions of Personality and Obesity

There is also a growing body of research focusing on the influence of personality traits on weight. In particular, many studies suggest that neuroticism (manifested in greater anxiety, depression, impulsivity, emotional vulnerability, hostility, and anger) is a risk factor for overweight or obesity, particularly for women. It is hypothesized that individuals with higher levels of neuroticism may be more susceptible to using food as a dysfunctional coping strategy. In addition, the literature indicates that for patients with obesity, there are higher rates of impulsivity with and without disordered eating (unhealthy eating patterns often characterized by distress and/or loss of control (see Tables 27.4–3 and 27.4–4). Similarly, high-reward sensitivity appears to be another risk factor for obesity. Researchers postulate that individuals with higher sensitivity to reward have a proclivity toward uncontrolled eating, resulting in sustained positive energy balance. However, higher levels of conscientiousness (regulation of internal urges) and self-control have been shown to be protective in regard to weight gain. Given this literature, it may be important to consider personality traits when working with patients struggling with obesity.

Table 27.4–3.
DSM-5 Diagnostic Criteria for Binge Eating Disorder

Recurrent episodes of binge eating (eating a larger than normal amount with loss of control at least once per week for 3 months) accompanied by at least three of the following:

- Eating very rapidly
- Eating until uncomfortably full
- Eating when not hungry
- Eating alone or hiding eating from others
- Feeling guilty or disgusted after a binge

No recurrent compensatory purging, exercising, or fasting

Marked distress

Table 27.4–4.
Proposed Criteria for Night Eating Syndrome (NES)

1. **Core criteria (One of the following):**
   A. Evening hyperphagia and/or
   B. Nocturnal awakenings with food ingestion (at least 2 × /week)
2. **Three of five associated symptoms:**
   A. Insomnia: Sleep initiation and maintenance insomnia
   B. Morning anorexia: Either in the form of lack of desire to eat in the morning or skipping breakfast more days than not
   C. Urges to eat at night
   D. Depressed evening mood
   E. A belief that one must eat to sleep

Symptoms must be associated with distress and occur for 3 or more months

Data from Allison KC, Lundgren JD, O'Reardon JP, et al. Proposed diagnostic criteria for night eating syndrome. *Int J Eat Disord*. 2010;43(3):241–247.

PSYCHIATRIC COMORBIDITIES OF OBESITY

Eating Disorders

Eating disorders are common psychiatric comorbidities of obesity and include BED, bulimia, and syndromes such as night eating, graze eating, and loss of control consumption of high-calorie liquids.

BED has been included in the DSM-5 as a stand-alone disorder and was previously included in the DSM-IV under the category Eating Disorder Not Otherwise Specified (Table 27.4–3). BED is characterized by eating large amounts in a short period of time with a feeling of loss of control. Associated symptoms include feelings of guilt, eating quickly, eating when not hungry, hiding eating patterns from others, and eating until uncomfortably full. The binge episodes must be distressing and occur at least once per week for 3 months to meet the criteria for BED. The prevalence of BED among patients with obesity is estimated to be 30%, and patients with BED tend to have obesity. BED appears to be the most common eating disorder, with estimated population rates of 2%.

Other eating syndromes sometimes associated with obesity include graze eating and night eating syndrome (NES). Graze eating syndrome is

less well-defined than NES and typically involves eating large amounts slowly over the day (e.g., nibbling or picking) or continuous eating. Graze eating is often associated with distress and eating for reasons other than hunger. However, unlike BED, there are limited consensuses around whether graze eating is characterized by feelings of loss of control. In fact, a 2016 study examining bariatric surgery candidates who graze eat found that a majority of patients who reported graze eating did not experience loss of control, instead endorsing a greater degree of overall distress and psychopathology. The minority of patients evidencing graze eating with loss of control reported an even greater risk of psychopathology. Further, a high-calorie liquid type of grazing has also been identified as a pattern of drinking high-calorie liquids continuously throughout the day. In addition, NES is a relatively understudied disorder involving a circadian delay in food consumption. According to the 2010 proposed criteria, the diagnostic criterion for NES requires the presence of evening hyperphagia or nocturnal awakenings with food ingestion. Additional symptoms include morning anorexia, urges to eat at night, insomnia, low evening mood, and a belief that one must eat to sleep (Table 27.4–4). There appears to be a relationship between NES and weight in some, but not all, studies. Within the research, NES has been associated with several correlates of distress, including depressed mood, anxiety, low self-esteem, poorer body image, and decreased quality of life. Not surprisingly, there are higher rates of mood and anxiety disorders in NES populations, including current and lifetime major depression. It is also important to note that more distress has been associated with patients who wake up and eat in the middle of the night versus patients with only evening hyperphagia. Given these findings, some consider patients with nocturnal eating episodes to be more severe than patients without nocturnal ingestions.

Bulimia nervosa is characterized by binge episodes followed by compensatory behavior such as vomiting, laxative use, or overexercise. Binge/purge episodes must occur at least once per week for 3 months to meet the criteria for the disorder, consistent with BED. Patients with bulimia may have obesity but are more typically in the normal BMI weight range.

Depression

Depression and obesity often overlap as disease processes. This is perhaps unsurprising as increased appetite and low-energy are among

the diagnostic symptoms of depression (DSM-5). There is a high-incidence of depression among patients with obesity, with estimates ranging from 19% to 66%. The relationship between obesity and depression appears to be reciprocal, with 80% of studies suggesting obesity contributes to depression and 53% of studies suggesting that depression leads to obesity. Obesity may lead to depression by negatively affecting health and body image, increasing functional impairment, decreasing quality of life and physical activity, and adding to the stigma. Depression may lead to obesity by contributing to an elevated stress reaction, impairing immunity, negative cognitions, eating behaviors, and poor adherence to treatment. Factors moderating the relationship between depression and obesity include gender, age, socioeconomic status, and severity of obesity. Women, those with increasing age or those with lower income, are more likely to experience depression with obesity. Other factors that increase the likelihood of depression with obesity include binge eating behaviors and experiencing stigma.

Anxiety

Anxiety disorders are the most common psychological disorders affecting 25% of the population. Obesity may lead to anxiety by causing distress from weight-related stigma. In addition, the physical comorbidities and negative effects of obesity on quality of life may lead to stress and cause anxiety disorders. However, the prospective evidence for obesity causing anxiety is weak. A review of the literature suggests there is a moderate amount of evidence for a weak but positive association between anxiety and obesity. There appears to be a stronger relationship between severe obesity and anxiety. Among anxiety disorders, specific phobia, social phobia may have the strongest associations with obesity. Although no longer in the anxiety category, post-traumatic stress disorder may be as well. Anxiety disorders may contribute to obesity through the hypothalamic pituitary adrenal axis dysfunction, and anxiety may increase cravings for high-sugar and high-fat foods. Anxiety may also be related to obesity through negative childhood events such as abuse and eating disorders, with patients developing anxiety in response to trauma and those with anxiety having a higher risk of eating disorder behaviors.

Severe Mental Illness

Patients with severe mental illness (SMI), such as schizophrenia and bipolar disorder, are at increased risk of obesity, with identified rates up to 60%. Although weight gain side effects of psychotropic medications appear to play a major role, there is some evidence of being overweight among medication naïve patients. Patients with SMI also have an increased risk of medical conditions related to obesity, including type 2 diabetes, cardiovascular disease, and metabolic syndrome. Individuals with schizophrenia and bipolar disorder have a shorter lifespan and an increased risk of death from medical causes. Weight gain side effects of psychotropic medications are a cause for obesity in persons with SMI, with atypical antipsychotics associated with more weight gain than typical agents, and patients treated with a combination of atypicals and mood stabilizers showing the highest weight gain. In persons with SMI, binge eating behaviors and female gender are also associated with higher rates of obesity. Clinicians should closely monitor weight in patients with SMI and include regular measurement of BMI, waist circumference, lipid profile, and plasma glucose level. Consideration of adjunctive therapy such as cognitive-behavioral weight management and diet/exercise/lifestyle changes can mitigate weight gain effects in persons with SMI. Other options include choosing the medication that best treats the patient's mental disorder with the least weight gain profile, switching antipsychotics to promote weight loss in patients who experience significant weight gain, and considering adjunctive treatment with medications that promote weight loss.

Psychiatric Medications and Weight Gain. Weight gain may contribute to nonadherence to psychotropic medications, and the majority of antidepressants, antipsychotics, and mood stabilizers contribute to weight gain (Table 27.4–5). Antipsychotics appear to have some of the highest rates of weight gain, including olanzapine (2.3 kg/month), quetiapine (1.8 kg/month), and clozapine (1.7 kg/month).

Table 27.4–5.
Psychotropic Medications and Weight Gain

Psychotropic Medication	Weight Gain Profile
Antipsychotics	
Olanzapine (Zyprexa)	+++
Quetiapine (Seroquel)	+++
Risperidone (Risperdal)	++
Ziprasidone (Geodon)	+
Asenapine (Saphris)	+
Iloperidone (Fanapt)	++
Paliperidone (Invega)	0
Aripiprazole (Abilify)	+
Clozapine (Clozaril)	+++
Antidepressants	
Imipramine (Tofranil)	+
Amitriptyline (Elavil)	+
Trazodone (Oleptro)	+
Fluoxetine (Prozac)	0/+
Citalopram (Celexa)	+
Fluvoxamine (Luvox)	0
Duloxetine (Cymbalta)	+
Escitalopram (Lexapro)	+
Bupropion (Wellbutrin)	–
Mirtazapine (Remeron)	+
Paroxetine (Paxil)	++
Sertraline (Zoloft)	+
Venlafaxine (Effexor)	0
Mood Stabilizers/Anticonvulsants	
Divalproex (Depakote)	++
Lamotrigine (Lamictal)	0
Carbamazepine (Tegretol)	++

Lithium (Lithobid)	++
Zonisamide (Zonegran)	–
Topiramate (Topamax)	–

–, Weight loss; 0, Weight neutral; +, Weight gain (mild); ++, Weight gain (moderate); +++, Weight gain (significant).

Weight gain due to antidepressants appears to be under-recognized yet an important consideration, given the high prescribing volume of these medications. Tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) appear to have higher rates of weight gain than serotonin selective reuptake inhibitors (SSRIs). Weight gain is associated with mirtazapine, whereas bupropion may be the only antidepressant agent that contributes to weight loss. On average, antidepressants result in a 1 to 3 kg weight gain. The short-term weight loss seen with fluoxetine appears to be transient, with later weight gain offsetting this effect. Weight gain is a common side effect of mood stabilizers, with divalproex, carbamazepine, and lithium appearing to cause the most gain (0.9 to 15 kg). Lamotrigine appears to be more weight-neutral, and zonisamide may promote weight loss.

The causes of weight gain with psychotropic use may include increased calorie intake, slowing of the metabolism, and increased appetite. Patients should be alerted to weight gain as a potential side effect and closely monitored with routine blood work for hyperlipidemia, hypertension, and hyperglucosemia. Patients being prescribed psychotropics with weight gain side effects should be given recommendations simultaneously for diet and exercise as a preventative measure. Careful consideration of the weight gain profile of medication should be given, especially in patients already with increased BMI and comorbidities. In cases where the benefits of the medication on the psychiatric symptoms appear to outweigh the risks of weight gain, consideration of adjunctive weight loss medications may be considered. Of note, there is an emerging literature base looking at the effects of metformin in mitigating antipsychotic-induced metabolic dysfunction via changes in the gut-brain axis.

Substance Use Disorders

Researchers have found similarities in the neurobiology between obesity and substance use disorders, suggesting that these common paths might

also have treatment indications. Some conceptualize obesity as an FA with compulsive overeating, as previously discussed. Drugs and addictive foods may activate similar brain regions involved in reward processing and decision-making.

There appears to be a positive relationship between nicotine dependence and obesity. Epidemiologic studies also point to a relationship between alcohol use disorders and obesity, although no consistent relationships between cocaine/stimulant use and obesity have been found. The cooccurrence of substance use disorders and obesity suggests that treatments such as cognitive behavioral therapy (CBT), diet/exercise, and medications targeting underlying biologic mechanisms in the reward circuitry of the brain may be useful for both conditions. Considering that substance use remission often results in weight gain, awareness of weight management in treating substance use disorders is important.

Table 27.4–6.
Types of Diets

Type of Diet	Calorie Deficit	Weight Loss	Summary
Low-calorie diet (LCD)	800–1,500 cals/day	0.5–1 kg/wk	Carbohydrates 55% Protein 15% Fat <30%
Very low-calorie diet (VLCD)	500–800 cals/day	1.5–2.5 kg/wk	70–100 g of protein/day via liquid meal replacements
South Beach diet/Atkins/Zone diet	<30 g of carbohydrate/day	Rapid initial weight loss followed by steady weight loss	Low carbohydrate Some promote high fiber, lean meats, and low-glycemic carbohydrates
Weight Watchers	Promotes balanced food choices via a points system based on the amount of fats, carbohydrates, protein, and fiber in foods.	1–2 lb/wk	Mod fat, balanced nutrition Focus on activity Group/online support
Jenny Craig/Nutrisystem	Prepackaged low-calorie food	1–2 lb/wk	Meal replacements (1,200–1,500 calories/day) with gradual return to grocery foods in maintenance phase Individual consultant

	and/or online support

TREATMENT

Treatments for obesity are tailored to the risk level and individual needs of the patient (Table 27.4–2). The basis for all weight management treatment is behavioral lifestyle intervention, including behavioral modification, diet, and exercise. Patients in the overweight range (BMI between 25 and 30) are encouraged to engage in behavioral weight management. Patients with mild obesity (BMI >30) are directed to add medical weight management, and patients with severe obesity (BMI >40) are candidates for weight loss surgery.

Benefits of Weight Loss

A large body of literature calls attention to the physical and psychological benefits of even small weight reductions. For instance, a weight loss of 5% to 10% of initial body weight has demonstrated clinically significant improvements across physical domains, including blood pressure and lipid levels. Similarly, a 3% decrease in weight has been associated with decreased metabolic risk factors. Weight loss of only 1 to 9 lb has even been correlated with decreased mortality in individuals who are overweight and have diabetes. In addition, studies have consistently shown a positive relationship between weight loss efforts and psychological variables, including body image, health-related quality of life, self-esteem, and depression. Arguably, this body of evidence supports the concept that a weight loss goal is never too small to result in benefit.

Commercial Diets

Despite the complex etiology of obesity, individual lifestyle and behavioral change can play a critical role in addressing factors influencing weight. Many individuals may initially attempt weight loss through commercial diets. For individuals who struggle with their weight, there are numerous commercial diets available with various food and activity goals (see Table 27.4–6 for details and comparisons of diets). Significant weight loss has been observed with many low-carbohydrate or low-fat diets. Generally, weight loss differences between diet types are minimal. Studies

suggest that behavioral support and exercise may play key roles in weight loss differences versus the diet regimen itself. Similarly, in comparing several popular diet programs (Atkins, Weight Watchers [WW], Ornish, and Zone diet), research indicates that adherence is the biggest predictor of weight loss, regardless of the type of diet. Therefore, adherence appears to be the critical factor in positive outcomes. Unfortunately, due to gradual nonadherence, it is not uncommon for patients who have attempted numerous weight loss programs to be at their starting weight or higher.

Behavioral Weight Loss

Although some individuals may experience success with commercial diets, many patients may need additional specialized support. In considering psychological treatment options for obesity, numerous studies demonstrate the efficacy of lifestyle and behavioral weight loss (BWL) interventions. In fact, based on a systematic review of the literature, the updated 2013 Guidelines for Managing Overweight and Obesity in Adults encourage clinicians to offer a rigorous, multicomponent behavioral intervention to patients with a BMI >30 or >25 with at least one comorbidity or risk factor. The basic tenets of BWL stem from Learning Theory, which assumes that behavior can be altered by modifying the context in which the behavior occurs. Thus, treatment aims to reduce maladaptive behaviors, such as the consumption of calorically dense food and sedentary behaviors, while reinforcing healthy alternatives (e.g., the selection of healthy food choices and implementation of exercise). Through psychoeducation and skill-based interventions, such treatments encourage patients to make permanent changes to their food intake, activity level, and environment. In an effort to promote new, enduring habits, patients are encouraged to take a balanced approach to food choices and exercise. For example, primary dietary goals often included reducing calorie and saturated fat intake while increasing the consumption of complex carbs, vegetables, and other nutritionally dense foods. Thus, BWL supports flexibility over rigid adherence.

In addition to general dietary and activity goals, BWL treatment focuses on learning behavioral strategies to facilitate weight loss. For example, self-monitoring and goal setting are incorporated into treatment to help patients observe their calorie targets and exercise objectives. It can be particularly important for clinicians to help patients set short-term,

reasonable behavioral goals that can be monitored over time. In addition, BWL protocols typically focus on teaching stimulus control techniques; modifying cues in the environment to increase the potential that a healthy behavior will occur. For example, to decrease the likelihood of an overeating episode, individuals may limit their access to trigger foods by purchasing a cone of ice cream versus a gallon container. Similarly, to increase the probability of being active, individuals may keep their workout clothes in their car so that they go straight to the gym after work before returning home. Behavioral strategies, such as stimulus control, have consistently been shown to be an effective component for decreasing sedentary behavior in the context of weight loss.

Commonly, BWL treatment is disseminated in a group format with 4 to 6 months of weekly sessions. Due to the skill-based nature of the treatment, information is typically delivered in a psychoeducational format with topics presented as stand-alone modules. The LEARN (Lifestyle, Exercise, Attitudes, Relationships, and Nutrition) Program is considered the gold standard for BWL group-based treatment. The protocol has been utilized in numerous clinical and research settings. Similar to standard BWL programs, LEARN encourages patients to implement gradual lifestyle changes. Following the federal nutritional and activity guidelines, the program focuses on moderate caloric restriction and a gradual increase in physical activity. The program is structured in a series of additive steps with some repetition to facilitate mastery.

On average, BWL interventions produce a 5% to 10% weight reduction over a 6-month period. An evaluation of the literature conducted by the American College of Cardiology, the American Heart Association in Dallas, Texas, and the Obesity Society found that comprehensive behavioral interventions involving a modification of diet, increased physical activity, and behavioral therapy skills resulted in an average weight loss of 8 kg; with most patients' weight stabilizing after 6 months of treatment. Despite these typical outcomes, both clinical experience and research suggest that many individuals with overweight and obesity seeking weight loss begin treatment with goals that are two to three times greater than the expected weight loss range. While some research suggests no association or a positive relationship between initial weight loss goals and results, several studies have found that greater weight loss expectations are related to poorer weight loss outcomes. Thus, it may be

important to discuss realistic expectations with patients prior to beginning BWL.

Weight Loss Maintenance

Although many patients can successfully lose weight during the initial phase of treatment, obesity treatments demonstrate limited effectiveness in regard to long-term weight loss maintenance. Unfortunately, a large body of literature suggests that following the completion of weight loss programs, most individuals regain a majority of their weight 3 to 5 years after treatment. In fact, it is estimated that less than 5% of patients who lose weight will have maintained their losses after 4 to 5 years. While some research suggests that metabolic changes may account for a small percentage of weight regain, the disappointing long-term results of standard behavior treatment are often attributed to decreased compliance with behavioral, dietary, and physical activity guidelines. In fact, it is posited that at the time of greatest weight loss, many individuals have already displayed marked deviations from their initial healthy behavior changes. Thus, the trend for individuals to regain weight underscores how difficult it can be to alter habits long-term.

In understanding the difficulties with sustained weight loss, it can be helpful to understand how some individuals are able to achieve weight loss maintenance. Across studies, when comparing individuals who have maintained weight loss long-term to individuals who have regained weight, maintainers typically report lower dietary fat consumption, higher levels of physical activity (specifically vigorous activity), increased use of general behavioral strategies, and more frequent self-weighing. Taken together, this body of literature indicates that sustained behavioral changes are associated with more long-term positive weight outcomes. Moreover, the National Weight Control Registry is a particularly useful database of individuals followed prospectively over time who have on average lost more than 65 lb and sustained their weight losses for more than 5.5 years. One study used this registry and found that several factors predicted weight regain versus maintenance over a one-year period. Risk factors for weight gain included a larger initial weight loss, heavier maximum weight, more significant history of weight cycling, shorter period of maintaining current weight, greater depressive symptoms, more disinhibition, and a greater desire to continue to lose weight. These results indicate that even among individuals who have lost a significant amount of weight and kept

the weight off for a period of time, there are still several risk factors that make some individuals more vulnerable to regaining weight.

Numerous studies have shown that dietary self-monitoring is associated with both greater initial weight loss and sustained maintenance of lost weight. Unfortunately, akin to other health behaviors, compliance with self-monitoring often decreases over time. Given this trend, one study sought to identify what aspects of self-monitoring are essential for long-term success. Researchers examined the effects of frequency (total number of food records), consistency (number of weeks with >2 records), and comprehensiveness of self-monitoring on weight loss maintenance in 220 women at 12 months into a weight loss journey. Results revealed that individuals who continued to self-monitor frequently and consistently at 12 months sustained weight losses more effectively. At the same time, the findings demonstrated that increased comprehensiveness of monitoring did not result in any added benefit above and beyond the effect of frequency. These findings indicate that continuing to complete food diaries frequently and consistently may help individuals to sustain a level of awareness and adherence, though the detail of self-monitoring appears to have less of an impact on outcomes.

Psychological Treatment of Obesity

Cognitive Behavioral Therapy for Weight Loss. In addition to general lifestyle and behavioral treatments, CBT is an effective, empirically supported psychological intervention for weight management in both youth and adults. CBT for obesity typically includes psychoeducation (especially around dietary guidelines and physical activity), behavioral skills (e.g., self-monitoring and stimulus control), and cognitive strategies. CBT can be utilized as a stand-alone treatment or can be used to improve behavioral lifestyle treatment components. Many of the tenets and skills taught in CBT treatment overlap with standard weight-loss interventions, including the use of psychoeducation, self-monitoring, stimulus control, and problem-solving. The literature suggests that CBT programs result in similar, if not slightly higher, weight losses than BWL, with most patients losing 5% to 20% of their initial weight. CBT may enhance traditional treatments by focusing on cognitive interventions targeting the maladaptive thinking that often triggers overeating, poor body image, and inactivity.

More specifically, cognitive restructuring is an important component of CBT that involves identifying and challenging negative thought patterns. For example, after eating a cookie, an individual may think, “I blew it. I might as well give up and eat the whole package.” As a result of this thought, the person may binge on the box of cookies. In an attempt to reduce such problematic behavioral patterns, patients are trained to identify cognitive distortions (irrational thoughts) and learn techniques to challenge beliefs that lead to unhealthy behaviors, such as identifying evidence for and against their thoughts. Clinicians often utilize Socratic questioning to help patients learn to challenge automatic thoughts and underlying beliefs. For instance, in the example above, clinicians may ask, “Why do you think it was difficult for you to accomplish your eating goals this week?” Similarly, clinicians may recommend that patients engage in behavioral experiments to challenge their negative assumptions. For example, patients can remain inactive as a result of thinking, “I’m too tired after work to do anything.” Such patients are asked to directly confront this thought by taking a walk despite fatigue. By the end of treatment, it is hoped that patients can elucidate and challenge dysfunctional thoughts and generate alternative thoughts at the moment.

Emotional distress often serves as a trigger for these negative thought patterns. Therefore, when using CBT, clinicians may also focus on stress-reduction methods outside of food. In particular, clinicians may teach relaxation strategies, such as guided imagery, diaphragmatic breathing, and progressive muscle training to help patients more effectively manage problematic emotional states. In high-stress situations, relaxation techniques are intended to directly decrease emotional distress while indirectly facilitating patients’ ability to identify negative thoughts. Ultimately, it is anticipated that relaxation skills and other stress-management techniques can help patients reduce emotional distress and focus on actions consistent with weight loss goals.

Mindfulness-Based Approaches. Developments in mindfulness and acceptance-based interventions have led to increased attention to alternatives to more traditional BWL approaches. Mindfulness and acceptance-based interventions focus on changing patients’ relationships with unpleasant thoughts, feelings, and bodily sensations. For example, acceptance and commitment therapy (ACT) targets experiential avoidance (the avoidance or attempt to control internal events, such as

difficult thoughts, emotions, or bodily sensations), with the primary aim of helping patients increase their willingness to experience negative emotional experiences through mindfulness, cognitive defusion, and values techniques. Presumably, by becoming more willing to observe the present moment, patients are able to reduce maladaptive patterns used for avoidance (i.e., eating) and focus on value-driven behaviors (i.e., engaging in activities in the service of health and quality of life). Within this framework, ACT contends that experiential avoidance is the core of both emotional eating and eating in response to environmental stimuli. More specifically, emotional eating typically occurs in response to emotional distress and serves as an attempt to reduce internal negative experiences. Although eating in response to external triggers does not necessarily stem from negative emotions, individuals often experience uncomfortable thoughts and feelings when trying to resist overeating in response to these cues. ACT seeks to promote healthy behaviors consistent with patients' values while reducing avoidance through mindfulness and acceptance techniques.

The research examining mindfulness-based interventions for weight loss supports the use of ACT and general mindfulness techniques to address disordered eating patterns, physical activity, food cravings, and body image dissatisfaction. In addition, a growing body of research demonstrates the positive effect of ACT on behavioral change in the context of weight loss and weight maintenance. One 2008 exploratory study examined the effectiveness of a brief ACT-based group treatment on 68 females randomized to ACT treatment or a control condition. Although no significant differences were initially found in BMI and mental health, intervention participants reported significantly increased physical activity levels at 6 months compared to controls. When participants who reported never using skills were excluded from the analysis, the ACT intervention participants showed significantly greater reductions in BMI. Further, a 2020 systematic review and meta-analysis of third-wave cognitive-behavioral therapies found that ACT-based interventions consistently demonstrated greater weight loss outcomes than standard behavioral treatment at 12- and 24-month follow-up; with other timepoints favoring ACT or demonstrating no significant differences between ACT and behavioral treatment. There is also a growing body of research suggesting that the combination of standard behavioral treatment and ACT may result in improved weight loss and weight maintenance. It is

postulated that standard behavioral treatment provides patients with tools to alter their eating patterns, while ACT targets psychological flexibility, cultivating patient's ability to effectively cope with new challenges as they arise.

Motivational Interviewing. As the weight loss maintenance research suggests, not all patients seeking weight loss are successful. Some patients may struggle to maintain behavioral change long-term, while others may never even begin to change before dropping out of treatment. The Transtheoretical Model (TTM), first proposed by Prochaska and DiClemente, helps to explain why some patients experience difficulty initiating small changes while others keep food diaries and make numerous behavioral modifications from the start. Although the TTM was initially developed to explain failure in smoking cessation interventions, it is now used to conceptualize a wide range of health behaviors, from condom use to exercise adoption and overeating. Regardless of the specific behavior, the TTM postulates that adopting a new behavior involves an evolution through six distinct stages of readiness to change (precontemplation, contemplation, preparation, action, maintenance, and termination) (Table 27.4–7). Within this framework, behavior change is theorized to be a process that develops over time.

Table 27.4–7.
Stages of Change

Stage of Change	Description
Precontemplation	▶ No intention to change in foreseeable future ▶ May be unaware of problem ▶ Often present to therapy because of pressure from others ▶ Usually feel coerced or threatened by treatment
Contemplation	▶ Aware problem exists ▶ Seriously considering change but no commitment to action ▶ Struggle with positive evaluation of problem behavior and effort it might take to overcome it
Preparation	▶ Intending to take action in the next month ▶ May have unsuccessfully taken action in the past year ▶ May report small changes (“baby steps”) ▶ Some reductions may be evident
Action	▶ Modifications in behavior, experience, and/or environment ▶ Overt behavior change ▶ One day to 6 months
Maintenance	▶ Prevent relapse and consolidate the gains ▶ Remaining free of the problem behavior and/or consistently engaging in incompatible behavior for >6 months ▶ Can be considered to last a lifetime for some behaviors
Termination	▶ Change process complete ▶ No longer working to prevent relapse ▶ Total confidence and self-efficacy across all high-risk situations ▶ Exited from the cycle of change

Data from Prochaska JO, DiClemente CC, Norcross JC. In search of how people change. *Am Psychol*. 1992;47(9):1102–1114.

Prior to initiating lifestyle interventions for obesity, it is critical to assess and understand a presenting patient's readiness for change. Patients in the precontemplation stage of change may have a limited appreciation that their obesity is a problem and only come to treatment due to pressure from others. It is not uncommon for patients in this stage to have little intention to change their lifestyle and therefore feeling threatened by treatment. Although patients in the contemplation stage are aware that a problem exists (i.e., "I need to lose weight in order to improve my diabetes"), they often remain stuck between a desire to change versus the perceived obstacles of change. Patients in this stage are sincerely contemplating change but have yet to make a commitment to action. One study indicates that patients commonly remain in the contemplation stage for at least 2 years prior to proceeding to the next stage of change. In the subsequent stage (preparation stage), patients are typically intending to take measurable action within the month and may have even unsuccessfully attempted changes over the past year. In addition, a patient in the preparation stage may describe currently making small changes in preparation for broader change. For example, patients may report that they have obtained a gym membership in anticipation of starting to exercise in the near future. Arguably, many patients coming for a medical weight management evaluation are in this stage of change. Often patients may be seeking professional support in order to take overt steps toward a lifestyle change.

When patients proceed into the action stage, they will typically begin to alter their behavior, environment, and/or experience in an attempt to address their obesity. For instance, patients may change their home environments by throwing away trigger foods and replacing these items with healthier purchases. Within the TTM, individuals are considered to be in the action stage if they have changed a dysfunctional behavior (e.g., inactivity and high-calorie food choices) from as little as one day up to 6 months. In the addictions literature, behavior change is typically defined as the absence of a given behavior (i.e., remaining sober). In weight management, the notion of elimination is less applicable, and instead, behavioral modification or reshaping may be more relevant. Overall, changes during this period are often the most visible. Subsequently, individuals frequently receive the most external recognition during this stage. In particular, it is not uncommon for patients to receive compliments about their weight loss, which can often serve to reinforce lifestyle

changes. Following 6 months of consistent change, patients enter the maintenance stage, where they work to consolidate gains and prevent relapse. Individuals are thought to be in the maintenance stage when they remain free of a behavior or implement a new, incompatible behavior for more than 6 months. In regard to lifestyle changes related to weight management, many consider the maintenance stage to be lifelong. However, technically, patients can enter the termination stage, where they have exited the cycle of change. In order to achieve this stage, patients must no longer be working to prevent relapse and have complete confidence in all high-risk situations.

Most individuals engaging in behavior change proceed through the stages of change in a spiral versus linear pattern. Relapse is the rule rather than the exception. Therefore, many patients will not maintain changes on their first attempt. In fact, as they modify their behavior, it is quite common for patients to regress back to an earlier stage and consequently cycle back through the stages. For instance, patients engaging in BWL may have consistently engaged in healthy eating patterns for a few months. However, while at a holiday party, they may have a binge eating episode and subsequently feel ambivalent about continuing to make positive behavior changes. At the beginning of treatment, it is essential to educate patients about the spiral nature of change and to normalize these common experiences.

Furthermore, given the varying levels of readiness for change, when presented with a patient seeking treatment for their obesity, it is important to consider stage-matched treatment. For instance, if patients are in the contemplation stage, giving them action tasks will likely result in failure or drop-out. Unfortunately, most treatments, including weight management programs, are action-oriented and assume that patients are in the action stage. Treatment is the most effective when clinicians match treatment goals to patients' stages of change. In fact, treatments focused on helping patients move just one stage a month can double the chances that patients will engage in change on their own in the future.

Movement through the stages of change has been shown to be influenced by mediating variables, including the decisional balance and self-efficacy. More specifically, the decisional balance is conceptualized as the balance between the perceived comparative gains and losses (pros and cons) of making a change versus the status quo. Typically, patients in the earlier stages (precontemplation and contemplation) identify more

disadvantages than advantages to behavior change. The decisional balance tends to shift as patients move through the stages of change, with patients often perceiving more advantages than disadvantages to change in the preparation, action, and maintenance stages. For example, in the contemplation stage, patients likely perceive many barriers to engaging in consistent activity, while those in the preparation stage may begin to recognize that increased activity results in increased energy and overall improved well-being. Similarly, self-efficacy (individuals' confidence in their ability to change) appears to be a key variable in movement through the stages. Studies suggest that self-efficacy typically increases linearly across the stages of change.

Table 27.4–8.
Strategies Using Motivational Interviewing Based on Stage of Change

Stage of Change	Potential Clinical Strategies
General techniques	*Express empathy *Increase self-efficacy *Roll with resistance *Develop discrepancy
Contemplation stage	*Identify pros and cons of change versus status quo *Normalize ambivalence *Explore barriers to change *Increase commitment *Support self-efficacy
Preparation stage	*Clarify goals *Explore options *Reinforce sense of personal choice *Practice skills *Develop a plan
Action stage	*Support self-efficacy *Engage in problem-solving *Reinforce commitment to change and success thus far

Adapted from Erol S, Erdogan S. Application of a stage based motivational interviewing approach to adolescent smoking cessation: the Transtheoretical Model-based study. *Patient Educ Couns.* 2008;72(1):42–48. doi: 10.1016/j.pec.2008.01.011.

Motivational interviewing (MI) is a treatment approach based on the stages of change model. MI is intended to enhance patients' motivation for change and thus support patients' movement through the stages of change. MI is considered a patient-centered counseling style with a heavy emphasis on collaboration and partnership between patients and clinicians. The treatment postulates that each patient holds an intrinsic motivation for change. In line with a collaborative approach, clinicians seek to enhance patients' motivation for change through eliciting personal

goals, values, and perceptions. Within this framework, the primary goal of MI is to help patients explore and resolve ambivalence around behavior change (see Table 27.4–8 for details regarding MI principles and techniques).

Given the high-rates of weight regain, MI has increasingly been examined and utilized as an alternative or addition to more traditional skill-based weight management techniques. Two large-scale weight loss studies (the Diabetes Prevention Program and the Look AHEAD trial) utilized MI as a part of their lifestyle intervention. In addition, a 2011 meta-analysis of randomized controlled trials using MI found that MI techniques moderately reduced BMI above and beyond control interventions. Across studies using weight as a primary outcome, MI significantly enhanced weight loss outcomes, with participants who received MI losing 1.47 kg more on average than participants receiving control treatments. Of note, in studies tracking change in BMI, MI produced improved but nonsignificant reductions in BMI over controls. Taken together, this body of literature underscores the potential utility of MI in addressing patients' motivation for change when engaging in weight loss treatments.

Case Example

The case of “Robin” exemplified some of the obstacles often seen in BWL treatment. Robin was a 24-year-old Caucasian female self-referred for weight and occasional binge eating episodes. At a BMI of 40, Robin identified several ways obesity negatively impacted her life. In particular, she discussed how she often avoided social gatherings as a result of poor body image and social anxiety related to her weight. Robin further acknowledged that she often used food to cope with stress and anxiety. At the initial session, Robin verbally endorsed a strong desire to lose weight and change her behaviors. However, across treatment sessions, Robin did not complete food monitoring forms and experienced difficulty meeting her exercise goals. Her clinician initially tried to address these difficulties by helping her identify and problem-solve barriers to change. Although barriers may have played a role in Robin’s noncompliance, it is likely that she was struggling with ambivalence around change and may have had low self-efficacy regarding her ability to engage in consistent healthy behaviors. Instead of continuing to focus on action, the clinician decided it was important to explore Robin’s ambivalence further. In particular, the clinician highlighted to Robin the discrepancies between her words and her actions. In addition, they spent time identifying the pros and cons to change. Once ready, Robin, along with her clinician, clarified goals and discussed several options moving forward. Through using MI techniques and increasing her intrinsic motivation for change, Robin was able to move forward into the action stage of change. Fortunately, the clinician realized by using MI that continuing to focus on action-oriented tasks, as most treatments promote, was likely to result in drop-out.

Psychological Treatment of Eating Disorders. Several psychological treatments are supported in treating eating disorders typically associated with obesity. The research examining inventions for BED highlights the various treatment options currently available for several disordered eating patterns. Given a strong evidence base, CBT is currently the gold standard treatment of BED. The treatment is typically disseminated in 12 to 19 weekly group sessions. Across studies, CBT has demonstrated marked improvements in binge eating episodes, symptoms of psychopathology, psychosocial functioning, and modest reductions in

weight. In fact, research indicates that patients may experience a clinically significant response by the fourth session. Similar outcomes have also been shown in research examining interpersonal psychotherapy (IPT), though results typically are not observed as quickly. While CBT focuses on dysfunctional behaviors and cognitions related to eating and body image, IPT aims to treat the interpersonal difficulties related to disordered eating patterns. IPT identifies four potential focus areas, including grief, interpersonal role conflicts, role transitions, and interpersonal deficits. In a collaborative, supportive environment, clinicians often utilize clarification, exploration, emotional expression, behavioral modification, and communication analysis to help patients address their interpersonal difficulties. Long-term follow-up in randomized control trials has further supported the sustained treatment effects of both CBT and IPT. For example, one study compared the efficacy of CBT and IPT on BED and associated symptoms 4 years after the cessation of treatment. Across treatments, 64.4% of patients continued to demonstrate full remission from binge eating, supporting the lasting efficacy of both interventions. While the IPT group showed improvements in binge eating symptoms over time, the CBT group demonstrated worsening of symptoms, though treatment outcomes were not significantly different at any time point. The authors propose that these differences in recovery trajectories likely reflect leveling-off between-treatment effects, given the rapid benefits typically observed with CBT. Further, for both treatments, patients continued to report significant improvements in associated eating disorder symptoms and overall psychopathology at four years, though a few variables, including binge episode days, restraint, and anxiety, trended toward relapse. Overall, these results support the continued efficacy of CBT and IPT several years following treatment of BED.

In addition to CBT and IPT, clinicians have utilized dialectical behavior therapy for BED (DBT-BED). DBT-BED focuses on treating emotion dysregulation associated with disordered eating patterns. In a group setting, DBT typically covers mindfulness, distress tolerance, and emotional regulation skills. Patients are further encouraged to use mindful eating and disordered eating-specific diary cards. Increasingly, research has supported the efficacy of DBT for binge eating. One study examined potential variables moderating the effect of DBT-BED treatment outcomes. Interestingly, the researchers found that higher baseline psychopathology was associated with better treatment results. Findings suggested that

avoidant personality disorder and the early onset of overweight and dieting (<15 years old) moderated the effect of treatment on post-treatment binge eating episodes. It is possible that patients who have a longstanding history of using food as an avoidant coping mechanism may specifically benefit from a treatment focused on adaptive emotional regulation. However, additional research is needed to elucidate these findings. In addition, CBT and IPT hold the strongest support for the psychological treatment of bulimia nervosa. Similar to outcomes with BED, patients appear to have a quicker resolution of binging and purging behaviors with CBT, though outcomes between CBT and IPT are typically similar around one year.

Less is known regarding the behavioral treatment of NES. However, there is strong emerging evidence for the use of CBT for NES. Treatment typically focuses on behavioral techniques (e.g., closing the kitchen at a specific time and delaying getting out of bed), increased awareness of thoughts and behaviors associated with night eating (i.e., “If I don’t eat, I won’t fall back to sleep”), cognitive restructuring, and sleep hygiene behaviors. A pilot study of a 10-session CBT intervention for NES demonstrated significant decreases in evening caloric intake, nocturnal ingestions, number of awakenings per week, and weight. Improvements were also seen in mood and quality of life. In addition, a small randomized clinical trial underscored the potential utility of providing NES patients with educational material and relaxation techniques as a means of helping patients to reduce the percentage of food eaten after the evening meal. Although this initial research is promising, continued investigation is needed in this specialized area of eating disorder treatment.

Medical Treatments

Medications for weight loss should be considered in patients with a BMI >30 or a BMI >27 with serious comorbidities (Table 27.4–2). Behavioral and lifestyle interventions, including a diet and exercise plan, are essential adjunctive therapies when using medications for weight loss. Medication treatment of obesity has a varied history, including concerns about addiction and serious side effects. Amphetamines were used for weight loss in the early 20th century but led to substance abuse. In the late 20th century, the combination treatment of di-fenfluramine and phentermine (“Fen-Phen”) became popular until valvular heart disease side effects were discovered. Over-the-counter (OTC) treatments such as ephedrine

with caffeine were linked with reports of death and pulled from the market. Research on the use of leptin to treat weight problems has been disappointing, and mood changes associated with potential weight loss drugs such as ecopipam and rimonabant have prevented their approval for use. Sibutramine (Meridia) was approved for several years but withdrawn after increased blood pressure, and adverse cardiovascular events were discovered.

Current medications approved for weight loss include orlistat (Xenical, Alli), phentermine/topiramate (Qysmia), naltrexone/bupropion (Contrave), phentermine (Adipex), and liraglutide (Saxenda) (Table 27.4–9). Orlistat acts as a lipase inhibitor, thereby reducing caloric absorption, and is available in prescription formulation (120 mg three times daily before meals) and an OTC formulation (60 mg). Orlistat typically results in an 11% weight loss, although oily stools and GI distress are common side effects. Orlistat may also cause a reduction in absorption of fat-soluble vitamins and, in rare cases, liver disease.

Phentermine/topiramate is approved for long-term use in doses of 3.75 to 15 mg phentermine and 23 to 96 mg extended-release topiramate and appears to work through a reduction in appetite. Weight loss with the medication appears to be 9% to 10%. Side effects may include paraesthesias, dizziness, altered taste, insomnia, constipation, and dry mouth. This medication, as with all weight loss medications, is contraindicated in pregnancy. Of note, other potential risks include suicide, mood, and sleep disorders.

Naltrexone/bupropion was brought to market in 2014 and appears to reduce food intake by acting on adrenergic and dopaminergic receptors in the hypothalamus. Significant weight loss and reduction in comorbidities were achieved on the medication. Side effects include nausea and potential interactions with SSRIs and MAOIs.

Table 27.4–9. Medications Approved for Weight Loss Treatment

Medication	Trade Name	Weight Loss	Approved Use	Side Effects/Contraindications
Orlistat	Xenical, Alli (OTC)	9–11% body weight	Long-term	GI distress, oily stool, vitamin malabsorption
Phentermine–topiramate ER	Qsymia	9–11% body weight	Long-term	Paraesthesias, dizziness, altered taste, insomnia, constipation, and dry mouth. Suicidal thoughts, mood, and sleep disorders.
Naltrexone–bupropion	Contrave	5–10% body weight	Long-term	Nausea and potential interactions with SSRIs and MAOIs
Phentermine	Adipex, many others	4–6% body weight	Short-term	Dry mouth, insomnia, anxiety, and increased heart rate and blood pressure. Not recommended for patients with a history of cardiovascular disease
Liraglutide	Saxenda	5–10% body weight	Long-term	Thyroid T-cell tumors, increased heart rate, renal disease, hypoglycemia, pancreatitis, suicidal ideation

Phentermine is approved for short-term use in treating patients with obesity. Because of the potential for abuse, its use is typically limited to 12 weeks. Phentermine is the most often prescribed medication for weight loss in the United States, but there is little data to determine its long-term efficacy. Effects of the medication appear to be dose-related, and side effects can include dry mouth, insomnia, anxiety, and increased heart rate and blood pressure. Phentermine is not recommended for patients with a history of cardiovascular disease.

Liraglutide is the newest addition to the drugs approved for weight loss. Its action on GLP-1 may regulate areas of the brain involved in appetite. Weight loss results are promising, but side effects/risks include thyroid t-cell tumors, acute pancreatitis, increased heart rate, and suicidal ideation. The most recent studies on GLP-1 agonists are promising and have suggested that patients taking this class of medication have the potential to lose more weight when compared to other weight loss medications; though weight-gain has been shown if patients discontinue the medication.

Further evaluation of antidiabetic drugs for weight loss indications is an area of future research in the field. There are concerns about the extended use of weight loss medications, as they typically do not produce permanent weight loss (i.e., when the drug is stopped, the weight is regained.) In addition, the history of approved weight loss medications with later emerging serious side effects is important to consider for future research.

FIGURE 27.4–3. Restrictive, malabsorptive, and combination weight loss surgery procedures. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2006–2015. All Rights Reserved.)

Surgical Treatments

Weight loss surgery is currently the most effective long-term treatment of severe obesity (Table 27.4–2). Patients with severe obesity (BMI >40) or moderate obesity (BMI >35) with associated obesity-related disease are candidates for weight loss surgery. Candidates should be well-informed, motivated, psychologically stable, have good social support, have no substance abuse, and be an acceptable operative risk. Patients seeking weight loss surgery should have documented nonsurgical weight loss attempts and be willing to make long-term lifestyle changes.

The current surgical treatments include both restrictive and malabsorptive procedures (Fig. 27.4–3). Laparoscopic adjustable gastric banding (LAGB) is a procedure that involves an adjustable device that creates a small gastric pouch and narrow outlet, thus restricting the amount of intake and inducing satiety. LAGB is reversible and has low early postoperative risks, but the weight loss tends to be lower than with other procedures. In addition, late postoperative risks such as erosion and slippage are common. Laparoscopic sleeve gastrectomy (LSG) involves the removal of 70% to 80% of the stomach, restricting intake, and appears to result in greater weight loss than the LAGB. Malabsorptive procedures, including the biliopancreatic diversion and duodenal switch (BPD-DS), bypass a segment of the small intestine, so less food is absorbed. These procedures are rarely performed because of the high-risk of nutritional deficiencies. The Roux-en-Y gastric bypass (RYGB) is a combination procedure using both restriction and malabsorption to promote weight loss and results in a 60% to 80% loss of excess body weight. Data from the American Society for Metabolic and Bariatric Surgery reported 2,56,000 surgeries were performed in the United States in 2019, with the most common primary procedure cited as the LSG (59.4%), followed by RYGB (17.8%), and LAGB and BPD-DS (both 0.9%).

The majority of bariatric surgeries are performed laparoscopically, which reduces the risk of infection, incisional hernia, postoperative pain, and wound complications. Benefits of weight loss surgery include weight loss of 40% to 80% excess body weight and resolution of comorbidities such as metabolic syndrome, hypertension, sleep apnea, liver steatosis, hypercholesterolemia, and gastroesophageal reflux disease. Other benefits include increased life expectancy and improved quality of life. Potential risks of weight loss surgery include bleeding, anastomotic leak,

wound infection, thromboembolism, anastomotic strictures, marginal ulcers, bowel obstruction, cholelithiasis, and nutritional deficiencies. The risk of perioperative death for RYGB is approximately 0.5%, with risks increasing for older patients, male patients, and lower surgeon volume.

Psychological Considerations for Bariatric Surgery. Psychological risks after weight loss surgery include increased risk of alcohol abuse, increased suicide rates, and possible problems with absorption of psychiatric medication. Researchers have established an increased risk of the development of alcohol use disorders in patients following RYGB and LSG that may be related to increased absorption. There appears to be a three-fold increase in suicide risk for patients following weight loss surgery, with patients in the first 3 years after surgery and men being at a higher risk of suicide. Another possible concern for mental health providers is the apparent decrease in absorption of SSRIs after Roux-en-Y. Given the high number of bariatric patients on antidepressants, recommendations include close psychiatric monitoring after surgery and movement to shorter-acting as opposed to extended-release formulations.

Other considerations are the stresses of adjusting to a new lifestyle, changes in family relationships due to role changes from weight loss, body image issues, and coping with excess skin. Research also suggests concern regarding eating disorder behaviors returning after surgery, such as loss of control eating, bulimia, and anorexia. Adjunctive counseling and psychotherapy can be helpful in monitoring psychological symptoms after surgery and helping patients adjust to a new lifestyle.

Psychological treatment of the bariatric candidate ideally involves a behavioral health professional such as a psychologist or psychiatrist who is fully integrated into the bariatric team. The rates of psychiatric disorders, such as depression, bipolar depression, BED, and anxiety disorders, are high among bariatric surgery patients. For example, one study of presurgical bariatric patients found a 68% lifetime incidence of Axis I disorders, and 38% of patients currently met the criteria for an Axis I diagnosis. Presurgical evaluation of the bariatric patient is standard and typically includes psychological testing and a psychosocial interview. Elements of the evaluation should include assessment of the patient's motivation, knowledge of surgery, and lifestyle changes needed, weight loss and other expectations, mental health, substance use, social supports, stressors, coping strategies, and eating patterns. Psychological

contraindications for surgery include unstable depression or psychosis, suicidal ideation, active bulimia, and active substance abuse.

Behavioral health specialists may also play a role in optimizing patients for surgery by engaging them in mental health treatment to address instability and treating eating disorder behaviors presurgically. The psychological team may work with inpatient bariatric patients presenting with anxiety or depressed mood in the perioperative period, and follow-up after surgery may help to monitor mood and behavior change as the patients adjust to their new lifestyle. The behavioral health specialist often plays a leading role in providing support groups as part of the bariatric program.

FUTURE DIRECTIONS

There is a well-established relationship between obesity and psychiatric disorders, but more needs to be understood about the common causes of obesity and psychological disorders and how best to provide treatment to patients with both obesity and mental health disorders. The field would benefit from additional clinical trials that utilize combination treatments such as medications with behavioral weight management/CBT to help mitigate weight gain from psychotropic medications and optimally treat mental health disorders with the lowest side effect profile for patients with obesity. Improving adherence to treatment and addressing factors related to weight regain will continue to be areas of study. The role of the behavioral health specialist in the treatment of obesity is likely to grow as health care moves toward a more integrated approach to patient treatment and understanding mind-body health. There are benefits to adjunctive psychological treatment at all stages of obesity treatment, including prevention, diagnosis, behavioral, medical, and surgical treatment. Future research should establish data to support the integrated treatment of obesity in the psychiatric field.

27.5 Respiratory Disorders

Thomas Ritz, Ph.D., Hannah O. Nordberg, M.A., Ph.D., Chelsey A. Werchan, Ph.D., and E. Sherwood Brown, M.D., Ph.D., M.B.A.

DEFINITION AND COMPARATIVE NOSOLOGY

Psychiatric symptoms and syndromes in respiratory disorders are less extensively investigated than those in other common medical illnesses. However, numerous clinical features of these illnesses may increase the risk of developing a psychiatric disorder. In individuals with comorbid psychiatric illness, clinical features may also influence psychiatric symptoms. Respiratory disorders are frequently associated with dyspnea, hypoxia, poor sleep quality, and insomnia, which all can increase the risk for a variety of psychiatric illnesses. Furthermore, severe respiratory disorders are associated with substantial functional impairment that can increase the risk of anxiety and depression. Comorbid respiratory and psychiatric conditions contribute to worse health outcomes including increased emergency care utilization. Many of the medications given for

lung diseases can have significant central and peripheral nervous system effects.

The psychiatrist's role in respiratory disease includes (1) diagnosis and treatment of comorbid psychopathology; (2) addressing individual psychosocial triggers of exacerbation; (3) assessment and treatment of emotional, neurocognitive, and psychosocial consequences of chronic respiratory disease and its management; and (4) supporting the management of the disease, including adherence, motivation for rehabilitation, devise management strategies, lifestyle interventions, and improvement in comanagement by families and partners.

ASTHMA

Asthma is a very common respiratory illness in both children and adults. Global data indicates an increase in asthma prevalence in recent years. Improvement in diagnosing the condition may contribute to rising prevalence rates, however, asthma remains poorly controlled in many individuals who receive medical care for their disease. Below is a case vignette illustrating the complex relationship between disease-related factors and vulnerability to psychiatric disorders in asthma, a relationship that also applies to other respiratory conditions.

A 34-year-old woman presents with a history of episodes of severe and prolonged coughing since childhood. Symptoms typically started following upper respiratory infections and resulted in persistent coughs that made it difficult for the patient to sleep through the night. Exercise also left her wheezing and coughing at the end of the day, particularly during summer. Asthma was diagnosed at 6 years of age, after a particularly severe exacerbation that required an emergency room visit. The patient was prescribed a low dose of inhaled corticosteroids as maintenance medication and a β-adrenergic bronchodilator for as-needed use. During her teens, the patient became highly self-conscious about her asthma symptoms and her medication adherence greatly decreased, resulting in poorer symptom control and increased bronchodilator use. During an emergency room visit at age 18, she received a burst of high-dose oral corticosteroids for a week. Her energy greatly increased, and she developed severe insomnia. She spent one sleepless night cleaning her room. She was also very irritable and had a verbal altercation with a classmate at school. These symptoms resolved within a week of stopping the corticosteroids, but similar symptoms emerged with subsequent corticosteroid courses prescribed for asthma exacerbations.

During college, the patient was provided with a brief asthma management training, which included a plan to avoid overexposure to outdoor air pollutants during critical days in summer and improvement in indoor environment by mold and house dust mite eradication. Because she also reported anxiety and depression, a psychiatric consultation was obtained, which revealed major depressive disorder, generalized anxiety disorder, and occasional panic attacks. Feelings of helplessness were accompanied by hyperventilation, which led to strong symptoms of shortness of breath, chest tightness, and dizziness. Symptoms sometimes spiraled out of control as the patient feared suffering from an asthma attack. Bronchodilators were only partly effective in relieving these symptoms. The treating psychiatrist initiated pharmacologic treatment, with an SSRI and cognitive behavioral training that also included slow and shallow breathing exercises to reduce hyperventilation.

Historical Perspective

Observations of labored breathing and asthma have a long history and can be traced back to ancient texts from Egypt and Greece. Already at that time, a connection between the brain and lungs was suspected. Hippocrates viewed health as a balance of healthy quantities of humors and an excess of humors was linked to illness. If one of these, phlegm, was produced excessively, it would condense in the brain and travel down to the lower organs, among these the lungs. Hence, the term *catarrh*, translated from Greece as “flowing” or “flowing down.” The psychoanalytic tradition viewed asthma as a vegetative manifestation of passive–regressive impulses that stem from unresolved conflicts related to maternal attachment, famously culminating in the interpretation of asthma as “suppressed cry for the mother.” With progress in elucidating molecular and cellular aspects of asthma pathophysiology, the psychological study of asthma became more heavily oriented toward illness management behavior in the 1970s and 1980s. Large-scale epidemiologic studies and psychophysiological laboratory experimentation have recently produced more convincing empirical evidence for influences of psychosocial factors and psychopathology on both etiology and pathophysiology of asthma.

Disease Manifestation and Pathophysiology

Asthma is a chronic, inflammatory airway disease that leads to episodic symptom exacerbations, which extoll a substantial burden on the patients’ well-being and can be life-threatening if not controlled adequately. Pathophysiologic changes include obstruction, inflammation, hyper-responsiveness, and remodeling of the airways. The airways are hyper-reactive in asthma, with stronger than normal narrowing of the bronchi in response to a range of triggers, including allergens, physical exercise, air pollutants, odors, smells and irritants, cold air, respiratory tract infections, certain drugs (e.g., aspirin), gastric reflux, or psychological stress, and emotions. Patients experience unpleasant breathing sensations (dyspnea), which are characterized by shortness of breath, chest tightness, coughing, and/or wheezing. Additionally, mood and energy levels are affected in symptomatic episodes, commonly leading to fatigue, irritability, anxiety, fear, and/or panic. In fact, there has been evidence to suggest that although breathing symptoms are often the primary focus of visits for patients with asthma, hyperventilation, and fatigue symptoms are endorsed quite often in adults with asthma, suggesting the importance of

screening and identification of extrapulmonary symptoms in patients with asthma.

There is no single diagnostic indicator for asthma. Evidence comes from multiple sources, such as disease history and manifestations (including symptom characteristics and precipitating factors); physical examination focused on upper respiratory tract, chest, and skin; mechanical lung function testing by spirometry; demonstration of reversibility of airway obstruction by bronchodilator application; assessment of airway inflammation; airway hyper-reactivity testing with methacholine, histamine, cold air, or exercise; and skin or blood tests for allergic sensitization. Similarly, asthma severity and control is determined by numerous factors including medication use and type of medications taken, lung function, symptoms recently experienced, functional limitations, and number of exacerbations requiring care.

Prevalence and Societal Burden

Over 334 million people worldwide suffer from asthma, with prevalence rates anticipated to increase by 100 million cases in 2025. Over 30 million individuals have asthma in the United States. Although a clear diagnosis is difficult in the first 5 years of life, both children and adults experience asthma. In children, asthma is the most common chronic disease, affecting more than 7 million children in the United States. Children from minority populations and socioeconomically disadvantaged backgrounds are disproportionally affected by asthma, in particular African American and Puerto Rican communities. With close to 250,000 deaths from asthma per year worldwide, asthma-related morbidity and mortality highlight the need for better control and prevention methods. The socio-economic burden of asthma is high in adult and child populations, with contributions from direct costs (e.g., outpatient care), indirect costs (e.g., missed school days), and intangible costs (e.g., increased limitations to physical activity).

Pharmacologic Treatment and Self-Management

The goal of asthma pharmacologic management is to achieve optimal control of asthma with the right type and dose of agents. Anti-inflammatory medication, in particular inhaled corticosteroids, is the first line of treatment and is required as daily maintenance medication. Short-acting bronchodilators (typically β-adrenergic) are used as rescue

medication on an as-need basis and provide relief from symptoms for approximately 6 hours. Long-acting β-adrenergic bronchodilators help prevent bronchoconstriction for approximately 12 hours, particularly throughout the night. Other anti-inflammatory agents are sometimes used as maintenance medication, such as leukotriene modifiers, which target specific inflammatory mediators and also have bronchodilatory properties. Biologics including immunoglobulin-E inhibitors are sometimes prescribed for severe allergic asthma. Severe cases or disease exacerbations typically require high doses of systemic corticosteroids.

Consistent efforts are required by patients with asthma to self-manage their condition, which includes adherence to medication schedules, action plan-guided self-adjustments of medication in exacerbations, self-monitoring symptoms or lung function, and control of critical environmental and endogenous asthma triggers. Typically, around half of patients show suboptimal medication adherence, which contributes to low asthma control and frequent exacerbations. Suboptimal medication adherence is seen more frequently in minority groups that are disproportionally affected by asthma. Barriers to medication adherence include disease belief of “no symptoms, no asthma.” Patients with this belief report poor adherence to daily maintenance medications and rely on rescue medications only when symptomatic. In addition, high costs of outpatient care can restrict individuals from lower income groups from affording daily medications and reaching optimal medication adherence. Comprehensive educational programs in self-management improve asthma outcomes and are generally recommended by guidelines. Designing and implementing interventions based on theories of behavior change, learning theory, or motivational interviewing techniques can enhance their effects. Involving families in self-management of children and young adolescents is essential and additional training in family problem-solving skills or parent coaching can benefit asthma-related quality of life. In addition, programs providing support to patients who more frequently report dysfunctional beliefs or have heavier trigger exposure (e.g., cockroaches and dust-mites in the home) can help optimize asthma care.

Stress and Emotion in Asthma

A long history of clinical and epidemiologic literature links asthma symptoms and exacerbations to patients’ reports of a variety of emotional

precipitants, typically various negative affective states, but also ambivalence or conflicts over emotional expression, or even positive states of excitement and mirth. Emotional triggers of asthma symptoms are identified by around one-fourth of patients as their top triggers. They are uniquely associated with lower asthma control and quality of life, as well as higher rates of exacerbations and emergency treatments, over and above other asthma triggers. Laboratory studies have established that bronchoconstriction can be elicited by stress and emotion-induction techniques, with an estimated 20% to 40% of patients responding with clinically relevant airway obstruction. Major physiologic pathways for obstruction due to psychological stimuli are parasympathetic excitation, hyperpnea (increased depth of breathing), and hypocapnia. In addition, distinct central nervous system pathways have been identified for effects of stress and emotion on the airways. Emotional triggers are specifically associated with hyperventilation symptoms, which in turn are related to lower perceived health, likely through reduced effectiveness of conventional asthma medication.

Observational studies have also expanded the current knowledge, showing that psychosocial stressors, negative life events, and adversity, such as low socioeconomic status, are linked to lung function decline, airway inflammation, and changes in immune status favoring asthma exacerbations. Recent theoretical models also emphasize a role in stress-induced infections, epithelial dysfunction, microbiome (dysbiosis), and epigenetic changes. In addition, studies indicate a role of family emotional health, including parent and caregiver emotions, in asthma symptomology, with disease control associated with parental mood states including depression. Consequently, emotions and stress are now listed among the well-established triggers of asthma symptoms, as reflected in current asthma management guidelines. Elevated anxiety and problems communicating emotions, a facet of alexithymia, have been found in patients who had experienced a near-fatal asthma exacerbation.

Evidence is also strong for an association between anxiety, depression, and patients' perception and report of asthma symptoms. Given that asthma symptoms are typically episodic, the patient's ability to detect and communicate symptoms effectively are key to successful management of the disease. Greater symptom exacerbations and worse lung function have been observed in children whose parents report high-anxiety levels, indicating an importance of family emotional environment in relation to

asthma. Anxious patients tend to overestimate or over-report airway obstruction. Consequently, they use more rescue inhalers and access more professional care than necessary, including emergency room treatments. Patients who develop an intense fear of asthma exacerbations may be more emotionally reactive to physical symptoms they experience, perceiving any somatic change as threatening. In turn, these patients can experience respiratory symptoms of anxiety, such as dyspnea. These patients may have difficulty delineating between asthma and anxiety symptoms, which can bidirectionally influence one another, and be treated with more oral corticosteroids than less fearful patients.

Neuroimaging studies have demonstrated that brain structures and pathways typically involved in emotional processing and psychopathology, in particular limbic structures, including right anterior insular, are also involved in the perception of dyspnea, thus improving the mechanistic understanding of emotional influences on airway symptoms. Furthermore, many patients with asthma have deficits in recognizing airway obstructions and thus underestimate the severity of their disease state. As a consequence, they show insufficient adherence to maintenance medication and delay necessary treatments, thereby risking life-threatening exacerbations.

Comorbidity with Psychiatric Disorders

Epidemiologic studies have shown that asthma is associated with an elevated risk of psychiatric conditions, including anxiety disorders (agoraphobia/panic, generalized anxiety disorders, post-traumatic stress disorder, and social phobia), depressive disorders, alcohol use disorders, schizophrenia, and suicide. Sleep disorders are experienced at higher rates in asthma, with individuals with asthma experiencing insomnia and obstructive sleep apnea 2.5 times more often than individuals without asthma. Sleep disorders can exacerbate already present mood problems or lead to the development of additional psychiatric conditions. Symptoms patients with asthma experience during exacerbations can include anxiety, panic, irritability, frustration, and fatigue, closely mimicking some of the psychiatric symptomatologies. The unsettling experience of the respiratory disease may lead to secondary psychiatric problems, or conversely, psychopathology may facilitate neuroendocrine and/or inflammatory/immunologic pathways involved in asthma pathogenesis. Thus, asthma symptoms experienced in childhood are associated with

greater levels of anxiety and shyness, and they predict the future development of anxiety disorders. Subsequent onset of panic disorder has been interpreted as evidence for a suffocation-alarm theory of panic, which views panic as an exaggerated response to CO_2 increases and posits that sensitization to rising CO_2 levels due to respiratory disease is a critical factor in the development of panic. Beyond direct pathways, third variables, such as shared genetic risk factors or specific childhood adversities leading to disease manifestations at different time points, also need to be considered. In support of such assumptions, elevated levels of a range of psychiatric conditions are typically found in first-degree relatives of adolescents with asthma, although these could also be secondary to the burden of asthma care in the family.

Existing psychiatric disorders and asthma can influence each other in a number of ways. Overlap of symptoms can cause challenges in the diagnosis of asthma. Prominent symptoms of a psychiatric condition, such as schizophrenia, can distract from comorbid asthma and lead to its underdiagnosis and undertreatment. Other complications can affect the course and treatment of asthma. Strong emotional states associated with psychopathology can affect asthma pathophysiology directly through pathways discussed earlier. In the case of psychiatric disorders, these states occur repeatedly over a prolonged period and thereby constitute stressors that affect organ function chronically. Thus, hyperventilation associated with panic disorder can worsen lung function and potentially exacerbate inflammation. Anxious or depressed mood can also affect disease management, for example, by over- or underuse of rescue inhalers, lack of adherence to prescribed maintenance medication, neglect of trigger control, problematic health behaviors affecting the airways (e.g., smoking), or delayed treatment seeking. Additionally, adoption of a lifestyle that is less health-promoting, such as increased alcohol use and poor diet can worsen disease-related outcomes.

Symptoms of asthma can be a source of panic or contribute to the fatigue and exhaustion experienced in mood disorders. Internalizing disorders in children seeking cognitive behavioral treatment are more severe in those with comorbid asthma. Earlier research has highlighted problems in patients who are prone to intense states of “panic-fear,” most likely indicating clinically significant anxiety disorders. Such patients were found to have excessive rates of hospitalization for asthma exacerbations. Asthma-related quality of life is typically reduced with comorbid

psychopathology. Conversely, asthma can also amplify the symptomatic appearance of psychiatric conditions and complicate their treatment. For example, nocturnal symptoms of asthma can impede sleep quality in asthma and worsen insomnia symptoms. Asthma-related factors influencing sleep when treating insomnia and other sleep disorders, such as nighttime wheezing, are thus important to consider. Additionally, nocturnal asthma symptoms may distract from comorbid sleep conditions (e.g., sleep apnea), leading to underdiagnosis of sleep conditions and exacerbation of psychiatric symptoms.

Asthma may also be associated with an increased risk of cognitive disorders. Large studies suggest that asthma is associated with an increased risk of mild cognitive impairment, and that an asthma diagnosis increases the risk of later development of dementia. The reasons for this association between asthma and cognitive disorders are not known, but could be related to reduction in respiratory function, inflammatory processes, or medication side effects. Recent findings suggest that greater rates of cognitive decline in older adults with asthma are associated with poorer lung function and earlier onset of the disease. Asthma is also associated with regional brain volume changes. A smaller hippocampus, a brain region involved in memory and emotion, was reported in people with asthma. Furthermore, asthma duration, control, and fear of exacerbations have been negatively associated with putamen and pallidum volume.

Treatment of Comorbid Psychopathology in Asthma. The psychiatric treatment of comorbid asthma patients requires specific considerations and precautions. However, despite findings of high comorbidity rates, the development of specifically adapted treatments for comorbid asthma patients has been lagging. Medication treatments for both conditions can have mutual adverse side effects. Psychotropic medication for anxiety can affect respiration adversely and thus may complicate asthma symptomatology. High-doses of benzodiazepines or hypnotics can lead to respiratory depression and are related to a greater risk of death from asthma. Overall, evidence to support pharmacologic treatment of anxiety and depression in asthma remains inconsistent.

However, there is evidence that cognitive behavior therapy (CBT) for anxiety disorders, and perhaps also depression, adapted for asthma, is beneficial in reducing anxiety and bronchodilator use and improving

quality of life. Treatments typically combined generic anxiety-related treatment elements, such as cognitive restructuring, interoceptive exposure to feared bodily sensations, progressive muscle relaxation, and psychoeducation, with asthma-relevant elements such as asthma education and breathing retraining and eliminated treatment aspects potentially detrimental to patients with asthma, such as voluntary hyperventilation as interoceptive exposure exercise. Empirical support from published psychological intervention studies is still largely missing, and there is a clear need for targeting asthma-related depressive deficits, including low self-esteem, social isolation, and reduced medication adherence and management behaviors. Treatment with CBT for insomnia, including web-based applications that may help reduce barriers to treatment, appears to be beneficial for adults with comorbid insomnia and asthma.

Adjunctive Cognitive and Behavioral Treatment Modalities for Asthma

Adjunctive cognitive and behavioral treatment modalities have been developed or adapted for asthma, which are not specifically directed at treating comorbid psychiatric conditions; but address psychiatrically relevant deficits in patients with asthma, such as maladaptive breathing patterns, inaccurate perception of airway obstruction, or suffering from excessive stress. They can significantly add to pharmacotherapy. Certain habitual breathing patterns that support hypocapnia or hyperpnea are targeted by dedicated training modules of slow, abdominal, shallow, more regular, and/or nasal breathing. Although breathing is under voluntary control, characteristics of the person's breathing pattern are typically quite stable and systematic, and instructed efforts are needed to change it permanently. Training in slow, abdominal breathing has been shown to reduce symptoms and improve patients' quality of life. Mechanisms underlying such improvements are largely unexplored but may include a better gas exchange efficiency or reduction in high-flow rates that can irritate and dry out the hyper-reactive airways. However, exaggerated deep breaths in slow breathing can also lower PCO_2 levels, thus making hypoventilation training a safer approach. Successful interventions train prolonged respiratory pauses or slower and shallower breathing with capnometry-assisted biofeedback. More sustained symptomatic improvements have been noted. Feedback can also be provided to

increase respiratory sinus arrhythmia by slow breathing, which has been associated with some of the same benefits. Although various forms of relaxation training, meditation, or yoga have considerable face validity for addressing the distress associated with a chronic condition, findings on benefits for patients with asthma have remained quite variable, and high-quality large-scale clinical trials are lacking. This is not surprising given that the rationale for such techniques is unclear. Relaxation aims to reduce sympathetic activity and increase parasympathetic activity, both of which support bronchoconstriction, and may therefore be contraindicated.

Interoception training can address a potentially dangerous lack of awareness of airway obstruction in patients with asthma. It is administered in protocols of systematic exposure to added resistive loads that vary in the extent to which they impede airflow. Patients learn to better distinguish different loads or to lower their perceptual thresholds for just noticeable loads.

Lifestyle Interventions in Asthma

Lifestyle interventions promote health-related behaviors including eating a nutritious diet, improving sleep hygiene habits, and regularly exercising for asthma. Dietary interventions influencing inflammatory pathways in patients with asthma are promising, with emerging research suggesting associations between nutrient-rich food intake and better asthma control. Obesity is known for causing complications in asthma, making weight control interventions an important treatment modality for affected patients. Sleep interventions have been found to benefit sleep quality, but little is known about effects on asthma symptomology. Physical activity interventions suggest some improvements in reduced asthma symptomology, with some studies suggesting reduction in exercise-induced asthma and systemic inflammation, although studies vary regarding type of exercise, outcome measures, and lengths of interventions.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)

Chronic obstructive pulmonary disease (COPD) is a group of progressive and irreversible lung diseases (e.g., emphysema and chronic bronchitis) in adults that lead to progressive reduction in airflow in the lungs.

Common symptoms include chronic cough and dyspnea, breathlessness that is continuous, often frightening, and is associated with considerable limitations on daily activities. COPD is strongly associated with tobacco smoking in approximately 80% of patients, but environmental exposures, in particular fumes from biomass fuel stoves and open fireplaces, are prominent risk factors in developing countries. Genetics may also play a role in the development of COPD. The prevalence of COPD in adults is approximately 13%. COPD is currently a leading cause of death worldwide with an increasing trend in prevalence for adults over 40 years of age.

Diagnosing COPD involves obtaining patient history, symptoms, current and past tobacco use, information on exposure to fumes and other irritants, and pulmonary function testing. A diagnosis of COPD is typically made around 40 years of age or later when symptoms from exposure begin to develop.

Pharmacologic treatment of COPD involves bronchodilator medication, antibiotics, or inhaled corticosteroids. Oxygen therapy, lung volume reduction surgery, or lung transplantation may be necessary in severe cases or later stages. Individuals with COPD experience increased rates of psychiatric problems, and experiencing psychiatric problems is also linked to greater rates of a later COPD diagnosis. Multidisciplinary rehabilitation is not only focused on physical exercise, but also includes education and self-management skills, nutritional components, and psychosocial support. It is associated with improved exercise tolerance, reduced exacerbations, and improved dyspnea and quality of life.

Comorbidity with Psychiatric Disorders

The prevalence of depression in COPD ranges from about 25% to 50%. Greater disease severity, dyspnea, female sex, and disability appear to be risk factors. When depression is present in COPD, it is associated with reduced quality of life and poorer adherence to pulmonary rehabilitation programs. The presence of depression may be more strongly associated with functional impairment than lung disease severity.

Although the results are somewhat inconsistent, cognitive behavioral treatment with or without pharmacologic therapy appears to improve depressive symptoms in people with COPD but has modest effects on disease-related outcomes. Depressive symptoms are related to poorer disease management and reductions in other health behaviors, including

physical activity in individuals with COPD. Pulmonary rehabilitation, particularly if it includes stress reduction or psychotherapy, appears to be associated with improvement in depression.

Anxiety disorders, particularly panic disorders, are much more common in patients with COPD than in the general population. As with depression, anxiety appears to be associated with the poor functional status. The treatment of anxiety in COPD has been the topic of few studies. A potential concern with the use of benzodiazepines is decreased respiratory drive.

Sleep disorders are increasingly common among individuals with COPD. Insufficient sleep has been related to worse health outcomes for patients, including hospitalization, in particular sleep-disordered breathing. Comorbidities, such as metabolic and cardiovascular disease, are seen in patients with comorbid COPD. Obstructive sleep apnea also occurs at higher rates, which, if untreated, exacerbates health issues associated with COPD. Insomnia symptoms are present in around 3 of 10 patients. Worse sleep quality in COPD has been linked to greater anxiety and depression in a community sample of adults, however, relations between improvements in sleep, psychiatric presentation, and COPD outcomes remain to be studied.

Cognitive impairment (e.g., working memory and attention) is also common in COPD. The cognitive deficits appear to worsen with pulmonary disease progression and comorbid obstructive sleep apnea, emphasizing the importance of early intervention and targeting comorbid sleep disorders to preserve function. Some data suggest improvement in cognition with pulmonary rehabilitation.

In psychiatric assessments of COPD patients, it is important to consider that the majority have a significant smoking history. Tobacco use is associated with increased rates of a variety of psychiatric disorders. The increased risk of both mood and anxiety disorders appears in large part to be explained by nicotine dependence. Furthermore, rates of tobacco use are much higher patients with major psychiatric disorders, particularly schizophrenia, than in the general population. Thus, people with psychiatric illnesses are at an increased risk of developing COPD. Therefore, the etiology of the elevated rates of psychiatric disorders in COPD may be particularly complex and may reflect effects of hypoxia, functional impairment, feelings of breathlessness, as well as preexisting vulnerability related to tobacco use.

Adjunctive Cognitive and Behavioral Treatment Modalities for COPD

CBT for anxiety has been shown to reduce anxiety and healthcare utilization of patients with COPD. Short-term CBT has shown promise in helping to reduce psychological and physical symptoms, and depressive symptoms have been reduced in fewer sessions than anxiety symptoms. Learning CBT skills to manage anxiety and dyspnea symptoms as part of treatment may have the potential to improve COPD self-monitoring and disease management. Given the mostly older age of patients, with some approaching end of life prematurely, qualitative research has also emphasized the need for therapies revolving around acceptance and existential themes.

Lifestyle Interventions in COPD

Regular physical activity is an encouraged practice for those suffering from COPD. Exercise programs remain limited primarily to pulmonary rehabilitation, but physical activity interventions should also be embedded in daily life, although longitudinal improvements in health and mood are yet unknown. Although patients are encouraged by physicians to be more physically active, specific exercise prescriptions or individualized training programs are rare. Pulmonary rehabilitation including exercise components can reduce anxiety, depression, and cognitive function. Yoga and water-based activity have also been explored as promising exercise programs for COPD.

Although smoking is the major cause of COPD, many patients do not quit smoking after diagnosis and continue despite exacerbation of their symptoms. Smoking cessation programs thus remain a critical avenue for intervention, with counseling and nicotine replacement therapy as options as supportive elements.

Although comorbid sleep conditions can worsen COPD and other health outcomes, little research has assessed sleep interventions in this population. Continuous positive airway pressure treatment to manage obstructive sleep apnea can lead to improvements in health status, suggesting that a referral to a sleep specialist should be prioritized when indicated in psychiatric care. The effectiveness of psychoeducation on sleep hygiene and interventions for insomnia in COPD remain to be explored.

INTERSTITIAL LUNG DISEASE

Interstitial lung disease includes a diverse group of illnesses of the interstitium surrounding the alveoli of the lungs. The illnesses are characterized by progressive scarring and fibrosis of the lungs. Examples include sarcoidosis, asbestosis, hypersensitivity pneumonitis, drug reactions, and even infections including COVID-19. Progressive worsening of dyspnea is a characteristic feature. These illnesses can be idiopathic, familial, or result from a variety of environmental exposures or certain medications. The prognosis is poor. No treatments are presently available that substantially alter the course of interstitial lung diseases.

The literature on the nature or prevalence of psychiatric disorders in interstitial lung disease is modest. High rates of depression and anxiety that are related to the severity of dyspnea are reported in patients with idiopathic pulmonary fibrosis.

CYSTIC FIBROSIS

Physiology and Manifestations

Cystic fibrosis (CF) is an autosomal recessive disease that is characterized by lung and digestive symptoms and affects approximately 75,000 individuals worldwide. It is the most common genetic disease among White individuals, and it is caused by a mutation on chromosome 7 that leads to malfunction of the cystic fibrosis transmembrane regulator (CFTR) protein, which facilitates movement and concentration of chloride ions across the cell membranes of the sweat glands, sinuses, lungs, pancreas, gastrointestinal tract, and reproductive organs.

Individuals with CF experience a wide range of varying symptoms, including recurrent cough and lung infections, wheezing or shortness of breath, salty skin, sinus infections, pancreatic insufficiency, poor nutrition and growth, and difficulty with digestion and bowel movements, resulting in significant variations in individual presentations of the disease. Over time, recurrent respiratory infections and bacterial colonization result in gradual loss of lung function, and respiratory failure is the most common cause of mortality. In adulthood, individuals are at increased risk of the development of CF-related diabetes due to deterioration of the pancreas and osteopenia or osteoporosis as a result of poor nutrition and bone density.

Diagnosis and Treatment

Diagnosis of CF is commonly made through the results of a sweat test that examines the salt concentration of an individual's sweat. Due to the malfunction of the CFTR protein, individuals with CF have abnormally high concentrations of chloride in their sweat. Additionally, genetic testing can be used to make a definitive diagnosis and to identify the individual's specific mutations.

Currently, there is no cure for CF. Treatment is aimed at slowing the progression of the disease and preventing infection. Since discovery of the CFTR protein in the late 1980s, medical treatment of CF has progressed rapidly and life expectancy for those with the disease has likewise increased dramatically over the years, with treatment including CFTR modulators that improve functioning of the protein and lung transplantation when severity progresses. CFTR modulators are effective for specific mutations. White individuals appear to have the mutation susceptible to treatment at higher rates than non-White patients, contributing to a health disparity in care across racial groups. Non-White individuals with CF report worse health outcomes, including worse lung function in Black individuals.

Treatment of CF involves an extremely complex and time-consuming daily regimen that may include airway clearance, aerosolized medication, nutritional support, dietary supplements, and other medications, such as antibiotics and anti-inflammatories. Patients in North America are often followed by a CF center, accredited by the Cystic Fibrosis Foundation, which involves care from a team of specialists, including pulmonologists, nurse practitioners, respiratory therapists, dieticians, physical therapists, and social workers. They are routinely monitored every 3 to 4 months through their clinics in order to adjust treatment approaches as necessary.

Self-Management and Psychosocial Considerations

As with many chronic illnesses, self-management in CF is a vital component of medical maintenance of the disease and the patient's overall quality of life. Effective self-management involves many skills, including adherence to airway clearance and other respiratory treatments, monitoring of symptoms of exacerbations, and regular coordination with the CF care team. Research suggests that adherence to different aspects of self-management in CF varies, with the lowest rates of adherence often found with chest physiotherapy recommendations.

Psychosocial considerations for health care professionals treating patients with CF will include a variety of issues, depending on the patient's overall level of functioning, medical status, and phase of life. Common psychosocial issues impacting quality of life in CF include pain management, lost time at work or school due to doctor's appointments and attending to disease management, management of pain, transitions from child to adult CF care, fertility concerns, coping with disease management (including consideration of end-of-life care and lung transplantation during severe progression of the disease), and psychiatric conditions. Coordination of care during childhood will necessitate consideration of family dynamics and the mental health of adult caregivers. Overall family functioning has been found to significantly impact quality of life and health status in patients with CF.

Emerging Adulthood/Transition

The growing adult population has necessitated the development of adequate protocols for transition of patients to adult CF care. This transitional phase has yet to be thoroughly addressed by existing research and available recommendations are uncommon and often vague. This transition is an adjustment for many patients who have had prolonged care with a single multidisciplinary team for several years. Continuous and effective communication between the medical providers and the patient is recommended during the stage of transition in order to ensure proper continuation of care and well-being of the patient.

Fertility Issues. Fertility issues and family planning may become matter of concern as patients with CF enter adulthood. Most males with CF lack a vas deferens, causing infertility, and a significant portion of females may also experience fertility problems. Additionally, genetic counseling may be warranted as patients consider whether their offspring will be carriers of the disease or potentially have the diagnosis itself.

Psychiatric Comorbidities

Rates of depression in CF vary by age and type of screening tool being used. On average, 5% to 19% of adolescents and 13% to 29% of adults with CF reported symptoms of depression. Overall, prevalence rates for symptoms of anxiety range from 14% to 35% across different countries, with an average of 30% of patients reporting symptoms. Additionally, a

high degree of comorbidity occurs between anxiety and depression, with those reporting anxiety symptoms being from 13.6 times (adults) to 15.0 times (adolescents) more likely to also report symptoms of depression than those without elevations in anxiety.

Elevated rates of depression and anxiety are also reported in caregivers of patients with CF, with prevalence rates ranging from 48% (mothers) to 36% (fathers) for anxiety and from 37% (mothers) to 31% (fathers) for depression. When caregivers are experiencing elevated symptoms of depression or anxiety, adolescents with CF are more likely to report symptoms.

In patients with CF, higher rates of depression and anxiety are negatively associated with health status and may have several negative outcomes, such as poor treatment adherence, increased health care costs, lower lung function, and decreased quality of life. Sleep disorders and higher BMI have also been linked to higher levels of depression and anxiety in CF. Careful and regular monitoring of psychological functioning is recommended in order to provide appropriate intervention or mental health referrals as needed. Prescription of psychiatric medications would require careful consideration, particularly with regard to side effects, dosages, and potential interactions with other medications that patients are prescribed. The need to cope with symptoms, treatment, and progression of the disease can also increase the likelihood of a psychiatric presentation.

Psychological Interventions

Psychological interventions for patients with CF may target several different outcomes, including education about their disease, emotional functioning, quality of life, treatment adherence, airway clearance techniques, and dietary intake. Doubts about the effectiveness of medication for management of CF are related to depressive symptoms in patients. Previous psychological interventions have primarily been educational or behavioral in nature and target specific treatment concerns rather than broader psychosocial functioning. There were limited significant effects, including CBT for nutrition adherence and lung transplant planning.

Few studies have examined the importance of factors such as social support. There is limited evidence that social support can encourage more mental wellness in CF. Potential cross-infection is a barrier that limits in-

person interaction between individuals with CF; online social support interventions could be promising in relation to psychiatric functioning and health outcomes. Interventional research in this area has lagged in comparison to the medical advances in treatment and disease management. Increased attention is needed to develop effective interventions that improve treatment adherence, quality of life, and independent self-management in this population, given that better treatment options have prolonged life expectancy significantly beyond adolescence.

Lifestyle Interventions in CF

Limited findings suggest that physical activity in CF may provide benefits to psychological functioning and lung function. Physical activity appears to provide benefits for mental health in CF when beneficial to patients' overall health, indicating a need to also explore contraindications (e.g., severe CF symptoms). Exercise programs can also alter patients' perceptions of their health. Given gastrointestinal tract complications in CF, maintaining a healthy diet may be important, although the effects of dietary intake on psychiatric symptoms remain to be investigated.

RESPIRATORY FAILURE

Over one million persons in the United States are admitted to intensive care units annually due to respiratory failure. Respiratory failure can be a consequence of a variety of lung diseases. As with other serious illnesses, delirium is common with respiratory failure. Both hypoxia and hypercapnia can occur in respiratory failure and in severe cases, mechanical ventilation is needed. Therefore, the psychiatric syndromes observed in this illness include those of severe lung disease as well as depression and post-traumatic stress disorder or other anxiety disorders related to mechanical ventilator support and the intensive care unit. Some data suggest that the administration of corticosteroids may decrease the risk of developing post-traumatic stress disorder during an intensive care unit admission.

SOMATOFORM RESPIRATORY DISORDERS

A variety of dysfunctional and distressing respiratory regulation abnormalities have been identified in adults and children under various terms in past decades. Typically, diagnosis has relied heavily on exclusion of somatic diseases and a lack of demonstrable pathophysiologic processes, which can produce most of the same symptoms. The adequacy of these disorders as diagnostic entities has often been debated. Efforts have been made more recently to distill common characteristics of these conditions and formulate positive diagnostic criteria under the umbrella of *somatoform respiratory disorders*. These would distinguish subgroups of functional disorders of respiratory regulation (e.g., vocal cord dysfunction), stereotypic respiratory disorders (e.g., habit cough), and psychogenic respiratory disorders (e.g., suffocation anxiety). However, the label "psychogenic" has become increasingly obsolete as contemporary neuroscience demonstrates tight associations between mental, neurophysiologic, peripheral autonomic, and somatic processes in health and disease. Common to all conditions is that a psychiatric background and specific behavioral interventions and/or psychotherapy are often suggested, but the available evidence is mostly limited to case reports and uncontrolled studies. Although the patients' quality of life is often reduced, the prognosis is good to excellent with adequate treatment. Reassurance that the symptoms are not indicative of a somatic disease and that the symptoms are treatable already provides significant relief for patients and their families.

Chronic Hyperventilation

Hyperventilation is defined as breathing in excess of metabolic demand leading to a fall in arterial PCO_2 levels. The respiratory pattern is often deep and/or fast, leading to exaggerated minute ventilation relative to demands from physical activity. As a consequence, patients complain about symptoms of dizziness, headaches, chest pain, peripheral paresthesia (lips and limbs), and anxiety. Despite overbreathing, patients have paradoxical sensations of air hunger and shortness of breath. Levels of PCO_2 <30 mm Hg have been proposed as an indicator of unequivocal chronic hypocapnia, but many of patients' symptoms are less tightly linked to PCO_2 levels than previously thought, which is not surprising given the complexity of regulation of respiratory sensations. Whereas acute respiratory hyperventilation leads to disturbances in acid–base balance

with high pH levels (acute respiratory alkalosis), pH levels in chronic hyperventilation are often near-normal due to compensatory bicarbonate changes.

Triggers of hyperventilation are often emotional, and hyperventilation is most frequently observed in panic disorder. However, chronic hyperventilation is also found without evidence of anxiety disorders (idiopathic hyperventilation). Breathing training focused on reducing hypocapnia (hypoventilation training) is the mainstay of therapy. Slow, shallow, abdominal, and nasal breathing is ideally supported by measurement and feedback of actual PCO_2 values. Rebreathing techniques using bags are discouraged because they reduce oxygenation and may trigger panic by raising CO_2 levels. Patients profit from identifying individual triggers, decatastrophying, and reattribution of benign symptoms, and education about hyperventilation and anxiety.

Vocal Cord Dysfunction

Patients with vocal cord dysfunction suffer from sudden, intermittent adduction (narrowing or closure) of the vocal cords during inspiration. The inspiratory occurrence is most common and paradoxical, but obstruction can also be observed during expiration or both phases of the breathing cycle. Proposed positive diagnostic criteria are presentation with sudden onset of dyspnea, problems with inspiration, intermittent symptoms that resolve spontaneously after a few minutes, and symptoms self-localized in the throat. Diagnostic confirmation in the acute stage can be obtained by flexible laryngoscopy (closure of vocal cords >50%) or abnormal inspiratory and/or expiratory features of the flow-volume loops in spirometry.

Episodes are often associated with considerable fear of suffocation and panic, and anticipatory anxiety of an additional attack is common. A variety of triggers can be identified, including stressful life events, anxiety, exercise, irritants, gastro-esophageal reflux, respiratory infections, postnasal drip, or olfactory stimuli. A psychiatric background can be found in up to 75% of patients and anxiety disorders, a history of early life traumatic experiences, or abuse are not uncommon. The condition can co-occur with asthma or mimic it, complicating differential diagnosis and treatment and leading to extensive and costly measures. Unresponsiveness to bronchodilator therapy and lack of airway hyper-reactivity can help exclude asthma. The recommended treatment is ideally

multidisciplinary and may include speech and behavioral therapy. Underlying somatic conditions such as reflux, infections, or nasal allergies require adequate medication treatment.

Chronic Cough Disorder (Habit Cough and Psychogenic Cough)

Cough is an integrated evoked, reflexive, or voluntary motor pattern that has important functions in airway protection and clearance. It is elicited by irritation of the vocal cords or airways and is a nonspecific symptom of a range of diseases and conditions, including respiratory infections, asthma, COPD, gastroesophageal reflux, allergic rhinitis, and postnasal drip. Chronic cough that is persistent, without evidence for any of these causes, has often been labeled as habit cough or psychogenic cough. It is most frequently reported in children and adolescents. The disruptive nature of the phenomenon can have negative social consequences. Reduction or cessation during the night or with distraction has also been frequently observed, although use of these clinical presentations as defining criteria has been debated. A recent expert panel advocated replacing habit cough with “tic cough,” aligning it with tic disorders as it shares their central features of suppressibility, distractibility, suggestibility, and variability, as well as the presence of a sensation of urge (premonitory sensation), regardless of whether the cough is the only tic or one of many. The panel also favored the term *somatic cough disorder* to replace psychogenic cough, placing it within the DSM-*5* framework of somatization disorder, in which a psychological distress is expressed as a physical symptom. The diagnosis should only be given if a tic disorder and other causes can be excluded, and the patient meets criteria for DSM-5 somatization symptom disorder. Somatic cough disorder and other psychogenic and functional breathing disorders appear to be associated with high rates of psychiatric comorbidity including ADHD, tic disorders, and phobias. Hypnosis and suggestion therapy are the most successful treatment modalities for somatic cough disorder and tic cough, in particular in children.

Sighing Dyspnea

A sigh breath is characterized by a sudden increase in depth, and often also length, of the breathing cycle. It occurs intermittently and is usually limited to a single breath. There is no clear convention as to the magnitude of volume change necessary, with some sources requiring a

full inspiration to inspiratory capacity and others requiring 2 to 2.5 times the regular tidal volume. The clinical manifestations of sighing dyspnea include a more frequent rate of sighing, which is often episodic and accompanied by sensations of breathlessness or chest pain, and sometimes also yawning. Most observations have been in children, adolescents, or young adults. Proposed positive criteria are self-limited sighing with intensified inspiration, normal respiration rate, perceived respiratory effort greater than sensation of respiratory distress, and no nighttime awakening from sighing. Elevated sigh breathing has also been observed in adult anxiety patients, particularly in panic, and is thought to maintain hypocapnia. Breathing training focused on regularity of breathing (without suppressing occasional sighs) and reducing hyperventilation appears as the most relevant primary treatment. For psychotherapy and anxiolytic drug therapy, a psychiatric background should be clearly established in the individual case.

PSYCHIATRIC SYMPTOMS ASSOCIATED WITH RESPIRATORY DISEASE MEDICATIONS

As illustrated by the representative case vignette at the beginning of this section, medications used to treat respiratory illnesses can have effects on the brain and the patients' experience. Oral corticosteroids such as prednisone are frequently prescribed for patients with lung diseases. The use of these medications ranges from brief "bursts" for asthma exacerbations or other acute and reversible pulmonary changes to chronic therapy that can last for years for several lung diseases. Long-term use of corticosteroids is associated with a variety of systemic side effects, including suppression of the hypothalamic–pituitary–adrenal axis, glaucoma, cataracts, weight gain, infections, and osteoporosis. These side effects are sometimes termed iatrogenic Cushing syndrome because of the frequent development of truncal obesity, moon faces, and buffalo hump. Inhaled corticosteroids are also frequently used for some lung diseases. While these corticosteroid preparations are designed to be locally acting, when used at high doses for extended periods, they can be associated with many of the side effects observed with oral corticosteroids.

Shortly after the widespread use of corticosteroids began in the early 1950s, reports of psychiatric symptoms from their use began to appear in

the literature. A Hollywood movie, “Bigger than Life,” was even released that provided a fictionalized account of the potential for corticosteroids to induce psychiatric side effects and even lead to abuse.

The use of corticosteroids is associated with an increased risk of mood symptoms that include depression, irritability, mania, and mixed features. Acute, higher-dose corticosteroid therapy, as with bursts for asthma exacerbations, may be more strongly associated with mania or hypomania while depression may be more common with chronic, lower-dose therapy. Psychotic features, such as delusions and hallucinations, can also occur with corticosteroids.

Perhaps even more common than mood symptoms are changes in cognition. In animal models, the hippocampus appears to be particularly sensitive to the effects of corticosteroids. Consistent with effects on the hippocampus, memory appears to be a cognitive domain that shows changes with corticosteroid therapy. In healthy controls, even a single high-dose exposure to corticosteroids is associated with a decline in declarative and working memory performance. Structural brain changes, including a reduction in hippocampal volume, appear to accompany memory changes, even during very brief corticosteroid administration. More generalized cognition changes, as with delirium, also occur during corticosteroid therapy, especially in older persons.

The most clearly established risk factor for psychiatric side effects with corticosteroids is dose. Thus, the lowest effective dose of these medications should be used when treating lung diseases or other conditions. If the dose cannot be reduced or if this approach is ineffective, the treatment, like the symptoms, is similar to that of bipolar disorder. Although placebo-controlled trials have not been conducted, mood stabilizers such as lithium, anticonvulsants, and antipsychotics seem to ameliorate mood changes and psychosis with corticosteroids.

Other medications used for lung diseases may also have psychiatric side effects. Anxiety, agitation, and depression have been reported with theophylline and beta-2 adrenergic agonists. Theophylline may also be associated with an increased risk of suicidal ideation. Postmarketing reports suggested a possible link between leukotriene inhibitors and a variety of psychiatric symptoms, including agitation, insomnia, anxiety, depression, and suicidal ideation. However, the data do not appear to support an association of these medications with completed suicide with a

recent report even suggesting a decreased risk of depression with montelukast as compared to inhaled corticosteroids.

FUTURE DIRECTIONS

The psychiatric symptoms associated with respiratory illnesses have been less extensively studied than those in other common medication conditions, such as coronary artery disease. The underlying mechanisms are not well understood but are likely multifactorial. Furthermore, little is known about the treatment for depression, anxiety, and other disorders in this population. The increasing prevalence of respiratory illnesses, in particular, COPD and asthma, and current population trends in aging, pose considerable challenges to scientists and clinicians. In addition to psychological interventions for improving mental health symptoms, lifestyle interventions that may aid in managing psychiatric health along with symptoms of respiratory disease remain to be investigated. Potential underlying processes involved such as systemic inflammation and gut microbiota in dietary interventions, for example, are critical to explore and remain understudied.

Interdisciplinary collaboration will be needed to further elucidate the interaction of psychosocial factors with respiratory illness and to develop and implement adequate pharmacologic, cognitive, and behavioral interventions. Consideration of electronic methods of intervention including mobile applications and telemedicine for mental health will need to be explored, with the potential benefit of increasing accessibility to treatments aimed at improving patient care.

27.6 Diabetes: Psychosocial Issues and Psychiatric Disorders

Paul Ciechanowski, M.D., M.P.H., and Robert J. Boland, M.D.

Diabetes is one of the most complex chronic medical conditions, requiring a high degree of patient self-management within a supportive social network to ensure optimal outcomes. Psychiatric illness can adversely affect patients' self-care behaviors and ability to interact with others. Psychiatric illnesses, such as depression, may also lead to neurohormonal changes, such as changes in the hypothalamic–pituitary axis, which may adversely affect glucose control.

DIABETES: THE NATURE OF THE ILLNESS

Diabetes results from insufficient insulin secretion or resistance to insulin. Persons with type 1 diabetes produce no or minimal insulin; the onset is typically early in life. Type 1 diabetes accounts for 5% to 10% of all patients with diabetes. Type 1 diabetes is due to an autoimmune,

predominantly T-cell process that selectively destroys insulin-producing pancreatic β cells. This autoimmune process likely has a multifactorial origin with environmental and genetic factors. The onset of type 2 diabetes generally occurs during adulthood, although childhood onset is increasing. Individuals with type 2 diabetes usually have insulin resistance, but as they age, they have decreased insulin production, with many eventually becoming insulin dependent. Genetic vulnerability and obesity are the most common causes of this condition, and dietary restriction and exercise are often sufficient early-stage treatments. In later stages, patients usually require oral hypoglycemic medications and insulin for adequate control.

Individuals with diabetes are at significantly increased risk of heart disease, stroke, peripheral vascular disease, kidney disease, lower extremity ulcers and amputations, retinal disease, neuropathy, infections, digestive disease, and periodontal disease. The Centers for Disease Control and Prevention (CDC) estimates that the cost of diabetes in the United States is $327 billion annually due to medical costs and lost work and wages. Diabetes is the seventh leading cause of death in the United States.

Obesity Epidemic

There is an epidemic of obesity and type 2 diabetes worldwide, including in the United States. The CDC estimates that as many as 37 million Americans have diabetes, which is more than triple the prevalence in 1980. They also report that from 1999 to 2000 through 2017 to 2020, the obesity prevalence increased from 30.5% to 41.9%. In addition, there are differences in the genetic predisposition for type 2 diabetes among different ethnicities. For example, per the CDC, non-Hispanic Black adults had the highest age-adjusted prevalence of obesity (49.9%), followed by Hispanic adults (45.6%), non-Hispanic White adults (41.4%), and non-Hispanic Asian adults (16.1%).

The epidemic of obesity in the United States has also caused a marked increase in the prevalence of metabolic syndrome. This prediabetic syndrome includes central obesity, elevated blood glucose, elevated blood pressure, low–high-density lipoproteins (HDL), and elevated triglycerides. Elevated blood glucose is related to increased insulin resistance, and in the United States, over 96 million U.S. adults (1 in 3 adults 18 or older) have “prediabetes.” Prospective studies have shown that metabolic

syndrome raises the risk of developing coronary vascular disease by over 50% and the risk for type 2 diabetes by approximately threefold compared to individuals without metabolic syndrome.

PSYCHIATRIC COMORBIDITY

Thomas Willis, an early British physician, stated in the 17th century that diabetes is caused by “sadness or long sorrow and other depressions and disorders.” However, despite the early recognition of this association, it was not until the latter part of the 20th century that several epidemiologic studies began to address this problem.

Epidemiology

These studies demonstrated that depression is more likely to occur in people with diabetes regardless of whether the person is aware of having diabetes. Many others who do not have a depressive disorder experience considerable distress, putting them at risk for many psychiatric disorders. Multiple studies report a prevalence of depressive disorders in people with diabetes at about 10% to 15%, thus, roughly twice that of the average population. Perhaps as many as 25% of persons with diabetes experience subsyndromal depressive symptoms. Of note is that some recent studies suggest that this rate is increasing. This possibility is especially alarming as many cases remain undiagnosed. Specific populations may be harder hit. For example, in the United States, one review suggested that a quarter of African Americans with diabetes have depression.

A meta-analysis of 39 studies reported a 12% prevalence of major depression in patients with diabetes. This meta-analysis also showed that in controlled studies, there was a twofold increased prevalence of depression in patients with diabetes compared to controls. A large health maintenance organization-based study found that 12% of approximately 4,800 adult patients with predominantly type 2 diabetes (96%) met the criteria for major depression and 8.5% for minor depression. The group with major depression and diabetes compared to those with diabetes alone were younger, more likely to be female, were less educated, had significantly higher medical comorbidity, had more diabetes complications, had a longer duration of diabetes, had higher hemoglobin A1c (HbA1c) and BMI values, and were more likely to be smokers. In addition, the

patients with depression and diabetes developed diabetes an average of 5 years earlier than those with diabetes alone.

Depression tends to be either a chronic or recurrent condition in patients with diabetes. For example, data from the large HMO study described above showed that 63% of patients with diabetes and major depression had 2 years or longer of significant depressive symptoms. Another study found that 79% of patients with diabetes with major depression relapsed over a 5-year follow-up period with a mean of four episodes per patient.

Diabetes and Depression in Non-Western Countries. Most of the data on the prevalence of diabetes and depression is from Western and higher-income studies. However, some data from other parts of the world suggest an even higher prevalence of depression in patients with diabetes. For example, a review of studies done in South Asia reported that the prevalence of type 2 diabetes and elevated depression symptoms ranged from 11.6% to 67.5%. A meta-analysis of studies done in Iran estimated that the prevalence of depression in patients with diabetes was 54%. In Saudi Arabia, a study of children with type 1 diabetes reported a depression prevalence of 27%. Investigators in India found a similarly high rate of depression in patients with diabetes. In addition, the investigators found that depression was associated with younger age, female sex, low socioeconomic status, and poor self-management.

Diabetes and Depression in Youth. Less research has focused on depression among youth with diabetes. The prevalence of elevated depressive symptoms in youth with type 2 diabetes is approximately 20% (this includes syndromal and subsyndromal cases). Some studies suggest that these symptoms adversely affect glycemic control, most likely because of their adverse effects on medication adherence and diet. Fewer studies have examined the effect of comorbid depression on youth activity or physiology.

A study examined the rate of depression in 2,672 youth (aged 10 to 21 years), most of whom had type 1 diabetes. Based on a depression screening measure, 14% were mildly depressed, and 8.6% were moderately to severely depressed. In addition, participants with depression and diabetes had significantly higher HbA1c levels and a higher number of emergency room visits. Another study from an extensive national database found that youth hospitalized with type 1 diabetes with

comorbid depression were twice as likely to be rehospitalized in the following 12-month period compared to those with a diabetes diagnosis alone.

Depression and Diabetes May Share Similar Biologic Mechanisms

The close relationship between diabetes and depression suggests that the two disorders may share common mechanisms. Most commonly, experts suggest that the link between the two is psychological: the burden of a chronic disease such as diabetes predisposes to depression, or depression affects motivation and causes poorer self-management, for example. However, there may also be shared biologic mechanisms. Hyperglycemia, for example, can affect mood states, and high plasma glucose in the brain can increase oxidative stress, ultimately leading to neuronal damage, which causes depression. Alternatively, the microvascular changes associated with diabetes and identifiable in the brain may also predispose to depression. Finally, we increasingly appreciate the role of inflammation in psychiatric disorders, including depression. Type 2 diabetes is associated with low-grade systemic inflammation, and this same inflammation may underly the depression seen in diabetes. Others have suggested calcium/cAMP signaling as the underlying cellular mechanism linking the two disorders. Unfortunately, most of the work investigating this to date is cross-sectional and limited to correlations, and we need longitudinal research to understand potential shared mechanisms better. One example is an intriguing but preliminary study using mice with type 2 diabetes that demonstrated that a swimming exercise decreased depressive-type behaviors and glucose and inflammatory cytokines in the mice.

Psychiatric Symptoms Often Occur at Key Developmental Stages in Patients with Diabetes

Patients and their family members are most likely to exhibit psychiatric symptoms at critical stages of diabetes management, including reactions to initial diagnosis, when a complication (i.e., neuropathy, retinopathy) develops, or when intensifying a treatment regimen is needed, such as starting insulin. Conversely, chronic stressors and psychiatric symptoms may markedly interfere with adherence to self-care regimens (e.g., diet, exercise, taking medications, cessation of smoking) and diabetic disease control. In addition, family conflict regarding diabetes tasks, such as

following a new dietary regimen or increasing exercise, may also interfere with treatment.

Opportunities for clinicians to screen for psychosocial difficulties and specific psychiatric disorders include at the time of initial diagnosis of diabetes, during regularly scheduled diabetes visits, during visits with diabetes nurses or educators, during hospitalization or development of a diabetes complication, and when discussing problems with glucose control or adherence to lifestyle or medication regimens. In addition, clinicians may want to consider using validated brief screening tools for depression and anxiety, such as the Patient Health Questionnaire (PHQ-9) and Generalized Anxiety Disorder (GAD-7), respectively, or use the Problem Areas in Diabetes (PAID) instrument as a way of better understanding diabetes-specific emotional distress.

Patient–Provider Relationship: Effect of Psychiatric Comorbidity and Maladaptive Attachment Styles

Effective self-management of either type 1 or type 2 diabetes requires a close working relationship with a physician, other health care providers, and family members. This partnership with the health care provider allows the patient and their providers to work in an interactive, iterative fashion to achieve ideal medication management that maximizes benefits and minimizes side effects while implementing essential lifestyle changes (e.g., losing weight, increasing exercise, cessation of smoking).

Satisfaction with the quality of care of a patient's physician is associated with enhanced adherence to medical regimens in patients with diabetes. Depressive disorders and maladaptive attachment styles are associated with decreased ratings of satisfaction with care in patients with diabetes. Moreover, primary care effectiveness studies testing interventions that improve major depressive outcomes showed that enhanced depressive outcomes were associated with increased satisfaction with care.

Depression and anxiety disorders in adulthood are also associated with higher rates of having experienced childhood adversity (abuse and neglect) and with maladaptive attachment styles, which are associated with lower levels of trust in others. Maladaptive attachment styles may make it difficult for patients to develop trusting relationships with others, including health care providers. Two styles, dismissing and fearful attachment, are associated with difficulty in trusting others and are the predominant relationship styles in 48% of adult primary care patients with

diabetes. Adults with a dismissing attachment style develop strategies early in life in which they become highly independent and uncomfortable trusting others. In contrast, adults with a predominantly fearful attachment style may have an initial desire for social contact at times of distress that is inhibited by fear of rejection, resulting in approach-avoidance behavior.

Among over 4,000 primary care patients with type 2 diabetes, those with dismissing and fearful attachment styles had 46% and 64% more missed primary care appointments, respectively, and both styles were associated with less satisfaction with care compared to those with secure attachment styles. In the same sample, compared to patients with a secure attachment style, those with dismissing attachment style had lower levels of exercise, foot care, diet adherence, oral hypoglycemic medications, and higher rates of smoking. Other studies have also shown that in individuals with diabetes, dismissing and fearful attachment styles had decreased glucose monitoring, nonadherence with insulin injections, higher glucose levels, and higher mortality over 5 years. The adverse impact of dismissing and fearful attachment described above was independent of the effect of depression.

Depression may also increase the severity and impact of maladaptive attachment style traits. One study demonstrated that decreased depressive symptoms over 10 months were associated with transitioning to more adaptive attachment behaviors and greater trust in others. This study suggests that affective illness increases maladaptive interpersonal behaviors, potentially making collaboration with the physician more difficult and contributing to patients with these disorders receiving suboptimal preventive medical care and having poorer diabetes outcomes.

Type 1 Diabetes: Developmental and Family Issues

Having a child with a chronic illness often causes great stress for families and may interfere with normal childhood development. For example, research suggests higher divorce rates in families where one child has a significant chronic illness or developmental disability, and children with chronic illnesses such as diabetes have twofold higher rates of affective illness and anxiety disorders.

Type 1 diabetes may be particularly taxing for children and their families. Family-based care for diabetes requires checking blood glucose several times a day and altering insulin doses depending on blood

glucose levels. This illness also requires following careful dietary regimens and getting consistent levels of exercise. When children develop this illness early in life, much of the responsibility for diabetes care depends on parents and may add significantly to parental stress. Recurrent hospitalization, inability to participate in usual childhood outings (particularly those away from home), and parental overprotectiveness can all delay normal childhood progression toward mastery and autonomy.

Moreover, as the child moves into adolescence, there may be more significant conflict as the child tries to separate and individuate. Acting out behavior such as dietary indiscretions, missing insulin doses, and avoiding checking blood sugars can all lead to poor glucose control during adolescence. Individual and family therapy approaches may be necessary to improve the quality of diabetes care and to help adolescents and their families adjust to new developmental phases.

Effects of Depression on Diabetes Symptom Burden

Comorbidity between depression and diabetes increases a patient's risk for morbidity from both illnesses, including diabetes-related complications, disease management, quality of life, and mortality.

Several studies have examined the association of comorbid depression and anxiety in patients with diabetes on physical symptoms characteristic of poor glucose control (i.e., polyuria, polydipsia). These studies have shown that depression and anxiety disorders were more highly associated with self-reported diabetes symptoms than were HbA1c levels or the number of diabetes complications. For example, a study by Ludman and colleagues found that, after controlling for potential confounders, patients with diabetes and depression were significantly more likely to report 10 diabetes symptoms than patients with diabetes alone (odds ratios between 2 and 5 for each symptom). Interestingly, patients with two or more diabetes complications compared to those with fewer than two complications had a significantly higher likelihood of having 9 of 10 diabetes symptoms, but the odds ratios were only between 1.3 and 2.0. These findings demonstrate that depression is more highly associated with diabetes symptom burden than the number of diabetes complications. In addition, a study that compared collaborative care versus usual primary care in treating depression in 387 patients with diabetes found that not only was collaborative care associated with better depression outcomes but also significantly decreased diabetes symptom

burden compared to usual care despite not having a significant effect on glycated hemoglobin levels.

Some symptoms of diabetes, such as chronic pain due to neuropathy, may lead to bidirectional adverse experiences with depression. Depression can amplify pain complaints, thus preventing habituation to aversive symptoms. Biologic evidence suggests that depression-associated serotonin and norepinephrine depletion may lead to the dysregulation of descending pain pathways that typically dampen aversive symptom perception. Longitudinal studies have also shown that chronic pain is associated with a higher incidence of depression. Antidepressant medications, such as venlafaxine and duloxetine, that increase norepinephrine and serotonin are effective in treating diabetic neuropathy, even in nondepressed patients.

Effect of Depression and Anxiety on Functioning

Multiple studies have shown that depression and anxiety lead to additive social and vocational disability in patients with chronic medical illnesses. For example, the Pathways Epidemiologic Study has longitudinally surveyed over 4,000 patients in a large health maintenance organization with diabetes and shown that comorbid major depression in patients with diabetes was associated with a 10-fold increase in the likelihood of functional impairment on the World Health Organization (WHO) Disability Scale and a fourfold increased odds of having 20 or more days of reduced ability to do housework in the past 90 days after controlling for diabetes complications, medical comorbidity, and glycemic control. Among 1,642 nonelderly persons in the Pathways Epidemiologic Study (excluding homemakers and retired persons), those with comorbid depression had a fourfold increased likelihood of missing more than 5 days of work in the prior month, more difficulty performing work tasks, and greater levels of unemployment after controlling for comorbid chronic medical illness, diabetes complications, and glycemic control.

A large longitudinal epidemiologic study that followed approximately 2,800 older adult Hispanic Americans in the Southwest over 7 years found that the interaction of depression and diabetes was synergistic in predicting the greater incidence of decrements in activities of daily living, even after controlling for sociodemographic characteristics. Both depression and diabetes independently predicted increased incidence of

decrements in function, and when they were comorbid, there was more than an additive adverse effect on functioning.

A study that compared a collaborative care intervention to usual primary care in enhancing the quality of depression care in over 400 older adult patients with diabetes found that the intervention patients not only had improved depressive outcomes but also had improved physical functioning over 12 months.

THE RELATIONSHIP BETWEEN DIABETES, DEPRESSION, AND OBESITY

The relationship between diabetes, depression, and obesity is complex and not necessarily linear. Patients with obesity and depression are more likely to have other chronic diseases, including diabetes. The relationship may be, in part, genetic. Genetic studies estimate that 12% of the variants linked to obesity are shared by depression, and the associations between obesity and type 2 diabetes are much higher in large genome-wide association studies (GWAS). Serotonin is critical to many functions that involve one or more of the disorders, including mood regulation, satiety, insulin and leptin action, carbohydrate metabolism, and inflammatory cytokines, and it may represent a pathway linking these disorders. The same could be valid for the HPA axis, which modulates stress, metabolic rate, appetite, and inflammation.

Adverse health habits such as smoking, poor diet, and sedentary lifestyle also occur in a higher prevalence in patients with mental illness than in those without, which may also increase the incidence of obesity, metabolic syndrome, and type 2 diabetes. However, the most important may be decreased physical activity associated with depression.

EFFECT OF DEPRESSION AND OTHER PSYCHIATRIC AND MEDICAL COMORBIDITIES

Patients with diabetes must optimally follow complex self-care regimens, including changing their diet, increasing exercise, checking blood glucose and altering medication dosages based on glucose fluctuations, stopping smoking, and taking multiple disease control medications. Depression may adversely affect these self-management activities by decreasing energy, concentration, memory, and motivation. A meta-analysis of over

20 studies of patients with chronic medical illness found that depression and anxiety were associated with a threefold higher rate of nonadherence to medical regimens.

In the Pathways Epidemiologic Study, patients with major depression and diabetes, compared to those with diabetes alone, were less likely to eat a healthy diet, more likely to eat high-fat foods, less likely to exercise, and more likely to smoke. Depressed patients were also more likely to have lapses in refilling prescriptions for oral hypoglycemic, lipid-lowering, and antihypertensive medications. These medication lapses may lead to a higher risk of diabetes complications.

Other psychiatric illnesses such as bulimia, night eating syndrome, binge eating syndrome, and chronic psychiatric illnesses such as schizophrenia and bipolar illness are associated with poor self-management of chronic illnesses such as diabetes and poor quality of medical care. For example, patients with schizophrenia and bipolar disorder are twice as likely to die from cardiovascular disease as the general population. In addition, research has shown that patients with diabetes and schizophrenia are treated less aggressively for their cardiovascular risk than patients with diabetes without a mental disorder. To worsen matters, patients with diabetes and schizophrenia have an elevated rate of depression compared to patients with diabetes who do not have schizophrenia.

A meta-analysis examined the prevalence of eating disorders among patients with type 1 diabetes versus controls. The prevalence of anorexia nervosa was not significantly different in patients with type 1 diabetes versus controls (0.27% vs. 0.06%). In comparison, the prevalence of bulimia nervosa (1.73% vs. 0.69%) and anorexia nervosa and bulimia nervosa combined (2.00% vs. 0.75%) were significantly higher versus controls in patients with type 1 diabetes. Some patients with insulin-dependent diabetes also try to lose weight by skipping or reducing their insulin injections—a phenomenon called “insulin withholding”—predisposing them to poor glucose control and future complications.

Psychiatric Illness and Diabetes Complications

A meta-analysis of 22 studies involving more than a million participants showed that depression was associated with an increased risk of macrovascular (HR = 1.38; 95% CI: 1.30–1.47) and microvascular (HR = 1.33; 95% CI: 1.25–1.41) complications in patients with diabetes.

Furthermore, the relationship was bidirectional in that diabetes complications also increased the risk for depression.

Similarly, a meta-analysis of 11 studies with 34,185 subjects found that patients with diabetes were at significantly elevated risk of developing diabetic retinopathy, if they had comorbid depression (fixed effects OR = 1.50, 95% CI 1.39–1.63; random effects OR = 1.58, 95% CI 1.35–1.84). The risk was somewhat higher for individuals greater than those aged 60.

The mechanisms of this association are not entirely understood but likely involve poor self-care and, perhaps, shared biologic mechanisms, such as increased cortisol levels and inflammation.

Several longitudinal studies have also shown that depression was associated with increased complications. For example, in a large longitudinal study of Hispanic older adult respondents in the southwestern part of the United States, older adult patients with diabetes who were initially depressed versus those with diabetes alone were three times as likely to develop macrovascular and microvascular complications over 7 years. In the Pathways Epidemiologic Study that followed over 4,000 patients with diabetes over 5 years, those with depression and diabetes versus those with diabetes alone were 36% more likely to develop microvascular complications and 24% more likely to develop macrovascular complications. A large longitudinal study of children with type 1 diabetes also showed that the risk for developing retinopathy was independently associated with three risk factors: duration of diabetes, time spent with poor glucose control, and time spent in major depression.

One study demonstrated that antidepressant use decreased macrovascular complications and mortality risk. However, it did not affect microvascular disease.

Depression and Diabetes: Cardiac Risk Factors. Approximately 50% of mortality in patients with diabetes is related to myocardial infarction or stroke. In addition, a recent meta-analysis of 17 studies including over a million patients found that, for patients with type 2 diabetes, depression was associated with a higher risk of both nonfatal (relative risk 1.35, 95% confidence interval [CI] 1.20 to 1.53) and fatal (relative risk 1.47, 95% CI 1.21–1.77) cardiovascular events.

Several mechanisms might explain this increased risk. Depression can adversely affect autonomic activity, heart rate variability, catecholamine levels, inflammation, and endothelial and platelet dysfunction, all of which

are risk factors for cardiovascular events. More work must be done to understand this relation and identify interventions to lessen the risk.

Diabetes, Depression, and Dementia. Type 2 diabetes is associated with a greater prevalence of cognitive impairment, cognitive decline, and Alzheimer disease. A review of 25 prospective studies found that people with diabetes had a 1.2 to 1.5 greater odds of developing cognitive decline than those without diabetes. Patients with type 2 diabetes have reduced sensitivity to insulin (i.e., increased insulin resistance) and reduced neuronal sensitivity to insulin. Reduced neuronal insulin sensitivity may exacerbate neurodegeneration, causing cognitive decline and dementia. Diabetes is also associated with a higher risk of vascular disease, including stroke, which may increase the risk of dementia, particularly vascular dementia. Hypoglycemia is a complication of treatment with glucose-lowering drugs, particularly insulin. Severe hypoglycemic episodes associated with emergency room visits or hospitalizations have increased the risk of dementia in patients with diabetes. Comorbid depression can further contribute to the association between diabetes and cognitive decline. The Diabetes and Aging Study, a cohort investigation examining risk factors for dementia in individuals with diabetes, examined more than 19,000 patients over a 3- to 5-year period. Patients with comorbid depression had a 100% increased risk of dementia during the observation period.

Cognitive decline is likely to interfere with the self-management of diabetes, potentially worsening insulin resistance and hyperglycemia. In addition, both depression and diabetes can adversely affect executive functioning. Therefore, screening patients with diabetes using tools like the Mini-Mental Status Examination or the Montreal Cognitive Assessment (MoCA) is essential to ensure early recognition. In addition, enlisting family support for patients with cognitive impairment and diabetes is essential to slow the progression of diabetes.

Two studies have also found that patients with comorbid depression and type 2 diabetes, compared to those with diabetes alone, had an approximately twofold greater risk of developing dementia. A study of approximately 29,000 patients with type 2 diabetes developed a risk prediction model for dementia and identified depression as an important clinical risk factor. Another study that analyzed data from a large randomized trial designed to control glucose and cardiovascular risk

factors in patients with diabetes found that those with comorbid depression and diabetes versus those with diabetes alone had a greater risk of cognitive decline in neuropsychological tests over 40 months. Most recently, a study of 3,742 individuals with type 1 diabetes, 50 years or older, found that depression was associated with a 72% increase in dementia (fully adjusted HR = 1.72; 95% CI:1.12–2.65). This study followed subjects for 25 years and estimated that the presence of depression doubled the incidence of dementia. Similarly, the Edinburgh type 2 diabetes study followed 1066 subjects for an average of 10 years and found that depression was associated with a more than 2.5-fold risk for dementia (HR 2.59 [95% CI 1.62, 4.15]) after adjusting for age and sex. In their study, systemic inflammation did not seem to explain this risk.

Effect of Depression on Medical Costs

Given the adverse effect of depression on somatic symptom burden, functional impairment, poor adherence to self-care, and increased complications, it is not surprising that several studies have shown that total health service costs of patients with diabetes and depression are significantly higher than those with diabetes alone. Studies that have carefully controlled for demographic factors, the severity of diabetes, and medical comorbidity have found that total health service costs are approximately 70% higher for individuals with major depression and diabetes than for diabetes alone. This finding is crucial for health care systems because patients with diabetes have approximately two- to fourfold higher medical costs than those without diabetes. Therefore, a 70% increase in the costs of these already expensive patients adds a disproportionate amount of total costs to a health care system. Other studies have also shown that patients with depression and diabetes, compared to those with diabetes alone, have more than twice the risk of needing an intensive care unit (ICU) admission after controlling for sociodemographic factors and the severity of diabetes. ICU admission costs are about double the costs of regular hospital admissions. Another study showed that those with depression and diabetes, compared to those with depression alone, were about 40% more likely to have an ambulatory care-sensitive hospitalization (a potentially avoidable hospitalization if patients received a higher quality of primary care).

Studies have also shown that the increase in mental health care costs does not explain the increased cost for patients with diabetes and

depression compared to those with diabetes alone. Instead, there is an increase in costs in every category that is measured, including primary care visits, medical specialty visits, nonpsychiatric prescriptions, x-ray and lab costs, emergency room and urgent care visits, inpatient medical care and mental health visits, and prescriptions. In addition, two large primary care-based studies (the Pathways and IMPACT [Improving Mood—Promoting Access to Collaborative Treatment for Late Life Depression] studies) testing collaborative care interventions showed that improving the quality of care and outcomes of patients with depression results in cost savings in medical costs that offset the additional costs of the collaborative care mental health intervention.

Psychiatric Illness and Mortality in Patients with Diabetes

A systematic review of 10 longitudinal studies found that comorbid depression in patients with diabetes was associated with a 50% increased mortality risk. One study showed that depression or diabetes in older adult patients increased mortality risk by almost one-third, and respondents with both disorders had a fourfold increase in mortality compared to older adult with neither disorder.

Among patients with diabetes in the Pathways Epidemiology Study, after controlling for age, gender, and socioeconomic factors, comorbid major depression was associated with a twofold increase in mortality over 3 years compared to nondepressed patients. Minor depression also increased the risk of mortality by 67%. Even when controlling for diabetes, medical disease severity, and adverse health behaviors (smoking, obesity, sedentary lifestyle, HbA1c), major and minor depression were still associated with an approximately 50% increase in mortality.

Similarly, a study of 3,923 patients in Spain with type 2 diabetes found that depression was associated with higher mortality risk (HR = 1.40, 95% CI:1.20–1.65, P <.001). The strongest predictors were age, insulin use, amputation, heart failure, and male gender.

TREATING DIABETES AND DEPRESSION

One systematic review of treatment studies by van der Feltz-Cornelis and colleagues identified 43 studies with 4,602 patients with diabetes mellitus and either a depressive disorder or subthreshold depression. Most studies reported that depression treatment had a positive effect on depressive

symptoms. This finding might seem obvious; however, this is encouraging given that psychiatric disorders comorbid with medical illnesses tend to be less responsive to treatment. Whether depression treatment also improves diabetes outcomes is less clear. A meta-analysis of the 43 studies showed a small but significant positive effect on glycemic control. The effect size was greatest for pharmacotherapy (0.987, 95% CI 0.127; 1.846, P = .024) and group-based therapy (0.953, 95% CI 0.185; 1.722, P = .015) with a lesser (although significant) effect reported for psychotherapy (0.607, 95% CI 0.147; 1.066, P = .010) and collaborative care (0.207, 95% CI 0.050; 0.364, P = .010) approaches. The effect sizes for exercise, online, and phone treatment did not differ from usual care.

As with all meta-analyses, combining various studies, often with different protocols and aims, is complex and coming to meaningful conclusions is difficult. Nevertheless, some individual studies have had more positive results.

Three efficacy studies that randomized patients with major depression and diabetes to antidepressant versus placebo or CBT versus a diabetes education group found significant improvement in depression in all studies (effect sizes in antidepressant trials between 0.62 and 0.63, and 1.16 in the CBT trial) but only one study showed a beneficial effect on HbA1c levels.

Among patients with depression and diabetes in the above three large trials, 60% to 80% were diagnosed with double depression (i.e., concurrent major depression and persistent depressive disorder, i.e., dysthymic disorder). Double depression predicts treatment resistance and recurrence or relapse. Comorbid chronic medical illness in patients with depression is associated with a more chronic course, slower recovery, and less treatment response. Given the high rates of relapse and chronicity in patients with depression and diabetes, researchers have begun to test the effect of maintenance antidepressant treatment. Several antidepressant trials that tested the effect of maintenance treatment have suggested that long-term improvements in treatment that resulted in enhanced rates of recovery and remission are associated with improved glycemic outcomes. One maintenance trial randomized 152 patients who had recovered with an open-label trial of an SSRI to either SSRI or placebo for up to 52 weeks. Patients who received maintenance treatment with the SSRI had a significantly greater depression-free interval than those treated with a placebo. In addition, patients using an SSRI who recovered from

depression and sustained remission for at least 1 year had improved HbA1c levels.

A second maintenance trial that treated 93 patients with type 2 diabetes with acute phase bupropion (Wellbutrin) offered maintenance-phase bupropion treatment to patients who remitted (N = 63). BMI, total fat mass, and HbA1c values decreased significantly, while composite diabetes care improved over the initial acute phase, and these effects persisted through the maintenance phase. In addition, a reduction in BMI and depression severity with bupropion treatment predicted lower HbA1c levels after acute phase therapy, but only a reduction in depression predicted lower HbA1c levels during the maintenance phase of treatment.

How Can Depression Treatment Improve Diabetes Care?

Piette et al. have proposed a model to explain how depression treatment may improve the outcomes of comorbid chronic disease, which they applied to diabetes. In this model, effective treatment of depression may be more difficult because of the adverse health behaviors (smoking, obesity, sedentary lifestyle) and higher symptom burden and functional disability associated with depression. Adverse health behaviors do not necessarily improve with effective depression treatment alone and are negative prognostic factors for depression outcomes (e.g., obesity is associated with negative social feedback, lower self-esteem, and less exercise, which all affect mood). New treatment models that provide interventions aimed at improving the quality of depression care, optimizing positive health behaviors (exercise, diet, self-management), and treating chronic medical illness by optimizing medication treatment have shown improvement in depression and medical disease control outcomes. Furthermore, studies show that a significant contributor to suboptimal outcomes in primary care is *clinical inertia*, that is, lack of timely treatment intensification by the primary care physician or endocrinologist, such as titrating medications for reducing blood glucose, blood pressure, and cholesterol. For example, among 161,697 Kaiser Permanente patients with diabetes, 50% were above target for A1c, blood pressure, and LDL cholesterol. Lack of treatment intensification by health care teams was a more significant contributor to out-of-target values than poor patient treatment adherence.

Collaborative Care

Three large primary care-based randomized trials tested collaborative care treatment of depression among patients with diabetes: 418 patients with diabetes and depression age 60 and over in the IMPACT trial; 329 mixed-age patients with diabetes and depression with a mean age of 59 years in the Pathways trial, and 387 predominantly Hispanic patients in which 52% of patients were 55+ years old. These trials tested a stepped-care nurse intervention for depression versus usual primary care. All three trials showed marked intervention versus usual care effects in quality of depression care and significant improvements in depression outcomes (effect sizes between 0.47 and 0.68), but no significant changes in self-care such as diet or checking blood glucose and no significant difference in HbA1c levels. In addition, approximately half of the usual primary care controls were treated with antidepressants by their primary care physician during the 12-month trials.

Using Multicondition Collaborative Care to Reduce Clinical Inertia. The TEAM care clinical trial was a landmark study that expanded the collaborative care model from primarily focusing on treating depression to addressing multiple chronic conditions simultaneously using one case manager per patient, who focused on "A-B-C-D," that is, A1c, blood pressure, cholesterol (LDL) and depression. This clinical trial investigated 214 patients with depression and with poorly controlled diabetes or heart disease (i.e., patients had to have either an HbA1c level of at least 8.5%, a systolic blood pressure >140 mm Hg, or a low-density cholesterol level (LDL) of >130 mg/dL). The patients were randomized to a *multicondition collaborative care intervention* to improve the quality of medication treatment for depression and these medical illnesses and improve self-care (exercise, diet, cessation of smoking, and taking medications as prescribed). In addition to treat-to-target and systematic case review methods, this intervention included motivational enhancement, problem-solving treatment, and behavioral activation clinical methods by front-line nurse case managers. The intervention was associated with significant improvements in depression, HbA1c, SBP, LDL control, and exercise.

Another randomized trial of 180 patients prescribed medications for diabetes and depression in primary care tested an intervention that utilized care managers integrated into primary care to offer education, guideline-based treatment recommendations, and monitoring of adherence and clinical status. This intervention was significantly more

likely than usual primary care to achieve HbA1c levels <7% and remission of depression. Another study evaluated the impact of a telephone-delivered cognitive behavioral therapy intervention targeting depressive symptoms, a pedometer-based walking program aimed at increasing physical activity levels and improving diabetes-related outcomes in 291 patients with type 2 diabetes and significant depressive symptoms. Although the investigators found no differences between the intervention and usual care patients on the primary outcome of HbA1c levels, the intervention group had more significant reductions in depressive symptoms, systolic blood pressure, and step counts.

These trials show that to improve depression and medical outcomes, programs need to address clinical inertia by combining interventions for depression, as well as interventions aimed at improving adherence and intensifying diabetes disease control medications and self-care activities (e.g., providing pedometers to encourage increased exercise).

Summary

The meta-analysis and the individual studies discussed above suggest three conclusions. First, organized depression treatment programs such as collaborative depression care are effective for patients with diabetes. Second, the effects of depression treatment may be smaller for patients with chronic medical illness than in general primary care samples. Third, short-term treatment programs limited to improving depression may not have clear or consistent effects on medical outcomes such as HbA1c values. Finally, the maintenance trials tend to show that patients who have remitted in acute phase treatment and remain on antidepressants over the next year have improved glycemic control, whereas acute phase trials of antidepressants have inconsistent effects on HbA1c levels.

PSYCHIATRIC MEDICATIONS, OBESITY, AND TYPE 2 DIABETES

The widespread use of atypical antipsychotic medications for patients with bipolar illness, schizophrenia, and to a lesser extent, treatment-resistant depression has led to concerns about these psychiatric medications causing obesity, metabolic syndrome, and type 2 diabetes. Table 27.6–1 lists the antipsychotics and their associated weight gain. Clozapine (Clozaril) and olanzapine (Zyprexa) have the highest risk. In addition,

numerous case reports describe the less common occurrence of acute hyperglycemia after initiating these medications before a substantial weight gain. In addition, some but not all cases report hyperglycemia resolved after discontinuing the medication. These data suggest a direct role of atypical antipsychotic medications in increasing insulin resistance and causing type 2 diabetes, in addition to an indirect role in causing obesity.

Data have shown two- to fourfold increased rates of metabolic syndrome in patients with schizophrenia treated with typical or atypical antipsychotic agents. An estimated 16% to 25% of patients with schizophrenia have type 2 diabetes. However, the risk of developing diabetes with atypical antipsychotic agents appears to be higher than with typical antipsychotic agents. Data from a large Veterans Administration study of over 38,000 patients treated with atypical versus typical antipsychotic agents show an approximately 10% increased rate of diabetes associated with treatment with atypical antipsychotic agents. The large-scale CATIE trial also showed significantly more weight gain associated with atypical antipsychotic medications such as olanzapine and clozapine than those treated with perphenazine (Trilafon), a typical antipsychotic agent.

Table 27.6–1.
Antipsychotics and Associated Weight Gain

Likelihood of Weight Gain	Antipsychotic
High	Clozapine Olanzapine
Moderate	Chlorpromazine Quetiapine Risperidone Paliperidone
Low	Aripiprazole Amisulpride Asenapine Haliperidol Ziprasidone Lurasidone

Given the increasing concerns about the atypical antipsychotic agents causing obesity, metabolic syndrome, and type 2 diabetes, experts recommend using monitoring protocols. These protocols include eliciting a personal and family history of diabetes, heart disease, and other risk factors such as smoking and regularly monitoring weight, waist circumference, blood pressure, fasting blood glucose, and lipid profiles.

It is important to emphasize that other psychiatric medications can also lead to weight gain. The use of anticonvulsant agents such as valproic acid (Depakene, Depakote) and carbamazepine (Tegretol), as well as lithium carbonate (Eskalith, Lithobid) in patients with bipolar disorder, are also frequently associated with weight gain. Lamotrigine (Lamictal), another anticonvulsant medication increasingly used in bipolar disorder and treatment-resistant depression, is generally not associated with weight gain. Although topiramate (Topamax) has not been FDA-approved for use in bipolar disorder, psychiatrists often use lower dosages of this medication as an adjunctive medication due to its effect on decreasing appetite and inducing weight loss. Metformin (Glucophage) can also induce weight loss in patients taking atypical antipsychotics.

Among antidepressant agents, tricyclic antidepressant medications and mirtazapine (Remeron) cause weight gain in many patients. However, SSRIs appear to induce weight gain in only 5% to 10% of patients compared to placebo. Bupropion is the only antidepressant showing no weight gain or slight weight loss in placebo-controlled trials.

Using Technology to Reach Larger Populations

Telehealth and other approaches that harness readily available technology can help clinicians reach many otherwise difficult-to-access populations. For example, the pharmacist-led telehealth management program significantly improved medication adherence (for diabetes and depression). This finding is promising since collaborative care approaches also rely on similar technology. However, there are a growing number of web-based or app-based interventions for diabetes and depression, and there is a great need for more research to test the efficacy of these approaches.

A Clinical Approach to Treating Depression in Patients with Diabetes

Table 27.6–2 outlines a diabetes-focused clinical approach to treating depression and other psychiatric problems in patients with diabetes. Because of the increased prevalence of depression in patients with diabetes, clinicians should use screening tools such as the PHQ-9 to recognize depression in diabetes settings. Frequently, patients with diabetes and comorbid depression presenting to a health care provider are unaware of their depressive symptoms. Instead, they may experience physical symptoms of diabetes, such as polyuria and fatigue. In addition, they commonly present with high levels of frustration, resignation, or guilt related to increased difficulties in managing glucose and other diabetes-specific tasks. These symptoms may result from depression's effects on the HPA axis or the aforementioned negative effects of depression in patients with diabetes, such as amotivation, fatigue, anhedonia, lack of concentration, and hopelessness, which make diabetes self-management a problematic task.

Table 27.6–2.
Diabetes-Focused Depression Care

In addition to standard evaluation of current (and past) episodes of depression:

1. Assume depressed patient is experiencing “loss of control” of disease self-management or outcomes resulting in frustration, bewilderment, resignation, etc.
2. Assess for understanding of bidirectional link between stress and suboptimal disease self-management and outcomes.
3. Define depression and how it overlaps with (and is distinct from) “stress.”
4. Review symptoms of depression and how these symptoms overlap with or mimic diabetes symptoms. Discuss depression-related symptom amplification.
5. Consider “biologic” sequelae resulting from comorbid depression:
   - e.g., increased glucose levels (increased glucometer mean + SD, higher HbA1c)
   - e.g., increased neuropathy pain, i.e., increased intensity, functional impairment
6. Consider “behavioral” sequelae resulting from comorbid depression:
   - e.g., decreased self-care (refilling prescriptions for medications and monitoring strips; glucose monitoring; exercise; diet). Look for helplessness/ “giving up” or sense of being overwhelmed around disease self-care
   - e.g., missed appointments or high health care utilization (labs, visits, urgent care)
   - e.g., decreased satisfaction with care
   - e.g., decreased ability to rely on others
7. Screen for comorbid anxiety ± panic attacks and look for inability to differentiate anxiety symptoms from diabetes symptoms (e.g., hypoglycemia).
8. Screen for associated eating concerns (e.g., emotional eating in response to sadness/loneliness/anger, etc.; binge eating ± purging; night eating).
9. Break down tasks (self-management of diabetes, depression, heart disease, other illnesses) and help patient prioritize in order of importance
10. For patients with comorbid anxiety, consider using SSRI or SNRI
11. For patients with sexual dysfunction, consider using bupropion or mirtazapine (consider weight gain with mirtazapine)

12. For patients with significant neuropathy, consider bupropion, venlafaxine, or duloxetine
13. Consider adjunctive brief psychotherapy for:
    - emotional eating (CBT)
    - breaking down problems (problem-solving therapy)
    - improving treatment adherence (motivational interviewing)
    - improving effective patient–provider interactions (patient coaching)

SD, standard deviation; HbA1c, hemoglobin A1c; SSRIs, selective serotonin reuptake inhibitors; SNRI, serotonin and norepinephrine reuptake inhibitor; CBT, cognitive-behavioral therapy.

The clinician treating individuals with diabetes and depression may benefit from the concept of *diapression,* which recognizes that individuals with diabetes who develop depressive symptoms may experience specific characteristics.

- Depression can mimic and amplify diabetes symptoms
- Depression is associated with poor diabetes self-management and treatment adherence
- Depression can lead to adverse lifestyle habits
- Depression is associated with changes in health care utilization patterns
- Symptoms of depression reduce levels of trust and satisfaction with care

A powerful way of engaging patients experiencing depressive symptoms may be to nonjudgmentally validate their experience of a recent “loss of control” of their diabetes. Furthermore, this approach helps provide opportunities to educate patients about the interaction between stress, depression, and anxiety on one hand and diabetes outcomes on the other. Patients are often relieved to hear that it is not their fault that their glucose control has become suboptimal.

Screening for comorbid anxiety is critical since symptoms of anxiety and panic disorder may worsen the control of diabetes. Furthermore, it is often difficult to disentangle anxiety symptoms from hypoglycemic symptoms for patients on insulin who may have frequent hypoglycemic episodes because of poor self-management. As a result, patients may eventually ignore significant hypoglycemic symptoms or catastrophize when anxious because they misinterpret anxiety as hypoglycemic symptoms. Using

screening tools for anxiety, such as the GAD-7, can help when working with patients with diabetes.

Asking about eating behaviors and achieving emotional regulation through eating is vital since patients with diabetes and depression have a higher risk of bulimia, binge eating disorder, and night eating syndrome. A subgroup of patients eat a significant proportion (e.g., more than 25%) of their caloric intake after supper time, and such “night eating” behaviors are associated with higher HbA1c levels, more complications, and higher BMI. A nonjudgmental approach that optimally treats underlying anxiety or depression and potentially uses CBT techniques for problematic eating behaviors can effectively relieve emotional eating in patients with diabetes.

Other practical strategies for patients with depression include problem-solving treatment, behavioral activation, CBT for depression, and the use of medications, with care to choose medications that may add benefits for pain control in patients with neuropathy pain (about one-third of patients with diabetes have neuropathy).

FUTURE DIRECTIONS

The United States is facing an epidemic of type 2 diabetes, and psychiatric illness comorbidity with this medical illness is very high. Despite the cost of comorbidity, depression screening is not a routine part of most diabetes care, and many cases of depression in patients with diabetes remain undiagnosed. Therefore, it is important to screen patients with diabetes for psychiatric illnesses and to screen patients with psychiatric illnesses for diabetes since comorbidity is associated with adverse medical and psychiatric outcomes.

ACKNOWLEDGMENT

This chapter represents an update and revision of previous chapters in this series, authored by Wayne Katon, MD., and Dr. Ciechanowski. Dr. Katon, a pioneer in collaborative care mental health care and leader in consultation-liaison psychiatry, died in 2015. The authors are indebted to Dr. Katon for his work on the Kaplan and Sadock series and mental health and primary care fields. This edition includes much of his work and ideas and retains much of his excellent prose.

27.7 Endocrine and Metabolic Disorders

Katherine E. Williams, M.D., Kathleen Watson, Ph.D., and Natalie Rasgon, M.D., Ph.D.

Endocrine disorders are prevalent illnesses that a psychiatrist is likely to see in clinical practice regularly. This chapter will focus on the most common endocrine illnesses with neuropsychiatric symptoms and those commonly associated with primary psychiatric disorders. Recently, there has been considerable progress in understanding the intimate and complex relationships between endocrine and psychiatric disorders, including increasing evidence for a bidirectional relationship between the two classes of illness. For instance, insulin resistance has been associated with major depression and vice versa. Treatment with insulin-sensitizing agents has been shown to treat insulin resistance and depressive symptoms. Research is currently underway to elucidate the complex relationship between endocrinopathies and psychiatric illnesses.

GENERAL PRINCIPLES

Endocrinology is the study of hormones or biochemical mediators that travel from their production site to influence the function of other tissues. They exist in the form of peptides, steroids, and amines. Endocrinopathies result from excessive or deficient amounts of a hormone or resistance to a hormone's action. For example, target tissues may not respond to a normal level of a hormone. These latter cases are primarily hereditary and are characterized by normal or elevated hormone levels, despite an absence or deficiency of the hormone's action. Elevated levels result from the lack of negative

feedback on the hormone's production, which results from the failure or deficiency of the hormone's action.

Hormone production is primarily regulated by the levels and activity of the hormones themselves and additionally by hormones from other sites. For example, hypothalamic-releasing factors regulate the production of pituitary hormones. The pituitary gland, situated in the sella tursica at the base of the skull, is divided into the anterior and posterior lobes.

The anterior pituitary produces six hormones

- **Thyroid-stimulating hormone (TSH):** regulates the production of thyroid hormones
- **Growth hormone (GH):** promotes growth and development
- **Prolactin (PRL):** stimulates lactation
- **Luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)**: necessary for gonadal function in men and women
- **Adrenocorticotropic hormone (ACTH):** controls adrenal cortex production of glucocorticoid.

The posterior pituitary gland stores two hormones produced by the hypothalamus

- **Antidiuretic arginine vasopressin (AVPJ):** regulates fluid balance
- **Oxytocin:** necessary for milk let-down during breastfeeding

The hypothalamus additionally produces releasing factors that influence pituitary hormone production.

- **Growth hormone-releasing hormone (GHRH) and growth hormone release inhibiting factor (GIH; also known as somatostatin)**: influence production of GH
- **Gonadotropin-releasing hormone (GnRH)**: influences the production of LH and FSH
- **Prolactin-inhibiting factor (PIF)** (i.e., dopamine)
- **Prolactin-releasing factor (PRF)**: influences PRL production
- **Thyrotropin-releasing hormone (TRH)**: influences TSH release

- **Corticotropin-releasing hormone (CRH)**: influences ACTH release

In addition to the hypothalamus and the pituitary, the major endocrine organs include the adrenal, thyroid, parathyroid glands, ovaries, and testes. Endocrinopathies may lead to heterogeneous psychiatric symptoms, as hormones affect various organ systems. Patients are more likely to present primarily with psychiatric symptoms early in the course of endocrine disease and experience a worsening of their psychiatric condition and the emergence of physical symptoms with the disorder's progression. Endocrinopathies should also be considered as a possible cause of treatment-resistant psychiatric disorders. Because endocrine disorders are common medical conditions, an evaluation of endocrine function is an essential part of the initial diagnostic workup. A laboratory evaluation should include serum electrolytes, fasting blood glucose, TSH, and calcium concentrations to identify potential endocrine etiologies. Psychiatric symptoms will not resolve until the underlying endocrine disturbance is corrected and may worsen with psychotropic agents. When psychiatric disorders appear to result from a medical condition, they are categorized accordingly in the fifth edition of the Diagnostic and Statistical Manual (DSM-V), e.g., "depressive disorder due to another medical condition."

THYROID DISORDERS

The thyroid hormones triiodothyronine (T3) and thyroxine (T4) are produced from the thyroid gland and are necessary to regulate metabolic activity and protein synthesis. They are formed from a common precursor, thyroglobulin (TG), stored in the thyroid follicles. T4 is converted to T3 in extrathyroidal tissues, the metabolically active hormone. TSH (thyrotropin), produced by the anterior pituitary, promotes the synthesis and release of these hormones and is regulated by TRH, produced in the hypothalamus. Low serum levels of thyroid hormones stimulate the release of TRH and TSH. Notably,

central nervous system (CNS) dopamine decreases TSH secretion and glucocorticoids.

Thyroid function depends partly on varying serum, androgen, estrogen, and TSH levels. In the case of T3 and T4, they are tightly protein bound to thyroxine-binding globulin (TBG) so that only 0.3% of T3 and 0.02% of T4 are free. Total serum T4 levels vary with TBG levels; for example, exposure to estrogens (pregnancy and oral contraceptive) raises TBG and, therefore, serum T4, whereas androgens have the opposite effect. The free T4 index (FT4I), which measures the percentage of free T4 (FT4), produces a more accurate determination of thyroid function. FT4I is elevated in hyperthyroid and low in hypothyroid patients and is an essential test for assessing thyroid status. Measures of TSH levels are also necessary for the workup of thyroid disorders. Levels are elevated in thyroidal hypothyroidism and are usually low in pituitary–hypothalamic hypothyroidism. The range of normal levels of TSH is 0.3 to 4.7 mIU/L, and free T3 index (FT3I) ranges from 5 to 11 mIU/L and 75 to 175 mIU/L, respectively. Varying hormone production levels are indicative (or predictive) of thyroid function and play an essential role in our assessment of TRH.

The TRH stimulation test (TRH infusion test) is sometimes performed to evaluate thyroid function. After the patient's baseline TSH level is obtained, TRH is administered intravenously (IV), and TRH levels are then measured at regular intervals. A normal response is a rise in TSH of at least 5 mIU/mL above the baseline TSH value within 30 minutes of an injection of TRH. In hypothyroid patients, this response is exaggerated, whereas, in hyperthyroid patients, it is blunted. With the development in the 1990s of highly sensitive TSH testing, the TRH stimulation test is seldom used clinically. Tests of radioactive iodine (RAI) uptake are used to determine the activity of the thyroid gland. A patient receives a small amount of oral RAI, and a scan then determines the amount taken up by the thyroid gland. These tests can help us understand the influence of thyroid hormones on larger bodily systems, including the CNS.

Thyroid hormones have widespread actions on the CNS, including genomic and nongenomic effects that underlie the changes in mood and cognition seen in hypothyroidism. T3 is the primary thyroid hormone available to peripheral organs, whereas T4 is the primary hormone available to the brain. The symptoms of hypothyroidism may result from alterations in receptor functioning, neurotrophin production, or changes in intracellular signaling that occur due to alternations in thyroid hormone levels. For instance, decreased postsynaptic B receptor number and function are associated with low levels of thyroid hormones. Brain synthesis of serotonin (5HT) is reduced in hypothyroidism. PRL and cortisol responses to the 5HT agonist fenfluramine are blunted compared to euthyroid controls, suggesting reduced central 5HT activity.

Serum 5HT levels correlate with serum T3 levels. Thyroid hormone is associated with reduced sensitivity of 5HT1A autoreceptors in raphe nuclei and increased 5H2 sensitivity. Studies of regional cerebral blood flow have found decreased regional blood flow in the bilateral amygdala, hippocampus, and anterior cingulate cortex in hypothyroid patients. Treatment with thyroid hormone reduced neuropsychiatric complaints and restored regional blood flow, especially in the ventral anterior cingulate cortex. Many, but not all, studies of major depressive disorder have reported that the hypothalamic-pituitary-thyroid (HPT) axis is perturbed at multiple levels, including increased cerebrospinal fluid (CSF), TRH, TRH-stimulated TSH blunting, and nocturnal TSH blunting. Neurobiologically, this thyroid activation has been proposed to represent a compensatory mechanism to a pathologic process, i.e., depression or the primary pathology itself.

Hypothyroidism

Definition and Comparative Nosology and Epidemiology. Hypothyroidism results from inadequate production of thyroid hormone. In overt hypothyroidism, serum TSH levels are elevated, and serum T4 levels are low compared to normal levels within the general population. Subclinical hypothyroidism (SCH) is diagnosed

when TSH levels are elevated, but T4 levels are normal. Hypothyroidism must be distinguished from the euthyroid sick syndrome, which is associated with several medical illnesses, including myocardial infarction, chronic kidney disease, diabetic ketoacidosis, anorexia nervosa, and cirrhosis. In this condition, conversion from T4 to T3 is decreased, leading to normal TSH but lower T3 levels.

Etiology. The most common cause of hypothyroidism in adults worldwide is iodine deficiency. In countries where iodine is added to salt, Hashimoto thyroiditis (chronic lymphocytic thyroiditis) is the most common cause. In this autoimmune condition, high serum concentrations of autoantibodies to the enzymes thyroglobulin (TGAb) and thyroid peroxidase (TPOAb) are found in the serum.

Lithium is another common cause of hypothyroidism. After long-term lithium use, 20% of patients develop overt hypothyroidism with a goiter, and another 20% develop SCH. This risk is elevated in women and patients with antithyroid antibodies. The longer the exposure to lithium, the greater the risk of developing either overt or SCH. Other causes of hypothyroidism are hypopituitarism due to tumor or postpartum hemorrhage, previous thyroid surgery, or antithyroid drugs (ATDs).

Epidemiology

GENERAL POPULATION. Overt hypothyroidism is more common in women than men in the general population, affecting 2% of women compared to less than 0.1% of men. SCH also predominates in women, occurring in approximately 7% of women compared to 3% of men. The prevalence of hypothyroidism increases with age, and SCH is prevalent in postmenopausal women, occurring in approximately 20% of this population. The progression of SCH to overt hypothyroidism is approximately 5% to 8% per year. Risk factors for conversion include higher baseline TSH, female sex, age, the presence of antithyroid antibodies, and a family history of autoimmune disorders.

PREGNANCY. Overt hypothyroidism is estimated to occur in 0.3% to 0.5% of pregnancies and SCH in 3% to 5%. The presence of elevated antithyroid peroxidase (TPO) and anti-TG titers are also common in euthyroid pregnant women, and higher titers are associated with an increased risk of developing postpartum thyroiditis that occurs in 7% of postpartum women. Twenty to forty percent of women with this condition develop permanent hypothyroidism. Women with recurrent spontaneous abortion also have higher overt and SCH rates.

PSYCHIATRIC POPULATIONS. Hypothyroidism is even more common in psychiatric patient populations, and the gender difference persists. Bipolar disorder patients who are not treated with lithium have a high prevalence of hypothyroidism, that is, 25% in women and 12% in men. Hypothyroidism is especially common in rapid-cycling bipolar disorder. It is estimated that 20% of patients treated with lithium develop hypothyroidism, and up to 50% may develop a goiter.

With lithium treatment, females are five times more likely than men to develop hypothyroidism. Older age and the pretreatment presence of thyroid antibodies are also risk factors for hypothyroidism and lithium use. Due to the high prevalence of postpartum thyroiditis in women with postpartum depression, the American Thyroid Association recommends that women with postpartum depression have TSH, free T4, and anti-TPO screening.

Diagnosis and Clinical Features

PHYSICAL SYMPTOMS. Physical symptoms associated with overt and SCH are diverse and reflect the widespread influence of the thyroid hormones on metabolic, gastrointestinal, cardiac, neurologic, reproductive, and even skin functioning. Symptom onset is usually insidious, and classic symptoms include weight gain, constipation,treatment may not lead to full remission cold intolerance, muscle cramps, dry skin, brittle and thinning hair, especially lateral eyebrows, slowed deep tendon reflexes (DTRs),

paresthesias, and menstrual disturbances, including amenorrhea and menorrhagia.

Hypothyroidism may also be associated with bradycardia and diastolic or systolic hypertension. Laboratory abnormalities associated with hypothyroidism include elevated cholesterol and triglycerides and normochromic, normocytic anemia.

NEUROPSYCHIATRIC SYMPTOMS. Neuropsychiatric symptoms are classically associated with overt hypothyroidism; however, mood and cognitive symptoms have also been found in patients with SCH, as well as euthyroid antibody-positive patients. The ongoing autoimmune process underlying the majority of cases of hypothyroidism may be associated with nonspecific symptoms of decreased energy and decreased motivation, as seen in other autoimmune conditions. Depressed mood, apathy, psychomotor retardation, slowed cognition with memory and concentration complaints occur in overt hypothyroidism. Neuropsychiatric testing confirms the subjective complaints, as hypothyroid patients demonstrate decreased scores on complex attention tasks, memory, especially verbal memory, information processing speed, impaired working memory, and implicit learning. SCH is also associated with cognitive impairment, primarily in patients younger than 75 years old. Both overt and SCH are associated with poorer antidepressant treatment response in patients with major depressive disorder.

A dramatically altered mental status can occur in patients with chronic autoimmune thyroiditis who develop encephalitis or vasculitis. This rare condition, Hashimoto encephalopathy, is associated with altered sensorium, delusions, auditory hallucinations, and catatonia, as well as cognitive dysfunction and even coma. Acute episodes of focal neurologic deficits suggesting a stroke may occur, as well as generalized tonic–clonic seizures and status epilepticus have been reported.

Postpartum thyroiditis may be present with hypothyroidism alone (43%), with hyperthyroidism alone (32%), followed by hypothyroidism (25%). The most common symptoms of the hyperthyroid state are anxiety, palpitations, and fatigue. The

hypothyroid state is associated with decreased energy, depressed mood, and impaired concentration. Patients who are euthyroid, but are thyroid antibody positive, have been found to have a higher prevalence of depressive symptoms in some studies.

Ms. A, a 54-year-old woman with no previous psychiatric history, experienced depressed mood, lethargy, apathy, weight gain, and problems with memory and concentration over the past year. Initially, she attributed her symptoms to menopause, but her symptoms have not improved after six months of hormone replacement therapy. Her TSH level was elevated at 14 mIU/L. The patient was started on levothyroxine (Levoxyl) 0.05 mg/day, and within 8 weeks, she experienced an improvement in energy, interest in her activities, and subjective memory. A TSH drawn 8 weeks after initiation of thyroid replacement was normal at 3.3 mIU/L.

Ms. K, a 32-year-old woman with recurrent spontaneous abortion and recurrent major depressive disorder presented to the ER at 14 weeks postpartum for major depression with passive suicidal ideation. Ms. K had discontinued her antidepressant in the first trimester of pregnancy and remained euthymic until she became increasingly anxious a few weeks before delivery. Her pregnancy was complicated by gestational diabetes, and she delivered prematurely at 36 weeks. She restarted her serotonin reuptake inhibitor (SSRI) at her prepregnancy dose within a week of delivery, but her mood continued to deteriorate. She experienced the new onset of tachycardia, increasing insomnia, agitation, irritability, inability to focus, and complaints of panic.

After approximately a month, her symptoms developed into severe depression with lethargy and apathy. Lithium 600 mg at bedtime was added for treatment-resistant depression, but her symptoms did not improve. When she experienced a decrease in milk supply and increasing problems with memory and concentration, she began to feel she could not care for her infant, experienced suicidal ideation, and was voluntarily admitted to the hospital. Laboratory tests were as follows: TSH 8 mIU/L, free T4 0.5 ng/dL, T3 normal. Anti-TPO and antithyroid antibody titers were elevated.

Physical examination revealed a painless goiter and ultrasound hypoechogenicity. Ms. K was diagnosed with postpartum thyroiditis, and Ms. K and her husband responded well to psychoeducation about autoimmune thyroiditis and its role in her treatment resistance. Synthroid was initiated, and lithium was discontinued. Buproprion was also added to her SSRI, and within 4 weeks, she experienced significant improvement in her mood and cognition. At 6 weeks, Ms. K's TSH and T4 levels were normal, and she continued on Synthroid with plans for thyroid function tests (TFTs) again in 6 months, a trial taper off the Synthroid after 12 months, and TFTs a third time 1 to 2 months after that.

Pathology and Lab Examination. Serum TSH is used to screen for hypothyroidism, and normal values range from 0.3 to 7.5 mIU/L. The upper limits of normal increase with age and obesity. Elevated TSH levels with decreased FT4 and T3 levels indicate hypothyroidism.

When the TSH is elevated, but the thyroid hormone levels are in the normal range or lower limit of normal, this is consistent with SCH. When the FT4 is low, but the TSH level is normal, this suggests the rarer central hypothyroidism caused by hypothalamic or pituitary dysfunction.

Differential Diagnosis. The differential diagnosis of hypothyroidism includes affective disorders, including major depression and dysthymia. Since autoimmune thyroiditis may have periods of acute thyrotoxicosis en route to hypothyroidism, the patients may appear to suffer from a primary panic disorder or generalized anxiety disorder. The cognitive complaints in hypothyroidism should be differentiated from primary dementia disorders such as Alzheimer disease or multi-infarct dementia.

Course and Prognosis. Rates of conversion from SCH to overt hypothyroidism vary from 4.3% to 17.7%. Risk increases with higher baseline TSH levels and the presence of TPOAb. Measurement of TPO and thyroglobulin antibodies (Tg) antibodies is useful for confirming hypothyroidism's immunologic cause and evaluating conversion risk. While 70% of patients with postpartum thyroiditis are euthyroid 12 to 18 months postpartum, a subset of patients will progress to permanent hypothyroidism and require long-term thyroid replacement. Furthermore, the recurrence risk is high at 42%.

Treatment. Oral synthetic thyroxine replacement therapy is used to treat overt central hypothyroidism. Starting doses are adjusted to the patient's age, comorbid medical conditions, body weight, and the severity and duration of hypothyroidism. Doses are adjusted until T4 concentrations have increased and TSH serum levels decrease to normal values.

Despite normalization of TSH and FT4 levels, primary subclinical and overt hypothyroidism treatment may not lead to full remission of neuropsychiatric symptoms. Treatment-resistant depression is frequently associated with SCH, and treatment with T3 is beneficial for treatment response and remission when added to either selective SSRIs or tricycle antidepressants (TCAs). Hashimoto encephalopathy is treated with corticosteroids, and 90% to 98% of patients respond to this treatment.

Hyperthyroidism

Definition and Comparative Nosology. Hyperthyroidism, or thyrotoxicosis, results from the overproduction of thyroid hormone by the thyroid gland. The most common cause is Graves disease. Toxic nodular goiter causes another 10% of cases among middle-aged and older adult patients. Other causes include hyperfunctioning solitary thyroid adenomas, thyroiditis, use of exogenous thyroid hormone, TSH-producing pituitary adenoma, pituitary resistance of suppression of TSH secretion by thyroid hormone, thyroid carcinoma, choriocarcinoma, hydatiform moles, and struma ovarii.

Subclinical hyperthyroidism describes a condition in which circulating thyroid hormone levels are normal, but the TSH response to TRH is blunted or absent. Patients may experience symptoms of hyperthyroidism, such as nervousness, irritability, fatigue, and tachycardia. Subclinical hyperthyroidism may progress to overt hyperthyroidism.

A thyroid storm (thyrotoxic crisis) is a life-threatening syndrome that is usually precipitated by illness or injury but may also develop after withdrawal of ATDs or after therapy with RAI. Symptoms include marked tachycardia, weakness, fever, and altered mental status.

Epidemiology. In the general population, the prevalence of hyperthyroidism is approximately 0.5%. Graves disease is the most common cause, accounting for 80% of cases. Graves disease occurs four times more frequently in women than men and occurs

primarily in the third and fourth decades of life. The prevalence of thyroiditis is estimated to occur in 5% to 9% of women in the postpartum period, usually resolving spontaneously by one year after delivery.

Etiology. Patients with Graves disease produce thyroid-stimulating antibodies that activate the TSH receptor, producing increases in thyroid hormone. These patients frequently have a family history of other autoimmune disorders, such as systemic lupus erythematosus and myasthenia gravis. Hyperthyroidism from toxic nodular goiter results from the lack of response of thyroid nodules to normal feedback regulation. In the case of thyroiditis, hyperthyroidism results from inflammation-induced damage to the thyroid gland, which then spills the stored colloidal thyroid hormones. Other causes of hyperthyroidism include excessive thyroid hormone intake and decreases in estrogen levels. Pregnancy or estrogen replacement therapy may increase thyroid-binding globulin, leading to decreased free T4. Thyroid doses need to be adjusted downward to avoid iatrogenic hyperthyroidism when estrogen levels fall.

Diagnosis and Clinical Features. Signs and symptoms of hyperthyroidism include increased pulse, arrhythmias, elevated blood pressure, fine tremor, heat intolerance, excessive sweating, increased appetite, weight loss, palpitations, tachycardia, frequent bowel movements, menstrual irregularities, muscle weakness from the catabolism of muscle protein, exophthalmos, lid lag, infrequent blinking, and hyperactive DTRs. In cases of thyroiditis, the patient may experience pain and tenderness in the thyroid region. Psychiatric features include nervousness, fatigue, insomnia, mood instability, and dysphoria. Speech may be pressured, and patients may demonstrate a heightened activity level.

Neuropsychiatric symptoms include a short attention span, impaired recent memory, and an exaggerated startle response. There may be visual hallucinations, paranoid ideation, and delirium in severe cases. Although some symptoms of hyperthyroidism resemble those of a manic episode or mixed manic episode, an

association between hyperthyroidism and mania has rarely been observed.

Pathology and Laboratory Examination. Laboratory examination reveals elevated levels of total T4 and FT4. Levels of total and free T3 are usually elevated but are not necessary to diagnose hyperthyroidism. TSH level is abnormally low, as elevated thyroid hormones suppress its production, and the TSH response to TRH is blunted. The uptake of RAI by thyroid hormone is increased, except in cases of hyperthyroidism due to thyroiditis or ingestion of thyroid hormone.

Differential Diagnosis. Panic disorder, generalized anxiety disorder, and social and simple phobias present with symptoms that resemble hyperthyroidism, including tachycardia, diaphoresis, and tremulousness. Other conditions that produce symptoms of autonomic hyperarousal include hypoglycemia, diabetes, dehydration, and pheochromocytoma. Chronic obstructive pulmonary disease may produce anxiety, diaphoresis, dyspnea, and tachycardia. In some cases, hyperthyroidism may produce severe agitation resembling a manic state. Certain medications, for example, appetite suppressants, stimulants, and street drugs, such as cocaine and amphetamines, may also produce these symptoms. Laboratory testing distinguishes between hyperthyroidism and other medical conditions.

Course and Prognosis. Rates of remission of Graves disease depend on the type and length of treatment. Patients treated with radioiodine rarely experience a recurrence of hyperthyroidism. However, permanent hypothyroidism is a common complication of RAI.

Patients treated with ATDs for six months have approximately a 30% remission rate compared to 80% in patients treated for two years. Patients who undergo surgical ablation have a relapse rate of approximately 10%; these patients are also at risk for permanent hypothyroidism. Hyperthyroidism due to thyroid nodular disease

usually remits with RAI therapy. Thyroiditis is usually a short-lived condition, lasting only a few weeks to months and resolving spontaneously. Treatment of thyroiditis includes supportive measures such as B-adrenergic agents for tachycardia and close follow-up of TFTs since patients with thyroiditis, especially postpartum thyroiditis, are at an increased risk of hypothyroidism.

Treatment. Treatments for Graves disease include ATDs, RAI, and surgical thyroidectomy. The ATDs, propylthiouracil (PTU), and methimazole (Tapazole) inhibit thyroid hormone synthesis. PTU additionally inhibits the monodeiodination of T4 to T3. Methimazole has the advantage of single-day dosing. Initial doses of methimazole range from 10 to 40 mg and, for PTU, from 75 to 100 mg three times a day (t.i.d.). The doses should be adjusted as the patient returns to a euthyroid state. Usual maintenance doses of methimazole are 5 to 10 mg a day, and doses of PTU are 50 to 100 mg a day. A rare and serious side effect of these medications is agranulocytosis. Other side effects include pruritus, rash, and fever. Length of treatment varies from 6 months to 2 years. These medications may not produce a therapeutic effect for several weeks because of the long half-life of T4. Some clinicians combine the ATDs with T4 replacement to prevent iatrogenic hypothyroidism.

Although some patients with Graves disease respond to ATDs, most require RAI. An RAI uptake test done before administration of iodine-131 allows for determining the appropriate dose. Hypothyroidism may be a complication of RAI, and patients may subsequently require thyroid hormone replacement.

A subtotal thyroidectomy is an option for patients who are allergic to ATDs or are unwilling to undergo RAI therapy. Patients should receive ATDs or potassium iodide or b-adrenergic antagonists to be euthyroid before surgery and reduce the risk of postoperative thyrotoxic crisis. Subtotal thyroidectomy has several potential complications, such as hypoparathyroidism and recurrent laryngeal nerve injury. Patients may have recurrent hyperthyroidism after surgery if insufficient thyroid tissue is removed. In general,

thyroidectomy is used only if other forms of treatment are not possible.

Beta-blockers, such as propranolol (Inderal), metoprolol (Lopressor), atenolol (Tenormin), or nadolol (Corgard), can provide symptomatic relief while treatment is in progress. Atenolol at 50 to 100 mg per day and nadolol at 80 mg per day have the advantage of once-daily dosing. These medications should be used cautiously in patients with asthma or heart failure. Iodine (given as a potassium iodide solution or as Lugol solution) inhibits thyroid hormone. As the duration of its antithyroid action is brief, its use is limited to pretreatment before surgery, management of thyroid storm, and after radioiodine therapy to speed the reduction in thyroid hormone levels. Treatment for thyroid nodular goiter consists of beta-adrenergic antagonists and radioiodine. Treatment of thyroiditis consists of a brief course (a few weeks) of beta-adrenergic antagonists, as this condition is short-lived. For patients with psychotic symptoms, antipsychotic agents can be used. However, specific antipsychotic agents are best avoided. For example, those most likely to produce tachycardia, like low-potency antipsychotics or QT interval prolongation. Similarly, TCAs should be used with caution, if at all, in these patients. In general, the psychiatric symptoms resolve with successful treatment of hyperthyroidism.

ADRENAL DISORDERS

The adrenal gland produces three major classes of steroid hormones: glucocorticoids, mineralocorticoids, and sex steroids.

The main steroid hormones produced by the adrenal gland are cortisol, aldosterone, testosterone, estrone, and estradiol. The function of glucocorticoids is to promote gluconeogenesis, lipolysis, and glycogenesis, increase catecholamine activity during stress, and inhibit inflammatory reactions. Aldosterone’s effect is primarily to increase renal sodium reabsorption and potassium excretion. Only a small proportion of circulating sex steroids are produced by the adrenal glands, as their primary production site is the gonads.

Production of cortisol is under control of ACTH from the anterior pituitary, which, in turn, is regulated by CRH from the hypothalamus. Negative cortisol feedback occurs at pituitary, hypothalamic, and suprahypothalamic levels. CRH secretion follows a circadian pattern, subsequently producing circadian patterns of ACTH and cortisol levels, with their levels peaking in the early morning and reaching a nadir in the evening. CRH release is also influenced by emotional and physical stress.

Hypercortisolism

Definition and Comparative Nosology. Spontaneous Cushing syndrome results from excess cortisol from the adrenal glands, such as a cortisol-producing adenoma, or from excessive secretion of ACTH, which stimulates the adrenal gland to produce cortisol. Cushing disease, the most common form of spontaneous Cushing syndrome, results from excessive pituitary secretion of ACTH, usually from a pituitary adenoma or rarely ectopically from neuroendocrine tumors. Cushing syndrome is ACTH dependent if the syndrome results from the effect of ACTH on the adrenal gland, and non-ACTH dependent, in cases of excessive cortisol regardless of ACTH levels, for example, as a result of an adrenal adenoma. The hypothalamic–pituitary–adrenal (HPA) axis responsivity to stressors may be influenced by stress in infancy and even in utero. Studies in primates and rodents show that prenatal stress may induce long-lasting effects on the HPA axis regulation. Offspring whose mothers were stressed during pregnancy show greater HPA axis response to stressors than control offspring.

Epidemiology and Etiology. The most common cause of hypercortisolemia is iatrogenic since corticosteroids are used for various medical conditions. The prevalence of Cushing syndrome is approximately 40 per million, and it occurs far more frequently in women, particularly in the third and fourth decades of life. The most common etiology of endogenous Cushing syndrome is an ACTH-producing pituitary adenoma at 70%, while adrenal adenomas are

estimated to comprise 20% of cases. Other causes are autonomous ACTH-producing tumors, such as oat cell carcinoma of the lung, islet-cell pancreatic tumors, or thymomas.

The relationship between stressful life events and the onset of Cushing syndrome is controversial, with some studies finding a greater frequency of adverse life events before the development of the disorder, whereas others have found no such association. Similarly, the relationship between depressive symptoms and the onset of Cushing syndrome remains inconclusive. Some studies have reported a high frequency of depression preceding the physical manifestations of the illness, whereas others have found no greater prevalence of depressive symptoms than noted in control groups.

The etiology of cognitive impairment in hypercortisolemic patients is believed to result from the effect of corticosteroids on hippocampal neuronal damage. Prolonged exposure to elevated corticosteroid levels is associated with hippocampal damage and smaller hippocampal volume. The hippocampus is involved in selective attention, learning, and memory, and reduced hippocampal volume is associated with lower scores on memory tests. In electrophysiologic studies, acute cortisol administration reduces the response to relevant but not irrelevant stimuli. This finding suggests that cortisol can impair selective attention and discriminate important information. Several researchers have suggested that the cognitive impairments in patients with clinical depression, many of whom have HPA axis dysregulation, may result, in part, from cortisol effects on the hippocampus. Furthermore, animal models have shown that corticosteroids downregulate brain-derived nerve growth factor (BDNF). BDNF is essential for neuronal growth and plasticity and can facilitate learning and memory.

The exogenous use of steroids may also produce psychiatric sequelae. The likelihood of psychiatric side effects increases in direct proportion to prednisone dosage. A dosage of fewer than 40 mg per day is associated with less than a 2% incidence of psychiatric symptoms, but this rate rises to almost 20% when the dosage exceeds 80 mg per day.

Diagnosis and Clinical Features. Weight gain is a common nonspecific symptom in hypercortisolemia. Other more unique features of Cushing syndrome include a characteristic moon facies or rounded face from the accumulation of adipose tissue around the zygomatic arch, and truncal obesity, as well as the “buffalo hump” appearance from cervicodorsal adipose tissue deposition. The catabolic effect of cortisol on protein produces muscle wasting, slow wound healing, easy bruising, and thinning of the skin, leading to abdominal striae. Bones become osteoporotic, sometimes resulting in pathologic fractures and loss of height. Diabetes may occur in some patients due to gluconeogenesis stimulated by the high level of glucocorticoids. Chronic ACTH stimulation of the adrenal glands may lead to excess androgen production, with secondary hirsutism, acne, and amenorrhea. Hyperpigmentation may also occur, as ACTH is a precursor of a melanocyte-stimulating hormone, which produces a skin-darkening effect. Although cortisol’s mineralocorticoid effects are mild, it produces sodium retention, potassium loss, metabolic alkalosis, and edema at high concentrations. Hypertension occurs in the majority of patients.

Psychiatric symptoms in Cushing syndrome patients are frequent, diverse, and often severe. Approximately 75% of patients report depressed mood. Of these, approximately 60% experience moderate or severe depression. However, the severity of depression does not appear to be influenced by the etiology underlying Cushing syndrome. Depressive symptoms occur more commonly in female patients than male patients with Cushing syndrome.

Hypersensitivity to stimuli and emotional lability are common, especially irritability, which is increased in 86% of patients and is often an early manifestation of the illness. Anxiety is also prominent and usually characterized as generalized anxiety, although panic attacks can occur. Appetite can be dysregulated and may be either increased or decreased, and most patients experience fatigue. Over 65% of patients will complain of sleep problems, and early morning awakening is common. Patients with Cushing syndrome have disrupted sleep patterns similar to patients with major depression: lower sleep efficiency, less total sleep time, shortened time to onset

of rapid eye movement (REM) sleep. Somatic symptoms and elevated neuroticism scores on Eysenck Personality Inventory have also been reported with significant improvements after reducing cortisol levels. Social withdrawal may develop due to shame regarding one's physical appearance. Paranoia, hallucinations, and depersonalization are estimated to occur in 5% to 15% of cases.

Manic and psychotic symptoms occur much less frequently than depression, at a rate of approximately 3% to 8% of patients but rising to as much as 40% in patients with adrenal carcinomas and iatrogenic steroids. In cases of iatrogenic hypercortisolemia, the risk of mania and psychosis appears to be dose-dependent, with doses over 80 mg/day of prednisone resulting in 18% of patients suffering severe psychiatric symptoms. The psychiatric disturbances in prednisone-treated patients often appear within the first few days to two weeks of treatment and occur more commonly in women than men.

Cognitive changes are common in Cushing syndrome, with approximately 83% of patients experiencing deficits in concentration and memory. Declarative and verbal memory deficits predominate. The severity of these deficits correlates with plasma cortisol and ACTH levels. However, the severity of cognitive changes does not correlate with the severity of depression; hypercortisolemia appears to have independent effects.

Cognitive deficits are also common in patients exposed to high doses of exogenous steroid hormones, and steroid-induced reversible dementia syndromes have been reported. Neuropsychiatric studies in healthy volunteers have confirmed that acute high-dose steroids may be associated with reversible declarative memory, episodic and working memory deficits, while chronic hypercortisolemia is associated with impaired spatial memory, arousal, attention, and executive functioning.

The withdrawal of steroids can also produce psychiatric disturbances, particularly depression, weakness, anorexia, and arthralgia. Other steroid-induced withdrawal symptoms include emotional lability, memory impairment, and delirium. Withdrawal symptoms have been noted to persist for as long as eight weeks

after corticosteroid withdrawal. Rapid withdrawal of steroids can precipitate an adrenal crisis, a potentially life-threatening condition.

Hypercortisolemia is associated with glucose intolerance in 30% to 60% of patients, and diabetes develops in 20% to 50%. Dyslipidemia is also common; patients have high triglyceride levels and elevated cholesterol.

Ms. A, a 42-year-old marathon runner, was diagnosed with tendinitis prior to her 10K race and began prednisone at 60 mg/day. Within a day of starting the medication, she developed insomnia, and sleep decreased from 8 to 6 hours per night. Her speech was pressured, and her energy level increased. She reported that even though she had been advised to decrease her activity, she was unable to resist cleaning her house “from top to bottom.” She also described increased irritability and anxiety. Within two weeks of discontinuing the prednisone, her mental state returned to baseline.

Pathology and Laboratory Examination. In Cushing syndrome, plasma and urine levels of cortisol are elevated, and normal circadian rhythms of cortisol secretion are blunted or absent. Administration of metyrapone (Metopirone), which blocks cortisol synthesis, is usually followed by increased cortisol production. It produces no such increase in cases of adrenal or ectopic origin, whereas, in cases of pituitary origin, postmetyrapone response is augmented.

Another test that distinguishes the pituitary from adrenal etiologies of Cushing syndrome is the dexamethasone suppression test (DST). In cases of Cushing from an adrenal origin, administration of 1 mg of the synthetic steroid dexamethasone (Decadron) does not suppress cortisol. In contrast, it suppresses cortisol in the pituitary Cushing syndrome. The overnight DST is considered the procedure of choice for screening for Cushing syndrome. It involves administering 1 mg dexamethasone at midnight, and a plasma cortisol level is obtained the following morning. A plasma cortisol level of greater than 200

nmol per liter indicates a high likelihood of Cushing syndrome. The overnight 1 mg DST is simple to administer and produces greater specificity and sensitivity than other screening procedures, such as measuring urinary-free cortisol. As plasma cortisol levels vary considerably across the day, isolated measurement of plasma cortisol does not provide adequate screening for Cushing syndrome. DST may also show nonsuppression in major depression, alcoholism, pregnancy during acute physical or emotional stress.

The cognitive problems classically associated with hypercortisolemia appear to be related to the hippocampal neuron damage as neuroimaging studies show smaller hippocampal, cingulate gyrus, and medial frontal gyrus volumes in patients. Computed tomography (CT), magnetic resonance imaging (MRI) scans, and autopsy studies show global cerebellar and cerebral volume loss in endogenously and exogenously corticosteroid-exposed patients. A quarter of patients continue to have residual mood and cognitive complaints after treatment, and brain volume often does not completely return to the previous volume.

Differential Diagnosis. Patients with Cushing syndrome commonly have mood changes similar to those with a major depressive episode. Both groups of patients have a shortened REM latency, elevated levels of cortisol, and abnormal findings on DSTs. The physical manifestations of Cushing syndrome help distinguish between the two diagnoses but may be absent early in the illness. Other distinguishing symptoms of Cushing syndrome are greater irritability and mood lability than in most patients with unipolar depression and a greater tendency to feel best in the morning hours, in contrast to patients with major depression, melancholic subtype, who tend to feel worse at that time.

Treatment and Course. The treatment of choice for pituitary ACTH-producing tumors in Cushing disease involves surgical resection, transsphenoidal adenotomy, and if unsuccessful, pituitary irradiation. Adrenal adenomas and carcinoma are removed surgically, and in the case of carcinomas, chemotherapy is

subsequently instituted. Medications that inhibit cortisol production, such as ketoconazole or metyrapone, are used when patients are awaiting surgery or radiation or have unsuccessful first-line treatments. These drugs are limited by side effects, such as hepatotoxicity (ketoconazole).

Mifepristone (RU486), a progesterone and glucocorticoid receptor antagonist, is a new addition to the medical treatment of Cushing syndrome. It received FDA approval in 2012 for the treatment of hyperglycemia in patients who are not surgical candidates or who have not achieved remission after surgery. Mifepristone has also been studied in patients with psychotic depression, a condition associated with HPA axis dysregulation and abnormalities in glucocorticoid receptors.

After treatment for hypercortisolemia, either with surgery or medication, most patients experience improved hypertension and corrected electrolyte imbalances. The physical stigmata and subtle cognitive deficits may take months or years to resolve. After successful treatment of Cushing syndrome, most patients experience significant improvement in depressive and anxiety symptoms. For patients undergoing prednisone treatment, the simultaneous use of lithium and typical (haloperidol) or atypical antipsychotic medications help prevent the development of manic or psychotic symptoms. Steroid psychosis resolves after discontinuation of the medication. Prednisone should be tapered, rather than discontinued abruptly, to allow the pituitary gland to resume its production of ACTH.

Adrenocortical Insufficiency

Definition and Comparative Nosology. Adrenocortical insufficiency occurs when the adrenal gland inadequately produces three major steroid hormones—glucocorticoids, mineralocorticoids, and sex steroids. In cases of primary adrenal insufficiency, adrenal hypofunction results from adrenal gland disease (e.g., autoimmune disease, infection, idiopathic atrophy, and metastatic tumor).

ACTH and CRH levels rise in response to low levels of adrenal steroids. Secondary adrenal insufficiency results from deficient ACTH secretion because of pituitary disease. Tertiary adrenal insufficiency refers to the deficient hypothalamic secretion of CRH. Adrenal aldosterone production tends to be less affected by secondary or tertiary forms of adrenal insufficiency.

Epidemiology. The prevalence of primary adrenal insufficiency (Addison disease) is estimated at 110 cases per 1 million population, with an incidence of 5.6 cases per 1 million per year.

Etiology. Autoimmune destruction of the adrenal cortex produces more than 90% of primary adrenal insufficiency disease cases. Secondary and tertiary adrenal insufficiency result primarily from the withdrawal of exogenous corticosteroids or ACTH, as their administration suppresses the HPA axis. Adrenal insufficiency secondary to HPA axis suppression is now the most common cause of adrenal insufficiency as these medications are now so widely used in multiple medical conditions, from asthma to organ transplantation. Less common etiologies include pituitary tumors, trauma, infectious disease (e.g., human immunodeficiency virus [HIV]), infarction, and surgical ablation.

Diagnosis and Clinical Features. Clinical symptoms usually do not become apparent until more than 90% of the adrenal cortex is damaged. Adrenal insufficiency often goes misdiagnosed for years due to its insidious onset and generally generic early symptoms. Patients often undergo extensive medical testing before receiving a diagnosis; many are initially diagnosed with primary psychiatric or gastrointestinal problems. Adrenal insufficiency can be life-threatening, particularly in cases of acute adrenal insufficiency, such as after adrenal hemorrhage from an infectious process or the use of anticoagulants. Physical signs and symptoms include weakness, hypoglycemia, hyponatremia, hyperkalemia, nausea, diarrhea, fever, and hypotension.

Chronic adrenal insufficiency produces more subtle symptoms, including loss of libido, fatigability, salt craving, weight loss, vitiligo, nausea, loss of body hair, muscle cramps. ACTH is metabolized to alpha-melanocyte–stimulating hormone, which promotes melanocyte activity, so hyperpigmentation of the skin may develop as ACTH levels rise.

Psychiatric symptoms of adrenal insufficiency include apathy, irritability, anxiety, and depression, ranging from mild to severe. Symptoms may develop slowly over months or years. Even patients receiving corticosteroid replacement therapy are at an increased risk of developing severe affective disorders. While psychosis is rare in adrenal insufficiency compared to hypercortisolemia, case reports exist.

The suspicion of adrenal insufficiency occurs if plasma cortisol levels from the early morning are low since this is the time when they should be peaking. A diagnosis of adrenocortical insufficiency is primarily based on plasma cortisol measures during the ACTH stimulation test. After intravenous administration of 250 micrograms (ug) cosyntropin, cortisol levels usually peak in 30 to 90 minutes. A normal test is defined as a baseline cortisol level of at least 5 ug/dL, a rise between baseline and stimulated cortisol levels of greater than 7 ug/dL, and a stimulated cortisol level of greater than 18 ug/dL. Low cortisol responses to this test indicate adrenal insufficiency. Adrenal insufficiency due to hypothalamic disease is associated with an adequate response of ACTH to CRH administration, but cortisol levels may fail to rise because of adrenal atrophy after prolonged ACTH deficiency.

Pathology and Laboratory Examination. Common laboratory findings include low serum levels of sodium and elevated levels of potassium and low or normal plasma cortisol levels. The diagnosis of adrenal insufficiency is particularly likely if plasma cortisol levels are drawn in the early morning (when cortisol levels should be peaking) and are low (less than 3 ug/dL). In cases of primary adrenal insufficiency, ACTH levels are elevated, and cortisol levels do not rise after ACTH stimulation. In adrenal insufficiency resulting from

pituitary disease, ACTH levels are low or normal, and the response to CRH is blunted. If the adrenal insufficiency results from hypothalamic disease, the ACTH response to CRH administration is adequate, but cortisol levels may fail to rise because of adrenal atrophy after prolonged ACTH deficiency.

Differential Diagnosis. The symptoms of chronic adrenal insufficiency significantly overlap with those of depression. The symptoms of easy fatigability, muscle cramps, anorexia, and lethargy may also lead to chronic fatigue syndrome. In cases of acute adrenal insufficiency, such as after abrupt discontinuation of steroid administration, patients may develop a psychotic or delirious syndrome.

Course and Prognosis. Physical and mental symptoms respond quickly to steroid replacement. A patient's prognosis depends largely on the underlying cause of the adrenal dysfunction. In cases of chronic adrenal insufficiency, patients have an unremitting illness requiring lifelong steroid treatment.

Treatment. Acute adrenal insufficiency requires immediate treatment with IV hydrocortisone (Hydrocortone), in addition to fluid replacement with saline solution and potassium supplementation. In cases of primary adrenal insufficiency, a mineralocorticoid (e.g., fludrocortisone) is also required. In cases of chronic adrenal insufficiency, prednisone or hydrocortisone is administered orally as maintenance treatment. Patients should be encouraged to carry a card or bracelet identifying their diagnosis, medications, dosages, and physician.

Recently, treatment of adrenal insufficiency has focused on the prevention of adrenal insufficiency due to steroid withdrawal. Discontinuation of steroids should be slow to prevent adrenal insufficiency associated with abrupt steroid withdrawal. When adrenal insufficiency is primary, a mineralocorticoid is required. In cases of chronic adrenal insufficiency, prednisone or hydrocortisone is administered orally as maintenance treatment.

DIABETES MELLITUS AND INSULIN RESISTANCE

Diabetes is a significant health problem affecting over 34.2 million Americans, and 20% do not know they have diabetes. Twenty-six percent of all Americans are prediabetic, whereas 80% do not know they are prediabetic. It currently ranks as the eighth most common cause of mortality in the Unites States. Most of the morbidity and mortality of diabetes are from long-term complications. The increasing economic and medical burdens of diabetes currently exceed 327 billion dollars annually, and the medical burdens of diabetes have made this condition a focus of intense public health concern.

Furthermore, the socioeconomic cost of diabetes is expected to escalate with the increase in its prevalence due to the aging population, the increase in visceral obesity in American society, a trend toward physical inactivity, and a growing population of susceptible African Americans, Native Americans, and Asian Americans. Furthermore, diabetes is of great concern in the psychiatric population, as recent research has shown an increased prevalence of noninsulin-dependent diabetes mellitus (NIDDM) in psychiatric patients compared to the general population. Many psychiatric medications increase the risk of the development of this disorder.

Diabetes mellitus is a syndrome that includes a heterogeneous group of disorders characterized by hyperglycemia and absolute or relative insulin deficiency. Type I diabetes (DMI) accounts for approximately 10% of the cases, whereas type II diabetes (DMII) accounts for more than 85%.

Type I Diabetes

Definition and Comparative Nosology. DMI (insulin-dependent diabetes), previously known as juvenile-onset diabetes, occurs because the pancreatic Islets of Langerhans beta cells are damaged due to an autoimmune attack. Pancreatic islet cell antibodies are

present in 95% of new-onset DMI patients. Over time, insulin deficiency develops, and glucose cannot be mobilized into the body's cells for use as energy, resulting in hyperglycemia. While the damage to insulin-producing cells in DMI occurs over years, the symptoms may occur over days to weeks, and patients may present in a hyperglycemic crisis.

There is considerable evidence that genetic and environmental factors are significant determinants of DMI. Although the general public has a 0.4% chance of developing DMI, the risk increases to approximately 2% if the mother has diabetes and 6% if the father or siblings have DMI. Concordance rates for DMI reach 50% in monozygotic twins. In terms of genetic markers, DMI is primarily determined by genes in the HLA region of chromosome 6. The HLA-DQ locus appears to be the best single marker of susceptibility, particularly among whites. However, recent genome screens have identified at least 50 additional loci that may also contribute to disease risk. Although DMI is likely a polygenic disorder, epidemiologic patterns, including seasonal and temporal changes in incidence, suggest that environmental factors are involved. However, except for the possible role of viruses and infant nutrition, the environmental factors that precipitate DMI have not been well established.

Epidemiology and Etiology. DMI is the most common form of diabetes in people younger than 20 years of age, but it can occur at any age. Most cases occur before 35 years of age, with peak onset during the second decade of life. DMI affects approximately 1.7 to 3.4 million people in the United States and is the most common chronic metabolic disorder to affect children. It is most prevalent in White populations, especially those in Scandinavia, and is rare in people of Asian or African descent.

Type II Diabetes

Definition and Comparative Nosology. Unlike people with DMI, people with DMII produce insulin. DMII is generally preceded by a

clinically silent phase of impaired fasting glucose or impaired glucose tolerance. Insulin resistance, defined as a defect in the ability to drive glucose to its main target tissues, is the primary pathophysiologic feature in most cases. Despite intensive research, the pathologic mechanisms behind insulin resistance are still not fully understood. A variety of cellular and molecular defects have been implicated in the condition. These include dysfunctional insulin receptors, aberrant receptor signaling pathways, and abnormalities in glucose transport or glucose metabolism. Despite a continuing decline in insulin sensitivity, hyperinsulinemic individuals maintain normal or near-normal blood glucose levels. However, as insulin resistance gradually increases over time, the pancreas cannot compensate by increasing insulin secretion, and progressive hyperglycemia develops. Not all people with insulin resistance develop diabetes. Beta-cell function also plays an essential role. Whether beta-cell dysfunction is a primary or secondary factor remains unclear. Impaired beta-cell function may result from exhaustion—long-term exposure to insulin resistance—and prolonged, increased demand for insulin secretion that eventually exceeds beta-cell capacity. Minimal elevation of plasma glucose during the deterioration of glucose tolerance may also impair beta-cell function—glucose toxicity. Some people may maintain high levels of sustained insulin secretion, whereas others may have acquired or inherited an abnormality that makes beta cells susceptible to exhaustion of glucose toxicity. Such defects could include reduced islet-cell mass, limited replicative capacity, and more rapid age-related functional or structural abnormalities.

Epidemiology and Etiology. DMII affects approximately 10% of the U.S. population. It is most common in people older than 45 years of age who are overweight, although the incidence of DMII among young obese individuals is rising.

Obesity appears to be the strongest risk factor for the development of DMII, especially among women. Among the psychiatric population, obesity may be iatrogenic, specifically with antipsychotic use. Lack of exercise, smoking, and a poor diet are risk

factors for developing DMII. DMII is most prevalent among African Americans, Latinos, Asian-Pacific Islanders, and Native Americans.

Diagnosis, Clinical Features, and Laboratory Examinations

Classic symptoms of DMI and DMII include polyphagia, polyuria, and polydipsia. Other symptoms include blurred vision, fatigue, weight loss, poor wound healing, dry mouth, dry or itchy skin, or recurrent infections (e.g., vaginal yeast infections, groin rash, and external ear infections). Patients with either type of diabetes may also present with acute metabolic compensation and dehydration, nausea, vomiting, abdominal pain, confusion, or coma. Individuals with DMI often experience weight loss developing over several days associated with the early stages of the disease. The onset of these first symptoms may be fairly abrupt or more gradual. Many patients with DMII remain asymptomatic for years with subtle signs and symptoms, such as neuropathy.

Three clinical measures may be used to diagnose diabetes:

1. A fasting plasma glucose test and a value of ≥126 mg/dL.
2. A nonfasting plasma glucose value of ≥200 mg/dL in people with diabetes symptoms.
3. An abnormal oral glucose tolerance test with a 2-hour glucose value of ≥200 mg/dL.

The hemoglobin A1c test (HbA1c) has become a standard method of diagnosing DMI and DMII and monitoring treatment over time. The HbA1c reflects glycemic control over the past 2 to 3 months; two values over 6.5% are diagnostic for diabetes.

Insulin Resistance, Diabetes, and Psychiatric Illness

An emerging body of literature indicates associations between DMI, DMII, and insulin resistance (a frequent precursor to DMII) and psychiatric illnesses.

DMI. Eating disorders (ED) occur reasonably often in adolescents with DMI and present challenges in diagnosis and management. A

meta-analysis of recent studies reports that ED occurs in 8.2% of DMI patients compared to 2.8% of controls. Insulin omission is a unique purging behavior found in up to 40% of DMI patients; risk factors include female sex and higher BMI, as insulin is omitted to lose weight. EDs should be considered in patients with poor glycemic control or multiple episodes of diabetic ketoacidosis.

DMII. DMII and major depression appear to have a bidirectional relationship in disease incidence. For instance, major depression has been demonstrated to be a significant factor in causing hospital admissions and death in persons with DMII, and antidepressant therapy with selective 5HT reuptake has been reported to ameliorate insulin sensitivity in DMII patients.

Conversely, while the risk estimates vary depending on populations studied, measures, and diagnostic criteria, studies consistently report that DMII is associated with an increased risk for major depression. Depression is associated with an increased risk for insulin resistance and DMII.

Shared lifestyle factors and histories, and biologic mechanisms underlie this complex relationship. For instance, there may be shared genetic mechanisms, and several genes have been identified that may play a role in both conditions, including genes that encode glycogen synthase kinase 3 and the dopamine 2 receptor. Another potential shared pathology is insulin resistance. Insulin resistance is a proinflammatory state associated with elevations in cytokines. Inflammation has been associated with the development of symptoms of depression in both animal models and humans, and patients with major depression with elevated inflammatory markers are less responsive to antidepressants and lithium. In addition, shared risk factors such as a sedentary lifestyle, or a diet rich in saturated fat and low in vitamin D, also contribute to the risk for both diseases.

Finally, psychotropic medication use, particularly atypical antipsychotics (SGAs), increases the risk of DMII. Olanzapine and clozapine have been associated with the highest risk for incident DMII, while aripiprazole, ziprasidone, and lurasidone appear to

present a lower risk. While the weight gain and risk for DMII differs among the SGAs, the American Diabetes Association, the American Psychiatric Association, and the International Society for Bipolar Disorders each have published guidelines that call for a thorough screening of patients before initiation of SGAs that include weight, blood pressure, fasting glucose and lipids, and documentation of the family history of diabetes and cardiovascular disease. Consensus guidelines recommend metabolic monitoring at regular intervals to intervene early in developing a metabolic syndrome.

Insulin Resistance. Insulin resistance, even in the absence of a DMI or DMII diagnosis is increasingly recognized as an important regulator of mood and cognition. Insulin resistance has recently been linked to increased mood instability in unipolar and bipolar patients. A meta-analysis of 20-plus studies showed significantly increased insulin resistance in depressed patients compared to control subjects. A Dutch cohort study found that individuals with insulin resistance had 51% greater odds of nonremitted major depression than nondepressed controls. In the same study, insulin resistance was also positively associated with depressive symptoms and chronicity. A subsequent study among people with no history of mood disorder found that a moderate increase in insulin resistance was associated with an 89% increased rate of incident major depressive disorder over a nine-year follow-up.

A meta-analysis of adjuvant pioglitazone, an insulin-sensitizing agent, improved nonremitted major depression in nondiabetic patients. However, more research into the mechanisms that underpin the link between insulin resistance and psychiatric disease and how this affects treatment is required.

Treatment. DMI patients require insulin treatment. While patients with DMII can partially manage it by controlling their weight, watching their diet, and exercising regularly, the American Diabetes Association recommends treatment with diabetes oral glucose-lowering medication (e.g., sulfonylureas, meglitinides, biguanides, thiazolidinediones [TZDs], and alpha-glucosidase inhibitors) upon

diagnosis. Generally, metformin (Glucophage) is first-line and titrated to the maximum dose unless side effects develop. If one agent is ineffective in reaching the HbA1c goal, a second agent is added. Some patients require therapy with three oral hypoglycemics. Insulin treatment is indicated for people with DMII when lifestyle changes and oral medications fail. Insulin can be combined with oral agents.

At the time of diagnosis, 20% of people with DMII already have other risk factors that contribute to the high incidence of chronic complications, including blindness, renal failure, neuropathy, peripheral vascular disease, stroke, and myocardial infarction. Therefore, it is recommended that patients with DMII undergo a complete assessment of the adequacy of their metabolic control, risk factors for vascular complications, and extensive education on self-management. Because 80% of patients with DMII are overweight, particular emphasis should be placed on nutritional education and exercise. Because of the complications associated with diabetes, frequent follow-up visits should be scheduled, dependent on the severity of complications that a patient may be experiencing. At a minimum, patients with DMII should have an annual complete physical examination, including a foot examination and examination of any systems found to be abnormal previously. A dilated eye examination should be performed annually by an ophthalmologist. The Center for Disease Control recommends that HbA1c be checked at least twice a year. A fasting lipid profile and testing for microalbuminuria should be performed annually.

More data are needed on the effect of oral hypoglycemics on psychiatric outcomes among patients with comorbid psychiatric illness and DMII. Furthermore, psychiatric illness, particularly major depression, is associated with reduced medication compliance and self-care behavior among people with DMII. Therefore, coordinated care for psychiatric illness and DMII may be beneficial.

POLYCYSTIC OVARY SYNDROME

Definition and Clinical Features

Polycystic ovary syndrome (PCOS) is the most widespread endocrine disorder among women. Based on the Rotterdam criteria adopted by the National Institute of Health in 2012, PCOS occurs in up to 15% of women in the general population of reproductive-age women. The prevalence of PCOS is 30% to 75% among women presenting for menstrual irregularities or hirsutism. First, the clinician should exclude other causes of hyperandrogenism, such as congenital hyperplasia, Cushing syndrome, and androgen-secreting tumors. PCOS is then diagnosed if two of three conditions or symptoms are present: oligo-ovulation or anovulation, clinical or biochemical signs of hyperandrogenism, or ultrasound-documented polycystic ovaries. Notably, normal-appearing ovaries no longer rule out this diagnosis if the other two criteria are met, as PCOS is now recognized as primarily an endocrine disorder. Clinical features of PCOS include hirsutism, coarse hair distributed in a male pattern such as the chin, upper lip, periareolar breast area, male pattern alopecia, and acne. Irregular menstrual cycles and infertility may be the presenting symptom in some women.

BMIs over 25 kg/m (overweight) and 30 kg/m (obese) are common in PCOS, affecting 20% to 80% of patients. However, some women with PCOS are normal or underweight, and weight is not a diagnostic criterion. Sleep apnea is also increased in PCOS.

Etiology

The fundamental defect in PCOS remains unclear, but theories implicate dysfunction of the hypothalamic–pituitary–gonadal axis (HPG) (Fig. 27.7–1). GnRH appears to be insensitive to ovarian steroids, leading to a normal negative feedback mechanism failure. Increased LH pulse amplitude and frequency result in increased thecal cell androgen synthesis.

FSH synthesis is reduced in the granulosa cells, resulting in impaired follicular development. An elevated LH to FSH ratio is one of the most common laboratory results in PCOS. Normally, FSH regulates aromatase activity, leading to estrogen production from androgen precursors in the ovary, but in PCOS, the impaired FSH

secretion leads to less estrogen production and more androgen production.

FIGURE 27.7–1. Proposed mechanism for perpetuating peripheral endocrine disorders. FSH, follicle-stimulating hormone; LH, luteinizing hormone.

Insulin resistance is also a critical pathogenic mechanism in PCOS, and women with PCOS have high rates of glucose intolerance regardless of weight. Hyperinsulinemia is a compensatory increase in insulin secretion due to peripheral insulin resistance. Approximately 50% of women with PCOS are obese, which may contribute to insulin resistance and other symptoms of PCOS. A strong association between insulin resistance and obesity has been recognized for years, yet the mechanism by which insulin resistance may provoke obesity, and vice versa, are still unclear. Obesity itself increases the risk of insulin resistance, although insulin resistance can also occur in the absence of obesity. Insulin

sensitivity is decreased by 35% to 40% in PCOS patients, independent of obesity.

Furthermore, increased androgen levels are associated with insulin resistance and obesity. Insulin is known to increase ovarian androgen production in women with PCOS via stimulation of the thecal cell of the ovaries. Furthermore, increased insulin levels lead to decreased sex hormone-binding globulin production by the liver, which leads to more free-circulating testosterone.

Clinical and Laboratory Examination

Central obesity is common, but many women with PCOS are normal weight. On ultrasonography, the ovaries are commonly enlarged alongside multiple cystic follicles. Normal-appearing ovaries, however, do not rule this condition. Because of the absence of ovulation, estrogen is unopposed by progesterone, and vaginal ultrasound may reveal endometrial hyperplasia and carcinoma.

LH levels are usually elevated, whereas FSH levels are low or normal, and androstenedione, testosterone, and estrone levels are elevated. Fasting blood sugar, HbA1c may be elevated later in the illness due to insulin resistance. Undiagnosed DMII is 7 to 10 times more common in women with PCOS than women without PCOS of similar age.

Differential Diagnosis

Rapid onset of marked virilization, such as low voice or clitoromegaly, should raise the suspicion of an adrenal or ovarian androgen-secreting tumor. Serum testosterone and dehydroepiandrosterones (DHEAs) are significantly increased. Hyperprolactinemia and thyroid disorders are associated with menstrual irregularities and should always be ruled out through serum PRL levels and TFTs. Congenital adrenal hyperplasia caused by 21-hydroxylase deficiency is a rare cause of virilization and menstrual abnormality.

PCOS and Psychiatric Illness

Women with PCOS have an increased prevalence of major depression compared to age-matched controls, and a meta-analysis controlling for BMI found rates as high as four times greater than controls.

The etiology of this higher rate of depression is controversial since studies are conflicting, and total and free testosterone and androstenedione levels do not consistently differ between women with PCOS with depression compared to PCOS women without depression.

Insulin resistance may be a common pathologic link between depression and PCOS (see Fig. 27.7–1). Insulin resistance was found to be higher in PCOS women with higher depression scores than PCOS women with lower scores. Metformin has been shown to decrease depression and insulin resistance in PCOS patients. However, improvement in insulin resistance does not appear to be the only mechanism by which insulin-sensitizing drugs improve mood in PCOS patients. Treatment with pioglitazone, a TZD insulin sensitizer, was associated with a more significant reduction in depression symptoms than metformin in patients with major depression and PCOS. However, the homeostatic model of insulin resistance, HOMA-IR, did not differ.

Anxiety symptoms are also higher in women with PCOS compared to controls. However, few studies have examined the prevalence of anxiety disorders in this population using standardized measures. Psychological reactions to the physical changes associated with PCOS, including virilization and obesity, have been proposed to contribute to depressive and anxiety symptoms.

Bipolar disorder has been associated with PCOS, but controversy remains whether the higher prevalence of PCOS is associated with mood-stabilizing agents, underlying comorbidity, or shared pathologic mechanisms. For instance, genetic predisposition likely plays a role in developing insulin resistance in women with bipolar disorder. These women sometimes develop insulin resistance with exposure to mood stabilizers. At the same time, menstrual abnormalities have been found in some bipolar disorder patients to

precede medication initiation, suggesting an underlying predisposition to abnormal menstrual cycles in this population.

The antiepileptic drug valproic acid is associated with an increased risk of PCOS both in patients with epilepsy and bipolar disorder. Rates of incident PCOS vary across studies; in the most extensive study to date of bipolar disorder patients, 10.5% of women on valproic acid developed PCOS compared to 1.4% of women on other mood stabilizers.

Ms. K.B. was a 30-year-old white woman diagnosed with PCOS who had a history of treatment-resistant major depression, most recently treated with venlafaxine (Effexor XR). Ms. K. had a serum glucose level of 83 mg/dL and an insulin level of 19.0 µIU/mL. HOMA-IR measured her insulin resistance at 3.9. HOMA-IR values greater than 2.3 are indicative of insulin resistance.

Ms. K. B. subsequently began metformin (850 mg per day, titrated to 2,550 mg per day) and spironolactone (Aldactone) (100 mg per day). After two weeks of these medications, Ms. K.B.'s mood had improved, and at a follow-up visit 3 months later, Ms. K.B. reported feeling euthymic, had lost 10 pounds in the last 3 months, and she began menstruating approximately every 33 days. She continued to experience low mood, decreased energy, and irritability during the week before menses. However, these symptoms resolved with the onset of menses. Because these symptoms did not significantly impair Ms. K.B., no antidepressant medications were prescribed. Laboratory tests showed that her serum glucose level was 89 mg/dL, and her serum insulin level at this time was 15.0 µIU/mL. Her insulin resistance as measured by HOMA-IR had decreased to 2.0.

Treatment

In PCOS treatment, oral diabetic medicines are utilized to improve insulin resistance. Metformin inhibits hepatic glucose production,

increasing peripheral insulin sensitivity, although it does not modify pancreatic insulin secretion. The decrease in insulin resistance may be achieved via decreasing gut absorption of glucose, improving glucose uptake by tissues, increasing the number of insulin receptors, or a combination of these. Metformin is widely used to treat insulin resistance in patients with DMII. In treating PCOS, metformin has been shown to decrease insulin resistance, acne, hirsutism, and total and bioavailable testosterone. A significant decrease in body mass index and waist-to-hip ratio, as a result of treatment with metformin, has also been observed as restoration of ovulation.

Several agents can treat hyperandrogenism associated with PCOS. Low-dose oral contraceptives (containing estrogen/progesterone) are frequently first-line treatments for acne and hirsutism. They decrease LH secretion, which leads to decreased thecal cell androgen synthesis.

Some women cannot use oral contraceptives because of the increased risk of deep venous thrombosis. Instead, they may use spironolactone, an antimineralocorticoid, diuretic, and antiandrogen. It was originally used to treat hypertension but is also a weak inhibitor of testosterone biosynthesis. Spironolactone is an effective medication to reduce the hirsutism often seen in PCOS women, spironolactone has also been shown to decrease insulin resistance and fasting insulin levels in PCOS patients, and there has been an observed decline in testosterone levels. Other treatments include antiestrogens, such as clomiphene citrate (Clomid), the first-line treatment for PCOS women who desire pregnancy, and laparoscopic surgery. Weight reduction is strongly recommended in the over 50% of PCOS women who are obese. Hirsutism may respond to spironolactone, but it may be difficult to tolerate, as it may produce mood changes, decreased libido, and fatigue.

HYPERPROLACTINEMIA

Definition and Comparative Nosology

The anterior pituitary produces PRL, which stimulates milk production from the breast and modulates maternal behavior. Its production is inhibited by dopamine, produced by the tuberoinfundibular neurons in the arcuate nucleus of the hypothalamus. Normal levels in women vary from 5 to 25 ng/mL and from 5 to 15 ng/mL in men. Levels fluctuate during the day and peak during sleep. Exercise and emotional stress can elevate PRL levels.

Epidemiology and Etiology

Hyperprolactinemia occurs most frequently due to PRL-secreting pituitary adenomas (prolactinomas) and idiopathic hyperprolactinemia, two conditions more common in women. Typical neuroleptic medications can raise PRL levels as much as 20-fold and do so in a dose-dependent fashion, with PRL levels reaching a plateau. While all typical neuroleptics appear equally likely to raise PRL levels, haloperidol (Haldol) appears to be especially effective because of its strong dopamine receptor D2 (D2) blockade.

The atypical antipsychotics also increase PRL levels, but in general, less frequently than the typical antipsychotics, and the rise is much less, except in the case of risperidone (Risperdal).

The rate of hyperprolactinemia in patients on risperidone is very high, estimated at 70% to 100% in recent studies. Quetiapine (Seroquel) and olanzapine (Zyprexa) are less likely to raise PRL levels, and studies report 10% to 40%, while lurasidone (Latuda) and asenapine (Saphris) have not been found to raise PRL levels. Studies have shown that switching patients with risperidone-induced prolactinemia to aripiprazole, a partial D2 agonist, decreases PRL levels. Clinicians should be aware of the rarer hyperprolactinemia associated with antidepressants, especially when working with infertility patients. All the SSRIs have been associated with case reports. Only one study has been completed, which reported that in patients with normal prolactin levels, 4.5% of men and 22% of women developed hyperprolactinemia after 12 weeks of fluoxetine treatment. Other medications that may elevate PRL levels include oral contraceptives, estrogens, TCAs, metoclopramide, verapamil,

and propranolol. Hypothyroidism results in elevated levels of PRL since TRH stimulates PRL release. Acromegaly is also associated with hyperprolactinemia as a result of the lactogenic properties of GH. Hypothalamic disease, such as craniopharyngiomas, is also associated with hyperprolactinemia, as the hypothalamus exerts an inhibitory influence on PRL secretion. Physiologic hyperprolactinemia occurs in pregnant and breastfeeding women; nipple stimulation also elevates PRL levels.

Traumatic childhood experiences, such as separation from parents or living with an alcoholic father, have been reported to produce a greater predisposition to hyperprolactinemia. Stressful life events are also associated with galactorrhea, even in the absence of elevated PRL levels.

Diagnosis, Clinical Features, and Laboratory Examinations

Patients with elevated PRL levels may be asymptomatic, although symptoms usually develop when PRL levels reach 60 to 100 ng/mL. Women may experience amenorrhea, as PRL suppresses normal menstrual cycling, and men may develop gynecomastia. Women and men may experience low libido, decreased fertility, and galactorrhea (inappropriate lactation), although the latter occurs primarily in women. Headache and visual impairment may result in cases of pituitary adenoma. Women with pathologic hyperprolactinemia have been reported to experience elevated levels of depression, anxiety, and hostility compared to controls, which lessen with normalization of PRL levels.

Treatment

A laboratory workup is the initial step in treatment and should include TFTs, a pregnancy test, and a chemistry panel. A brain imaging study should be obtained, either using an MRI with gadolinium or CT with contrast. Bromocriptine (Parlodel), a dopamine agonist, reduces the synthesis and secretion of PRL. In approximately 80% of cases, bromocriptine at dosages of 2.5 to 5 mg twice a day (b.i.d.) or t.i.d. is an effective treatment. However, many patients cannot tolerate the

side effects of bromocriptine, which can include severe nausea and dizziness. Alternative medications include quinagolide (Norprolac), pergolide (Permax), and cabergoline (Dostinex). Medication use must continue indefinitely, as medication discontinuation usually leads to a relapse of hyperprolactinemia. Radiotherapy is another treatment strategy for patients who are refractory to medication treatment. Surgical removal through transsphenoidal surgery is used far less often than before the 1990s because of the high recurrence rate of prolactinomas.

27.8 Psycho-Oncology

Daniel McFarland, D.O., M.S., Yesne Alici, M.D., and William S. Breitbart, M.D., F.A.C.L.P., D.F.A.P.A., F.A.P.O.S.

Psycho-oncology is a sub-discipline of consultation-liaison psychiatry that requires specialized knowledge of cancer and psychiatry. It deals with diagnosing and treating the psychological aspects of cancer along a continuum from prevention to survivorship to the end of life. While the origins of psycho-oncology can be attributed to Donald Sutherland's study of women after mastectomy, the field did not begin to form until the mid-1970s alongside an emerging concern for patient outcomes in oncology. The field is concerned with the psychological response of patients, their families, and health care providers to the effects of cancer and its treatments. The psychological, behavioral, and social factors that influence cancer risk, detection, adaptation, and survival are encompassed by the field of psycho-oncology and applied to its practice. Psycho-oncology is inherently inter-disciplinary and reflects ideal oncologic approaches to patient-centered care as a multi-disciplinary endeavor. Many fields touch psycho-oncology such as consult-liaison psychiatry, nursing, social work, chaplaincy, psychology, behavioral medicine, integrative medicine, along with complementary and alternative approaches to cancer care. Along with an active proliferation of clinical psycho-oncology programs attached to cancer centers, research centers devoted to psycho-oncology form a vital part of psycho-oncology whose researchers come from many interrelated disciplines, including palliative and integrative medicine oncologic sciences, health, and social psychology, as well as other psychological disciplines. Psycho-oncology training programs, clinical researchers, and practitioners exist throughout the world and

are represented by over 50 national organizations as well as an international organization. The American Psychosocial Oncology Society (APOS) is the multidisciplinary national organization representing the subspecialty of psycho-oncology in the United States. The International Psycho-Oncology Society (IPOS) is an international organization that was formed in 1984 in recognition of the need for communication among professionals with interests in psycho-oncology worldwide. Psycho-oncology principles and practice have been established and are part of clinical practice guidelines in oncology. The National Comprehensive Cancer Network (NCCN) publishes distress screening guidelines, which continue to serve as foundational for the intercalation of psychosocial care into oncology. The Institute of Medicine (IOM) published the first policy statement regarding psycho-oncology in 2008. The IOM reported that routine oncology practice must integrate psycho-oncology to achieve quality cancer care. This was further reinforced by the American College of Surgeons Commission on Cancer. The Commission on Cancer now requires accredited cancer centers to have instituted and established psychosocial distress screening programs. In addition to research efforts, psycho-oncology offers evidence-based treatments for common psychological issues experienced in oncology settings. The future of psycho-oncology rests in the implementation and dissemination of evidence-based treatments along with improving recognition of psychosocial issues in oncology.

This chapter will describe the history of psycho-oncology, the psychosocial challenges experienced by cancer patients, the common psychiatric disorders in cancer patients, the psychiatric syndromes specific to tumor site and cancer treatment modality, the therapeutic interventions available, pediatric and geriatric psycho-oncology, issues specific to cancer survivors, patients at genetic risk for cancer, and psychiatric aspects of cancer screening.

HISTORICAL BACKGROUND

The field of psycho-oncology would not be possible without being able to discuss cancer. Unfortunately, cancer was an off-limits discussion for centuries, and patients generally suffered silently. Over the 20th century, descriptions of stigma and cancer-related experiences as well as disclosure of cancer diagnoses emerged as socially accepted. These changes paralleled improvements in oncologic care through surgery, radiation, and systemic therapies. Also, the latter half of the 20th century saw the advent of social sciences where patient self-report was deemed scientifically valid. Thus, psycho-oncology began as an empirically based science of psychological phenomena related to cancer. Yet, the shame, stigma, and superstition of cancer continue to lurk in common parlance and vernacular. Beliefs about cancer and what it signifies continue to haunt patients, families, and societies despite technologic and treatment advances.

For centuries, truth-telling about cancer was seen as cruel and lacking in compassion. This idea is still prevalent in distinct cultures and parts of the world where cancer treatments are not accessible. This paradigmatic approach prevailed as a manifestation of patriarchal medical care. The 20th century also saw advances in informed consent requiring both disclosure and an assessment of patient understanding. The American Cancer Society (ACS) was formed in 1913 to educate the public on the warning signs of cancer and to fight fatalism that interfered with the early presentation for treatment. In 1937 the National Cancer Institute (NCI) was established to seek etiologies and treatments for cancer. In the 1950s, the addition of chemotherapy to the combined treatment modalities resulted in the cure of several childhood tumors. By the early 1970s, with improvements in survival, oncologists became more comfortable in discussing cancer diagnoses with their patients, and the patients' reluctance to identify themselves as cancer patients diminished. Alongside, hospice programs were developed to improve pain management and palliative care with increasing interest in delivering the best supportive care to patients at the end of life. Clinicians' enhanced comfort with communicating a diagnosis of cancer, increased concern for palliative symptom control, and the

growing interest in quality of life and patient rights emphasized the need for supportive and psychological aspects of care. In the 1980s, psycho-oncology units began to develop in larger cancer centers. First, prevalence studies of psychiatric and psychological sequelae in cancer were reported. Special units were developed throughout Europe and the United States during the 1970s, followed by societies such as the British Psychosocial Oncology Group (1983), the IPOS (1984), and the Japanese Psycho-Oncology Society (1985). Conferences, journals (*Journal of Psychosocial Oncology*, 1982; *Psycho-Oncology*, 1992), textbooks, and training programs followed thereafter. In the 1990s, behavioral research in changing habits (e.g., smoking), diet, and lifestyle improved the education of the public on cancer prevention. Health-related quality-of-life assessments and, more recently, patient-reported outcomes have become part of outcome measures in clinical trials. In the early 21st century, psycho-oncology, a discipline almost 40 years old, continues to grow, with the development of novel psychotherapy modalities for advanced cancer patients; intervention trials to improve symptom control in the terminally ill; increased awareness of the role of communication skills training; researchers' efforts to understand and conceptualize the effects of cancer therapies on the CNS; and recognition of the special needs of older adult cancer patients with the rapidly growing older adult population worldwide.

It is important to emphasize that despite all the developments outlined, historical attitudes toward cancer have contributed to the reluctance of patients and families to identify their emotional problems to the clinicians, even today, especially in underserved populations, different cultures, and several parts of the world.

INCIDENCE OF CANCER AND CANCER MORTALITY RATES IN THE UNITED STATES

In the United States, the lifetime risk of developing cancer is slightly less than one in two for men and slightly more than one in three for women. Cancer is the second most common cause of death after

heart disease, accounting for one in every four deaths. The 5-year relative survival rate for all cancers diagnosed between 2007 and 2013 is 67%; this has improved from 50% between 1975 and 1977. Prostate and breast cancers are the most common cancer type in men and women, respectively, but lung cancer is responsible for the highest rates of mortality in both groups. Lung cancer accounts for about 15% of cancer diagnoses. The incidence rates of lung cancer have been declining in men since the 1980s; the incidence rates in women are approaching a plateau after a long period of increase. Incidence rates of prostate cancer have changed substantially over the past 20 years, rapidly increasing from 1988 to 1992, declining sharply from 1992 through 1995, remaining stable from 1995 to 2000, and decreasing since 2000. These trends largely reflect increased prostate cancer screening with prostate-specific antigen (PSA) blood testing. Death rates from breast cancer in women have decreased since the 1990s due to a combination of earlier detection and improved treatment. Colorectal cancer is the third most common cancer in both men and women. The incidence of colorectal cancer has decreased over the past two decades with screening colonoscopies, through the removal of polyps before they become cancerous, and also by detecting a higher proportion of cancers at early and more treatable stages. Given these incidence and mortality figures, it is rare that a family is spared the experience of cancer in one of its members, and many live through it repeatedly, given shared environmental or genetic factors.

COMMON PSYCHOLOGICAL RESPONSES TO CANCER

The diagnosis of cancer creates a crisis requiring the patient to adapt quickly to catastrophic news. Major concerns are fear of death, dependency, disfigurement, disability, and abandonment, as well as disruptions in relationships, role functioning, and financial status. The diagnosis of cancer induces distress, and individuals show an initial characteristic response of shock and disbelief that usually lasts less

than 1 week. Patients try to control the level of emotional distress while making crucial treatment decisions. The presence of a relative or friend can help with the processing of important information. Research has shown that the way the news is conveyed by health care professionals can influence a patient's beliefs, emotions, and attitudes toward the future as well as the medical staff. There are guidelines and recommendations on how to deliver the diagnosis, treatment plan, and prognosis. The patient's response to diagnosis is often followed by a period of commotion with mixed symptoms of psychological distress, anxiety, and possibly depression, irritability, insomnia, poor concentration, and inability to function. These symptoms, if transient, begin to resolve with support from family and friends and from the physician who outlines a treatment plan that offers hope. At some point, the patient adapts to the diagnosis, its treatment, and what is often termed "a new normal." The patient may incorporate new and additional coping skills or expand upon previously used coping strategies. Patients who are diagnosed with cancer have varying levels of psychological maturation and the ability to adapt to the threat of cancer. All patients employ some form of coping strategy to integrate the new information and reality that cancer brings to their lives.

Factors in Adaptation to Cancer

Patient responses are based on their previous experiences, societal and cultural expectations, cancer type, stage, and treatment, and the meaning the patient gives to this diagnostic event. Most patients seek to understand what caused the cancer, how they may have contributed to its development through genetics or behavior, and if there's anything they can do to correct the situation. For many patients, the role of society and stigma has been lessened in contemporary science-driven culture, yet the residue of moral culpability remains, which may lead to feelings of personal failings, hopelessness, or demoralization. Patients are immediately struck by a potential change in their family structures and adapted familial and

professional roles. The patient's sense of self is challenged as the 'new normal' is integrated.

Thankfully, public knowledge and awareness of cancer as a variable threat to life and liberty as opposed to an immediate "death sentence" has helped ease this transition from a societal standpoint, but this outlook and worldview are not necessarily applicable or useful for all patients and families. Multicultural issues are paramount for patients who are attempting to integrate this information. The threat of cancer is perhaps more nuanced, and society has begun to see it that way as well. This has created less of a threat from alienation and stigma as many patient advocacy groups provide patient education, support, and community. As a starting point, the legal requirement of informed consent has improved communication between the physician and the patient about illness, treatment options, prognosis, and participation as part of the treatment. However, this may be experienced as an additional burden to some patients who may not be ready or able to cope with the severity of their illness. Even following curative-intent cancer treatment, patients are constantly monitored for recurrence and the development of new cancers, which may continue to precipitate fear and anxiety, even if just periodically (e.g., fear of cancer recurrence or progression).

The patient-derived factors that modulate adaptation to cancer originate from three sources: intrapersonal factors, interpersonal factors, and socioeconomic and social class. The *intrapersonal factors* include pre-existing character style, coping ability, ego strength, developmental stage of life, and the impact and meaning of the cancer at that stage. *Interpersonal factors* refer to the social support derived from others. *Socioeconomic status* influences the third set of patient-derived factors. Lower socioeconomic status can be a barrier to health literacy and access to health care due to lack of education and fewer resources. The cancer-derived factors that affect adaptation to cancer are related to characteristics of the disease itself, such as stage of the disease, symptoms, site, prognosis, type of treatment, and the impact in functionality.

Of note, historical literature evaluated the role of stress, personality, and psychiatric disorders in the development or initiation of cancer. While some large epidemiologic studies suggest a small but potential association, well-designed studies do not confirm that depression, personality, stress, or major life events cause cancer despite the popularity of this concept. Personality factors, traumas, and other life stressors should be distinguished from behaviors that do underlie the development of many cancers (e.g., tobacco consumption, obesity).

EPIDEMIOLOGY OF PSYCHIATRIC DISORDERS IN CANCER PATIENTS

Psychiatric disorders are either present premorbidly before cancer or develop concomitantly with cancer. Although most psychiatric disorders develop following a diagnosis of cancer, attention to patients with cancer and serious mental illness is increasing. Most psychiatric disturbances in patients with cancer relate to the cancer itself or treatment side effects. The prevalence is highest among patients with advanced cancer and poor prognosis. The prevalence of any psychiatric disorder in patients with cancer is approximately 50%. More than two-thirds of those diagnoses are adjustment disorders, followed by major depression (10% to 15%) and delirium (10%). Inpatient studies show a higher incidence of both depression (20% to 45%) and delirium (up to 75% with advanced disease). Studies of psychiatric consultation data reveal that treatable syndromes, such as major depression and delirium, continue to be underdiagnosed and undertreated, despite their known prevalence in patients with cancer.

Table 27.8–1 lists the most common symptoms found in a group of cancer patients with advanced cancer. Five of the top seven symptoms are in the psychological realm and are found in more than 50% of patients. Three of the next 10 symptoms are present in 12% to 45% of patients. Other studies have given comparable results. Recognizing the magnitude of the symptom burden of cancer

patients has led researchers to an increased interest in identifying patients by their symptoms (e.g., symptom clusters) rather than by their psychiatric diagnosis.

In order to capture the prevalence of psychiatric disorders in patients with cancer, screening instruments and measures are employed. In place of screening for anxiety and depression directly, psychological distress screening is mandated as part of the oncology standard of care by numerous professional societies, including the NCCN. Psychological distress is seen as less stigmatizing and provides for a multitude of reasons for distress beyond psychiatric symptoms. The NCCN developed the Distress Thermometer and Problem List for this purpose. It is a one-item measure of distress attached to several problem domains. It has been translated into numerous languages and is used globally. In addition, many studies have used a wide range of validated instruments, and more focused subpopulations have documented the high prevalence of moderate to severe distress in different subtypes of cancer. Breast cancer remains the cancer type with the most available data regarding psychological distress. The impact on caregivers is receiving increasing attention as caregiver distress is compounded by patient distress.

Table 27.8–1.
Symptoms in Patients with Cancer

Symptom	% Positive
Fatigue	74
Worry	71
Sadness	66
Pain	63
Drowsiness	61
Dry mouth	56
Insomnia	54
Poor appetite	45
Nausea	44
Bloating	39
Difficulty in concentration	38
Change in taste	36
Constipation	33
Cough	30
Sexual dysfunction	24
Incontinence	12
Nightmares	11

GENERAL PRINCIPLES OF ASSESSMENT AND TREATMENT IN PSYCHO-ONCOLOGY

The hallmark of treatment in psycho-oncology is therapeutic activism. In addition to its focus on symptom management, psycho-oncology seeks to reintegrate personhood in the face of cancer. A growing understanding of how cancer and its treatments may be traumatic events informs this integrated, present-focused approach.

The physician must also address the caregiver and the family, as well as the caregiver and/or family–staff interface. The psycho-oncologist should remain available and present through all stages of the illness. Psychiatrists must be prepared for the existential plight of the cancer patient, which intensifies the expectable countertransference reactions. They must resist the urge to distance themselves from a painful situation while guarding against overinvolvement. They must be aware of the patient's physical condition and yet must not allow acute physical or emotional distress, feelings of despair, and barriers to communication (e.g., tracheostomies) to prevent a thorough evaluation. This requires a clear assessment of the clinician's personal feelings that should be addressed prior to extensively visiting with a patient. Feelings of fear, guilt and existential plight are quite common but are also barriers to engaging with the patient in an attempt to understand their psychological ailments.

Areas of Assessment

The standard psychiatric history should also include an exploration of the patient's understanding of the illness and its meaning. What is the patient's understanding of their disease? Can the patient review what they've been told? Are there discrepancies in understanding between patients, family members, and staff, which may lead to unnecessary stress and disruption? The next area is the impact of medical factors on mental state, and the last area is the role of the environment, especially the patient's family and their interface with the health care system. The recurrent demands of cancer treatments promote intense relationships between the patient and family and their medical caregivers, which, if dysfunctional, can lead to psychiatric symptoms and impairment of care.

Treatment Modalities

Psychopharmacology. Because there is frequently a physiologic cause or component to psychological symptoms, the psycho-oncologist must encourage an etiologic work-up and must

recommend medical treatments, such as correction of electrolyte abnormalities and removal of offending drugs. However, symptomatic relief must be provided without waiting for the results. Relief from pain and insomnia goes a long way toward relieving psychological distress. Insomnia is recognized but is often mistreated with hypnotics or antihistamines, which cause habituation or daytime sedation and may worsen symptoms of depression and delirium. The depressed patient may benefit from a low-dose sedating antidepressant, such as mirtazapine (Remeron) or trazodone (Desyrel); or the mildly confused or anxious patient may benefit from a low dose of antipsychotic, such as olanzapine (Zyprexa), risperidone (Risperdal), or quetiapine (Seroquel) at bedtime. Short- to medium-acting benzodiazepines are good hypnotics for intermittent use in the absence of complicating factors, such as delirium.

Fatigue is the most common symptom in patients with cancer. It can be caused by a psychiatric disorder, the cancer itself, more often, the cancer treatments, or, most often, a combination of the three. Cancer-related fatigue is extensively reviewed later in this section.

Given the interrelatedness of physical and psychological symptoms, it is more important than ever that psychiatrists be comfortable discussing the treatment of symptoms such as nausea, vomiting, diarrhea, dry mouth, and shortness of breath.

Medication management is discussed in detail under specific psychiatric conditions later in this section.

Psychotherapeutic Interventions. Telepsychiatry is being increasingly used as an effective form of intervention, particularly for isolated homebound patients, patients in isolation, or children who need to maintain a sense of connection to a hospitalized parent. Video instruction as a form of psychoeducation is used frequently but is more effective when used in combination with face-to-face counseling rather than as standalone tools.

Opportunities for patient education, counseling, group interventions, and informal patient-to-patient connections are

facilitated over the Internet. However, the dissemination of false or harmful information over the Internet is an increasingly important concern. Unfortunately, many people and organizations post biased and unreliable information to which patients are susceptible. These days, patients are generally well informed about their cancers, but the information gathered on the Internet may need to be changed or modified. It is increasingly common for patients to come into the physician's office having done research on their disease. Exploring the patient's Internet experiences can be a productive interaction, but the psychiatrist should maintain an open mind without relinquishing their professional stance.

Reviews of the many available psychotherapeutic modalities, such as cognitive-behavioral therapy, crisis intervention, problem-solving techniques, group psychotherapy, and supportive psychotherapy with an educational and a psychodynamic focus, describe a beneficial effect for all of them. Structured interventions are efficient, showing benefit after a brief course of treatment. Some studies have demonstrated persistent effects after 1 year. Working with individual patients or groups, the psychotherapies lower distress, increase self-esteem and self-image, decrease anxiety, and give patients a better sense of control. Dynamically oriented therapy still has a place in individuals whose personal issues overshadow the cancer, a situation that is more frequent than one might imagine. However, it should remain flexible to reflect the patient's shifting condition.

Referrals often begin with a crisis intervention but rapidly move into other modes. Many cancer patients are happy to leave psychotherapy when they feel better and return only episodically, when in relapse or crisis. This is not treatment resistance; it is inherent in the original treatment contract. Two major issues for patients are the reality of living a shortened life span and the coming of death. Despite their close connection, these are often dealt with separately, the first as a negotiable issue on a continuum with other life problems, the second as the mysterious and frightening absolute that it is. Psychiatrists must overcome their own reflexes to stay with the first issue and to avoid the second. Later in their course, many patients come to an ambivalent acceptance of and even a yearning

for death. It is important to recognize both sides of the ambivalence and to help families and staff tolerate and accept it as well. Families may be feeling ambivalent at this time and are also in need of support. If the patient dies, one is in a unique position to offer bereavement counseling.

Families should be routinely involved in the treatment of ill or physically dependent patients; hence, family-focused therapy and family groups are now more common and are under intensive study. Caregiver groups have developed in recognition of their heavy burden. Cancer survivors are being studied and treated in the family context, understanding that the entire family is permanently altered and that the welfare of several individuals is at stake.

Patient groups provide education, problem-solving exercises, mutual support, ventilation, validation of feelings, reassurance and help about side-effect management, and help in negotiating the doctor–patient relationship and the interface with the medical system. These effects are so positive that groups have multiplied. When a patient describes a negative response to a support group, the reaction should be respected but explored because it usually reveals important psychological concerns.

Groups can be led by mental health professionals who facilitate psychological work and oncology staff members who represent an authoritative source of information. Patients appreciate both kinds of help, and combination groups with a mix of structured and unstructured meetings satisfy the greatest number of patients. Self-help groups increase patients' sense of empowerment and can be helpful, but, over time, they may be overtaken by individual members and make some patients feel excluded or minimized. Putting in democratically defined structures and guidelines can increase their longevity. Fifteen years after its publication, efforts to duplicate a group intervention that prolonged survival in breast cancer patients have been unsuccessful. However, even if the effect on survival is in doubt, the improved quality of life, coping skills, self-esteem, pain management, and interpersonal relations were never questioned and remain as important as ever.

Meaning-Centered Psychotherapy (MCP) is a novel modality that is designed to help patients with advanced cancer to sustain or enhance a sense of meaning, peace, and purpose in their lives even as they approach the end of life. Inspired primarily by the works of Viktor Frankl and further informed by the contributions of Irvin Yalom, Breitbart and colleagues adapted Frankl's concepts involving the importance of meaning in human existence and created MCP. While MCP relies heavily on Frankl's concepts of meaning, it also incorporates other fundamental existential concepts related to the search, connection, and creation of meaning. Using didactics and experiential exercises in each session, the therapist and the patient(s) work together to help patients understand the importance and relevance of sustaining, reconnecting with, and creating meaning in their lives through common and reliable sources of meaning. Furthermore, patients are taught that these various sources of meaning may serve as *resources* during especially difficult times to help diminish despair near the end of life. Both individual and group formats of MCP have been developed and tested in randomized controlled studies. These studies provide strong support for the efficacy of MCP as a treatment for psychological and existential/spiritual distress among patients with advanced cancer.

Educational and support programs can be built into the medical routine, as in pre-surgery education groups, post-surgery rehabilitation groups, and even waiting room groups. The growing number of survivors has prompted the development of innovative posttreatment group programs. Behavioral techniques, such as hypnosis, self-hypnosis, active and passive relaxation, desensitization, and distraction, are useful in a wide range of situations in oncology, including relief of acute and chronic anxiety related to surgery and painful procedures; relief or prevention of conditioned symptoms, such as anticipatory nausea and vomiting (ANV) associated with chemotherapy; and, with age-appropriate modification, improved management of almost all pediatric problems. Their spectrum of use can be as varied as the expertise and initiative of available practitioners.

Social Services. Social workers who are available in large centers or community institutions are the first line of psychological support. They may provide extensive psychotherapeutic support, given the training and the opportunity, but, at the very least, they perform a triage function, alerting staff to patients with serious psychopathology. Their classic role is to help patients and families find their way to available resources, which is often the most helpful intervention that patients identify. If social workers are not available, or it is not part of their mandate, psychiatrists must do their best to fulfill this function by at least having a good file of local resources and a readiness to refer patients to them.

Chaplaincy Services and the Interface of Religion and Psychiatry. As many as 80% of cancer patients describe themselves as believing in God, and a large proportion of those state that faith is an important, if not primary, contributor to their coping ability. There is a large and growing literature on the role of spiritual belief in health behavior. Most of the studies are small and methodologically weak, and there may be a publication bias against negative results. Many more studies have found an association between religious beliefs and psychological variables. Several studies have shown that religious beliefs are associated with mature and active coping methods. A few studies have focused on negative effects, such as an irreducible sense of betrayal, a sense of being punished for personal failings, or strong feelings of guilt about anger and loss of faith.

There is some controversy in the pastoral community about the usefulness, or even the propriety, of doing research on religious phenomena and the appropriateness of doctors intruding on religious practices, especially in prescriptive ways. However, it is important for psychiatrists to become knowledgeable about the interface between spiritual beliefs and psychological experiences without a negative bias toward the former, especially with ill patients in whom existential concerns are universally present.

The psychiatric consultant should inquire about faith, its meaning, associated religious practices, and its impact on the coping

response. It can be a source of strength or guilt at all stages of the disease, ranging from the earliest “What did I do to cause this?” to “Will God give me only what I can carry?” in midcourse to the poignant life review of the late stage. It is often a primary modifier of attitudes toward suicide and terminal care decisions. Mental health professionals should be prepared to deal with these areas in an unself-conscious, uncondescending manner, enabling the patient to fully integrate this aspect of their personality into the therapeutic relationship and the current crisis. However, this should never be mistaken for spiritual counseling. Some centers are fortunate to have chaplains available to patients on request. Psychiatrists should work with them, should let the patient know about their availability, and should arrange a visit if the patient shows interest. They should encourage the use of other spiritual guides in the community as well. Where specialized chaplains are not available, the psychiatrist should become familiar with selected religious leaders from the major faiths that appear in their practice to obtain advice and to make referrals.

The Wellness Movement. Wellness programs are a growing group of programs that demonstrate multiple and original uses of group modalities to help cancer patients and their families. The Wellness Community (TWC) and Cancer Support Community are good prototypes in addition to many locally based programs throughout the country, some of which provide additional personal services, such as transportation or accompaniment to doctors’ appointments. These organizations are generally not-for-profit organizations, are free of charge, and are devoted to helping cancer patients and their families cope and grow through the illness. They create an upbeat, welcoming environment for the whole family and position themselves as complementing standard medical treatment. They encourage patients to take a more active role in their care and coach them to interact more effectively with their medical caregivers. Although volunteers play a large role, and patients themselves are welcome to help, the specialized offerings are all run by trained professionals.

Volunteerism. The programs described previously, created and maintained by dedicated local and national volunteer workers and philanthropists, are only a small part of the support provided to cancer patients through volunteer activities. The ACS, the Leukemia Lymphoma Society of America (LLSA), and numerous institutions and family foundations have developed patient services along with their major research funding. “I Can Cope” is one of the largest. Cancer Care runs numerous groups and has established telephone and Internet groups. One organization fulfills the wishes of extremely ill children (e.g., a trip to Disneyland or a visit from a famous sports hero). Another provides free transportation to medical centers in executive jets. Most of them originated with grateful survivors or bereaved families trying to give meaning to their loss. This does not include the hundreds of thousands of individuals who volunteer their time in hospitals and clinics and are willing to do whatever is asked to make the patient’s experience more tolerable. For the volunteers who provide the help, it is a source of increased self-esteem and life purpose, whether they have a personal cancer experience or not. The magnitude and variety of offerings are encouraging for medical and familial caregivers and a reminder that selfless initiatives are still an important aspect of society.

DIAGNOSIS AND MANAGEMENT OF PSYCHIATRIC DISORDERS IN CANCER PATIENTS

Delirium, Dementia, and Other Cognitive Disorders

Cognitive disorders due to chemotherapy, radiation, cancer, and paraneoplastic syndromes will be reviewed separately later in this section. Dementia will be reviewed under the geriatric psycho-oncology section.

Delirium. Delirium is the most common and often serious neuropsychiatric complication in the management of cancer patients

characterized by an abrupt onset of disturbances in the level of consciousness, awareness, attention, cognition, and perception that tend to fluctuate over the course of the day, precipitated by an underlying medical condition. Delirium is a medical emergency that needs to be identified and treated vigorously. Unfortunately, delirium is frequently underdiagnosed and untreated in the medical setting, which leads to increased morbidity and mortality, interference in the management of symptoms such as pain, an increased length of hospitalization, increased health care costs, as well as distress for patients and their caregivers. Delirium is associated with increased morbidity in the terminally ill, causing distress in patients, family members, and staff. Fifty-four percent of patients were found to have recalled their delirium experience after recovery from delirium in a study of hospitalized cancer patients. Factors predicting delirium recall included the degree of short-term memory impairment, delirium severity, and the presence of perceptual disturbances. The most significant factor predicting distress for patients was the presence of delusions. Patients with hypoactive delirium were just as distressed as patients with hyperactive delirium.

EPIDEMIOLOGY. In cancer patients, delirium is present in 25% to 85% depending on the stage of illness. Prevalence rates of delirium range from 15% to 30% in hospitalized cancer patients; they are higher in the last weeks of life, at 40% to 85%. The reported prevalence of delirium in hospice may approach as high as 85%. Older adult patients who develop delirium during a hospital stay have an estimated mortality rate of 22% to 76% during that hospitalization.

ETIOLOGY. Frequently, a combination of factors (three or more etiologies) contributes to the development of delirium. Delirium is irreversible 30% to 40% of the time, especially in the terminally ill. If the etiology of the delirium is unidentifiable or irreversible, relief from the distressing symptoms of delirium may be provided to the patient. Predisposing factors including age, functional impairment, and the nature and severity of illness increase the risk of experiencing delirium during hospitalization. Dementia is an important

independent risk factor for developing delirium. Physical impairment, sensory impairment, low BMI, cachexia, and malnutrition have been associated with increased risk for delirium. With an increase from zero to three risk factors, the incidence of delirium rises from 2% to 50%, bringing longer hospital stays and poorer outcomes. In patients with advanced cancer, delirium can be due either to the direct effects of cancer on the CNS or to indirect CNS effects of the disease or treatments (e.g., medications, electrolyte imbalance, dehydration, major organ failure, infection, vascular complications, paraneoplastic syndromes). Given the large numbers of drugs, cancer patients require and the fragile state of their physiologic functioning, even routinely ordered hypnotics are enough to tip patients over into a delirium. Narcotic analgesics such as levorphanol (Levo-Dromoran), morphine sulfate (Roxanol), and meperidine (Demerol) are common causes of confusional states, particularly in the older adults and terminally ill. Chemotherapeutic agents are known to cause delirium including methotrexate (Rheumatrex), ifosfamide (Ifex), fluorouracil (Adrucil), vincristine (Oncovin), vinblastine (Velban), bleomycin (Blenoxane), BCNU (carmustine, Gliadel), cisplatin (Platinol-AQ), asparaginase (Elspar), procarbazine (Procanbid), and corticosteroids. Most patients receiving chemotherapeutics will not develop prominent CNS effects unless dexamethasone (Decadron) or prednisone (Deltasone) is included in the regimen. In addition, drug withdrawal may be a common cause of delirium, especially in postoperative patients whose drugs have been interrupted for surgery and have not been promptly restarted (Table 27.8–2).

CLINICAL FEATURES AND DIAGNOSIS. Clinically, the diagnostic gold standard for delirium is the clinician's assessment utilizing the *DSM-5* criteria. Clinical features of delirium include abrupt onset, fluctuating course, attention disturbances, altered level of alertness, awareness, and arousal, increased or decreased psychomotor activity, disturbance of sleep–wake cycle, affective symptoms, altered perceptions, disorganized thinking, and incoherent speech, disorientation, and memory impairment. Neurologic abnormalities including cortical (aphasia, apraxia, dyssomnia, dysgraphia) and

motor symptoms (tremor, asterixis, myoclonus, changes in muscle tone, and deep tendon reflexes) can also be present. It is this protean nature of the symptoms and the fluctuation of clinical findings that make delirium so difficult to diagnose and treat.

Delirium is classified into three clinical subtypes, based on psychomotor behavior, including the hyperactive, the hypoactive, and the mixed subtype. Approximately two-thirds are either of the hypoactive or mixed subtypes. The hyperactive form is most often characterized by hallucinations, delusions, agitation, and disorientation, while the hypoactive form is characterized by confusion and sedation but is rarely accompanied by hallucinations or delusions.

Table 27.8–2.
Causes of Delirium in Cancer Patients

Direct
Primary brain tumor
Metastatic spread to the brain
Indirect
Hypoxia
Metabolic encephalopathy due to organ failure
Electrolyte imbalance
Alcohol and drug withdrawal states
Treatment side effects from
Chemotherapeutic agents, steroids, biologic response modifiers
Radiation
Opioids
Anticholinergics
Antiemetics
Benzodiazepines
Infection
Hematologic abnormalities
Nutritional deficiencies
Vitamin deficiencies (thiamine, folate, vitamin B_{12}, and niacin)
Paraneoplastic syndromes
Endocrine disorders
Tumors of the pituitary, thyroid, parathyroid, and adrenal
Multiple endocrine neoplasia syndromes
Carcinoid tumors, mainly of the ovary and lung

Many of the clinical features and symptoms of delirium can also be associated with other psychiatric disorders such as depression, mania, psychosis, and dementia. For instance, delirious patients, not uncommonly, exhibit mood disturbances such as anxiety, fear, depression, irritability, anger, euphoria, apathy, or lability. Delirium, particularly the hypoactive subtype, is often initially misdiagnosed as depression. In distinguishing delirium from depression, particularly in

the context of advanced cancer, an evaluation of the onset and temporal sequencing of depressive and cognitive symptoms is particularly helpful.

Many scales or instruments have been developed that can aid the clinician in rapidly screening for cognitive disorders or in establishing a diagnosis of delirium, including the Delirium Rating Scale-Revised 98, the Confusion Assessment Method (CAM), the Abbreviated Cognitive Test for Delirium, and the Memorial Delirium Assessment Scale (MDAS).

The MDAS is a 10-item delirium assessment tool validated among hospitalized patients with advanced cancer and acquired immunodeficiency syndrome (AIDS). The MDAS is a delirium diagnostic screening tool as well as a reliable tool for assessing delirium severity among patients with advanced disease. A cutoff score of 13 is diagnostic of delirium. Recently, MDAS was further examined for clinical utility and validation in a population of advanced cancer patients in a palliative care unit. These investigators found the MDAS to be useful in this population and found that a cutoff score of 7 of 30 yielded the highest sensitivity (98%) and specificity (76%) for a delirium diagnosis in this palliative care population.

ASSESSMENT AND MANAGEMENT OF DELIRIUM. The standard approach to managing delirium in the medically ill, and even in those with advanced disease, includes a search for underlying causes, correction of those factors, and management of the symptoms of delirium. The desired and often achievable outcome is a patient who is awake, alert, calm, cognitively intact, not psychotic, and communicating coherently. Studies in patients with earlier stages of cancer have demonstrated the potential utility of a thorough diagnostic assessment. When such diagnostic information is available, specific therapy may be able to reverse delirium. The diagnostic evaluation includes an assessment of potentially reversible causes of delirium. A full physical examination should assess for evidence of sepsis, dehydration, or major organ failure. Medications that could contribute to delirium should be reviewed. A

screen of laboratory parameters will allow assessment of the possible role of metabolic abnormalities. Imaging studies of the brain and assessment of the cerebrospinal fluid may be appropriate in some instances.

In the terminally ill patient who develops delirium in the last days of life (referred to as terminal delirium), the management of delirium is unique, presenting a number of dilemmas, and the desired clinical outcome may be significantly altered by the dying process. When confronted with delirium in the terminally ill or dying patient, a differential diagnosis should always be formulated as to the likely etiology or etiologies. There is an ongoing debate as to the appropriate extent of diagnostic evaluation that should be pursued in a dying patient with terminal delirium. Most palliative care clinicians would undertake diagnostic studies only when a clinically suspected etiology can be identified easily, with minimal use of invasive procedures, and treated effectively with simple interventions that carry minimal burden or risk of causing further distress. Diagnostic work-up in pursuit of an etiology for delirium may be limited by either practical constraints such as the setting (home, hospice) or the focus on patient comfort, so that unpleasant or painful diagnostics may be avoided. Most often, however, the etiology of terminal delirium is multifactorial or may not be determined. Etiology is discovered in less than 50% of terminally ill patients with delirium. When a distinct cause is found for delirium in the terminally ill, it is often irreversible or difficult to treat. One study found that 68% of delirious cancer patients could be improved, despite 30-day mortality of 31%. Another found that one-third of the episodes of cognitive failure improved following an evaluation that yielded a cause for these episodes in 43%. In a recent prospective study of delirium in patients on a palliative care unit, investigators reported that the etiology of delirium was multifactorial in the great majority of cases. Even though delirium occurred in 88% of dying patients in the last week of life, delirium was reversible in approximately 50% of episodes. Causes of delirium that were most associated with reversibility included dehydration and medications. Hypoxic and metabolic encephalopathies were less likely to be reversed in terminal delirium.

TREATMENT. The standard approach to the management of delirium includes the identification and elimination of factors contributing to delirium, in addition to nonpharmacologic and pharmacologic treatment interventions. Nonpharmacologic approaches include creating a calm, comfortable, well-lit environment, using orienting objects such as calendars and clocks, early mobilization, having family members around, limiting room and staff changes, and allowing patients to have uninterrupted periods of rest at nights to improve their sleep–wake cycle. One-to-one nursing observation may also be necessary and useful. Fluid and electrolyte balance, nutrition, and vitamins may be useful.

Supportive techniques alone are often not effective in controlling the symptoms of delirium, and pharmacologic treatment is necessary in most cases. Antipsychotics constitute the primary pharmacologic intervention. Antipsychotics such as haloperidol (Haldol) are frequently utilized as antiemetics in the medical setting; however, only 0.5% to 2% of hospitalized cancer patients receive haloperidol for the management of the symptoms of delirium. In terminally ill populations, only 17% receive an antipsychotic for agitation or psychological distress, despite an estimated prevalence of delirium ranging from 25% in the hospitalized cancer patient to 85% in the terminally ill.

Haloperidol (a “typical” antipsychotic) is the gold-standard medication for the treatment of delirium among cancer patients due to its efficacy and safety (e.g., few anticholinergic effects, lack of active metabolites, and availability in different routes of administration). Haloperidol in low doses (1 to 3 mg per day) is usually effective in targeting agitation and psychotic symptoms. In general, doses of haloperidol need not exceed 20 mg in a 24-hour period; however, some clinicians advocate higher doses in selected cases. In severe agitation related to delirium, clinicians may add lorazepam to haloperidol. This combination may be more effective in rapidly sedating patients and may help minimize any extrapyramidal adverse effects of haloperidol. However, there is evidence that benzodiazepines can worsen delirium, and switching to a more

sedating antipsychotic is another option. The FDA has issued a warning against the risk of QTc prolongation and *torsades de pointes* with IV haloperidol; thus, monitoring QTc intervals daily among medically ill patients receiving IV haloperidol has become the standard clinical practice.

Oral or intravenous (IV) chlorpromazine is considered to be an effective alternative to haloperidol (with or without lorazepam) when increased sedation is required, especially in the ICU setting where close blood pressure monitoring is feasible, and for severe agitation in terminally ill patients to decrease distress for the patient, family, and staff. It is important to monitor chlorpromazine's anticholinergic and hypotensive side effects, particularly in older adult patients.

Atypical antipsychotics, such as olanzapine (Zyprexa), risperidone (Risperdal), quetiapine (Seroquel), and aripiprazole (Abilify), are increasingly used in the treatment of symptoms of delirium. Several studies have been conducted with atypical antipsychotics, including olanzapine, risperidone, quetiapine, aripiprazole, and ziprasidone, in the treatment of delirium.

A Cochrane review comparing the efficacy and the incidence of adverse effects between haloperidol and atypical antipsychotics concluded that, like haloperidol, selected newer atypical antipsychotics (risperidone, olanzapine) were effective in managing symptoms of delirium. Haloperidol doses greater than 4.5 mg per day were more likely to result in increased rates of EPS compared with the atypical antipsychotics, but low-dose haloperidol (i.e., less than 3.5 mg per day) did not result in a greater frequency of extrapyramidal adverse effects.

APA practice guidelines provide directions for the use of antipsychotics in the treatment of delirium, and growing evidence supports their use. The APA guidelines for the treatment of delirium recommend the use of low-dose haloperidol (i.e., 1 to 2 mg PO every 4 hours as needed, or 0.25 to 0.5 mg PO every 4 hours for the older adults) as the treatment of choice in cases where medications are necessary.

In the light of existing literature, risperidone may be used in the treatment of delirium, starting at doses ranging from 0.25 to 1 mg

and titrated up as necessary, with particular attention to the risks of EPS, orthostatic hypotension, and sedation at higher doses. Olanzapine can be started between 2.5 and 5 mg nightly and titrated up, with sedation being the major limiting factor, which may be favorable in the treatment of hyperactive delirium. The current literature on the use of quetiapine suggests a starting dose of 25 to 50 mg and a titration up to 100 to 200 mg per day (usually at twice-daily divided doses). Sedation and orthostatic hypotension are the main dose-limiting factors.

Important considerations in starting treatment with any antipsychotic for delirium may include EPS risk, sedation, anticholinergic side effects, cardiac arrhythmias, and possible drug–drug interactions. The FDA has issued a “black box” warning of the increased risk of death associated with the use of typical and atypical antipsychotics in older adult patients with dementia-related psychoses. Clinicians should attempt to use low doses only for short periods of time, especially when treating older adult patients with delirium. However, leaving delirium untreated may impose a greater risk of morbidity and mortality (Table 27.8–3).

Table 27.8–3.
Antipsychotics in the Treatment of Delirium

Generic Name	Approximate Daily Dose Range (mg)	Route[a]
Haloperidol	0.5–2 mg every 2–12 hrs	po, iv, sc, im
Chlorpromazine	12.5–50 mg every 4–12 hrs	po, iv, im
Olanzapine	2.5–10 mg every 12–24 hrs	po, ODT[b]
Risperidone	0.25–2 mg every 12–24 hrs	po, ODT[b]
Quetiapine	12.5–200 mg every 12–24 hrs	po
Ziprasidone	10–40 mg every 12–24 hrs	po
Aripiprazole	5–30 mg every 24 hrs	po, ODT[b]

po, orally; iv, intravenous; sc, subcutaneous; im, intramuscular.

[a]Risperidone and aripiprazole are available in liquid formulations.

[b]Orally disintegrating tablet (ODT) forms are available for olanzapine, risperidone, and aripiprazole.

Several researchers have studied both pharmacologic and nonpharmacologic interventions in the prevention of delirium among older patient populations, particularly in surgical settings, with mixed results. The applicability of these interventions to the prevention of delirium in cancer patients is limited.

Anxiety Disorders

Anxiety is the most common response in the setting of cancer. It is a natural human response mechanism when confronted by a threat, but it can become maladaptive when the response is excessive. For

example, during treatment, a patient sometimes will learn that their treatment has failed or that the disease has recurred. These situations are often met with disbelief and denial followed by emotional upheaval, characterized by mixed symptoms of depression and anxiety, together with loss of appetite, insomnia, and lack of concentration. These symptoms typically decrease gradually and resolve over a 7- to 10-day period. Anxiety may represent an acute reaction to cancer; however, some patients have premorbid psychological issues that are exacerbated by the diagnosis of cancer. This premorbid psychological functioning is influenced by the developmental state, personality, and prior psychiatric history.

Symptoms and Classification of Anxiety Disorders. Anxiety is manifested by a broad array of physical signs and measures of autonomic activation, changes in thinking (i.e., intrusive thoughts), and behaviors. The most common anxiety disorders in cancer patients are standardized in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5).

Generalized anxiety disorder is characterized by excessive anxiety across different settings. The worrying is difficult to control, evoking fatigue, irritability, muscle tension, and sleep dysfunction.

Panic disorder entails recurrent unexpected panic attacks, marked by intense fear or discomfort associated with palpitations, diaphoresis, dyspnea, sense of choking, nausea, dizziness, or derealization. The attacks may occur from a calm or anxious state and are followed by worry, concern, and behavior changes related to the attack.

Specific phobias are characterized by persistent and excessive fear elicited by the presence or anticipation of a specific object or situation. Phobias of blood, needles, hospitals, magnetic resonance imaging machines and radiation simulators may complicate treatment adherence. Patients undergoing chemotherapy have nausea and vomiting, and about 25% to 30% develop ANV despite adequate antiemetic regimens. Patients experience nausea when they are exposed to stimuli that remind them about drug infusions.

The classification “anxiety disorder due to a general medical condition” is meant to describe cases in which the symptoms are a direct physiologic consequence of the illness. Anxiety is ubiquitous and can be found with many of the conditions that cause other psychiatric disorders. Anxiety in cancer can be caused by different medical conditions, including pulmonary embolism, hypoxia, hypoglycemia, and cardiac disorders. Hormone-secreting neoplasms and paraneoplastic syndromes can also cause anxiety (Table 27.8–4).

Anxiety due to substance withdrawal is recognized and treated by most clinicians. Nicotine withdrawal is less commonly recognized. Many patients stop smoking abruptly on receiving their diagnosis and may experience severe anxiety symptoms, sometimes associated with dissociative symptoms and bizarre behaviors. Behavioral smoking cessation programs are an indispensable adjunct and are commonly offered to family members as well, taking advantage of what is known as a window of opportunity when defenses are shaken and motivation is high.

Substance-induced anxiety is a common cause of anxiety in cancer patients. They include bronchodilators, frequently used in lung cancer patients in whom they compound the anxiety caused by air hunger, corticosteroids, the mainstay of many protocols; anti-inflammatory cytokines, which are being increasingly used for treatment, and antipsychotics, including some of the ones that are used as antiemetics, such as metoclopramide (Reglan). Akathisia is often mistaken for anxiety by patients and staff; thyroxine, psychostimulants, sympathomimetic agents, serotonergic agents, and antihistamines may produce symptoms of anxiety.

Table 27.8–4.
Medical Conditions Associated with Anxiety

Metabolic	Hyperkalemia Hyperthermia Hypoglycemia Hyponatremia Vitamin deficiencies
Cancer	Central nervous system neoplasms Carcinoid syndrome Lung cancer
Endocrine	Adrenal abnormalities Thyroid abnormalities Parathyroid abnormalities Pituitary abnormalities Pheochromocytoma
Cardiovascular	Arrhythmia Congestive heart failure Myocardial infarction Angina pectoris Valvular disease
Pulmonary	Pulmonary embolism Asthma Chronic obstructive pulmonary disease Pneumothorax Pulmonary edema
Medication/toxic conditions	Corticosteroids Neuroleptics Thyroxine Sympathomimetic agents Serotonergic agents Antihistamines Withdrawal states (alcohol, opioid analgesics, sedative-hypnotics, caffeine)

	Antibiotics (cephalosporins, acyclovir, isoniazid)
Other symptoms	Pain

Treatment. Treatment aims include reducing the patient's overall level of emotional distress as well as reducing specific target symptoms that may impair social or occupational function. Treatment of anxiety in cancer patients depends on the etiology and the timing of the onset of symptoms. In some situations, anxiety symptoms can represent disorders that started before the onset of a medical illness. In that case, the treatment approach should be directed to the premorbid condition. In other instances, anxiety can be the consequence of a medical condition or its treatment. In such cases, the treatment should target the underlying condition.

Current or past delirium can contribute to anxiety in cancer patients. Delirious patients can present with early symptoms of restlessness, irritability, altered sleep patterns, and impaired concentration. Patients who have been delirious may have persistent worry related to their memory of this experience or their behavior during episodes of delirium.

PHARMACOLOGIC TREATMENT. Medications used to treat anxiety in cancer patients are also used in primary anxiety disorders. These medications are benzodiazepines, antidepressants, and atypical antipsychotics.

NONPHARMACOLOGIC TREATMENT. Nonpharmacologic treatment involves several approaches: psychotherapy, education, and supportive measures. There are different types of psychotherapy, including but not limited to interpersonal psychotherapy, supportive psychotherapy, and cognitive-behavioral therapy. MCP should be considered in advanced cancer patients with anxiety symptoms. Several behavioral methods have been used, such as progressive muscle relaxation, breathing exercises, meditation, biofeedback, and guided imagery.

Trauma- and Stressor-Related Disorders

Trauma- and stressor-related disorders are a group of diagnoses that entail both a traumatic or stressful exposure and a subsequent change in emotions and behavior. These include adjustment disorders, acute stress disorder (ASD), and PTSD.

Adjustment disorders with depressed mood, anxious mood, and mixed emotional features represent the largest group of psychiatric diagnoses found in cancer patients. Diagnosis of cancer may invoke a normal reaction to stress where mood can be affected in cancer patients. They may use their coping mechanisms and continue with their life without it affecting their functioning. Patients with cancer are on a continuum, with acute stress responses at one end and mood and anxiety disorders at the other. Adjustment disorders represent a maladaptation in one or more of the psychosocial areas. This disorder may resolve when the stressor is over, but it may become chronic, requiring medications along with counseling. The prevalence of adjustment disorder in oncologic care settings is around 20% but often co-occurs with anxiety and mood disorders.

ASD follows exposure to a traumatic event. Having cancer is perceived as a life-threatening event. The symptoms of ASD include the combination of one or more intrusion, dissociative, avoidance, or arousal symptoms, and negative mood. Dissociative symptoms include an altered sense of one's self or surroundings or an inability to remember aspects of the event. These symptoms typically begin immediately after the trauma and persist for 3 days to 1 month after exposure; PTSD should be considered for symptoms that have persisted for more than 1 month after such an event. The prevalence of ASD has not been established in cancer patients.

The essential feature of PTSD is the development of problematic symptoms following the experience of a traumatic event that involves the threat of death or injury. The syndromal presentation includes intrusion symptoms, negative cognitions and mood, persistent avoidance of stimuli associated with the trauma, and marked alteration in arousal and reactivity associated with the trauma. PTSD differs from ASD in that the disturbance lasts for longer than 1

month. Prevalence of PTSD has been reported as high as 37% among survivors of non-Hodgkin lymphomas at a median of 12.9 years after diagnosis. It is difficult to assess classic PTSD symptoms in cancer patients. Evaluation of intrusive symptoms is nonspecific since cancer patients often report fears related to the future and rarely flashbacks or intrusive memories. Avoidance behavior is difficult to ascertain, as patients are frequently confronted with the disease and its treatment with potential trauma-related stressors, and there have been reports of patients who felt worse because of premature interventions directed toward re-experiencing the trauma so as to integrate it. Acute posttraumatic denial needs to be approached cautiously, if at all. PTSD can be acute (immediate and lasting less than 3 months), chronic (lasting more than 3 months), delayed (if starting more than 6 months after the event), and recurrent (when a recurrence of symptoms is precipitated by another event that is reminiscent of but not necessarily as severe as the initial event). This latter type is more frequent than reported and should be sought out because patients themselves do not make the connection. In a paradoxical case, a Vietnam veteran was unaware of the striking parallels between his severe depressive response to being told that he did *not* have lung cancer and his reaction on returning stateside many years earlier. He experienced both events as undeserved reprieves from death that aroused profound survivor guilt about his dead buddies and the living ones that he had left behind.

Because avoidance of people and places associated with cancer, such as a clinic, is part of PTSD, this syndrome may interfere with optimal medical care delivery. Therapies used to treat PTSD include crisis intervention to lessen symptoms and improve functioning, cognitive-behavioral therapy to change thinking and behavior, and support groups for further support and to normalize the presentation. Patients with severe symptoms may benefit from medications, such as antidepressants, anxiolytics, and neuroleptics.

Cancer-related posttraumatic stress (PTS) is a syndrome much like PTSD, though the presentation is generally less severe. Patients with a new diagnosis of cancer may experience recurrent frightening

thoughts, distractibility, insomnia, and a sense of detachment or depersonalization. Helplessness is also a common symptom. Cancer-related PTS can occur anytime during or after treatment. Risk factors for cancer-related PTS can include diagnosis of cancer that recurs, a longer course of treatment, and a history of anxiety or trauma. Good social support and clear communication are thought to be protective against PTS symptoms. Treatments used for PTS are similar to those for PTSD, including early identification, crisis intervention, and relaxation training. Support groups may be helpful. For patients with severe symptoms of PTS, antidepressant and anxiolytic medicines may be used, especially in cases of comorbid mood and anxiety disorders.

Depressive Disorders

In DSM-5, depressive disorders include major depressive disorder, depressive disorder due to another medical condition, and substance/medication-induced depressive disorders. This section will principally review depressive disorders in cancer patients. Depressive symptoms are common in the oncology setting. Depression is a common psychiatric complication of cancer and is an important risk factor for suicide. Cancer patients are vulnerable to these symptoms at all stages of the illness, from the appearance of the first symptoms of cancer to the time of diagnosis, during treatment, palliative care, and even after remission or cure. Evaluating the nature and intensity of depressive symptoms is important. For the clinician, the relevant clinical question is how to identify the point when normal sadness or distress associated with cancer has become a depressive disorder. Diagnosis of depression in the context of cancer is challenging. Recognizing the risk factors for depression, with careful attention to the signs and symptoms of depression, leads to improved recognition and treatment of depressive disorders, thus increasing adherence to cancer treatment, improving quality of life, and reducing serious consequences such as a desire for hastened death and suicide.

Prevalence of Depression in Cancer Patients. Many studies have documented the prevalence of depression in cancer patients. The prevalence estimates of major depressive disorder in cancer patients have varied widely in different studies, from a low of 1% to a high of 50%. The use of different diagnostic measures and cutoff criteria impacts prevalence estimates. The site of cancer, the physical symptoms, and the stage of cancer are additional factors that contribute to differences in prevalence. In a study of terminally ill cancer patients, a symptom threshold consistent with DSM-IV-TR criteria was associated with a depression diagnosis in 13% of patients. A relatively minor reduction in the symptom severity threshold elevated the depression diagnosis to 26.1% of patients. A 2011 meta-analysis that stratified for various diagnostic systems and stages of disease reported a 25% prevalence rate for depressive or adjustment disorders and 29% for all types of mood disorders among cancer patients.

Risk Factors for Depressive Disorders in Cancer Patients. There are several risk factors for depression in cancer patients. The site of cancer and several chemotherapy regimens tend to increase the risk. Vinblastine, vincristine, interferon, procarbazine, asparaginase, tamoxifen, cyproterone, and corticosteroids are associated with greater risk. A higher prevalence of depressive disorders has been found among patients with pancreatic, head and neck, breast, and lung cancers, with relatively lower rates observed among those patients with lymphoma, colon, and gynecologic cancers. Depression is a common symptom of pancreatic cancer, with some early data suggesting that the mood disturbance is mediated by alteration of brain serotonergic function through proinflammatory cytokines (Table 27.8–5).

Depression may also develop secondary to organ failure or from nutritional, endocrine, and neurologic complications of cancer. Other risk factors for depressive disorders are advanced disease stage and physical disability, presence of other chronic medical illnesses, a previous history of depression, family history of depression, uncontrolled pain, low social support, social isolation, recent

experience of a significant loss, and low self-esteem. Although it is well established that depression is more prevalent among women than men in the general population, the gender difference is not evident among cancer patients. Older individuals are at greater risk for depression even in the absence of medical illness.

Evaluation and Diagnosis of Depression in Cancer Patients. Diagnosis of depression is challenging in cancer patients due to the neurovegetative symptoms that mimic many symptoms caused by cancer or its treatment, such as loss of appetite, fatigue, sleep disturbances, psychomotor retardation, apathy, and poor concentration. The assessment of depressive symptoms in cancer patients should focus on the presence of dysphoria, anhedonia, hopelessness, worthlessness, excessive or inappropriate guilt, and suicidal ideation. The presence of these symptoms helps distinguish depression from cancer-related symptoms. Changes in appetite, sleep disturbances, fatigue, and loss of energy can still be used to diagnose the cancer patient who is physically well, although one must bear in mind that chemotherapy- and radiation therapy–induced fatigue and other vegetative disturbances continue for a long time. Poor memory and impaired concentration are more likely to be the initial chief complaints in older adult depressed patients. Although rare, delusions or hallucinations may accompany depression. In medically ill depressed patients, the presence of delusions and hallucinations might be reflective of a diagnosis of delirium, which should be ruled out first. If present, the diagnosis of delirium precludes the diagnosis of a mood disorder with depressive features.

Table 27.8–5.
Medical Causes of Mood Disorders in Cancer Patients

- Electrolyte disturbances
- Vitamin B_{12}, folate, or other vitamin deficiencies
- Cancer-related
  - Primary CNS tumors
  - CNS metastasis
  - Paraneoplastic syndromes
  - Pancreatic cancer, small cell lung cancer, breast cancer, carcinoid tumor, adrenocortical tumors
  - Neurologic diseases
  - Cerebrovascular disease
  - Dementia
  - Cerebral trauma
  - CNS infections
- Systemic disorders
  - Autoimmune disorders
  - Inflammatory disorders
  - Infections
- Endocrine abnormalities
  - Hyper- or hypothyroidism
  - Adrenal insufficiency
- Medications
  - Corticosteroids
  - Interferon and interleukin-2
  - Cardiac and antiarrhythmic drugs
  - Antibiotics, antivirals
  - Psychotropic drugs (antipsychotics, benzodiazepines, other sedative/hypnotics)
  - Opiates
  - Cimetidine
  - Levodopa, methyldopa
  - Pentazocine
  - Tamoxifen
  - Analgesics, and anti-inflammatory drugs
  - Some chemotherapeutic agents: vincristine, vinblastine, procarbazine, asparaginase, tamoxifen, cyproterone,

	mithramycin, L-asparaginase
Other conditions	
	Cardiorespiratory disease
	Renal disease, anemia, uncontrolled pain

CNS, central nervous system.

Four conceptual approaches have been proposed to evaluate depression in the medically ill: inclusive, exclusive, etiologic, and substitutive approaches. No single approach is inherently superior to the others. When selecting a conceptual approach, it is important to consider whether a diagnosis of depression is being made for clinical or research purposes. The inclusive approach, in which all symptoms of depression are counted regardless of their suspected etiology, is highly sensitive, making its use more appropriate for diagnoses in clinical settings. The substitutive approach replaces somatic symptoms of depression (i.e., fatigue, sleep disturbance, change in weight or appetite, difficulty concentrating) with psychological symptoms such as depressed appearance, social withdrawal, brooding, self-pity, pessimism, and anhedonia. This approach is conceptually reasonable, but there is little evidence for its superiority. The etiologic approach requires that the clinician include a symptom as part of a clinical depression only if it is clearly not a result of medical illness. It is theoretically sound; however, it is difficult to apply this reliably in oncology settings due to the overlap of symptoms. The exclusive approach eliminates the somatic symptoms from the diagnostic criteria. The high specificity associated with the exclusive approach makes it valuable for research purposes, but it is not desirable in clinical practice due to the risk of missing a diagnosis of depression.

Several subcategories of DSM-5 depressive disorders diagnoses are found in the context of cancer. A diagnosis of depressive disorder due to another medical condition is the appropriate diagnosis when the depressive disorder is due to underlying cancer, such as pancreatic cancer. When a medication (such as interferon) is the underlying cause of a depressive disorder, the diagnosis of

substance/medication-induced depressive disorder is used. Corticosteroids are used in a wide range of situations and can result in depression to the extent that patients may become suicidal or psychotic. Establishing the etiology of symptoms of depression in cancer patients is difficult, and usually, multiple factors contribute to depressive symptoms in most of these patients. Self-report symptoms inventories, such as the Patient Health Questionnaire-9 (PHQ-9) or the Beck Depression Inventory (BDI), are useful for screening purposes but do not discriminate between a major depressive disorder and depressive disorder due to another medical condition. Major depressive disorder is defined as an episode of clinically significant persistent and pervasive depressed mood or anhedonia, accompanied by cognitive and behavioral symptoms. The DSM-5 criteria for major depression are consistent with the etiologic approach in which symptoms that are deemed to be due to a medical condition or medication do not count toward the diagnosis. Patients who have had a major depressive episode in the past are at risk of a recurrence in the context of cancer. Patients may have a pre-existing dysthymic disorder, which may become more manifest or worse in cancer patients.

Management of Depression in Cancer Patients. Management of depression in cancer patients requires a comprehensive approach that addresses the evaluation, treatment, and follow-up. The initial management begins with the establishment of a therapeutic alliance with the clinician and recruiting support from family or friends. It is important to note that a relationship with the oncologist is the key component of support for cancer patients. Maintaining ongoing contact with depressed cancer patients, especially terminally ill patients, ensures that continual evaluation and caring are available.

The NCCN has applied the APA practice guidelines for the treatment of depressive disorders in physically healthy individuals to the treatment of depression in cancer patients. There are several pharmacologic and psychotherapeutic strategies available. Prior to selecting an appropriate treatment, the site of cancer, current cancer treatment, comorbid medical conditions, and medications should be

taken into consideration, any of which may contribute to depressive symptoms. Reversible conditions such as thyroid function abnormalities should be ruled out. If the depressive disorder is thought to be secondary to a medical condition or caused by a drug, the clinician should treat the underlying condition or change the drug; however, antidepressants are usually started concurrently to relieve the patient's suffering as quickly as possible.

PHARMACOLOGIC TREATMENTS. The use of antidepressant medications in cancer patients creates unique challenges. Rapid onset of action is preferable in cancer patients, especially in the terminally ill; however, antidepressants may take several weeks to have a therapeutic effect due to their delayed onset of action. An appropriate antidepressant should be selected based on the potential side effects of each antidepressant, drug–drug interactions, the patient's prognosis, primary symptoms of depression, and comorbid condition. Antidepressants should be started at low doses and titrated up slowly in medically frail cancer patients, especially in the older adults.

SSRIs have become the first line of treatment for depressive disorders in the medically ill. They are efficacious, generally well tolerated, and are not as toxic in overdose as TCAs. Some SSRIs, such as fluoxetine (Prozac) and fluvoxamine (Luvox), are inhibitors of cytochrome P450 isoenzymes. It is therefore important to monitor for the possibility of drug–drug interactions. Sertraline (Zoloft), citalopram (Celexa), and escitalopram (Lexapro) are less protein-bound and may have a lower risk of drug interactions with the P450 system. Citalopram (Celexa) causes dose-dependent QT interval prolongation and has an FDA-restricted maximum dose of 20 mg daily for subgroups of patients, including those taking a cytochrome P450 2C19 inhibitor and those older than 60 years. Many of the SSRIs are available in liquid forms, making it easier for patients who cannot swallow pills.

SNRIs are a growing class of antidepressants, which include venlafaxine (Effexor), desvenlafaxine (Pristiq), duloxetine (Cymbalta), and levomilnacipran (Fetzima). They are generally well

tolerated, with a benign side-effect profile similar to SSRIs. However, norepinephrine reuptake inhibition may result in palpitations and hypertension. Therefore, blood pressure monitoring is recommended for patients on an SNRI. It is important to note that venlafaxine mainly inhibits serotonin reuptake at low doses; its effect on norepinephrine reuptake inhibition is seen at doses higher than 150 mg per day. Duloxetine shows serotonin and norepinephrine reuptake inhibition at starting doses. All four medications have a low P450 effect and moderate plasma protein binding, which minimize drug–drug interactions and allow for their common use in depressed cancer patients. These medications have proven effective for the treatment of neuropathic pain and are commonly prescribed as adjunct pain medications.

TCAs have been around for many years and are less expensive than many of the SSRIs. Because of their anticholinergic, antiadrenergic, and antihistaminergic side effects, they are less frequently used in cancer patients. Anticholinergic side effects should be especially avoided in older adult patients at risk for anticholinergic delirium or patients at risk for GI dysmotility or obstruction. Their role as adjunct pain medications, especially for neuropathic pain, has become their most common indication for use in cancer patients.

MAOIs are rarely used in the treatment of cancer patients with depression due to the risk of fatal hypertensive crisis when concurrently used with tyramine-rich food or sympathomimetic drugs.

Of the other antidepressants, bupropion (Wellbutrin) acts primarily on the dopamine system and may have a mild stimulant effect, which can be beneficial for cancer patients with fatigue or psychomotor retardation. It is generally tolerated well in the medically ill. Bupropion is associated with an increased risk of seizures at higher doses and should be used with extreme caution in individuals with CNS tumors or seizure disorders. Trazodone is often used in lower doses as a sleep aid rather than a primary antidepressant because its most common side-effect is sedation. Vilazodone (Viibryd) is a serotonin reuptake inhibitor with 5-HT_{1A} receptor partial agonism; it

has a less adverse impact on sexual function than other antidepressants. Mirtazapine (Remeron) acts by blocking the 5-HT_2, 5-HT_3, and α-2 adrenergic receptor sites. Its side effects of sedation and weight gain are beneficial for many cancer patients with insomnia and weight loss. It also has antiemetic properties. It is also available in a dissolvable tablet form, which is particularly useful for patients who cannot swallow or who have difficulty with nausea and vomiting. Mirtazapine has minimal drug–drug interactions. Vortioxetine (Trintellix) is a serotonin modulator and stimulator that is approved for the treatment of MDD. It is rarely used in patients with cancer due to the high risk of serotonin syndrome when used alone or in combination with other antidepressants, opioids, or CYP2D6 inhibitors.

Psychostimulants and wakefulness-promoting agents are helpful to treat depressed cancer patients' symptoms of fatigue, psychomotor retardation, and poor concentration. Not only can they induce an antidepressant effect, but they can quicken the response to concomitant antidepressants. Psychostimulants exert dopaminergic effects. Psychostimulants used in cancer patients include dextroamphetamine (Dexedrine), methylphenidate (Ritalin or Concerta), and lisdexamfetamine (Vyvanse). They have a major advantage over antidepressants due to their rapid onset of action and their role in relieving fatigue, promoting wakefulness, and countering opioid-related sedation. Side effects may be anorexia, anxiety, insomnia, euphoria, irritability, and mood lability. However, side effects are not common at low doses and can be avoided by slow titration. Hypertension and cardiac complications can occur; thus, it is advisable to monitor cardiac function. For depressed cancer patients with short survival expectancy, psychostimulants provide rapid relief from distressing depressive symptoms. Modafinil (Provigil) and armodafinil (Nuvigil) are known as wakefulness-promoting agents. They produce increased alertness, wakefulness, and energy. They are presumably better tolerated than psychostimulants but may also cause anxiety, restlessness, and

insomnia. They should be used with caution in patients with poorly controlled hypertension.

PSYCHOTHERAPY. Several psychotherapeutic techniques have been successfully employed with depressed cancer patients. Psychotherapy is often combined with pharmacologic intervention. Supportive psychotherapy and cognitive-behavioral therapy are commonly used in cancer patients. MCP is a novel therapeutic modality that has been shown to improve depressive symptoms among advanced cancer patients both in individual and group therapy settings.

Group therapy can be helpful to improve social networks, connecting the patient with others who have the same diagnosis or treatment, decreasing the patient's sense of isolation. Supportive–expressive and cognitive-existential group psychotherapies have been studied and used successfully for cancer patients.

ELECTROCONVULSIVE THERAPY (ECT). ECT is an effective treatment modality for depressed patients. ECT should be considered in patients who are refractory to psychopharmacological treatment (i.e., at least two trials with antidepressant medicines from different pharmacologic classes that are adequate in dose, duration, and adherence), have severe weight loss secondary to depression, exhibit acute psychosis, or have a high suicide risk. Although CNS tumors and cardiac problems are not absolute contraindications, ECT is used with caution in these individuals.

Suicide Assessment and Management in Cancer Patients. The incidence of suicide is higher in cancer patients compared with the general population. Studies suggest that although a small number of cancer patients commit suicide, the relative risk of suicide in this population far exceeds that of the general population, particularly early after diagnosis. Compared to cancer-free persons, the relative risk of suicide after a cancer diagnosis is 12.6 in the first week and 3.1 during the first year; the risk elevations lower rapidly in subsequent years after diagnosis. Suicide may also occur in

advanced cancer patients with escalating depression, hopelessness, and the presence of poorly controlled symptoms, particularly pain. Suicidal thoughts in patients with advanced disease, poor prognosis, or poorly controlled symptoms should not be viewed as rational. It is important to note that those patients may have a treatable major depressive episode influencing their suicidal ideation. Clinicians should evaluate for hopelessness and a diagnosis of depression in terminally ill patients with a persistent desire for death or suicidal intention (Table 27.8–6).

Table 27.8–6.
Suicide Risk Factors in Cancer Patients

Depression
Hopelessness
Uncontrolled pain
Extreme fatigue
Anxiety
Delirium
Substance abuse or dependence
Feeling alone in the world
Objective lack of social support
Stressful family relations
Intolerance of loss of control, dependence, and loss of dignity
Severe financial problems
Positive family history
History of severe trauma
Presence of active statements and plans
Personality disorder
Previous history of depression and suicide attempts

Prior history of psychiatric illness, previous history of depression or suicide attempts, recent bereavement, history of alcohol or other substance abuse or dependence, male gender, family history of depression or suicide and lack of family or social support, and recent

losses are common risk factors for suicide. Untreated delirium may lead to unpredictable suicide attempts due to impaired judgment and impulse control. Older patients and individuals with head and neck, lung, breast, urogenital, GI cancers, and myeloma seem to have an increased risk of suicide. An international population-based study from Denmark, Finland, Norway, Sweden, and the United States has shown a small but statistically significant, increased long-term risk of suicide, 25 or more years after a breast cancer diagnosis.

Evaluation of suicidal thoughts should take into account the disease stage and prognosis. It is helpful to consider the issue of suicidality from four perspectives: (1) the suicidal thoughts that occur transiently in many patients with cancer, (2) suicidal thoughts in patients who are in remission with a good prognosis, (3) suicidal thoughts in patients with poor prognosis or poor symptom control, and (4) patients in terminal stages. Suicidal ideation or plans to commit suicide in cancer patients with a good prognosis or those in remission also require careful assessment. A Finnish survey of suicides in 1 year revealed that 4.3% had cancer, half of whom were in remission at the time of suicide. Patients were noted to have had a history of psychiatric illness prior to cancer diagnosis, in particular substance abuse.

It is important to recognize and aggressively treat high-risk patients for depression and address suicidal risk with acute psychiatric hospitalization, if necessary. Maintaining a supportive relationship, symptom control (e.g., pain, nausea, depression), and involving the family or friends are the initial steps in the management of a suicidal patient. A study examining the suicidal ideation and past suicidal attempt in adult survivors of childhood cancer found a strong correlation between physical health and suicidality, which underscores the importance of symptom control in cancer patients. Early psychiatric involvement with high-risk individuals can often avert suicide in cancer patients. A careful evaluation includes an exploration of the reasons for suicidal thoughts and the seriousness of the risk. The clinician should listen empathically, without appearing critical or judgmental. Allowing the patient to discuss suicidal thoughts often decreases the risk of suicide despite common belief

to the contrary. Patients often reconsider and reject the idea of suicide when the physician acknowledges the legitimacy of their option and the need to retain a sense of control over aspects of their death. Rarely a competent patient presents a difficult problem by continuing to threaten suicide or to ask for help in dying. Patients must be given intense ongoing support, including open discussions about treatment options. Medical staff and family may need to be reminded of the competent patient's right to refuse all treatments, even life-saving ones.

Bipolar Disorder

Cancer patients with bipolar disorder are most likely brought to the attention of consultation psychiatrists due to the complexity of their management. Acutely manic patients must be brought under control as rapidly as possible. The rigors and dangers of chemotherapy and radiation treatment require a level of consistent cooperation that manic patients cannot be trusted to sustain, even when they understand their situation and earnestly desire treatment. These are difficult cases that require patience and multidisciplinary cooperation. Psychiatrists should carefully assess for safety and level of functioning to determine the best treatment setting. It is also important to screen for substance abuse or dependence and to assess whether the patient is suicidal or a risk to others (homicidal or violent ideation). When the patient cannot be rapidly controlled, a brief psychiatric admission may be necessary, preferably followed by a direct transfer from the psychiatric ward to the oncology ward.

In an acutely manic or hypomanic cancer patient (especially in the older adults), it is important to complete a comprehensive medical assessment to rule out medical conditions or medications as the possible culprit of the mood disturbance. Corticosteroids can cause hypomania or even mania with psychotic features, especially in patients with prior history of mood disorder or a family history of bipolar disorder. The spectrum of mental disturbances related to steroids includes minor mood lability, affective disorders (mania or depression), cognitive impairment, and delirium. The incidence of

these disorders ranges from 28% to 55% in noncancer populations, and they occur most commonly on higher doses. Symptoms usually develop within the first 2 weeks on steroids but, in fact, can occur at any time, on any dose, even during the tapering phase. These disorders are often rapidly reversible upon dose reduction or discontinuation. Manic symptoms can also be a part of postictal psychosis, most likely in patients with temporal lobe epilepsy or after temporal lobectomy. An EEG may be helpful for diagnostic clarity. Thyroid function abnormalities should also be ruled out, especially in patients with thyroid carcinomas or those who have undergone radiation to the neck.

Cancer patients with bipolar disorder in remission can be maintained on lithium (Eskalith) or other mood-stabilizing medications. Renal insufficiency is a contraindication to lithium use, but the end-stage renal disease can be managed with low-dose lithium after each dialysis. Medically ill patients must be monitored for lithium toxicity in the presence of vomiting and dehydration (as during chemotherapy), hypercalcemia, renal impairment (as with cisplatin [Platinol] treatment), possible hypothyroidism, or when there is an increased risk of cardiac arrhythmia (as in pre-existing heart disease or with the use of digoxin [Lanoxin], bronchodilators, or cardiotoxic chemotherapy agents, such as doxorubicin [Adriamycin]). Radiation therapy is not a contraindication, except for cranial irradiation, whose side effects mimic lithium toxicity, making monitoring difficult. Patients should be monitored carefully during the postoperative period for the development of nephrogenic diabetes insipidus (NDI), an uncommon but severe side effect. Patients may not report their symptoms of polyuria, polydipsia, or nocturia, as the insidious onset of the condition leads patients and families to believe that the increased intake and output are normal. The problem may go unrecognized for long periods if physicians do not specifically question their patients about the existence of polyuria, polydipsia, or nocturia. Serum lithium levels might be in the therapeutic range despite polyuria. Patients may present with severe hypernatremia during acute illness or after fluid deprivation in the perioperative period. Annual measurement of 24-hour urine volume may help

prevent this potentially fatal condition in cancer patients using lithium for the treatment of bipolar disorder.

Cancer-Related Fatigue

Cancer-related fatigue is a persistent, subjective sense of tiredness related to cancer or cancer treatment that interferes with usual functioning. Fatigue is a common and highly distressing symptom of cancer, associated with reduced quality of life, as well as considerable psychological and functional morbidity. Fatigue is more distressing than pain, nausea, or vomiting, which are manageable by medications in most patients. Cancer-related fatigue is usually refractory to sleep and rest. The reported prevalence of cancer-related fatigue ranges from 4% to 91%, depending on the specific cancer population studied and the methods of assessment. Fatigue is present at the time of diagnosis in about 50% of cancer patients. It occurs in up to 75% of patients with bone metastases. Fatigue is also prevalent in long-term cancer survivors and has a serious impact on a person's quality of life.

A group of expert clinicians proposed a set of diagnostic criteria that have been included in the 10th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). A standardized interview guide has been designed and studied for its reliability and validity to assess the proposed clinical syndrome, with results suggesting its utility in identifying patients experiencing clinically significant cancer-related fatigue. Fatigue is difficult to quantify. There are a variety of standardized self-report scales, most of which have been developed in the context of cancer. Different scales may measure fundamentally different aspects or even potentially distinct conceptions of fatigue. The challenge facing the clinician or researcher is to choose a reliable and valid tool for the measurement of fatigue that is most adequately suited to their purposes. Given the multifactorial nature of fatigue, accessory scales (e.g., depression scales) and measurements of certain biologic parameters should be used in addition to fatigue assessment tools in order to obtain a complete evaluation of a patient's fatigue.

Fatigue and depression may coexist in cancer patients, and there is a considerable overlap of symptoms of these two conditions. It is necessary to clarify the relationship between depression and fatigue in order to effectively evaluate and treat cancer-related fatigue. There are many symptoms common to both fatigue and depression, such as decreased energy and motivation, sleep disruptions, diminished concentration and attention, and problems with short-term memory. The clinician seeking to differentiate between depression and fatigue should remember that depressive symptoms due to fatigue are typically less severe and that patients tend to attribute such symptoms to the consequences of fatigue. Depression, on the other hand, is more likely in the presence of hopelessness, feelings of worthlessness or guilt, suicidal ideation, and a family history of depression. The nature of any causal relationship between cancer-related fatigue and depression is unclear.

Cancer-related fatigue is caused by various physical and psychosocial mechanisms, including tumor by-products, opioids, or other drugs (such as antidepressants, β-blockers, benzodiazepines, antihistamines), hypogonadism, hypothyroidism, cachexia, anemia, chemotherapy, radiation therapy, bone marrow transplantation, and treatment with biologic response modifiers. Cancer-related fatigue has been related to pain, depression, emotional distress, sleep deprivation, and reduced physical activity. Cytokines (interleukin-1 and -6 [IL-1, IL-6], tumor necrosis factor-α [TNF-α]) have a role in the development of cancer-related fatigue, which has led researchers to consider cytokine-antagonist drugs such as TNF receptor etanercept (Enbrel) and TNF-α antagonist thalidomide (Thalomid) to improve the tolerability of chemotherapy regimens and potentially to treat cancer-related fatigue and cachexia. Genetic variables have also been implicated to play a role in the development of fatigue among cancer patients. Advanced colorectal cancer patients with two variant forms of the dihydropyrimidine dehydrogenase (*DPYD)* gene —an enzyme that is involved in the breakdown of excess nucleotides involved in DNA, RNA, and ATP production—were significantly less likely than those patients with a form of the gene known as *DPYD*5*

to report fatigue following treatment with a chemotherapy regimen of 5-fluorouracil, irinotecan, and oxaliplatin.

All patients should be screened for fatigue at their initial visit, at regular intervals during and following cancer treatment, and as clinically indicated. The NCCN practice guidelines on cancer-related fatigue recommend the use of numerical self-report scales or verbal scales to assess the severity of fatigue. If moderate or severe (a score of 4 to 10 on a scale of 0 to 10 with higher numbers indicating increased severity), a focused history and clinical examination with evaluation of the pattern of fatigue, associated symptoms, and interference with normal functioning are recommended. Potentially reversible causes of fatigue (such as pain, emotional distress, sleep disturbance, anemia, hypothyroidism) should be identified and treated, and nonessential centrally acting drugs should be eliminated. If anemia is the main cause of fatigue, the physician should determine the necessity of a transfusion in severely symptomatic patients. Clinical trials have shown that anemic patients have improved energy and less fatigue after erythropoietin treatment.

Nonpharmacologic approaches have been recommended by NCCN guidelines for the treatment of cancer-related fatigue. Activity enhancement and psychosocial interventions (i.e., education, support groups, individual counseling, stress management training) have been well supported by research. Dietary management, attention-restoring therapy, sleep therapy, and mind–body interventions have also been recommended in the treatment of cancer-related fatigue.

Many pharmacologic interventions are being evaluated in clinical trials for the treatment of fatigue in cancer patients (http://clinicaltrials.gov/). Psychostimulants, wakefulness-promoting agents, and antidepressants are the psychotropic medications used in the treatment of cancer-related fatigue.

Psychostimulants have also been used in the treatment of fatigue-related conditions such as pain, depression, and cognitive impairment. Methylphenidate has been studied most and appears to be relatively effective and well-tolerated despite relatively common

side effects such as insomnia and agitation. Dexmethylphenidate is the d-isomer of methylphenidate, with a longer duration of action (about 6 hours) compared to methylphenidate. It has been found to be well tolerated and more effective than a placebo for improving fatigue in adult cancer patients.

Dextroamphetamine is the d-isomer of amphetamine and is more potent than methylphenidate, is commonly prescribed by clinicians for the treatment of cancer-related fatigue.

A meta-analysis of pharmacologic treatment options for cancer-related fatigue has concluded that methylphenidate might be effective for treating fatigue. A significant placebo response has been observed in randomized trials. There was also evidence that treatment with hematopoietic agents relieved fatigue due to chemotherapy-induced anemia.

Modafinil is a wakefulness-promoting agent, approved by the FDA in December 1998 for the treatment of excessive daytime sleepiness in patients with narcolepsy. Compared to other psychostimulants, modafinil has a novel mechanism of action and less abuse potential. It presumably enhances activity in the hypothalamic wakefulness center (i.e., tuberomammillary nucleus), activates tuberomammillary nucleus neurons that release histamine, and activates other hypothalamic neurons that release orexin/hypocretin. Modafinil is commonly used for the treatment of severe fatigue in multiple sclerosis and has been studied as a treatment option for cancer-related fatigue with an improvement of fatigue. The results are supportive of its use among cancer patients with severe fatigue. Further well-designed, randomized, controlled clinical trials are necessary to clarify the role of modafinil and armodafinil in the treatment of cancer-related fatigue.

Underlying depression should be treated with SSRIs, which are generally better tolerated than TCAs in cancer patients. When prescribing such medications, clinicians should remember that, as fatigued patients are generally more sensitive to antidepressant side effects, treatment should be initiated with small doses. Drug–drug interactions should also be carefully monitored. Studies have examined the role of paroxetine, sertraline, and bupropion in the

treatment of cancer-related fatigue. Paroxetine and sertraline were effective in improving fatigue among cancer patients with comorbid depressive symptoms. Bupropion was found to be effective and well tolerated in both depressed and nondepressed cancer patients in open-label trials. However, controlled studies are required to determine whether the effect of bupropion on fatigue is independent of its antidepressant effects.

Corticosteroids have been used in the treatment of cancer-related fatigue. Current evidence on the use of corticosteroids is anecdotal, and responses to corticosteroids appear to be temporary. Due to concerns for toxicity associated with long-term administration, the use of corticosteroids should be restricted to the terminally ill, with concomitant fatigue and anorexia, and/or those with pain related to bone or brain metastases.

Megestrol acetate (Megace) is a progestational agent that has been found to improve appetite in cancer-related cachexia and has also been suggested to have a role in the treatment of cancer-related fatigue. The effects of megestrol acetate on fatigue are not clear, but they probably involve anticytokine and corticosteroid-type effects (Table 27.8–7).

Personality Disorders

Personality disorders are chronic character styles that lead to clinically significant interpersonal and behavioral problems. Personality affects the way an individual copes with different life events. This aspect is important in the medical setting because it will influence how the patient will cope with cancer and its concurrent stressors such as hospitalization and treatment. During the evaluation, it is important for the consultant psychiatrist to identify maladaptive responses to stressors as defense mechanisms that the patient might be using to deal with cancer. Patients' symptoms are chronic and ego-syntonic, and it is the family and staff who feel stressed by a worsening of the patient's usual dysfunctional modes of adaptation and who ask for help because of increased conflict and disrupted treatment. Personality-disordered patients do have acute

stress syndromes, which may be overlooked because of the chronic issues. Evaluation should search for other psychiatric disorders. Comorbid anxiety or depression should be actively treated. Environmental measures should be implemented to decrease conflict and to improve patient care, including family and staff involved in the intervention. Patients with personality disorders are also distressed by unbearable emotional conditions and might require attention to basic needs such as sleep deprivation, hunger, and necessary medical and comfort care. Medications such as benzodiazepines or antipsychotics can be used to stabilize agitation or emotional upheaval. The psychiatrist should establish a working relationship by being empathetic with the patient and by being aware of transference and countertransference issues. The dynamics of difficult patients and ways of dealing with them have been well described in the psychiatric literature. The feelings of anger and guilt that patients with personality disorders routinely induce in mental health staff also occur in oncology staff. The latter, especially when inexperienced, may find these feelings harder to deal with because they are not trained to recognize these feelings as part of the patient’s pathology and are disarmed by the genuine pathos of the patient’s condition. Explanations, support, and guidance are helpful.

Table 27.8–7.
Psychotropic Medications Used in Cancer-Related Fatigue

Medication	Starting Dose	Dose Range	Comments
Psychostimulants			
Methylphenidate	2.5–5 mg daily or twice daily	5–30 mg/day, usually divided as twice daily	Longer-acting forms are available. Capsule forms can be sprinkled in food.
Dextroamphetamine	2.5–5 mg daily or twice daily	5–30 mg/day, usually divided as twice daily	Longer-acting formulations are available. Capsule forms can be sprinkled in food.
Wakefulness promoting agents			
Modafinil	50–100 mg daily	50–400 mg daily, may be divided as twice daily	Favorable side-effect profile
Antidepressants[a]			
Selective serotonin reuptake inhibitors			
Well-tolerated. Citalopram, escitalopram, and sertraline seem to have the least drug–drug interactions.			
Fluoxetine[b]	10–20 mg/day	10–60 mg/day	
Paroxetine	10–20 mg/day	10–40 mg/day	
Citalopram[b]	10–20 mg/day	10–40 mg/day	
Escitalopram[b]	5–10 mg/day	5–20 mg/day	

Sertraline[b]	25–50 mg/day	25–200 mg/day

Serotonin-norepinephrine reuptake inhibitors

Well-tolerated. Monitor blood pressure, especially at higher doses.

Venlafaxine	37.5–75 mg/day	37.5–225 mg/day
Duloxetine	20–30 mg/day	20–60 mg/day

Norepinephrine-dopamine reuptake inhibitor

Doses higher than 300 mg a day should be used twice daily to minimize the risk of seizures.

Bupropion	75 mg/day	75–450 mg/day

Tricyclic antidepressants

Drug–drug interactions are more common compared to SSRIs.

Secondary Amines

Desipramine	25–50 mg/day	25–200 mg/day
Nortriptyline[b]	10–25 mg/day	10–150 mg/day

Tertiary Amines

Amitriptyline	10–25 mg/day	10–150 mg/day
Doxepin[b]	25–50 mg/day	25–300 mg/day
Imipramine	10–25 mg/day	10–200 mg/day

α-2 antagonist/5-HT_2/5-HT_3 antagonist

Mirtazapine	7.5–15 mg/day	7.5–45 mg/day

[a]Antidepressant medications have not been proven to be efficacious in the treatment of cancer-related fatigue in the absence of a diagnosis of clinical depression.

[b]Available in liquid formulations.

Schizophrenia and Other Psychotic Disorders

Patients with schizophrenia may appear less often in doctors' offices because their disease interferes with the early and consistent seeking of care. They give idiosyncratic meanings to their symptoms and may tolerate them without complaint, often because of what is called a *high pain threshold*, although a more accurate description would be a different central processing mechanism. The patients' unreliability continues throughout the treatment course and may complicate postoperative and long-term medical management. When treating hospitalized patients with schizophrenia, it is important to ensure continuity of care. Ongoing medications can usually be continued, except for a brief operative period. The medical staff needs help in handling bizarre behaviors and reassurance about intimidating mannerisms. They need a precise protocol and written orders for the management of aggressive or disruptive episodes, as well as a clear understanding of the legal and ethical considerations governing the patients' right to refuse medical treatment and to leave the hospital. Decisional capacity is situation-specific and independent of the presence of a psychiatric disorder; hence, psychiatric consultation should be called to help establish its presence or absence in any conflictual situation.

Substance Use Disorders

In 2018, an estimated 164.8 million people aged 12 or older in the United States (60.2%) were past-month substance users (i.e., tobacco, alcohol, or illicit drugs). The 164.8 million past-month substance users in 2018 include 139.8 million people who drank alcohol, 58.8 million people who used a tobacco product, and 31.9 million people who used an illicit drug. While prevalence data for substance use disorders in cancer patients is limited, one can infer

that a significant proportion of patients with a new cancer diagnosis have problematic drug and alcohol use.

Oral, pharyngeal, laryngeal, esophageal, breast, liver, and rectal cancers are more common in alcohol users than in non-alcohol users. Smokers who also drink are at much higher risk. Alcohol withdrawal syndrome can greatly affect a patient's cancer treatment. During acute hospitalization, alcohol withdrawal may commence on the second or third day and elicit a psychiatric consultation for anxiety, poor coping, or postoperative delirium. Thoracic and head and neck cancer patients are at high risk for this and for nicotine withdrawal, given their high incidence of smoking. The symptoms of nicotine withdrawal include anxiety, irritability, and insomnia. Transdermal nicotine patches are commonly used to ease the distress of patients forced to stop smoking suddenly. A clinician must be mindful that cigarette smoke includes polycyclic aromatic hydrocarbons that contribute to the induction of several cytochrome P450 enzymes (specifically CYP1A1, CYP1A2, and CYP2E1) and induction of glucuronidation of some drugs. Abrupt cessation of smoking can affect medication levels; this effect is independent of nicotine and not countered with nicotine patches.

Managing cancer pain in addicted patients requires a multidisciplinary approach with the involvement of a psychiatrist, a palliative care physician, social workers, and nurses. The psychiatrist should manage psychiatric comorbidities and the countertransference of the team. It is also important to set limits to control harm with substantial emotional support. Pain management in addicted cancer patients is challenging and should be focused on the level of pain, with attention to the addiction. In treating patients with past or current opioid use disorders, the clinician must be mindful of the effect of tolerance and opioid-induced hyperesthesia, in which cases the patient will require higher doses for pain control. Patients will benefit from long-acting opioids such as methadone (Dolophine) and by limiting the use of short-acting or breakthrough doses. Furthermore, adjuvant medications such as SNRIs or antiepileptics may be helpful. Scheduled urine toxicology screens

with clear consequences and contingency plans are used to monitor patients' illicit drug usage.

Somatoform Disorders

The prevalence of somatoform disorders in cancer patients is unknown. The development of cancer in patients with a somatoform disorder can create difficult diagnostic problems because patients may incorporate the presenting signs and symptoms of cancer into their psychiatric disorder–associated illness behaviors. This results in complex syndromes with both oncologic and psychogenic components. Physicians may feel manipulated and frustrated by these presentations, which may lead to delays in treatment or suboptimal care through over- or under-treatment. A psychiatric evaluation and collaborative effort may allow the psychiatrist to work with the oncology staff to treat the patient appropriately through clarification of presentation, addressing psychiatric comorbidity, and setting limits on maladaptive behaviors.

PSYCHIATRIC SYNDROMES AND TUMOR SITE

CNS Cancers

Brain tumors are classified as primary or metastatic tumors. Brain metastases occur up to 10 times more frequently than primary brain tumors. Seventy percent of brain tumors are supratentorial. Primary brain and CNS tumors are relatively uncommon, accounting for approximately 23,380 (1.4%) new cancer diagnoses and 14,320 (2.4%) cancer-related deaths annually. Meningiomas, which are usually nonmalignant, are the most common tumor type. Glioblastomas are the most common primary malignant brain tumors, accounting for approximately 16% of all new primary brain tumors and 45% of primary malignant brain tumors. Unfortunately, they are generally associated with dismal prognoses, with 5-year survival rates of <5%.

Psychiatric symptoms of brain tumors are influenced by their anatomic location, interconnection of different areas of the brain, rate

of tumor growth, premorbid level of functioning, tumor type, and increased intracranial pressure. Psychiatric symptoms are present in almost all patients with supratentorial tumors and are the presenting symptom in 25% of the patients. Frontal lobe tumors are associated with behavioral symptoms in 90% of patients. Mood symptoms can include anxiety, irritability, depression, apathy, and euphoria. There have been reported changes in personality in 70% of patients. These changes include irresponsibility, disinhibition, and inappropriate sexual behavior. Psychotic symptoms, including delusions and hallucinations, have been reported in 10% of patients. Bifrontal disease typically causes impairment of memory, lability of mood, urinary incontinence, and frank dementia, with prominent grasp, suck, and snout reflexes. Psychotic symptoms are common in patients with tumors of the temporal lobe and pituitary gland. Tumors affecting the temporal lobe can present with auditory and olfactory hallucinations as well as abnormal behavior (apathy, irritability, expansive mood with mania or hypomania). Nondominant temporal lobe tumors can cause minor perceptual problems and spatial disorientation. Dominant temporal lobe tumors can present with an impaired perception of verbal commands and sensory aphasia. Parietal lobe tumors affect sensory and perceptual functions more than motor modalities. Tumors in either parietal lobe can produce sensory disorders ranging from mild sensory extinction or astereognosis to a more severe sensory loss such as hemianesthesia. Poor proprioception in the affected limb is common. Homonymous inferior quadrantanopsia, incongruent hemianopsia, or visual inattention also may occur. Nondominant parietal lobe tumors cause contralateral neglect and, in severe cases, anosognosia and apraxia. Dominant parietal lobe tumors lead to alexia, dysgraphia, and certain types of apraxia. Occipital lobe tumors can produce contralateral homonymous hemianopsia or complex visual aberrations affecting the perception of color, object size, or location. Bilateral occipital disease, rarely seen at presentation, can produce cortical blindness.

Delirium is a common psychiatric complication in patients with CNS tumors. The main causes of delirium in this population are CNS

insults, medications (corticosteroids), and metabolic changes. Dementia and other cognitive impairment are also symptoms and complications of the treatment of CNS tumors.

Management of Psychiatric Symptoms in Patients with Brain Tumors. Brain tumor patients will benefit from psychopharmacological, psychotherapeutic, and psychosocial interventions. The psychiatrist should work closely with the medical and surgical team to help patients function and improve their quality of life.

The data that support the pharmacologic treatment of patients with psychiatric symptoms come from clinical experience and case reports. Medications must be initiated at low doses due to frequent brain insults caused by the cancer and its treatment. Antipsychotics are indicated for treating delirium, anxiety, and mood disorders. The psychiatrist should be cognizant of several side effects in this population. Antipsychotics can lower the seizure threshold. Antipsychotics such as clozapine (Clozaril) and chlorpromazine have the greatest potential to lower seizure threshold; thus, they should be avoided. High-potency antipsychotics are indicated if sedation is not desired. Atypical antipsychotics should also be considered in treating psychotic and mood symptoms.

Psychostimulants such as methylphenidate and modafinil can improve attention, mood, and cognitive function. These medications should also be started at low doses and be used with caution due to the potential of causing hallucinations and decreasing the seizure threshold.

Antidepressant medications are effective in treating depression and anxiety. The SSRIs are frequently used due to their low anticholinergic activity compared to TCAs. Benzodiazepines for treating anxiety symptoms can induce disinhibition and delirium in patients with brain tumors.

Mood lability can be treated with lithium, carbamazepine (Tegretol), valproic acid (Depakene), and atypical antipsychotics.

Head and Neck Cancers

Head and neck cancers account for almost 3% of all cancer diagnoses. Head and neck cancers are diagnosed almost twice as often in men as in women. Time of diagnosis is more often after age 50, except for salivary gland and nasopharyngeal tumors, which may occur in younger age groups. Cigarette smokers have an increased risk for multiple head and neck primary cancers as well as lung cancer. Alcohol use has also been implicated as a causative factor for certain head and neck cancers, and the effects of alcohol and tobacco use seem to be additive. Infection with some types of human papillomavirus (HPV), particularly HPV-16, is a risk factor for head and neck cancers, especially oropharyngeal cancers that involve the base of the tongue and tonsils. In the United States, the incidence of oropharyngeal cancer associated with HPV infection is increasing. Patients with head and neck cancers have an increased risk of developing esophageal and lung cancers.

Surgery and radiation therapy are necessary to induce a cure. Chemotherapy and other systemic treatments (e.g., immunotherapy) are useful in the (neo)adjuvant setting or along with radiation, but when used alone, systemic treatments are not curative. Most head and neck cancers present with early or locally advanced disease that can be treated for cure. But the treatments are quite long and intense generally.

The diagnosis of head and neck cancer brings many psychosocial challenges. Patients are confronted with fears of death, pain, and loss. Patients also are concerned with disfigurement and disability from cancer treatment. In anticipation of surgery, patients experience distress and anxiety. An incidence of adjustment disorders as high as 36% to 50% has been reported. Recent studies have also demonstrated prevalence rates of clinically significant depression diagnosed by various self-reporting and structured interview techniques of between 17% and 30%, specifically in head and neck cancer patients. Both pharmacologic and psychological interventions are effective in treating depression in these patients.

Another challenge is managing the sensitivity to the stigma associated with HPV-positive oropharyngeal cancers as a sexually transmitted disease. Established risk factors for developing HPV-

positive oropharyngeal cancers include having greater than six lifetime oral sex partners, concurrent anogenital squamous cell carcinoma, and HIV infection. Furthermore, husbands of women with cervical cancer are at a threefold increased risk of HPV-positive oropharyngeal cancer. Psychotherapy may focus on addressing the perceived shame of the transmission method.

In a suicide study among cancer patients, unmarried men with head and neck cancers were found to have the highest incidence of suicide. Other risks factors for suicide are personality disorders, alcoholism, and treatment sequelae such as facial disfigurement. Postoperative patients are at risk of developing delirium due to alcohol withdrawal, metabolic disturbances, and other medical complications. Extensive reconstructive operations affect swallowing physiology, leading to aspiration events and situational anxiety.

GI Cancer

Newly diagnosed cancers of the oral cavity, pharynx, and digestive system account for 21% of total cancer incidence and 25% of total cancer mortality in the United States.

Patients who suffer from GI tumors must adjust to several psychosocial changes. Patients have to deal with severe eating-related problems, weight loss, abdominal discomfort, diarrhea or constipation, as well as other disease-related issues such as ostomy and repeated operations.

The psychological issues in patients with colorectal cancer are related to the cancer itself and the impact of treatment of bowel function in relation to social and sexual activity. Patients who require ostomies may interpret this procedure as a significant loss. Different strategies have been recommended to patients with ostomies at different phases of recovery. Patients may feel anxious, hopeless, and helpless when an ostomy is recommended. It is important to involve the family and provide adequate teaching of ostomy procedural management and troubleshooting to minimize distress. Patients may experience shame, low self-esteem, anxiety, or sexual undesirability following their operation. Community ostomy support

groups can provide guidance and counseling to patients and their families.

Surgical procedures involving the pelvic area may lead to sexual dysfunction through the removal of the posterior wall of the vagina, weakening of muscles of the pelvic floor, or damage to the pudendal and associated nerves. Determining the etiology of sexual dysfunction is challenging but dictates the potential treatments.

Lung Cancer

Lung cancer is the leading cause of cancer mortality in men and women in the United States, accounting for an estimated 154,050 deaths in 2018. Lung cancer accounts for 20% of all cancer deaths worldwide. In the United States, lung cancer is the leading cause of cancer-related death and exceeds deaths from breast, colon, and prostate cancers combined. Although lung cancer is increasingly more common in patients who have never smoked (especially for females), tobacco use is still associated with approximately 85% of lung cancer prevalence and is the primary risk factor for lung cancer. The overall 5-year survival for lung cancer is approximately 18% despite offering many new targeted and immunologically based treatments. Since the 5-year overall survival for localized lung cancer is 56%, the major reason for poor survival is the lack of early detection. Low-dose CT scans are now offered for patients with a significant smoking history (over 20 pack-years), but not enough patients receive screening. The most common histologic type of cancer is non–small cell (NSCLC), followed by small cell lung cancer (SCLC), which accounts for about 15% of all lung cancers.

Patients with lung cancer experience high levels of emotional distress following diagnosis and persistently through treatment. Disease-related symptoms such as pain, fatigue, and dyspnea are detrimental to the emotional well-being of patients. Studies of distress in patients with lung cancer reveal significant problems in the areas of emotional functioning, family relationships, and lack of information about the diagnosis, physical functioning, and cognitive functioning. In a study that included 987 patients, the prevalence of

depression in lung cancer patients was found to be as high as 33%, and in half of those, the depression persisted at the first follow-up visit, 14 to 35 days after beginning chemotherapy for SCLC and 21 to 56 days after starting radiotherapy for NSCLC. An epidemiologic study by Sullivan and colleagues found that depressed lung cancer patients had inferior survival outcomes when compared to nondepressed patients with lung cancer. However, the survival disadvantage was only observed in patients who were persistently depressed on follow-up. Survival returned to baseline (nondepressed) levels for patients whose depression had remitted on follow-up. This longitudinal study not only demonstrates the importance of identifying and treating depression but demonstrates longitudinal variability based on depression status.

Given the overwhelming physical and emotional symptom burden for patients with lung cancer, cognitive disorders are also highly prevalent in patients with lung cancer, especially SCLC. These disorders may be related to brain metastases or other comorbidities and complications of the illness and its treatment. Paraneoplastic syndromes, brain radiation, and chemotherapy have been associated with cognitive impairment. Depression can also lead to cognitive impairment, and patients should be screened and treated for this condition.

Smoking is common in lung cancer patients, and some studies show that smoking cessation at the time of diagnosis of lung cancer may reduce the rate of development of tumors. In other words, patients who continue to smoke once diagnosed with lung cancer have inferior survival. Also, the relative risk of a second lung cancer developing following curative intent therapy of SCLC was lower for those who stopped smoking. Although the incidence of lung cancer never returns to exactly never smoker lung cancer incident, it begins to approximate it by about 15 years of smoking cessation. Active and recently quit smokers should be offered intensive tobacco cessation programs, including counseling, behavioral therapy, use of sustained-release bupropion and nicotine replacement, and telephone follow-up, to increase successful abstinence. Smoking cessation should be an active part of lung cancer treatment.

Genitourinary Cancers

Prostate Cancer. Prostate cancer is one of the leading causes of cancer death among men in the United States and is the most common cancer in men. Prostate cancer screening is a controversial issue, with many arguing that digital rectal examination (DRE) and PSA may lead to unnecessary and possibly harmful consequences. A mortality benefit has not been established from DRE or PSA screening. The U.S. Preventive Services Task Force and the Centers for Disease Control and Prevention recommend against the PSA. The American Society of Clinical Oncology and the American College of Physicians discourage screening in those expected to live less than 15 years and recommend others decide after weighing their potential risks and benefits. Treatment options for prostate cancer are surgery and external beam radiation or radioactive seed implants (brachytherapy). Hormonal therapy, chemotherapy, and radiation are offered for metastatic disease and as supplemental therapies for early-stage disease.

Men who have undergone curative-intent treatment with hormonal therapy plus radiation or surgery may experience mood liability associated with antihormonal therapies as well psychological issues regarding the risk and reality of impotence. A large component of therapy with men with prostate cancer is learning to adjust to this chronic disease state and find meaning and fulfillment outside these areas.

Testicular Cancer. Testicular cancer comprises a morphologically and clinically diverse group of neoplasms, most of which are germ cell tumors (GCTs) and are the most common solid tumors in men between the ages of 15 and 35 years. The pathognomonic presentation of a primary testicular tumor is a painless testicular mass that may range in size from a few millimeters to several centimeters. A radical inguinal orchiectomy minimizes local tumor recurrence and aberrant lymphatic spread. It is the only acceptable therapeutic and diagnostic procedure. GCT is classified into two major subgroups, seminomas and nonseminomas. Treatment for an

early stage of seminomatous tumors is orchiectomy and radiation therapy. For moderate and advanced disease, the treatment is combined radiation and chemotherapy. Nonseminomatous tumors are treated with orchiectomy and combined chemotherapy for more advanced disease.

Bladder Cancer. Bladder cancer is two and a half times more common in males than in females and more common in whites than in blacks. Approximately 53,000 new cases occur per year in the United States, which is a 20% increase from 20 years ago. The incidence increases with age and peaks in the sixth and seventh decades of life. More than half of men and one-third of women with bladder cancer have a history of smoking cigarettes. The clinical stage of the primary tumor is determined by transurethral resection of the bladder tumor (TURBT). Surgery, alone or in combination with other treatments, is used in more than 90% of cases. Superficial, localized cancers may also be treated by chemotherapy or immunotherapy directly into the bladder. Chemotherapy alone or with radiation before cystectomy has improved some treatment results.

Kidney Cancer. Each year in the United States, there are approximately 31,900 cases of kidney and upper urinary tract cancers, resulting in more than 11,900 deaths. Renal carcinoma may remain clinically occult for most of its course. Approximately 30% of patients with renal carcinoma present with metastatic disease, 25% with locally advanced renal carcinoma, and 45% with localized disease. Surgery is the only known effective therapy for localized renal carcinoma. Adjuvant or palliative nephrectomy is frequently performed in patients with metastatic renal carcinoma. Many new targeted and immunotherapies are being offered to patients with localized and metastatic kidney cancer.

Management of Psychological Issues in Patients with Genitourinary Cancers. The causes of psychological distress in men with genitourinary cancers are related to the diagnosis of cancer, treatment options, potential sexual dysfunction, urinary

incontinence, fatigue, weakness, pain, and other side effects from cancer and its treatment. Patients in this population have difficulties coping with changes in sexuality, relationships, and lifestyle. Management of these psychological issues includes education, psychotherapy, couple and family therapy, behavioral interventions, and medications.

GCTs, bladder cancer, and kidney cancers are some of the most common primary cancer sites that can spread to the brain. Metastasis must be on the clinician's differential diagnosis if a patient with one of these cancers presents with delirium or altered mood, personality, or behavior. Genitourinary cancer survivor men may be left feeling an insult to their well-being and identification with their gender. They may also have psychological decompensation related to their physical symptom burden.

Breast Cancer

Breast cancer ranks second among cancer deaths in women. Breast cancer accounts for about a third of all new cancer cases in the United States. Death rates have declined by an average of 2.3% per year since the 1990s in all women, with larger decreases in younger (less than 50 years) women. Risk factors for breast cancer include age, inherited genetic mutations (*BRCA1* and *BRCA2*), personal or family history of breast cancer, high breast tissue density, and radiation to the chest. Reproductive factors include a long menstrual history, use of oral contraceptives, never having children, and having a first child after age 30. Other factors are obesity, postmenopausal hormone therapy, physical inactivity, and consumption of one or more alcoholic beverages per day. Treatment of breast cancer involves lumpectomy or mastectomy with removal of axillary lymph nodes, radiation therapy, chemotherapy, or hormone therapy such as aromatase inhibitors. These treatments are often used in combination. Breast cancer has a complex psychological impact on women. Three factors have been reported to contribute to this psychological impact: the sociocultural context in which treatment options are offered, the psychosocial and psychological factors, and

the medical factors. Breast cancer also has an impact on lifestyle due to physical discomfort, marital or sexual disruption, and disturbed body image. Women with breast cancer are likely to suffer from anxiety and depression. Prevalence of depression among early breast cancer women occurs twice as often as in the general female population, especially during the first year after diagnosis. In a study that included 4,496, the prevalence of depression among patients with breast cancer was estimated to be around 52.65%. Management of psychological distress includes providing patients with the skills to cope with their illness and to improve their quality of life. Antidepressant medications and psychotherapy are the gold standard treatments for mood and anxiety disorders in women with breast cancer. Antidepressants are also beneficial in the treatment of hot flashes in breast cancer. Approximately two-thirds of women with a history of breast cancer experience hot flashes due to cytotoxic or hormonal therapies that can cause premature menopause.

The current pathophysiologic hypothesis for hot flashes is the dysfunction of hypothalamic thermoregulatory processes due to low estrogen levels. Norepinephrine and serotonin are the two most recognized neurotransmitters involved in hypothalamic thermoregulation. In a study that included breast cancer survivors and menopausal women, each group was assigned to receive one of three different dose levels of venlafaxine (37.5 mg, 75 mg, and 150 mg daily) or placebo for 4 weeks. A dose-related diminution in average hot flash scores from baseline was noted (27% in the placebo group versus 37%, 61%, and 61% for the three venlafaxine groups, respectively).

Consideration should be given to potential drug interactions, including the potential for an antidepressant to affect hepatic metabolism of cancer drugs via cytochrome p450 enzyme induction or inhibition in all cancer patients. In breast cancer patients, tamoxifen has been widely studied in this context because of early reports that indicated an association between antidepressants with strong 2D6 inhibition (such as fluoxetine and paroxetine) and reduced efficacy of tamoxifen in maintaining remission in breast cancer. While several studies have confirmed that antidepressant

drugs that have strong 2D6 inhibition can reduce the conversion of tamoxifen to its active metabolite, more recent studies indicate that this effect does not appear to have an impact on breast cancer recurrence rates or survival. However, until further research resolves the debate, it remains prudent to avoid potent CYP2D6 inhibitors in preference for antidepressant options that have weak 2D6 inhibition (such as venlafaxine or citalopram).

Gynecologic Cancers

The group of gynecologic cancers includes those of the ovary, fallopian tube, uterine corpus, cervix, vagina, and vulva. Cancer of the endometrium is the most common gynecologic cancer. Ovarian cancer has the highest mortality of gynecologic cancers. Over the last 30 years, the cervical cancer death rate has gone down by more than 50% due to increased use of the Pap test. Furthermore, the HPV vaccine will continue to decrease the number of women affected by the cancer-causing pathogen. Vaginal and vulvar cancers are less common. They are often detected earlier and thus more responsive to treatment. Women may sometimes delay seeking evaluation because the symptoms are mild or are attributed to other problems. For instance, abdominal bloating may be mistaken for premenstrual syndrome.

Treatment for these cancers includes surgery, chemotherapy, and/or radiation. The cancer and its treatment have significant impacts on hormones, sexuality, fertility, and bladder and bowel function, causing psychological distress.

Hematologic Malignancies

Hematologic malignancies are associated with significant psychosocial distress in many patients, particularly those undergoing stem cell transplantation. Leukemia, lymphoma, and multiple myeloma (MM) account for approximately 9% of all cancers, with an estimated annual combined incidence in the United States of about 150,000. Blood dyscrasias can occur during childhood or early adulthood, thus impacting patients during a normally productive and

active time in their lives. Complicated treatment regimens with intensive, multicomponent protocols have greatly increased cure rates and have prolonged survival.

Distress is common before, during, and after treatment for hematologic malignancies and occurs along a continuum of severity that is elevated compared to the general population. Adjustment, mood, and anxiety disorders are particularly common. Individuals undergoing HSCT encounter major disruptions to social, family, and work life. They are separated from supports during transplant or chemotherapy induction and hospitalization. Challenges prior to allogeneic transplant may emerge as a result of stem cell donor selection, family stressors, and financial, housing, and other practical concerns. Patients are more vulnerable to distress during periods when prognosis or treatment course change (e.g., graft failure), severe adverse effects develop (e.g., GVHD), rehospitalization occurs, or changes occur to clinician follow-up (e.g., discharge from transplant center). Periods of immunologic compromise limit social contact, even after discharge. Illness-associated stigma and job loss can occur. Patients who have psychiatric issues such as anxiety or depression are at risk for poorer health outcomes, longer hospital lengths of stay, and higher mortality. Insomnia, delirium, fatigue, depression, and anxiety are common psychiatric symptoms and syndromes encountered during the treatment course. Survivors commonly experience PTSD, depression, anxiety, and cognitive impairment long after treatment completion. Psychosocial support is an essential component of the treatment of patients with hematologic malignancies at all stages of illness.

Paraneoplastic Syndromes

The term *paraneoplastic* refers to a group of disorders defined as indirect, remote, nonmetastatic effects of cancer. In 50% of the cases, symptoms precede the diagnosis of cancer and run an independent course. The syndromes may be due to (1) production of substances by the tumor that directly or indirectly cause distant symptoms, (2) depletion of normal substances that lead to a

paraneoplastic manifestation, or (3) host response to the tumor that results in the syndrome.

Paraneoplastic Neurologic Disorders. Any part of the CNS and peripheral nervous system can be affected. Most paraneoplastic neurologic disorders begin acutely or subacutely, progress over weeks to months, and then stabilize. Many of these disorders are associated with serum and cerebrospinal fluid antibodies formed against antigens that are also expressed within the tumor. Dementia, particularly memory loss (amnesia), is a common feature in several variants, which are grouped under the name *carcinomatous encephalomyelitis*. Most of these patients have SCLC and anti-Hu antibodies.

Limbic encephalitis is another paraneoplastic syndrome that usually presents with abrupt changes in mood, personality and with severe impairment in recent memory. Patients may appear agitated or confused and may experience hallucinations as part of complex partial seizures. The neoplasms associated with limbic encephalitis include testicular cancer, SCLC, thymoma, breast cancer, and Hodgkin lymphoma. The antibodies associated with limbic encephalitis are anti-Hu, anti-Ma2, CRMP5, and amphiphysin.

Opsoclonus-myoclonus ataxia syndrome consists of uncontrolled arrhythmic eye movements. It is also associated with diffuse or focal myoclonus, truncal titubation with or without ataxia, or other cerebellar signs. Ataxia, irritability, insomnia, and dementia often accompany the opsoclonus. The incidence of this disorder is less than 2%. In adults, it occurs in the presence of breast, gynecologic, or other types of cancers. In children, it can be due to neuroblastomas or viral infections. It is associated with anti-Ri antibody. Paraneoplastic syndromes that affect the motor neurons can also present with psychiatric symptoms in patients with degeneration of cortical neurons, resulting in frontotemporal dementias.

Neuromyotonia consists of several disorders that affect the neuromuscular junction. These include neuromyotonia, the cramp fasciculation syndrome, and Morvan syndrome. The disorder is

autoimmune and affects voltage-gated potassium channels. Morvan syndrome consists of memory loss, insomnia, changes in mood, and hallucinations. These disorders are associated with thymoma, SCLC, and Hodgkin lymphoma.

The treatment for paraneoplastic syndromes consists of treating the underlying tumor and suppression of the immune response using corticosteroids, plasma exchange, and intravenous immunoglobulin.

Metabolic and Endocrine Paraneoplastic Syndromes. Production of cytokines, hormones, or hormone precursors by the tumor may result in the development of endocrine syndromes in cancer patients. Tumors of endocrine glands may be physiologically active and produce anxiety, mood disorders, confusional states, and psychosis. In addition, glucocorticoid steroid medications are frequently used for almost all cancer as part of therapeutic regimens to reduce inflammation or as prophylactic antiemetic agents. These frequently cause insomnia, irritability, and depression.

Hypercortisolism (Cushing syndrome) can be caused by a pituitary adenoma, hypothalamic tumors, ectopic adrenocorticotropic hormone (ACTH) syndrome, and exogenous corticosteroids. Hypercortisolism presents with mood instability, depression, insomnia, fatigue, cognitive deficits, psychosis, and delirium.

A syndrome of inappropriate antidiuretic hormone secretion can be associated with SCLC, cerebral metastases, medications, and infections. This syndrome results in hyponatremia; the severity of the symptoms depends on the sodium level and the rate of drop in sodium levels. Patients can present with symptoms of nausea, vomiting, lethargy, stupor, delirium, cognitive impairment, seizures, agitation, focal neurologic deficits, and coma.

Carcinoid tumors cause anxiety, depression, and delirium. Carcinoma of the pancreas has been reported to be associated with an elevated incidence of depression, sometimes as the presenting symptom. Metabolic disturbances, including hypoglycemia, hyperglycemia, hypophosphatemia, and hypomagnesemia due to different types of cancers and can cause delirium, mood disturbances, and anxiety.

PSYCHIATRIC PROBLEMS DUE TO CANCER TREATMENT

Radiation and most of the drugs used in cancer treatment have significant side effects and are even carcinogenic in tumoricidal doses. Patients may become transiently more ill from the treatment than from the disease and develop side effects such as hair loss, all of which have a great emotional impact. Steady compliance requires a level of courage and endurance of which the medical staff is not fully aware. Patients may become upset about the side effects, convinced that they represent disease progression, depressed about the paradoxical nature of the treatment, and exhausted to the point at which they develop clinical depression and anxiety. If untreated, they delay or stop cancer treatment, moving to alternative treatments and jeopardizing their survival. Later adaptation is also impaired. Many patients, however, come to feel dependent on continued treatment as a means of holding the cancer at bay. There is a rise in anxiety level at the end of treatment associated with this fear and with the difficulty of making a transition to the survivor status. This can be assuaged by acknowledging it, exploring its cause, and making concrete plans for continued medical supervision and psychological support.

Radiation Therapy

About half of all the patients with cancer are treated with radiation therapy, either alone or in combination with other types of cancer treatment. Radiation therapy may be external or internal and may be curative or palliative. External radiation comes from a machine outside the body and is usually given on an outpatient basis. Internal radiation is implanted into or near the tumor in small capsules or containers. It may require a hospital stay. If the patient will have external radiation, the radiation oncologist uses a process called simulation to define where to aim the radiation. During simulation, the patient lies still on an examining table while the radiation therapist uses a special x-ray machine to define the treatment port or

field. Simulation may also involve imaging studies (CT scans) to help the radiation therapist plan on how to direct the radiation. Patients with anxiety disorders, claustrophobia, or pain have difficulties with simulation and radiation treatment. The early effects of radiation may be seen a few days or weeks after treatments have started and may continue for several weeks after treatments are completed. Late effects may not be seen until months, or even years, later. Side effects depend on the site, dose, and size of the radiation fields and the duration of treatment. The skin may be red, tender, and sensitive during the first 2 weeks. Dryness and peeling may occur in 3 to 4 weeks. Patients may suffer from fatigue, sore throat, and anorexia. Patients who receive total body irradiation are at the greatest risk for having nausea. Without effective prophylaxis or treatment, more than 90% will experience nausea and vomiting acutely. Affected patients may suffer from various adverse complications, including dehydration, electrolyte disturbances, malnutrition, and aspiration pneumonia. Treatment of nausea includes adequate nutritional support and hydration. Medications to treat nausea include treatment with 5-HT_3 receptor antagonists (5-HTRAs) with or without corticosteroids, dopamine antagonists, antihistamines, or anticholinergics. Sexual impairment is common after radiation to the pelvic area, in the form of impotence in men and dyspareunia in women. The latter, related to vaginal fibrosis, is improved by vaginal dilatation. Acute, transient GI problems, such as diarrhea and food intolerance, are common; severe, irreversible GI problems are rare. Fatigue is reported in 80% of patients and is sometimes the most debilitating and demoralizing. It overlaps with symptoms of depression but exists independently of it. The normal response to brain radiation has been divided into three phases based on the time of initiation of symptoms. Acute effects occur during the first weeks of treatment. Symptoms include headache, drowsiness, nausea, vomiting, and worsening of pre-existing focal symptoms. Treatment with dexamethasone usually relieves symptoms. Early delayed or subacute encephalopathy appears at 1 to 6 months after completion of radiation therapy with headache, somnolence, fatigue, and

deterioration of previous deficits. Subacute encephalopathy is caused by demyelination. It responds to steroids and is usually self-limited. The third is an irreversible late, delayed (months to years) form that is localized to the white matter and is probably secondary to vascular injury, demyelination, and necrosis. Late effects are also known as focal radiation necrosis, diffuse white matter injury, and combined therapy leukoencephalopathy. Symptoms of focal radiation necrosis include seizures, signs of increased intracranial pressure, and symptoms of localized lesions. Symptoms of diffuse white matter changes vary from lassitude to significant memory loss to severe dementia. Symptoms of combined therapy leukoencephalopathy include ataxia, confusion, dysarthria, seizures, dementia, or death. In long-term survivors (mainly from Hodgkin lymphoma and childhood leukemias) who have undergone whole brain radiation, a short-term memory deficit has been observed, as well as a decrease in intelligence quotient (IQ) of 10 to 25 points. Even in the presence of a normal IQ, neuropsychological problems and learning disabilities have been documented. The older adults and the young are the most affected.

Chemotherapy

Nausea and Vomiting. The immediate effects of chemotherapy include nausea and vomiting, which occur within 2 to 6 hours of treatment and may last up to 24 hours. The most emetogenic drugs cause symptoms in virtually all patients; the less emetogenic ones are variable. Some result in delayed vomiting, usually 8 to 24 hours after treatment. Chemotherapeutic agents and radiation cause vomiting by different mechanisms. Chemotherapy stimulates the chemoreceptor trigger zone directly, which is functionally outside the blood–brain barrier. This area, when exposed to toxins in the bloodstream and cerebrospinal fluid, can stimulate vomiting. This effect is mediated by 5-HT_3 and neurokinin type 1 receptors. Chemotherapy damages the GI mucosa and causes the release of neurotransmitters, including 5-HT_3, stimulating peripheral pathways via splanchnic and vagal nerves. It has also been reported that there

is a neurohormonal component mediated by arginine vasopressin and prostaglandins.

Classical conditioning has been shown to be an important mechanism in the causation of several reactions to chemotherapy: ANV, which had been documented in 25% to 75% of patients before the use of better antiemetics; anticipatory immune suppression (AIS), the clinical significance of which has not been established; and learned food aversions (LFAs), which can be minimized by avoidance of staples and favorites. Patients develop a conditioned response to sights and smells reminiscent of the chemotherapy experience. After termination of treatment, these symptoms decrease; however, one study found that 6 to 14 months after treatment, 63% of patients still reported nausea, 5% reported vomiting, and 80% still reported anxiety with specific stimuli.

These reactions are presumed to represent conditioned responses, and treatment approaches have been formulated accordingly. Prophylactic antiemetic and antianxiety treatments are used to prevent or decrease the initial episode or conditioned response and have greatly minimized what used to be a dreaded side effect. With the advent of highly specific, centrally acting antiemetic agents, such as the 5-HT_3 receptor blockers, ondansetron (Zofran), and granisetron (Kytril), the success of antiemetic regimens has greatly increased, and new ones with different mechanisms continue to appear. The evidence support that these agents are effective in chemo- and radiation-induced nausea and postoperative nausea. Other medications that are indicated for the treatment of nausea are dopamine 2 (D_2) receptor antagonists that block the chemoreceptor trigger zone. The literature has shown that for the most common etiologies of nausea and vomiting at the end of life, 5-HT_3 antagonists are no more effective than the less expensive D_2 antagonists. Tardive dyskinesia is rare due to the short-term use of these medications. Akathisia occurs in 10% to 20% of patients on metoclopramide, but the coincident use of lorazepam lowers the incidence to less than 3%. Mild sedation is acceptable or even welcome. Hypotension may limit the use of prochlorperazine

(Compazine) and chlorpromazine. Since some of the nausea is also anxiety-related, benzodiazepines are effective in preventing anticipatory nausea. In an open-label trial, mirtazapine, a potent antagonist of 5-HT_2 and 5-HT_3 receptors, was found to decrease nausea. The commercially available cannabinoids, nabilone (Cesamet) and dronabinol (Marinol), target ubiquitous cannabinoid (CB) receptors in the central (CB1) and peripheral (CB1 and CB2) nervous systems. Dronabinol is no more effective than other drugs and has a similar side-effect profile, plus a significant incidence of dysphoric reactions in older patients. Corticosteroids, such as dexamethasone, are generally included in most antiemetic regimens for their potential effect on tumor-associated inflammation.

Behavioral methods are important, effective ways to lessen the reactions to chemotherapy. They are most effective when instituted before the conditioned response is established. They include hypnosis and progressive muscular relaxation with guided imagery or relaxation with cognitive distraction to block the conditioned stimulus and the conditioned response; systemic desensitization, which extinguishes the conditioned response; and cognitive distraction, which blocks perception of the conditioned stimulus. Patients are also helped by reassurance about the frequency and normalcy of their responses.

CNS Toxicity. Chemotherapeutic agents may cause neuropsychiatric problems in one of the following ways: Indirectly by causing metabolic abnormalities or other organ failure and directly by causing CNS toxicity. The CNS, comprised of the brain and spinal cord, is responsible for the neurologic functions of mental status, level of consciousness, sensory and motor functions, and cerebellar and cranial nerve functions. The blood–brain barrier determines whether a cytotoxic agent can reach the nervous system. Chemotherapeutic agents that can penetrate the blood–brain barrier can alter the cranial nerves and cognitive, cerebellar, motor, and sensory functions. Patients themselves are keenly aware of the cognitive impairment and talk to each other about the so-called *chemo-brain* in the waiting room and on the Internet.

Initially, mood changes, personality changes, and subtle cognitive changes may predominate, leading to psychiatric consultation. Only later does the encephalopathic nature of the condition becomes manifest. Since the mid-1970s, cross-sectional and longitudinal studies have found an association between chemotherapy and cognitive changes. Cognitive functioning is objectively assessed by performing a battery of neuropsychological tests that allow comparison to a control group or normative data. The research data have shown that there is a discrepancy between objective measures of cognitive impairment and the patients' self-report of their cognitive functioning. Patients' perception of the dysfunction appears to be more deteriorated than what is detected by the objective evaluation and is associated with anxiety or depression. This discrepancy between patients' self-report and objective measures of cognitive function might be due to the inability of the neuropsychological tests to evaluate cognitive functioning in real-life situations and the fact they are performed under optimal conditions. Another explanation for the discrepancy is that patients tend to attribute their premorbid cognitive impairment to cancer or to depression or anxiety. It is imperative to evaluate premorbid cognitive functioning that serves as a parameter for comparison with cognitive impairment posttreatment. Although acute cognitive changes during chemotherapy are common, studies in survivors have shown long-term posttreatment cognitive changes in 17% to 34% of patients. The cognitive changes occur in different areas of cognition, including working memory, attention/concentration, executive function, and information processing speed. The cognitive functioning is reduced but often remains in the normal range.

Studies that have used imaging techniques have shown a reduction in the volume of brain structures. Changes in the integrity of white matter tracks that connect brain structures have been implicated in decreased cognitive functioning.

Possible mechanisms by which chemotherapy can cause cognitive deterioration include direct neurotoxic effects, oxidative damage, immune dysregulation with the release of cytokines, decreased delivery of oxygen secondary to anemia and blood clotting, and

hormonal changes. Genetic predisposition with a variability of genes that regulate neural repair or plasticity, such apolipoprotein E (APO E) and BDNF, may increase patients' vulnerability to chemotherapy-induced cognitive side effects. Certain drugs, such as the vinca alkaloids, especially vincristine, cause neurotoxicity at all doses; others, such as cisplatin, cause neurotoxicity only at higher doses. In some drugs, toxicity is mild and transient; in others, it is delayed, irreversible, or both. Toxicity is also usually, but not always, dose-related and cumulative. Certain drugs, such as methotrexate, when given intrathecally, may cause several CNS side effects, such as reversible encephalopathy, delayed irreversible encephalopathy, dementia, or developmental delay when coadministered with radiation therapy. Several studies have found an association between cognitive impairment and the number of cycles and higher doses of chemotherapy. A chemotherapy regimen that consists of methotrexate, cyclophosphamide (Cytoxan), and 5-fluorouracil (Adrucil) appears to be highly associated with cognitive impairment.

Several treatment interventions have been initiated and evaluated with methylphenidate, erythropoietin, Ginkgo biloba, and cholinesterase inhibitors, but the data are inconclusive, and further research is needed. Large longitudinal studies are needed to evaluate the duration of cognitive impairment, which remains uncertain (Table 27.8–8).

Table 27.8–9 lists agents that predominantly cause mood or psychotic symptoms. These chemotherapy agents and many more antineoplastic agents can cause delirium. Delirium due to chemotherapy agents is often reversible and remits spontaneously if the drug is stopped. This may take only a few days or up to several weeks. If the offending drug cannot be discontinued, symptomatic treatment should be instituted.

Disorders of special senses include ototoxicity, associated with cisplatin and several commonly used antibiotics; visual disturbances, associated with mitotane (Lysodren) and tamoxifen; gustatory and olfactory hallucinations, described with vinblastine. These disorders may occur slowly or suddenly and reversibly or permanently and often result in acute psychological distress requiring psychiatric

consultation. Long-term effects of ototoxicity add considerably to the educational and neuropsychiatric impairment of these patients. The diagnosis is often missed in younger children, in whom early intervention is essential to minimize later developmental impairment.

Ifosfamide is a highly active chemotherapy agent, but its neuropsychiatric toxicity is a challenging problem, occurring in 5% to 30% of patients with cancer. Clinical symptoms can range from mild confusion to stupor, coma, and death. Somnolence, confusion, disorientation, fatigue, hallucinations, agitation, blurred vision, aphasia, seizures, asterixis, extrapyramidal symptoms, mutism, stupor, coma, and death, have all been described. Delirium is the most common neuropsychiatric toxicity. Psychotic disorders with delusions or hallucinations in the presence of a clear sensorium and mood disorders with psychotic features induced by ifosfamide have also been described. Chloroacetaldehyde (CAA) is a cytotoxic ifosfamide metabolite. The principal effect of CAA is the depletion of intracellular glutathione, which results in neurotoxicity due to impaired detoxification of neurotoxic substances. CAA is structurally similar to metabolites of ethanol (acetaldehyde) and chloral hydrate (trichloroacetaldehyde) with CNS depressant effects. Discontinuation of ifosfamide, and intravenous hydration, are part of the initial supportive care. Methylene blue, an agent FDA approved for the treatment of methemoglobinemia, and lower genitourinary tract discomfort, was first reported for treatment and prophylaxis of ifosfamide neuropsychiatric toxicity in 1994. Intravenous methylene blue 50 mg every 4 hours is recommended until the symptoms of ifosfamide neuropsychiatric toxicity resolve. Methylene blue is hypothesized to reverse ifosfamide neuropsychiatric toxicity through several different mechanisms, namely restoring mitochondrial respiratory chain function by serving as an alternative electron acceptor, restoring hepatic gluconeogenesis by reversing nicotinamide adenine dinucleotide plus hydrogen (NADH) inhibition, preventing the formation of CAA. Psychotropic medications were not found to be helpful in controlling psychiatric symptoms induced by ifosfamide in the authors' experience, as also reported by other researchers.

Antineoplastic Hormones and Biologic Modifiers

The hormonal agents and biologic modifier agents are used in an increasing number of cancers. They are associated with depressive symptoms but also with many adjustment disorders related to their sexual side effects, such as feminization, masculinization, and disorders of sexual functioning. Besides the reversible effects already described, interferon can cause acute reversible encephalopathy, with confusion, lethargy, and hallucinations. One case of delayed progressive encephalopathy has been reported. IL-2 (Proleukin) causes headache, agitation, disorientation, and confusion, which are dose-related and reversible. A rare severe encephalopathy has also been reported. These drugs have become frightening to patients who hear of the multiple side effects. However, symptomatic treatment is effective for all but the rarest severe reactions. A randomized prospective study of melanoma patients given prophylactic paroxetine has raised some controversy, with some researchers decrying the indiscriminate use of an SSRI in a group of patients who may not all need it. Previous psychiatric history was a strong risk factor, as was the presence of baseline symptoms. It is easy for psychiatric consultants to help oncologists put in place a screening program asking patients about their psychiatric history and their baseline mood symptoms. Simple questionnaires, such as the Hospital Anxiety and Depression Scale (HADS), which has been developed for medically ill patients, have identified a 10% to 15% sample that would qualify for prophylactic treatment. Ongoing monitoring for depressive symptoms would allow early treatment and would spare patients from unnecessary suffering. Once a medical team has been educated, and a routine has been set in place, ongoing psychiatric consultation is not necessary for any but the new-onset or complicated cases.

Table 27.8–8.
Neurologic Complications of Selected Chemotherapeutic Drugs

Acute encephalopathy (delirium)

- Corticosteroids
- Methotrexate (Folex, Mexate) (high dose IV, IT)
- *Cis*-platinum
- Vincristine (Oncovin)
- Asparaginase (Elspar)
- Procarbazine (Matulane)
- 5-Fluorouracil (Adrucil) (± levamisole [Ergamisol])
- Ara-C (Cytosar-U)
- Nitrosoureas (high dose or arterial)
- Cyclosporine (Neoral)
- Interleukin-2 (Proleukin)
- Ifosfamide (IFEX)/mesna (MESNEX)
- Interferons
- Tamoxifen (Nolvadex)
- VP-16 (Toposar) (high dose)
- *N*-phosphoracetyl-l-aspartate (PALA)

Chronic encephalopathy (dementia)

- Methotrexate
- BCNU (BiCNU)
- Ara-C
- 1-Hexyl-5-fluozouracil (Carmofur; Mifurol)
- Fludarabine (Fludara)

Visual loss

- Tamoxifen
- Calcium nitrate
- Nitrosoureas (intra-arterial)
- *Cis*-platinum

Cerebellar dysfunction/ataxia

- 5-Fluorouracil (± levamisole)
- Ara-C
- Phenytoin (Dilantin)
- Procarbazine
- Hexamethylmelamine (Hexalen)
- Vincristine

Cyclosporine

Aseptic meningitis

Trimethoprim and sulfamethoxazole (Co-trimoxazole) (Bactrim)
IV immunoglobulin (Iveegam)
NSAIDs
Levamisole
Monoclonal antibodies
Metrizamide (Amipaque)
OKT3 (anti-C3 monoclonal antibody)
Ara-C
Carbamazepine (Tegretol)
Methotrexate

Headaches without meningitis

Retinoic acid (Avita)
Trimethoprim and sulfamethoxazole
Cimetidine (Tagamet)
Corticosteroids
Tamoxifen

Seizures

Methotrexate
VP-16 (high dose)
Cis-platinum
Vincristine
Asparaginase
Nitrogen mustard (Mustargen)
BCNU
Dacarbazine (DTIC-Dome) (intraarterial or high dose)
PALA
m-AMSA (AMSA P-D; Amsacrine)
Busulfan (Busulfex) (high dose)
Cyclosporine
Metronidazole (Flagyl)
Misonidazole
β-Lactam antibiotics
Iodinated contrast material (IV or IT)

Myelopathy (IT drugs)

Methotrexate
Ara-C
Thiotepa (Thioplex)

Peripheral neuropathy

Vinca alkaloids
Cis-platinum
Hexamethylmelamine
Procarbazine
5-Aza12cytidine (5-Aza-C)
VP-16
VM-26 (Vumon)
Misonidazole
Methyl-C
Ara-C
Paclitaxel (Taxol)
Suramin (Bayer 205)
Mitotane (Lysodren)

BCNU, bischloroethylnitrosourea; IT, intrathecal; IV, intravenous; NSAIDs, nonsteroidal anti-inflammatory drugs.

Table 27.8–9.
Chemotherapy Agents Associated with Mood and Psychotic Symptoms

Dacarbazine (DTIC-Dome): depression and suicide reported, especially when used with hexamethylmelamine (Hexalen)

Vinblastine (Velban): frequent reversible depression

Vincristine (Oncovin): 5% incidence of hallucinations; depression noted

L-Asparaginase (Elspar): reversible depression noted

Procarbazine (Matulane): monoamine oxidase inhibitor; concurrent tricyclics and selective serotonin reuptake inhibitors are contraindicated; associated with mania and depression; potentiates alcohol, barbiturates, and phenothiazines

Hydroxyurea (Hydrea): hallucinations reported

Interferon: anxiety, depression with suicidal ideation common at high doses

Steroids: frequent alterations of mental state, ranging from emotional lability through mania or severe, suicidal depression to frank psychosis

Tamoxifen (Nolvadex): rare depression or delusional syndrome, or both

Leuprolide (Lupron): depression

Tailor-made vaccines against various parts of the malignant cell are being developed in increasingly sophisticated ways, in particular, for melanoma. They remain difficult to make, the responses are usually measured in months, and they are limited to research-based programs, but they are of great scientific interest and have much unexplored potential.

Immune-Mediated Checkpoint Inhibitor Immunotherapy

This new class of antineoplastic agents targeted key regulatory proteins that are designed to shut down the production of immune antibodies. As part of normal homeostasis, checkpoint inhibitor

proteins prevent autoimmune disease and ensure that once an immune-mediated reaction is induced, it will be properly shut down. Checkpoint inhibitor therapy prevents the shutdown and allows for a greater and more sustained immunologic response. These therapies count on the immune system to have created its own unique immune response to the cancer, which appears foreign and helps to bolster the response by not allowing it to shut down. Of course, the checkpoint inhibitor is not specific to any one particular antibody response. However, side effects in patients with autoimmune diseases have not been as substantial as it was originally thought to be. Cancers induce immune responses at a variable rate, namely depending on how foreign the cell appears. Therefore, the number of mutation per cancer cell (appears more foreign) can predict response to checkpoint inhibitor therapy.

Surgery

Surgery continues to play a central role in the treatment of cancer. Several psychological and psychiatric issues arise around the time of surgery, such as an inability to give consent, preoperative anxiety, exacerbation of pre-existing psychiatric disorders, postoperative delirium, drug–drug interactions, drug withdrawal concerns, especially for patients on benzodiazepines, poor compliance with postsurgical rehabilitation recommendations, and many others. In addition to perioperative reactions common to different types of surgical procedures, psychological reactions specific to the surgery site and the related functional loss should be taken into consideration. Many studies on the psychological effects of mastectomy, hysterectomy, colostomy, and prostatectomy report the high cost paid in quality of life and recommend that more emphasis be placed on this dimension. Laryngectomy patients and those who undergo other extensive head and neck procedures experience considerable psychiatric morbidity; the loss of voice is catastrophic for many, and the blow to self-image is severe. Patients who have had curative limb amputations can have a good psychological outcome. There is little systematic information about patients who

undergo unusual and extreme procedures, such as pelvic exenteration.

Stem Cell and Bone Marrow Transplants

Stem cell transplantation is being used for an increasing number of childhood and adult cancers. It is commonly recommended for leukemias, lymphomas, MM, and myelodysplastic syndromes. It is a potentially curative treatment for otherwise lethal disorders and succeeds best when given to patients in remission, with as little previous treatment as possible. Yet, it has an uncomfortable course and a significant incidence of graft-versus-host disease. Undertaking this type of treatment, especially when the patient is doing relatively well, can be stressful for patients, families, and caregivers. However, successful transplants are indeed lifesaving. Comprehensive psychiatric assessment has become a part of the routine pretransplant evaluation in major cancer centers to identify patients at high risk. Patients sometimes need psychological intervention before the procedure and often need it if their posttransplant course is complicated. Delirium is common during acute periods. Anxiety and depression symptoms are common due to the rigors of the experience. Nevertheless, there are enough patients who leave the hospital after a few weeks, with variable degrees of emotional and physical depletion, but essentially cured of an incurable disease.

New Supportive Technologies

The use of life support and nutritional support in critically ill patients has created a spate of psychological, legal, and ethical issues that are widely discussed in the lay press. Less well known are developments in the nutritional support of cancer patients who can no longer take in food because of physical obstruction, as in head and neck cancers, or because of physiologic failure, as in radiation enteritis. In the former, percutaneous endoscopic gastrostomy (PEG) or percutaneous endoscopic jejunostomy (PEJ) and, in the latter, home parenteral nutrition (HPN) allows a significant improvement in quality of life. These home-based technologies create major changes

in family-structuring routines, such as the preparing and sharing of meals, and are time and labor-intensive, causing adaptational strains that may bring them to psychiatric attention.

PSYCHOLOGICAL CONCERNS IN PATIENTS WITH CHRONIC CANCER

Cancer has become curable in a growing number of cases, especially with improved screening techniques and early diagnosis. However, in many cases, it becomes a chronic disease, at which point treatment goals focus on management. While these efforts may be effective for many years, the patient's experience is nonetheless challenging and can involve navigating secondary prevention guidelines, episodes of acute disease, and sometimes coping with indolent tumors.

Patients vary in how they deal with these difficult life situations, and doctors vary in the style and content of their communications. Communication skills training has been identified as a neglected part of medical education and is being addressed by researchers and educators. All physicians communicate not only through their words but also with voluntary and involuntary nonverbal behaviors, which are similarly subject to interpretation, scrutiny, and sometimes distortion. In the case of cancer care, oncologists face the challenge of balancing the details of diagnosis, prognosis, and realistic expectations with the installation of hope. When treating patients with cancer, the psychiatrist must have an understanding of the medical reality, including the burden of illness and staging, treatment options and plan, and long-term ramifications of both the disease and treatment. Patients with cancer frequently ask their psychiatrists to clarify details of their treatment. This may happen for several reasons, ranging from having a better therapeutic relationship with their psychiatrist than their oncologist to limitations during oncology appointments such as anxiety, surprise/shock, or time.

Cancer Pain

The overall incidence of pain in cancer patients is approximately 50% but increases in frequency and severity with advancing disease. There are many pain syndromes that have been defined in cancer patients. Their variety illustrates the importance of evaluating and diagnosing the sources of pain in cancer patients because the treatments for each of them are different and, in many cases, specific. The psychiatrist has a special role to play throughout the course of the illness, especially as pain specialists can be difficult to access, and physicians still display reluctance to treat the pain of cancer patients aggressively enough. The primary goal of cancer pain management is effective symptom control to allow patients to participate in the necessary diagnostic and therapeutic approaches to treat their cancer and to achieve an acceptable quality of life at all stages of the disease.

The debilitating and demoralizing effects of pain give rise to an increased incidence of psychiatric symptoms and disorders at any stage of the disease. Pharmacologic treatment is essential. Patients and families may be comforted to know that pain treatment with opioids very rarely results in addiction, despite the emergence of physiologic dependence evident in tolerance and withdrawal. Addiction, or psychological dependence, is a pattern of behavioral and cognitive symptoms that indicate continued use of a substance despite significant substance-related problems. These symptoms include impaired control, social impairment, failure to fulfill major role obligations, and risky use. Patients' and physicians' fears of addiction are a major barrier to adequate cancer pain management. Patients with poorly managed or undertreated pain may mimic the signs of addiction, such as requesting higher and more frequent doses or exaggerating pain complaints; this behavioral presentation is sometimes referred to as pseudo-addiction.

Identification of the nature of the pain (somatic, visceral, and neuropathic) and the specific pain syndrome can facilitate the development of an approach for pain relief in patients with pain and cancer. It is well recognized that pharmacologic approaches represent the mainstay of therapy, but any therapeutic strategy must

also implement the use of psychological, behavioral, mechanical, anesthetic, and neurosurgical approaches as needed.

The guiding principles of a therapeutic strategy for cancer pain must include

1. detailed assessment of the patient's pain
2. individualization of the therapeutic approach
3. the assurance of available expertise to provide therapeutic strategies to patients
4. continual reassessment of the degree of pain relief and impact on mood, functional status, patient and family acceptance, and the patient's overall quality of life
5. choosing the simplest approach prior to the use of complicated and extensive techniques
6. ongoing communication between the physician and patient in defining the options for therapy and the potential risk and benefit ratios of any of the therapeutic approaches
7. defining the goals of pain management at or near the end of life

Critical to the development of a successful therapeutic strategy is the physician's ability to establish a trusting relationship with the patient. This requires a complete history of the pain complaint, including the patient's description of the site of pain, its quality, exacerbating and relieving factors, its radiation, if any, its exact onset and temporal pattern, and to what extent the pain interferes with activities of daily living, work, and social life, as well as the degree to which the pain has had a psychological impact. Multiple pain complaints, common in patients particularly with advanced disease, need to be prioritized and classified. In some instances, verifying the history from a family member may be necessary because the patient is either unable or unwilling to detail the pain symptom appropriately. Some patients may deny or minimize their pain; in these cases, family members may be more objective in assessing the disability of patients who underreport their symptoms. At the time of the initial assessment, the patient's psychological state should be evaluated, including the patient's psychiatric history, the current level of anxiety

or depression, suicidal ideation, and degree of functional incapacity. Numerous studies support the significance of psychological factors in accounting for differences in pain experiences in patients with cancer. In a study of the incidence of psychiatric disorders in patients with cancer, 39% of those patients who received a psychiatric diagnosis had significant pain. In contrast, only 19% of patients who did not receive a psychiatric diagnosis had significant pain. In this group with pain, the psychiatric diagnoses included adjustment disorders with depressed or mixed mood and major depression. Uncontrolled pain is a major factor in cancer-related suicide. Understanding the meaning of pain to the cancer patient is a critical component of a successful assessment strategy. It is not uncommon for patients during active therapy to endure significant pain for the promise of a successful outcome. With advanced disease, when curative therapy is no longer an option, it is common for patients and families to request that, if nothing else can be done, at least the patients' pain should be adequately managed.

Chronic cancer patients may have a constant source of pain or one that worsens slowly. The patient may become habituated to a given level of opiate and need increasing levels of opioids at a given level of disease and as the disease progresses. Persistent patient complaints should be heeded, even if scans and MRI do not reveal a new etiology. Chronic pain management modalities are important. Nonpharmacologic methods such as meditation, meditation-based stress reduction (MBSR), behavioral methods, group support, and supportive therapy focused on improving quality of life all have a role to play.

The principles of acute postoperative pain relief emphasize aggressive, immediate treatment, often with the use of patient-controlled analgesia (PCA) pumps. They should be carefully used in confused patients, and a bowel regimen should always be instituted at the same time that any opiate is prescribed. Sufficient initial relief is associated with an easier postoperative course and, in some studies, a shorter hospital stay. Pre-emptive anesthesia is known to prevent phantom pain, and there is one report of its beneficial effect in prostate cancer surgical patients.

Psychiatrists should be familiar with drug–drug interactions related to the use of opioids analgesics, and adjuvant pain medications (i.e., antidepressants, anticonvulsants). Tramadol (Ultram) is a commonly prescribed, weak mu-opioid receptor agonist that also inhibits serotonin and norepinephrine reuptake. As such, patients taking tramadol concurrently with antidepressants should be monitored for serotonin syndrome. Opioid analgesics, especially those with long elimination half-lives, increase the risk of delirium in cancer patients. Rotation of opioids, continual assessment, and prescribing the lowest effective dose are recommended approaches to minimize adverse effects.

Physicians should also remain alert to the possibility that cancer patients may experience pain from other causes. Through longitudinal evaluation of quality and persistence of complaints, psychiatrists play an important role in a collaborative approach to pain management.

Sexuality

Many patients hide their sexual concerns because they are embarrassed and perceive that their doctors are embarrassed. However, they are usually eager for information that is seldom provided. These complaints may vary from reports of sexual dysfunction and decreased libido to sudden onset of menopause symptoms.

Concerns for sexual function vary in younger and older cancer patients. Younger patients are more sexually active, and fertility remains an important issue. Research efforts have revealed conflicting results regarding the incidence of sexual dysfunction based strictly on the site of the primary cancer. A large sample of men with testicular cancer found no significant differences in dysfunction from population-based controls. However, a second study found that long-term male survivors of lymphoma had significantly more sexual dysfunction than matched controls. The sexual impairments associated with prostate, bladder, and rectal cancers match the amount of postsurgical sympathetic nerve

damage rather than gross anatomical change. Both radical prostatectomy and radiotherapy for prostate cancer, as well as adjuvant hormone treatment, are often followed by severe long-term erectile dysfunction; sexual recovery is seldom achieved. Any course of radiation or chemotherapy can result in some sexual dysfunction, with radiation causing a high rate of dyspareunia.

Young female breast cancer patients often experience a long-term lack of sexual interest. The attitude of their partners toward their body and femininity is very important for their sexual well-being. Women treated for gynecologic cancers may develop a lack of interest, vaginal dryness, and dyspareunia. Treatment-induced menopause is common to surgical, radiologic, and chemotherapeutic modalities of treatment. The symptoms are the classically described ones, but anecdotal evidence points to higher severe symptoms when menopause is induced by treatment. Hot flashes are among the most troubling to treat because estrogens are contraindicated in many cancer patients, especially those with estrogen receptor–sensitive tumors.

The incidence of sexual dysfunction increases over time, and spontaneous remissions do not occur, even in the presence of stable or improved physical states. Both men and women treated for colorectal cancer can have persistent sexual dysfunction 4 years after diagnosis. Dysfunction is greater in younger patients across all diagnoses and is particularly high for cancers of breast, head, and neck, and other physically disfiguring cancers. In an ideal world, sexual concerns should be routinely addressed before treatment, with a baseline assessment that models open communication from the start. A detailed sexual history can be used to explore all possibilities and make subsequent discussions easier. Patients need detailed information about what problems to expect and about their reversibility. The information should be combined with reassurance that some form of sexual expression is always possible. If there is a spouse or sexual partner, early joint involvement may be useful.

Early discussions are particularly necessary because sexual concerns play an important role in patient decision-making. Both men and women may decide against the optimal treatment because

of the fear of sexual impairment, which is not always justified. Then again, they may select very aggressive treatment in ambiguous situations without realizing the full impact it will have on their sexual functioning.

During the treatment, patients may experience direct pain and injury about which they may not grieve openly. Even in the absence of direct pain and injury, there is usually an interruption of sexual activity, which may be very threatening for patients who are uncertain about their partners' tolerance for the interruption. The extent of recovery needs to be clarified so that realistic coping can begin.

After the initial treatment period, patients should again be queried about sexual concerns. Patient workshops, support groups, and information sessions may be useful tools to complement individual treatment. A flexible format with a mix of information, emotional ventilation, and focused problem solving have been well received in several types of cancer.

The period after the end of active treatment is a critical one for future adjustment. The patient usually cannot resume premorbid functioning even in the absence of any direct injury, but fatigue, pain, disappointment, and fear about the future are maximal. It is also a time of uncertainty and, hence, a window of opportunity. Dysfunctional patterns have not yet crystallized, and given the opportunity, couples can work together toward a new equilibrium.

Recent studies reinforce the observation that psychological and relational factors play a large (often the largest) role in determining the degree of posttreatment recovery of sexual functioning. Given the lack of attention paid to sexual issues that is characteristic of much of medical treatment, psychiatrists and other mental health professionals can occupy an important role in the evaluation of sexual issues and facilitating treatment. They need to know the basic anatomy and physiologic potential of a patient's condition and should refer the patient for further work-up and interventions if needed. Psychological treatment includes couple psychotherapy and sex therapy. Sexual rehabilitation involves an adaptation of sex therapy principles and can be helpful. It is based on the desire-arousal-

orgasm model of the sexual response and requires a phase-specific diagnosis. Late-phase dysfunction is quite effective if there is no anatomical interdiction. Early-phase dysfunction is more difficult to treat and benefits from a specialized referral.

Cancer Survivors

There are more than 14 million Americans living with a history of cancer, according to the ACS. Almost two-thirds of cancer survivors were diagnosed 5 or more years ago, and nearly half of all cancer survivors are older than 70 years. The rising number of cancer survivors is a tribute to the human intellect and resiliency; however, it is important to recognize that successful treatment does not come without times of distress and often long-lasting problems. In fact, there is a movement to consider oneself a cancer survivor from the day of diagnosis onwards.

According to the recent estimates from the ACS, the most frequent sites for invasive primary cancer among survivors were

- breast cancer among women (22%)
- prostate cancer among men (20%)
- and colorectal cancer (9%)

More than half of cancer survivors had a history of one of these cancers.

Among male cancer survivors, the three leading types of cancer are

- prostate cancer (43%)
- colorectal cancer (9%)
- melanoma (8%)

Among female cancer survivors, the three leading types of cancer are

- breast cancer (41%)
- cancer of the uterus (excluding the cervix, 8%)
- colorectal cancer (8%)

Survivors of childhood cancer who are under age 20 make up a small fraction of all cancer survivors (1%). The survival rates are higher for white patients and lowest for African Americans, Native American/Alaska Native, and Hispanics. Cultural factors, including language, values, traditions, and trust in providers, can influence underlying risk factors, as can access to treatment, health behaviors, beliefs about illness, and approaches to medical care.

In early self-report studies, survivors were believed to be free of psychological residue because many of them used denial and emphasized positive beliefs, such as having learned deeper values and being grateful for life. However, studies of leukemia/lymphoma survivors and breast cancer patients, using the Brief Psychiatric Symptom Inventory, showed a level of psychiatric symptomatology one standard deviation greater than the norm, or halfway between normal controls and psychiatric patients. Many subsequent studies confirm this association. Data from an American cohort of 9,535 long-term survivors of childhood cancer showed a 43.6% incidence of self-reported impairment in one or more of six domains: general health, mental health, functional impairment, activity limitations, pain resulting from cancer treatment, and anxiety or fears directly related to cancer and cancer treatment. Mental health concerns were the most frequently mentioned, and risk factors included female gender, low educational attainment, and low household income. A Dutch study found lower educational achievement, a lower rate of employment, a lower rate of marriage, and a higher incidence of men living with their family of origin as compared with a healthy control group. A history of a brain tumor or cranial irradiation was the strongest independent predictor but did not account for all of the variation. A Danish study confirmed this finding; although long-term survivors had more psychological symptoms, they did not have an increased rate of psychiatric hospitalizations unless they had had brain tumors or brain irradiation.

Delayed Consequences of Treatment

Four categories of delayed consequences of treatment have major psychological impacts. *Infertility problems, premature ovarian failure, and interference with sexual response* are particularly distressing if patients have not been educated and prepared to face them. However, there is evidence of persistent patient denial even in the face of preparation, such as sperm banking. Intervention should include endocrinologic, gynecologic, or urologic evaluation and treatment. Psychotherapy, couples therapy, group therapy, veteran patient programs, and self-help programs can all be used to good effect.

Pituitary, thyroid, and other endocrine failures occur as a consequence of radiation therapy. Patients with these problems often present with psychiatric symptoms. Patients treated before or during puberty have short stature due to a lack of growth hormone. Chronic fatigue is a common symptom that calls for patient and family education because it is often given an unjustified psychological label.

Increased vulnerability to late organ failure and secondary malignancies and to the chronic anxiety that this vulnerability generates is another challenge for survivors. If such a complication comes to pass, it finds the survivor less able to cope and more prone to a posttraumatic response.

Social rejection, employment discrimination, and serious insurance problems may be the lot of survivors in a frightened, suspicious world. Survivors who are well enough to return to work may plateau in their careers, being passed over for advancement by employers who fear a recurrence. Similarly, the survivors may be averse to moving due to the risk of being uninsurable. Despite the Americans with Disabilities Act (ADA), which bars employers from firing patients, there are cases of summary dismissal, and the appeal process is complex and uncertain. However, there are also cases in which sick employees are given extensive sick leave, warm support, and reassurance about their position. Also, the stigma of cancer is slowly diminishing as there are more examples of public figures undergoing treatment and continuing to lead productive lives.

Predictors of Poor Coping. Predictors of poor coping include previous psychiatric problems, lack of social support, low educational and economic status, and stage of disease at diagnosis. In treating the cancer survivors psychotherapeutically, one should strive for a detailed understanding of the patient's experience. When the content is anxiety-provoking to the therapist, it is sometimes overlooked, leading to poorer outcomes even in the hands of seasoned therapists. Full knowledge is required to understand where the trauma response is primary and where it is a shield for deeper psychodynamic issues. Lingering too sympathetically on the trauma may deprive the patient of the opportunity to grow beyond it. Yet, failing to be sufficiently empathic in understanding its impact is obviously unproductive. There are many survivor programs that offer workshops, lectures, and groups for patients, couples, and families. The National Coalition of Cancer Survivors (NCCS) is emblematic of the possibilities for self-awareness and psychological and political empowerment.

Patients at Genetic Risk for Cancer

The advent of deoxyribonucleic acid (DNA) technology and sophisticated epidemiologic studies has permitted the identification of many healthy individuals at high genetic risk for developing cancer. Sources of genetic information include information from the patient's family medical history, physical examination, and medical records. There is a wide availability of information for the public on the Internet, which can cause concerns among patients and may lead them to consult with their doctors. Once patients are identified as being at risk of developing cancer, they should be referred for genetic counseling. After an individual is found to have an increased risk of having cancer, there are potential interventions with the goal of reducing the risk, such as having a colonoscopy to detect colon cancer. Information about familial cancer has psychological effects. High-risk individuals have chronic anxiety, lowered self-esteem, and problems surrounding marriage and childbearing. Self-estimates of risk are usually much higher than their real risk, even for those in the

highest risk bracket. Previously unsuspecting carriers do show increased distress, whereas decliners of testing remain anxious throughout. High risk and high anxiety often go hand in hand with denial and poor health maintenance behaviors, such as avoiding breast self-examination and surveillance testing. A group therapy intervention with educational and expressive components has been effective in reducing psychological distress, normalizing risk estimation, and improving health behaviors. Individual educational and supportive interventions have shown promise. Some form of psychological intervention should be a regular part of the surveillance programs that have been developed in many centers. Similarly, psychological support is crucial to deciding whether to enter surveillance trials, to have a prophylactic mastectomy, and, above all, to have testing. One study has shown that although only 71% of high-risk women would undergo testing for breast cancer, as many as 42% of average-risk women wished to undergo it as well. The consequences of testing go far beyond the psychological distress of the individual. Cooperation of unwilling family members may be required, and unwelcome knowledge may be forced on them. Marital, sibling and parent–child relations may suffer, at which point family-focused interventions come into play.

PSYCHOLOGICAL ASPECTS OF CANCER SCREENING

Screening for genetic risk is not the only area in which scientific and technologic advances have created ambiguous situations.

There are now many tumor markers, molecules associated with cancer, that can be used to

1. screen for the presence of cancer,
2. diagnose specific cancers,
3. determine prognosis in a given patient, and
4. monitor the course of the disease.

No test meets all requirements, but there is a tendency to overuse them. PSA for men is the most reliable. It is specific to the prostate, but an elevated level can signal prostatitis as well as cancer. It is extensively used both for screening and for monitoring prostate cancer and has resulted in many early diagnoses for a type of cancer that is found at autopsy in a large percentage of older adult men in whom it never grew to cause problems. The new patients are faced with difficult choices between watchful waiting, which some cannot tolerate, and treatment, which usually consists of either radiation or surgery preceded or followed by antiandrogenic hormonal therapy. All of these have significant and emotionally loaded side effects, such as impotence, incontinence, feminization, or depression. Cancer antigen 125 (CA125) is useful for following a known ovarian cancer but is not specific enough to be used for diagnosis, although it is often drawn for that purpose. Carcinoembryonic antigen (CEA) is even less specific for colon cancer.

Despite the potential for false positives, a recent study found that patients did not regret being tested. The author concluded that this enthusiasm would lead to the overuse of other screening methods, especially powerful, expensive techniques such as CT scans, MRIs, and positron emission tomography (PET) scans unless physicians have a higher threshold before ordering them without clear-cut criteria.

These patients may request counseling to cope with the many ramifications of test results and to help them decide on treatment. Asymptomatic patients who are told that they have cancer have an added burden when they undertake an arduous treatment. A part of them is never quite sure that there was really anything wrong with them. They continue to experience their illness as due to the treatment, and the more fragile patients with a tendency to denial, projection, mistrust, or paranoia may begin to doubt the reality of the cancer and the integrity of their physicians.

ETHICAL ISSUES

Psychiatry–Ethics Interface

In today's contentious social climate, ethical and legal dilemmas multiply with increasing stress, often resulting in psychiatric consultation. If inappropriate psychiatric labeling has occurred, psychiatrists must remove the label, redefine the situation, bring out the underlying ethical issues, and set a decision-making process in motion. To be effective, they must be clear about the difference between psychiatric issues on the one hand and ethical and legal issues on the other hand. They must diagnose and act decisively in the former, be restrained and humble in the latter, and educate others about the distinction. If they understand the ethical issues, have a precise knowledge of the legal constraints operating in the case, and call for appropriate consultation, their interviewing skills and experience in conflict reduction can make them valuable participants. Selected ethical issues in the care of cancer patients are discussed in the following sections, with emphasis on their psychological correlates.

Truth-Telling

At the extremes, cultures that put a high value on autonomy consider the need for truth-telling as self-evident, whereas cultures in which the patient is tightly embedded in a wider family unit consider truth-telling as an exercise in maleficence. The spreading breakdown in close kinship ties and the steady improvement of modern cancer treatments are combining to increase truth-telling in growing segments of the world. However, local cultural deviance continues to arouse strong objections to it and may generate the need for outside consultation for cultural and religious guidance.

Informed Consent

In the United States, informed consent is legally required for conventional and experimental treatment. Given the toxicity and noncurative nature of much cancer treatment, this does not seem unreasonable and is spreading to other Western countries. However, it comes at some psychological cost. Anxiety reactions and

occasional psychiatric decompensations are seen when patients feel overburdened by demands to make decisions. These often occur in predisposed individuals, even those with a good premorbid adjustment. Patients respond to active interventions, including support, medication, behavioral techniques, and active environmental manipulation of home and treatment settings. These interventions are usually sufficient to help patients make decisions on their own behalf and to undergo treatment, but posttreatment relapses may occur and are resistant to therapy.

Investigational Treatment

Investigational treatment is common in cancer. Most patients in academic centers will probably be considered for eligibility in an investigational protocol. Since the Nuremberg trials and the Helsinki Declaration, the moral requirement for informed consent from research subjects has been clearly spelled out and has been buttressed by regulations and institutions in the United States. Many critics feel it is honored in letter more than in spirit, but competent patients are known to systematically suppress information given to them to create the illusion of an old-fashioned paternalistic relationship; hence, the situation remains ambiguous, despite the efforts of lawyers, bioethicists, and well-intentioned physicians to tame it.

Randomized Clinical Trials. Critics of clinical trials claim randomization is incompatible with the doctor's basic responsibility to the patient. Overall, patient reactions are determined less by the protocol than by their relationship to the physician. They have an irreducible need to believe that their physician thinks that the study is good for them. This is not completely false because no treatment reaches human trials if it has not shown some promise, and a physician-researcher is morally obligated and scientifically well advised to remove a patient from a protocol that will harm them. However, career pressures and local power relationships may mold physician behaviors, so institutional ethics are just as important as

physician ethics but are much more complex and difficult to change. A good institutional review board and transparency in the presence of large medical teams are additional safeguards.

Some patients find randomization intolerable and refuse to participate or later demand to break the code. Most patients find trials with placebo versus treatment design emotionally more difficult to understand and tolerate than one with two treatment arms. Many patients seek experimental treatment with desperate intensity, peddling influence to enter limited protocols, or pleading to use untested agents that have not shown enough efficacy to warrant clinical trials. A few patients do participate in clinical trials out of strong altruistic motives, but, most of the time, these are secondary to the hope of personal benefit.

Alternatives to randomized clinical trials (RCTs) have been suggested, but they are unwieldy and less powerful than the trials. The results of large, multicenter RCTs are supposed to establish the standard of treatment, but there are inevitable intercenter differences even in the absence of any misconduct. In the case of the mastectomy-lumpectomy controversy of the 1970s and 1980s, RCTs from several countries gave consistent results that did indeed change standard medical practice. However, in the case of combined hormone replacement therapy (HRT), there have been contradictory trials, and only recently has there been a preponderance of results to establish that HRT not only lacks the cardiac and osteoblastic benefits that had been believed to offset their moderate but well-established increased breast cancer risk but also, in fact, comes at a higher risk for all of them.

PSYCHOLOGICAL PROBLEMS OF FAMILIES

Research on the family of the cancer patient is an active and exciting field, especially due to the integration of family therapy concepts. Some findings are disease-specific, but many of them can serve as a paradigm for understanding the impact of any major illness on the family.

Psychological Reciprocity

Awareness of the powerful reciprocity of emotional states and behaviors between a cancer patient and family members is well established from numerous studies of parents, spouses, and siblings that document levels of distress and functional impairment that can rival or even exceed that of the patient. More disturbingly, primary caregivers have been noted to worsen over time in the face of stabilization or improvement in the patient. Finally, studies of families after bereavement or cancer survival show a significant incidence of impaired functioning over extended periods of time and, again, a worsening over time in the distressed families. These findings have some urgency, given that most families experience cancer at some time and that it will probably be a drawn-out, chronic ordeal. High-risk families can be identified early and can be significantly helped by professional intervention.

Family Evaluation

Families can be evaluated from several points of view. The most traditional one is to examine how well the family is taking care of the patient. Medical staffs are quite sensitive to this and often call for help when families fail in this area. Another approach is to scan for psychopathology in family members. If the family member is acutely symptomatic and visible to the treatment team, a consultation follows, but absent members go untreated.

Areas for which the family is responsible include:

1. *Providing emotional support and containment*. Family members are expected and expect themselves to contain their own reactions and support the patient.
2. *Sharing responsibility for decision-making*. Family members often carry the lion's share in researching and selecting options, with or without patient approval. This goes hand in hand with an enormous and universally reported *need for information*.
3. *Concrete caretaking*. In today's budget-conscious climate and vanishingly short hospital stays, an ever-increasing amount of

care is being thrown onto the family. This is not acknowledged; hence, families receive little help or training.

4. *Meeting financial costs*. Even under socialized medicine, families absorb massive expenses and suffer significant downward mobility.
5. *Absorbing social costs*. In one study, 25% to 30% of primary caregivers lost their jobs, and more than half of the remaining primary caregivers moved to lesser-paying jobs to accommodate their need for flexibility.
6. *Maintaining stability*. The patient's role and contribution must be replaced, a difficult task in the case of young mothers or breadwinners. The new demands must be folded into ongoing functioning. Some members develop increased emotional needs that must be met. All of the standard family functions, such as emotional nurturing, feeding, clothing, sheltering, educating, and socializing, must continue unabated.
7. *Adapting to change*. It has been said that change may be the only constant during a cancer illness. However, it is useful to divide events into acute and chronic phases:
   a. *Characteristics of the acute phases*: An acute event is met with effective mobilization of family members but psychologically, they may be reacting quite asynchronously, with the denial of some and the pessimism of others causing significant friction. Members may protect themselves, under the guise of protecting each other, by colluding in a conspiracy of silence, which can rigidify and can be hard to change later. There is a universal need for information to decrease the uncertainty, to help the family problem-solve effectively, and to serve as a conduit for ensuring better communication, cohesion, and emotional containment.
   b. *Characteristics of the chronic phases*: Now, the family must return to developmental and maintenance tasks, which may expose conflicts between the patients' continuing needs and the needs of others. Initial mobilization is replaced with a paradoxical increase in psychological symptoms. Families isolate themselves, even when outside support is available, and may go into neutral gear, putting major decisions on hold.

Family-Centered Approaches

New and powerful methods of evaluation use family-centered approaches to examine how the family sustains itself and copes with the illness while still meeting the needs of all its members. Four concepts are important to understanding the impact of the illness and to devising interventions that are not instantly neutralized for the sake of family homeostasis.

Developmental Stages. Families go through developmental stages with specific tasks at each stage. Cancer disrupts the tasks at any point, sometimes permanently, if no help is offered. Any intervention must be compatible with helping the family carry out its phase-specific tasks.

Family Structure. One must understand how a family is organized to understand the caregiving dynamics and to intervene in ways that reinforce the family rather than threaten and destabilize it.

Family History, Beliefs, and Myths. Every family is permeated by stories that dictate unconscious responses to illness, dependency, loss, and other fundamental life experiences. They underlie behaviors that seem idiosyncratic or bizarre to untrained observers and must be factored into treatment. Explaining them to the treatment team minimizes scapegoating and polarization.

Family Style of Interaction. In past studies, when family researchers were studying family functioning outside the medical setting, good communication among family members was found to be the best predictor of outcome across several theoretical models. Other factors that were studied include cohesiveness, expressiveness, conflict, hostility, distance versus enmeshment, and adaptability, to name the most common. Cohesiveness in earlier models was thought to have a bimodal distribution, with too much cohesiveness having a negative impact on the development of individual members. Yet, that was not found to be the case when high cohesiveness was culturally determined. The study of families

undergoing severe illness or death of a member has found cohesiveness to be an even better predictor of good functioning than communication.

Communication in the medical setting has very specific content and functions. The truth-telling debates bear witness to the fact that medical information is not viewed as an unalloyed blessing. Perhaps cohesive families can put medical information to better use and become even closer as they process it, whereas it may further stress and disrupt noncohesive families. Cohesiveness has also been found to be the common factor in families that show strain during crises but heal themselves over time.

Nontraditional Families. Divorced or blended families, single-parent families, homosexual families, and families that are ethnically, culturally, or religiously discrepant from the ambient medical culture experience many of the problems described previously but also have specific characteristics that are beginning to be systematically recognized.

Staff–Family Interface

During a life-threatening illness like cancer, the medical staff plays an enormous role in the family dynamics, invading the family system to create a new ad hoc hybrid system. That hybrid is the milieu in which consultation requests are generated. It must be understood and used for any intervention to be effective.

Guidelines for Intervention

Although most families show generosity, courage, and resiliency, as many as 25% to 30% would clearly benefit from intervention. Of those, a much smaller number requires formal family therapy, which must be done with a realistic understanding of the medical facts and the medical milieu. Most families manage with short-term crisis interventions designed with an accurate understanding of the family factors described previously and a commitment to the family, not just to selected members. In family-focused grief therapy, the patient and

family meet to process the events and anticipate the upcoming loss. It continues for a few sessions after the patient's death, helping the family to consolidate the positive achievements made while the patient was still with them. The staff–family conference deserves special mention. It has the potential for being a powerful mutative event and has been known to resolve what had seemed to be knotty problems.

PSYCHOLOGICAL ISSUES FOR STAFF

Anatomy of Stress

The stress on caregivers has been documented in studies across many settings and many countries. Communication problems between doctors and patients lead not only to patient dissatisfaction but also to lower job satisfaction and self-esteem for the physician. The following stressors are more particular to the oncology setting:

1. *The negative aura* that still surrounds it.
2. *The toxic nature of treatment* and its inevitable side effects.
3. *The occupational hazards* surrounding chemotherapeutic and radioactive agents and the resistant infections to which immunocompromised patients are prone.
4. *The ambiguity of many treatment decisions*, which often breeds conflicts between staff members.
5. *The unsettled social and ethical climate* that surrounds palliative care and terminal care decisions.
6. *The extreme emotional reactions* engendered by cancer and projected onto staff in the form of overvaluation, ingratiation, magical expectation, and covert bargaining, followed by disillusionment and anger.
7. *Conscious and unconscious responses of staff to cancer*. At a conscious level, caregivers depend on their intellectual grasp of the situation and make a point of rejecting myth and superstition. They are proud of their ability to function under pressure with reliable emotional controls and to offer something in all situations,

even hopeless ones. Yet, at an unconscious level, there are covert adaptations that are idiosyncratic and irrational, often determined by historical precedent and resistant to change. They may include superstitious beliefs and stubborn fears and feelings. Their eruption into awareness makes the worker feel embarrassed and inadequate. Hence, the feelings are kept secret; the caregivers may believe that they are alone in having them. Thus, staff workers isolate themselves from one another.

8. *Social isolation*. Outside of the workplace, staff isolation is reinforced by family, friends, and a society that shuns reminders of a frightening topic. Caregivers are not singled out personally, but they may be discouraged from talking about their work and risk being shunned if they do not accept this taboo.

Clinical Spectrum of Staff Responses

Normal Adaptation and Coping. Staff undergo a developmental process when they begin to work intensively with cancer patients. A high initial level of dysphoria, anxiety, sadness and numbing recedes over the first few months, displaced by the need to demonstrate competence and the ability to survive. Over the next few months, existential issues are allowed to surface, and staff members shape a deeper adaptation that engages their whole personality. Formal support is not necessary, but informal support and peer group interactions are important to a successful resolution.

Adjustment Reaction. Adjustment reactions may occur during the formative stages of providing cancer care, but they also overtake staff members at any point in their careers when a personal loss resonates with their work (cancer in self or loved ones, in particular). These reactions are acute but time-limited and respond well to support or a brief change of venue. Rarely is psychiatric intervention needed. Sometimes adjustment does not improve with time, exposing an underlying psychiatric disorder, often pre-existing and precipitated by work stresses. Psychiatric evaluation is then

indicated and may result in transfer to a less emotionally stressful situation.

Supportive Interventions for Staff

Staff support interventions generally fall into three categories: Organizational, individual, and group. Organizational issues include leaders who model realistic expectations and monitor overinvolvement in themselves, as well as others. A team approach encourages the sharing of difficult tasks, prevents a sense of being indispensable, encourages staff cohesion, and eases time off and vacations. Open communication and good orientation procedures are important. Individual responses include peer support, supervisor support, access to an employee assistance program, and other confidential psychological support or psychiatric evaluation. There are many published reports about the benefits of staff support groups in many forms and many settings, but they are anecdotal. These groups are difficult to run, but when they work, participants value them. The group must not be perceived as undermining unit norms or leadership. The structure must be provided, as needed, to alleviate staff anxiety while still allowing unscheduled topics and feelings to be aired. Therapy issues must be avoided, and discussions should clearly flow from work-based topics. An active area of new and productive intervention is the development of group-based workshop formats for improving communication. Many have been described and found to be helpful; more are under development.

CANCER IN THE PSYCHOTHERAPIST

Unlike degenerative diseases, with their linear course and associated impairments, cancer may have an episodic course with no loss of cognitive functioning. It inevitably forces a blurring of psychological and, later, overt boundaries in therapy. An all-but-intolerable burden is placed on doctors and patients when therapists who have cancer continue treatment too long because of their own

need to deny their fate. This suggests that, difficult as it is, the therapist's most ethical course of action is to set a fixed termination date that allows the patients to transfer to someone else while the therapist is still alive and well enough to negotiate the termination. This may be asking too much of an individual in whom denial is both the main coping mechanism and the only impairment. The help of colleagues is invaluable at this time.

PEDIATRIC PSYCHO-ONCOLOGY

Magnitude of the Problem

The new cases of cancer in children under 15 years old continue to increase. Leukemias are the most common cancer in children, accounting for 30% of all new cases. Brain and CNS tumors are the second most common, making up 26% of childhood cancer cases. Caucasian children are more likely to develop cancer than any other ethnic group. The combined 5-year survival rates for all childhood cancers improved from 56% in the 1970s to 80% currently.

Child Patients

Sick children are benefiting from social and legal trends toward empowering them. They are being informed more honestly, and their cooperation is being thoughtfully enlisted. It has become evident that, like adults, children know or intuit a great deal without being told and are relieved by open communication. Its provision is complicated by the need to be age-appropriate and is more painful because of adult vulnerability to suffering in the young. As a result, adult denial often prevails, and children respond by increased behavioral symptoms or withdrawal.

Discussion about Diagnosis and Prognosis

A child can hardly remain oblivious to their diagnosis, given the endless clinic visits, repeated chemotherapies, flagrant symptoms such as hair loss, repeated exposure to other patients, and

statements of people around them. Studies note that immediate perception outweighs distant reality; hence, intrusive procedures can loom larger than prognosis, especially in younger children. The developmental stages of death awareness in healthy children are well described but are probably not applicable to children with cancer or to other children who have been exposed to death in an untimely and personally threatening way that results in earlier and keener awareness. Thus, discussions are clearly indicated, but they must follow the child's lead, looking for and responding to their sources of anxiety and remaining reassuring about care and comfort if they cannot be so about the outcome. It has been found that children who received truthful information had less subsequent anxiety than those who did not. However, parents often request and benefit from psychological guidance about how to proceed because truth-telling to young children is strongly molded by the child's circumstances and level of possible understanding. This is not always obvious to even the most loving parents. But they are usually eager to learn and very responsive to guidance.

Psychiatric Diagnosis and Treatment

In approaching the psychiatric diagnosis of a child, it is important to know the child's previous developmental profile and to assess current symptomatology, arrests, or regressions. Pre-existing disorders are aggravated by cancer and must be monitored and treated throughout. The stress of cancer can make a mild disorder more severe.

Anxiety, depression, and delirium occur routinely in children and respond well to treatment. Behavioral interventions are the first line of treatment for anxiety, but some situations may require the use of anxiolytic medications. Benzodiazepines are sometimes used but can cause a disinhibition syndrome that may be mistaken for more anxiety. Mild depressive symptoms are common and often complicated by demoralization. After paroxetine was reported to predispose children to suicide, warnings were issued against the use of SSRIs in children. But experts point out that the evidence is not

strong enough to warrant a categorical prohibition and suggest cautious use with close monitoring. Desipramine (Norpramin) is contraindicated owing to several reports of sudden death.

Children suffer from delirium during critical illness, similar to adults. Pediatric delirium occurs in at least 30% of critically ill children. As with adults, children with delirium have worse clinical outcomes than those unaffected by delirium, including days admitted to the pediatric intense care unit (PICU), memory deficits, and longer school absences. Haloperidol has been used for behavioral symptoms associated with delirium in children, such as agitation. There are no randomized placebo-controlled trials of atypical antipsychotics in children with delirium; however, risperidone (Risperdal), olanzapine (Zyprexa), and quetiapine (Seroquel) appear to be effective tools for safe management of behavioral symptoms during delirium. Pediatric psycho-oncologists should be quicker to use medications for behavioral symptoms than child psychiatrists. Starting with small doses, using the lowest effective dose for the shortest possible time, and diligent monitoring for side effects are advised. Further studies in this area are certainly needed.

Pain Management

Children are at high risk of receiving insufficient pain management. Contributing factors include misplaced beliefs about childhood pain perception, inappropriate use of as-needed dosing, unclear communication of pain experience from young children, and complaints made in the context of normal regression, which is sometimes used to disqualify the complaints. Exhausted, critically ill children, given relief of suffering, may enjoy opiates in a way that upsets some parents and caretakers, leading to lowering of dosing.

Recent findings indicate that the experience of pain in early life may lead to long-term behavioral and psychological consequences. It has also been found that chronic pain, including neuropathic pain, is far more common in children than was previously believed. These findings still wait to be extensively disseminated and translated into

proactive and even pre-emptive pain treatment in infants and children.

Management of Stressful and Painful Procedures. Recent work on PTSD in children reinforces the principle that aggressive prophylactic relief during stressful procedures is important not only for current comfort but also for long-term adaptation. Poorly managed painful procedures not only brutalize the child but also result in anticipatory fear of pain, loss of trust and cooperativeness, phobias, and posttraumatic symptoms that do not improve over time. Unlike adults, children are anesthetized for bone marrow biopsies. Multimodal behavioral methods may be taught to parents, which can be extremely helpful during procedures.

Family Involvement

The families of pediatric patients are even more vulnerable than those of adults because of the child's total dependency and the biologic, emotional, and social factors that make families uniquely responsible. No intervention has any hope of success if it does not address the family as much as the child. In one study, mothers had a greater rate of posttraumatic symptoms than their children.

Childhood Cancer Survivors

Child survivors face daunting tasks. They must move beyond lengthy hospital stays or repeated day hospital visits, painful procedures, and severe side effects. They may have endured separation from their family, incurred resentment from their siblings, and missed as much as a year of school. They may emerge with physical handicaps or disfigurements, but the most insidious problems are the cognitive and verbal deficits associated with chemotherapy and radiation therapy. These may be compounded by drug-induced hearing losses. Children need to be monitored and given remedial help promptly.

It has been noted that the child's own perception of risk and the intensity of cancer treatment is more predictive of PTS than the

objective ratings of health professionals. Hence, it is useful to monitor perceived health status. There is a role for psychological evaluation and support throughout the illness as well as during the post-illness phase.

Children and their families may also feel a sense of victory and relief that helps the children's self-esteem. Nonetheless, it is still important for families to be supported and queried for difficulties when they return for the follow-up appointments, as they have been found to function less effectively than nonaffected families. Contacting the child's school counselor and teachers is an effective intervention because the latter are eager to be educated about special needs and reassured about how to help the child. The ability to reintegrate comfortably into school life and school friendships is a major factor in the child's adjustment.

Consent in Pediatrics

All pediatric consents are third-party consents and carry the possibility of conflicts between parent and child. The parent may make a decision that is not in the interests of the child, as in the refusal of life-saving treatment. The courts have tended to overrule parental authority in such cases. Parent and child may disagree, especially adolescents, although disagreements occur with school-age children as well, presenting staff with painful problems. Psychiatric intervention may help resolve the conflict if the consultant does not impose personal beliefs. Legal recourse is used only after all attempts at conflict resolution have been unsuccessful.

Genetic Testing of Minors

Decisions about whether to offer genetic testing or screening should be determined in the best interest of the child. Genetic counselors discourage the use of genetic testing to abate parental curiosity and anxiety.

Staff Problems

The maintenance of staff morale, the prevention of dysfunctional norms, the support of faltering members, and the defusing of unconscious competitive feelings toward parents are important ways of contributing to the well-being of all participants. The need for staff members to acknowledge their grief with the repeated loss of children whom they came to know well has given impetus to the custom of memorial services for one pediatric oncology ward, where the staff members gather every few months to remember each child that died in the interim. There is also more attention being paid to families during the mourning process, with outreach offers of support and provision of support groups. Staff members may derive indirect benefit from this greater acknowledgment.

Team Approach

The multidisciplinary approach to patient care is most widely implemented in pediatric cancer patients. Psychiatrists who specialize in child psychology can play a useful role and, where the model is not in place, are in a good position to help organize it. Local teachers and clergy should be involved, and community resources should be used to help families reintegrate when they return home.

GERIATRIC PSYCHO-ONCOLOGY

The population of older people is growing rapidly throughout the world. Currently, there are about 35 million people in the United States over the age of 65. That number is expected to double by 2030 and comprise 20% of the population, according to the U.S. Census Bureau. Cancer is a leading cause of morbidity and mortality in the aging population, with approximately 60% of all cancers and 70% of cancer mortality occurring in people aged 65 years or older. Of the 24 million cancer survivors worldwide, 61% are 65 or older. Psychiatric care of older persons with cancer presents a unique challenge for clinicians due to differences in phenomenology, assessment, and treatment in this population. Differences in psychological sequelae or specific psychological needs of older

cancer survivors have not been well studied, despite their growing numbers. Capacity assessments, informed consent, advanced directives, and surrogate decision-making are commonly encountered issues in caring for older cancer patients and should be handled based on the specific needs of the older adults.

Several cross-sectional studies have found lower or similar rates of psychological distress in older adult cancer patients compared to the younger adult population. Longitudinal studies either found no difference or higher psychological distress in younger adults. It is important to note that older adult cancer patients are at risk for underdetection and undertreatment of their psychiatric diagnoses due to decreased self-report of psychiatric symptoms, cognitive deficits, comorbid medical conditions, poor access to mental health care, and differences in phenomenology. In palliative care settings, there is a need to appreciate the individual differences in physical and psychosocial needs in older adults. The older adult with cancer at the end of their lives are at greater risk for untreated pain and depression and are more likely to commit suicide compared to their younger counterparts.

The goal of identifying and treating these distressing problems is to improve the overall quality of life and the functional status of older people living with cancer. This section will review the assessment and management of common psychiatric conditions in older adult patients with cancer.

Depression in Older Adult Cancer Patients

The prevalence of depression is 3% in older adult people living in the community and 10% to 15% for those living in nursing homes. Estimates of depression in cancer patients vary widely, with averages between 17% and 25%. Although many early studies of depression in cancer patients included older patients, there was not often a description of findings based on demographic data such as age. Several studies have reported that older patients with cancer have lower rates of depressive disorders or self-reported psychological distress than younger patients. Risk factors for

depression in older adult cancer patients include loss of a spouse, functional disability, inadequate social support, uncontrolled pain, poor physical condition, advanced illness, previous history of depression, other life stresses or losses, family history of depression or suicide, and medications known to cause depression. A study of 420 older adult cancer patients showed that higher levels of symptom severity, lower levels of prior physical functioning, and greater physical functioning deficits predicted higher levels of depressive symptomatology. The prevalence rate for depression was 18%. Cancer site, gender, stage of disease, and treatment type had no significant effect in predicting depressive symptomatology. In a longitudinal analysis of the course of depressive symptomatology in older adult breast, prostate, colon, and lung patients, the prevalence of depression was 26.1% 2 to 4 weeks after diagnosis, compared to 15.8% 1 year after the diagnosis. Lung cancer patients had higher rates of depression, likely due to higher symptom severity. In a group of older adult colorectal cancer patients, a longitudinal study examining depressive symptomatology over the first year following cancer diagnosis has shown that gender, race, comorbid conditions, physical functioning, social functioning, and symptoms were significant predictors of depressive symptomatology. Female patients, African Americans, and patients with two or more comorbid conditions exhibited more depressive symptomatology. The highest prevalence rates for depression were at the time of initial assessment, 18%. A prospective study in head and neck cancer patients comparing older adult and younger cancer patients has shown that 28% of younger and 30% of older adult patients had depression. Both groups of patients had higher rates of depression 1 year after diagnosis. There was no significant difference between younger and older adult cancer patients regarding the prevalence of depressive symptoms.

Assessing depressed mood in older adult cancer patients is difficult. Neurovegetative symptoms of depression such as poor sleep, poor appetite, and decreased energy can be related to the cancer or the treatment; however, the older adult tend to have more somatic symptoms of depression than younger patients. Assessing

the cognitive symptoms of depression such as hopelessness, worthlessness, guilt, and suicidal thoughts in addition to the somatic symptoms is important in geriatric cancer patients. Geriatric Depression Scale (GDS), the Center for Epidemiologic Studies Depression Scale (CES-D), and the HADS are commonly used in screening for depression in older adult patients. These scales need to be validated in older adult cancer patients. The NCCN Older Adult Oncology Guidelines have recommended the use of the Distress Thermometer to assess distress in cancer patients.

Differential diagnosis is an important part of depression assessment in older adult cancer patients. Although a cancer patient may respond with an appropriately sad mood in the face of initial diagnosis or setbacks such as recurrence, it is important to note that depression is not a normal part of aging or of having cancer. Late-onset first episode depression presents a diagnostic challenge to the clinician as some of these patients may be in the preclinical stages of Alzheimer disease or vascular dementia. Poor memory or impaired attention may be the initial presenting symptom of depression in older persons. Delirium should be ruled out in the presence of disturbance of level of alertness, attention deficits, and psychotic symptoms. Medical conditions should be considered as possible causes for depression.

Several psychotherapy techniques (i.e., interpersonal, supportive, cognitive-behavioral, group, psychodynamic psychotherapy, hypnotherapy, relaxation, and biofeedback) have been used effectively to help older adult cancer patients who are suffering from depression. The efficacy of antidepressants for the treatment of depression in cancer patients has been well established. There is also good evidence that depression in older adult patients with chronic medical illnesses can be treated successfully. Older adult patients should be started at lower doses of the medications, and the dose titration should be slow. SSRIs are usually the first line of pharmacologic treatment in depression. Studies in geriatric patients have found SSRIs to be equally effective as TCAs in the treatment of depression. Although TCAs have been the most extensively studied medications for the treatment of geriatric patients, they have been

replaced by the newer antidepressants because of a preferable side-effect profile. In treating older adult cancer patients who have depression, it is important to carefully review medications for possible drug–drug interactions.

Of the newer antidepressants, bupropion can have a stimulant-like effect that may be helpful for older adult cancer patients with significant fatigue. Mirtazapine is associated with sedation and weight gain, which may be a beneficial effect in older adult cancer patients. Psychostimulants may be most helpful in older adult cancer patients where the depression is accompanied by psychomotor slowing, decreased energy, and apathy due to their rapid onset of action. ECT is a safe and effective treatment for depression in the older adult. However, it has not been specifically studied in older adult cancer patients.

Suicide in Older Adult Cancer Patients

Older persons account for 18% of all suicide deaths. The ratio of attempted to completed suicide is 4 to 1 among the older adult, compared to a ratio of 200 to 1 in a younger population. The incidence of suicide is also higher in cancer patients compared with the general population. Identification and prevention of suicide require the definition of risk factors. Physical illness is a common risk factor for suicide in late life. Older adult cancer patients, and individuals with head and neck, lung, breast, urogenital, GI cancers, and myelomas, seem to have an increased risk of suicide. It is important to recognize and aggressively treat high-risk patients for depression and address suicidal risk.

Anxiety in Older Adult Cancer Patients

Anxiety is not well studied in the geriatric cancer population. In patients with cancer, the prevalence of anxiety ranges from 21% to 28%. Anxiety may be a component of pain, delirium, or depression. The differential diagnosis of anxiety in older adult cancer patients can be difficult due to several factors contributing to anxiety.

Steroids, antiemetics such as prochlorperazine and metoclopramide, alcohol, or benzodiazepine withdrawal are associated with anxiety.

As in younger patients, older adult patients may benefit from meditation, guided imagery, progressive relaxation, and reframing of negative, irrational thoughts. Other psychotherapeutic techniques such as insight-oriented, supportive, and group psychotherapy may also help reduce anxiety. Benzodiazepines are generally useful for short-term relief of anxiety symptoms. The clinician should be cautious in the older adult population. Lorazepam, oxazepam (Serax), and temazepam (Restoril) are better tolerated by the older adult. However, with all benzodiazepines, side effects such as drowsiness, confusion, and motor incoordination must be monitored. One of the greatest morbidities is their potential to cause an imbalance in the older adult patient, leading to falls. Patients with dementia or brain injury may have a paradoxical reaction to benzodiazepines and become disinhibited, irritable, or agitated. Many of the antidepressants listed above are also useful in the treatment of anxiety disorders. Stimulants and stimulating antidepressants (i.e., bupropion) should be avoided in patients suffering from severe anxiety. Buspirone (BuSpar) is a nonbenzodiazepine antianxiety medication that can be a helpful anxiolytic in the older adult.

When patients cannot tolerate benzodiazepines or when their anxiety is not well controlled, the use of a low-dose atypical antipsychotic can be considered. Atypical antipsychotics do not have adverse effects on respiration as do benzodiazepines. None of the antipsychotic medications have been FDA approved for use in the treatment of anxiety disorders in the general adult or older adult population. It is also important to note that the FDA has recently issued a warning against the use of antipsychotics for behavioral disorders in older adult patients with dementia due to increased mortality from cardiac and cerebrovascular events.

Fatigue in Older Adult Cancer Patients

Fatigue is a common symptom in older cancer patients. A recent study of fatigue prevalence has found this symptom to be universal in the older adult age group. In 84% of the cases, patients' fatigue interfered with the general level of activity. Fatigue was the most reported symptom in a quality-of-life study among older adult cancer patients. Fatigue remained the most common symptom both at the time of diagnosis and 3 months after diagnosis.

In older adult patients, the common etiologies of cancer-related fatigue are immobility, pain, depression, sleep disorders, anemia, metabolic derangements, undernutrition, infections, side effects of cancer treatment, centrally acting drugs, and direct effects of the tumor. All of these conditions should be considered in the evaluation of fatigue. There are several fatigue assessment measures, such as the Brief Fatigue Inventory, the Multidimensional Fatigue Inventory, and Piper Fatigue Scale, none of which have been validated specifically for use in the older adult cancer population. The relationship between pain, fatigue, and depression is important. A statistically significant relationship was found between fatigue and depression, pain, number of medications, and physical function in a study of fatigue in the older adult. Another study has shown that 70% of patients with fatigue had psychiatric comorbidity. Due to the significance of this relationship, patients reporting fatigue should be assessed for pain and comorbid psychiatric conditions, particularly depression.

Treatment of fatigue in older adult cancer patients has not been well studied. The first approach should be to address any potentially identifiable etiologies, such as anemia, depression, insomnia, or any metabolic abnormalities. Exercise has been used as a treatment for fatigue in cancer patients receiving chemotherapy but has not been well studied as a treatment for fatigue in older adult cancer patients. Medications have been used to treat fatigue in cancer patients. Studies on the treatment of fatigue in older adult cancer patients have not been published. Psychostimulants such as methylphenidate or wakefulness-promoting agents such as modafinil have been used successfully for cancer-related fatigue. Modafinil may be a gentler, better-tolerated medication for the older adult.

Antidepressants with some stimulating effects such as bupropion or fluoxetine may be helpful to improve energy, especially when there are also concomitant symptoms of depression.

Delirium in Older Adult Cancer Patients

Delirium is a disturbance in the level of alertness, awareness, attention, cognition, or perception that develops over a short period of time (hours to days) and fluctuates during the course of the day. The older adult are particularly susceptible to the development of delirium. An estimated 30% to 50% of older adult patients develop delirium during medical hospitalization. Older adult patients who develop delirium during hospitalization have an estimated 22% to 76% risk of mortality during that admission. Major risk factors for delirium appear to be pre-existing cognitive impairment, advanced age, and severity of comorbid medical illness.

The etiology of delirium in older adult cancer patients is often multifactorial. Mini-Mental State Examination (MMSE) is a useful, commonly used screening tool for cognitive impairment, but it does not distinguish between delirium and dementia. The CAM, the DRS, and the MDAS are other tools that can be used in the assessment of delirium, as detailed above.

In the assessment of delirium in older adult cancer patients, one of the most challenging problems is to distinguish delirium from dementia. Further complicating the issue, patients with dementia can develop superimposed delirium. Patients with dementia appear relatively alert and have more stable cognitive deficits, as opposed to the fluctuating symptoms in delirium. The onset of symptoms in dementia is slower, with a chronically progressive decline in cognitive function rather than the relatively rapid onset of symptoms seen in delirium. The management of delirium in older adult cancer patients involves addressing the symptoms of the delirium while investigating and ultimately treating its underlying causes. The treatment of delirium in cancer patients, including the older adult, is extensively reviewed above.

Dementia in Older Adult Cancer Patients

There are an estimated 1.8 million older adult individuals in the United States who have advanced dementia requiring extensive care. DSM-5 classifies dementia syndromes under major neurocognitive disorders and allows for continued use of the term dementia. Patients with severe dementia often exhibit emotional and behavioral disturbances that make their care more difficult. Studies have shown that geriatric patients with cancer who are cognitively impaired have a worse performance status, higher incidence of depression, and are at greater risk for death. Alzheimer dementia is the most common type of dementia. It accounts for 60% to 70% of all patients with dementia. Another 15% to 25% of patients have vascular dementia, and approximately 10% to 15% will have mixed dementia. The remaining patients have other diagnoses such as Parkinson disease, dementia of Lewy body disease, and frontotemporal dementia. The recognition rates of cognitive impairment range from 25% to 90%, depending on the health care setting and the degree of impairment. Recognition of cognitive impairment in cancer patients is especially important due to issues of capacity and decision-making in older adults. A diagnosis of dementia does not automatically determine a lack of capacity. However, when cognitive impairment is identified, it should prompt further evaluation. Often a psychiatric evaluation will be necessary to determine the patient's ability to participate in the decision-making process. When a patient is deemed not to have capacity, a health care proxy must be determined. Given the potentially poor quality of life for an older cancer patient with dementia, the extent of aggressive treatment should be carefully determined in a patient with severe cognitive deficits. Cognitive impairment may present special problems in the control of pain and other symptoms due to limitations in the patient's self-report or active participation in assessment tools.

Dementia has also been noted to develop secondary to cancer treatment, including chemotherapy, radiation treatment, immunotherapy, hormonal therapy, and supportive medications. It is not well understood how chemotherapy or radiation therapy might

affect cognition and whether older patients are at greater risk. A study of lung cancer patients has shown that the treatment of chemotherapy-related anemia could increase the cognitive capacity of older adult patients. A recent review of the literature concluded that there was not sufficient information on cancer treatment-related cognitive impairment in the older adult due to the small number of individuals studied, the variety of cancer types and treatments surveyed, the low number of longitudinal studies, and the limited battery of neuropsychological tests employed.

CANCER RISK AND SURVIVAL

The role of psychosocial factors in altering cancer risk and survival fascinates the public, but the discussion is often blighted by wishful thinking and genuine confusion. Cancer risk and survival are often conflated, and great emphasis is placed on the direct role of the individual's psychoneuroimmune mechanisms in preventing or curing cancer while ignoring many psychologically mediated effects that are far stronger and better established. There are many distorted beliefs and overinterpretations on the subject that psychiatrists need to know the current state of the art to better understand and educate their patients.

Cancer Biology

The natural history of a given cancer begins when changes in a cell's DNA establish the potential for this cell to become malignant. This *cancer initiation* precedes by many years (anywhere from 3 to 30 years) the second event, known as *cancer promotion*, in which growth suppression is lost and malignant multiplication begins. This again precedes by a period of months to years the appearance of clinical symptoms. Finally, there is a variable period between the appearance of any clinical symptoms and the seeking of care. Cancer risk can relate to the risk of initiation or the risk of promotion. Cancer survival is measured from the time of diagnosis, but this

ignores the important factor of delayed diagnosis, for which initial disease staging is a partial but incomplete solution.

Psychosocial Factors

One attempt at clarifying the multifaceted impact of psychosocial factors on cancer is to think in terms of

1. The *external loop*, which refers to ways in which psychological, behavioral, and socioenvironmental factors affect the person's behavior and lifestyle and, hence, cancer risk. Even there, the actual behaviors must be teased out from their psychological determinants.
2. The *internal loop*, which refers to the ways in which the person's psychological status affects cancer risk and survival via changes in the internal milieu. This effect can be mediated in many ways, such as neurologic, immune, and endocrinologic mechanisms, individually and in varying relations to each other.

Psychologically Mediated Environmental Factors

Cancer Risk. By far, the largest role in the development of cancer is played by inescapable environmental insults, such as radiation, viruses, and chemicals, acting cumulatively over time on each individual's predetermined complement of potentially cancer-causing genes. The individual's exposure to injury is in part out of their control and in part mediated by social and psychological factors over which they have variable control. By far, the greatest volitionally determined contributors of the psyche to cancer incidence are personal lifestyle and habits. Smoking cessation, abstinence from alcohol, more exercise, and better eating habits would probably lead to a substantial decrease in the incidence of cancer in the United States.

Cancer Survival. The greatest contributor to decreased survival is a poor use of screening because early diagnosis is still the best predictor of prolonged survival for most cancer types. Many

psychologically determined factors can play a role in delayed diagnosis. Patients with cognitive impairment, mental retardation, and psychotic disorders are especially at-risk populations for delayed presentation to health care professionals, which makes cancer screening efforts immensely important in those groups.

Research Review

Methodologic Considerations. To be reliable, the studies of the role of psychosocial variables should involve large populations over long periods of time. In commonly used case-control studies, the index population is usually unrepresentative of broader populations, and the matching is incomplete; hence, it is unlikely that one can generalize the findings to larger unselected populations unless the effects are so large as to be inescapable. In retrospective studies, the index population is equally unrepresentative, but these are essential pilot studies pointing the way to later larger ones. In prospective cohorts, researchers can control for the confounding variables, but the task remains methodologically daunting.

Current Findings. All this notwithstanding, more than 50 psychosocial factors have been claimed to play a role in cancer initiation or promotion. A wave of recent reviews has shown that few of them are valid, in many cases because the quality of the studies is poor, but also because the question is difficult to answer, given that cancer initiation begins 20 years before there is any clinical evidence. The lack of impact of bereavement has been demonstrated with recent, large, population-based studies. The role of external stress had been thought to be significant, but later studies have disproved this.

On the other hand, several recent studies have shown that social support is a significant positive survival factor, a fact that has important implications for mental health professionals. Social class has a variable effect on cancer risk, with some cancers labeled *cancers of poverty* and others labeled *cancers of affluence*. However, low social class has an unequivocal negative effect on

cancer survival. One must take into account the fact that these individuals are less knowledgeable about and less able to avoid toxic exposures and unhealthy lifestyles and, more to the point, may lack access to decent, not to mention excellent, medical care.

Race is also a strong predictor of decreased survival, but the effect is much decreased or even disappears after correction for social class and shows great variability within racial groups. Two recent studies of race and ethnicity were published back to back, one showing significantly poorer results for nonwhite children with acute lymphoblastic leukemia, and the other showing that, given equal access to effective state-of-the-art therapy, children of both races could expect the same rate of cure. The experiment was possible because acute lymphoblastic leukemia has an acute onset and a well-defined course of treatment. Given access to the treatment, parents could be depended on to bring the child for life-saving treatment.

The effectiveness of interventions aimed at improving lifestyle and health behaviors has often been disappointing, usually because the complexity of the problem is underestimated or because unrealistically short-term results are being demanded, or both.

Internally Mediated Risk and Survival Factors

Recent developments in psychoneuroendocrinology or psychoneuroimmunology have confirmed the feedback loop between feelings and perceptions, on the one hand, and neurologic, endocrine, and immune changes, on the other. These are, in small part, an updating of classic psychosomatic concepts. More urgently, this is the area of research in which recent developments lend theoretical support to current popular beliefs about the power of the mind over the body.

Personality Traits, Feeling States, and Coping Styles. There are weak and conflicting results on the role of personality in cancer prevalence and survival beyond what is mediated through risk-avoidant behavior. Studies are handicapped by the absence of

comprehensive prognostic indicator profiles. Meanwhile, no strong relationship has been established between personality style and disease outcome. Feeling states, such as level of distress or anxiety, have not been found to have any predictive value. A weakly significant association between passive coping styles and poor disease outcomes has been demonstrated in several studies using measures of the so-called fighting spirit, helplessness and hopelessness, stoic acceptance, and anxious preoccupation. The role of denial, which can be viewed as the operative factor, remains an open question and points again to the complexity of what is being measured.

Immune Mechanisms. Although crucial discoveries of the immune system describe several associations with mood and environmental changes, direct links to personality and coping styles have not been forthcoming. Importantly, epigenetic mechanisms postulate how early life stress and trauma change the physiologic reaction to stress later in life. These findings are relevant for patients with newly diagnosed or recurrent cancers who are experiencing repeated chronic stressors.

Endocrine Mechanisms. The HPA axis mediates several downstream effects based on negative and positive feedback loops. Mood states and chronic stress has been shown repeatedly to alter these feedback loop, thus resulting in higher levels of anti-inflammatory cortisol and other mediators. Unfortunately, stress hormones have long-term consequences that are also associated with stress and sequelae from psychiatric disorders. The dysregulation of hormonal feedback loops influences and is influenced by the environment, attitude, personality, and coping.

Effect of Psychological Interventions

Inasmuch as psychological interventions improve mood function and prevent or treat depression, there remains a possible survival benefit. It may not be directly from the intervention but from reversal depression which is associated with inferior survival based on

numerous studies to date. Many psychological interventions have been studied and demonstrated level 1 evidence of efficacy in various cancer settings. These are most commonly cognitive-behavioral therapies, psychoeducation, expressive-supportive therapy, mindfulness-based stress reduction, and other mindfulness-based therapies.

ALTERNATIVE TREATMENTS

Complementary and alternative medicine (CAM) is often defined as any medical system, practice, or product that is not thought of as standard therapy for the treatment of cancer or cancer-related symptoms. Many of these therapies are incorporated into practice based on the field of Integrative Medicine. Of note, complementary treatments refer to adding a non-standard therapy, and alternative treatments replace the standard therapy. These interventions may be as essential as diet and understanding the roles of specific diets based on disease presentation. Patients and clinicians should be cautiously aware of the dangers of treatments that lack an evidence base and are used to replace standard treatment. The risk depends on the disease or symptom in question and the potential side-effect profile of the alternative agent if it is a medicine (e.g., herbal formulation). Of note, adherence to unproven therapies may reveal a distrust of the medical establishment, may feel consistent with the patient's value system or may be influenced by societal or cultural factors. Unfortunately, the stigma of cancer propels people into magical thinking, which can have deleterious consequences. The toxicity of traditional treatments also makes patients so anxious that other options become compelling. The amount of out-of-pocket expenses spent on nontraditional treatment is in the billions. In one study, a large percentage of patients at a tertiary medical center was seeking alternative treatment while still in traditional treatment. They did so early in their course of treatment and took both simultaneously, dropping the traditional treatment before they dropped the alternative one. Educated and wealthy patients were best represented. The main treatments were physical ones to

cleanse and to strengthen the body; special diets to purify and fortify the body, as well as avoiding harmful substances; immune therapies; faith healing; psychological methods to improve mental attitudes and to reinforce the body's defenses; and many Eastern modalities such as yoga, tai chi, and meditation that promote improved discipline and decreased anxiety.

Many such treatments give patients a sense of purpose and control. The last category, improving attitudes, is most troubling to the psychiatrist because it leads so readily to blaming the victim. Patients are told that they can influence their cancer by mental efforts. The unspoken corollary is that further disease will be due to inadequate efforts and, worse yet, that they caused the cancer in the first place. This plays directly on attribution mechanisms to which cancer patients are already universally prone. One can also see desperate family members grasping at these explanations and trapping the patient ever deeper in a web of guilt and responsibility as a means of coping with their own grief and frustration or an angry patient blaming a family member for causing the cancer.

The psychiatrist must remember that many patients are secretly involved in alternative care that makes them embarrassed and distant if they cannot share it. As time passes, if their condition worsens, the burden of failure and guilt makes a greater contribution to psychic distress. Hence, clinicians must encourage disclosure and must help patients extract something positive from the experience. Active cooperation from physicians in encouraging their patients to use the nonharmful modalities, especially the ones for which there is a consensus about the benefit, increases the patient's trust and adds to the placebo effect and synergy of all the patient's treatments. This is difficult to do if patients and families retreat into anger at the establishment and reduce cognitive dissonance by clinging desperately to their alternate beliefs.

Given how much cachet these therapies had achieved, recent surveys in breast cancer patients suggested that between 48% and 66% of patients are trying some form of CAM. A recent review showed that the current data available from RCTs fail to demonstrate the efficacy of CAM therapy as curative. A small number of CAM

therapies may help patients feel better and recover faster. Aromatherapy and massage enhance the well-being of cancer patients.

One way in which the positive effects of complementary medicine are being brought into the mainstream while discouraging the dubious offerings is through the creation of complementary or integrative medicine centers within traditional medical centers. They shun herbal remedies but offer acupuncture, nutrition counseling, massage, meditation, gentle yoga, music therapy, and other disciplines geared to help patients with stress and pain. Patients are generally pleased that the help they had been surreptitiously seeking is now accepted by their physician. Herbs and the so-called food supplements remain unregulated and can be dangerous. *Aristolochia fangchi* was found to cause urothelial cancer in a group of Belgian patients, and patients who use *St. John's wort* to medicate their depression without telling their physician are, in effect, taking a tricyclic antidepressant drug without supervision, and one whose side effects have been better demonstrated than its efficacy. The NCI and the National Center for Complementary and Alternative Medicine (NCCAM) are sponsoring clinical trials at medical centers to evaluate CAM therapies for cancer.

FUTURE DIRECTIONS

The study of the psychological aspects of cancer continues to lead to many fundamental human issues, starting with the basic existential confrontations with death and the sense of self. Despite continuing progress, the public continues its fascination with the role of psychological factors in altering the course of cancer while ignoring the 50% decrease in cancer occurrence that increased exercise, better-eating habits, and stopping smoking and drinking would achieve. The issues associated with genetic advances illustrate the double edge of scientific progress, great promise, and great psychological stresses for which physicians are not prepared.

Psycho-oncology is one of the disciplines whose vitality and scientific productivity encouraged the American Board of Psychiatry

and Neurology to make Consultation-Liaison Psychiatry a formal subspecialty. Integration of a psychiatrist into an oncology team that is familiar with the psychological aspects of cancer, which can identify vulnerable cancer patients at risk, and which can recognize and treat the common psychiatric disorders has become fundamental. Psycho-oncologists can look forward to further research to improve the treatment of psychiatric syndromes in cancer patients, to maximize the ability to identify high-risk patients and to offer them support, and to come closer to translating basic science insights into clinical practice.

WEBSITES

The APOS has a website at http://www.apos-society.org/clinical/default.asp. There is also an APOS hotline at 1-866-APOS-HELP, where individuals can call with cancer-related psychological problems and questions and are given appropriate referrals.

The IPOS has a website at http://www.ipos-society.org/index.htm. A multilingual core curriculum on psycho-oncology for professionals is available at the website.

The NCCN has a website at http://www.nccn.org and provides the complete library of NCCN Clinical Practice Guidelines in Oncology. Besides treatment guidelines, they include detailed supportive care guidelines (including distress) and the latest detection, prevention, and risk guidelines.

The NCI maintains an extensive website at http://www.cancer.gov, and the ACS has one at http://www.cancer.org. Both of these sites contain reliable information for the public, patients, families, survivors, and professionals. The NCI maintains a list of current research protocols.

27.9 End-of-Life and Palliative Care

Xiomara Rocha-Cadman, M.D., and Mindy Greenstein, Ph.D.

When a patient's death is close at hand, it is the physician's task is not only to ease it but also to remember that *a patient who is dying is a patient who is still alive!* For physicians, who work and train for many years, specifically learning how to forestall death, this crucial task is sometimes easier said than done.

THE CHANGING WORLD

In the 20th century, especially after World War II, science developed beyond our imagination, adding some 20 years to the life span in developed countries. Medicine today is a far cry from the doctors carrying black bags but armed mostly with compassionately shared explanations and predictions. Their reliable presence earned them their patients' trust and gratitude. While payment was necessary (sometimes in the form of bartering), it was really the shared feelings that sustained their sense of meaning.

In contrast, medicine today requires mastering more sophisticated knowledge, skills, and procedures than ever. While medical science is still driven by a fundamental desire to help, its relentless expansion makes demands on caregivers, even as it arms them for the fight. This tension can be particularly difficult to navigate when caring for patients at the end of life, as Atul Gawande describes so passionately in his acclaimed book, *Being Mortal*. He particularly emphasizes the importance of caring about patients' *total well-being* rather than focusing primarily on illness.

In an unexpected shock, the 21st century has reminded physicians that there are sometimes relentless and deadly illnesses against which they haven't been adequately prepared to do battle. For example, rare pandemics which they must fight before being armed with scientific data or even known treatments. While pandemics have often been thought of as once-in-a-century events, many fear that the modern global era has sped up that time clock.

This chapter will discuss the many ways in which physicians and other health care providers have used their ingenuity to improve this situation.

DEATH, LIVING, AND DYING

Death follows many trajectories, among which peaceful old age has never been the most common. It erupts in the midst of health, war, and peace or creeps along an episodic or deteriorating course. Different trajectories bring different experiences, and any death radically alters the future *life* trajectory of the bereaved. Death from chronic illness forces sufferers and their loved ones to live in its presence for a prolonged period. *Untimely* deaths take their own special toll on the survivors, especially when suicide was the method chosen.

The concept of *timely* deaths is problematic. Patients of any age can undergo such deterioration and suffering that death is viewed as liberation. Some older adults accept death, but many older adult patients find it premature, with many families wishing desperately to extend the life of a beloved parent. In such cases, only the medical caregivers think in terms of timeliness, and care must be taken lest the concept becomes a back door through which ageism creeps into geriatric care or, more commonly and painfully, widens the empathy gap that so troubles patients and families.

There is also a distinction of great psychological consequence between physical and social death. While the bearer endures physical death, the entire community experiences social death. In a car accident, the person dies an immediate physical death but can be said to have died a social death only after being buried and

mourned and after the family begins to cope with the void left behind. Contrast this with a neurodegenerative disease, whose sufferers lose more and more of the roles that defined their social existence before dying a physical death, having been watched for years by grieving caregivers.

Thus, good end-of-life care must address the physical, psychological, spiritual, familial, social, and cultural characteristics that define the unique life that will be extinguished. The term *dignity* has been suggested as an organizing principle, perhaps because it points to the respect that it should induce in every witness. Developed further under the name "dignity therapy," its goal is to preserve the dying person's sense of integrity while coping with unavoidable physical insults and losses along the way. This requires medical caregivers who derive satisfaction from working toward this goal. A smile, a few moments of peace, scenes of reconciliation, and loving farewells—these are precious gifts from those who are cherished.

AWARENESS OF DEATH

Dying has been described as a physical process that begins at birth, but, more importantly, living is a state of mind that endures to the last breath. Thus, the goal of good palliative care should be the same as any care, namely helping the patient *live* to the fullest under any condition. Yet, there is an emotional chasm between thinking about one's death and seeing its actual contours. It has been said, most notably by Ernest Becker, that denial of death is at the root of many, if not all, social and cultural accomplishments, and it is undeniable that the strength of many religious beliefs is buttressed by their effectiveness in helping humans cope with suffering and death. Yet, Sigmund Freud believed that death anxiety represented the fear of abandonment and loss while fear of death arose because the human psyche could not conceive of its own non-being. That is technically true but incomplete. A number of people accept their death with equanimity. Some are heard to say they feel comforted by the thought of joining Mother Earth or the better life they believe will

follow, bypassing the question of being or non-being altogether. Difficulty coping with it may be associated with long-standing psychological issues that had never been tackled effectively, but these are not necessarily major diagnoses. Some existential therapists believe that helping the living grow in the face of their mortality is at the core of strength. This may be useful to some patients but not likely for the ones whose mortality is already their relentless and increasingly intimate companion.

Theories aside, the involved emotions and grief can be so difficult to manage that many patients and families have a shifting perspective in which awareness alternates or coexists with denial. This has been seen in a particularly complex and painful way during the COVID-19 pandemic, where family members' and even patients' perspectives ranged from terror to denial so great that some referred to the pandemic as a hoax and anywhere in between.

This paradox is characteristic of ill patients and may confuse medical staff trying to meet the patient's needs in different ways. It is also seen when families make decisions for a permanently unaware relative. Ultimately, confrontations with death generate over-determined responses in *everyone*: patients, families (especially those members who fear [whether reasonably or not] that their behavior may have contributed to the patient's predicament), and sometimes health professionals, each playing out a personal script on a personal timetable. Discrepancies and misunderstandings are difficult to avoid and often become intense under such stress, all of which are the physician's responsibility to manage! One would be hard put to find discussions of what this responsibility really entails in medical texts of 30 years ago, but recent decades have seen major changes.

HUMANISM IN MEDICINE

Medicine used to be a tightly closed shop and still is from the strictly medical point of view. It now looks appreciatively on many other disciplines that were eager to help patients and that both studies and doctors' own experience have proven to be helpful. In addition to

nurses, psychologists, social workers, and physical therapists, all of whom have always been there, there are now art therapists, music therapists, and writers who volunteer to help patients write their stories, to name a few. There are also support groups of all stripes to help patients and family members. Participants have voted with their feet and described improved mood and enriched lives. Groups have also been helpful to residents and fellows in many guises, including T-groups and journal clubs.

Humanism has extended further into medical education, which now includes expanded communication skills and ethics education, as well as cultural and religious sensitivity. In a large number of major hospitals and medical schools, senior faculty members have spontaneously produced films to help doctors understand illness from the patient's perspective. The most moving are the ones that describe a young doctor's terminal illness. The community is also exposed to expert panels of patients, former patients, and family members, as well as relevant films and plays. The questions-and-answer sessions that follow can provide meaningful exchanges between caregivers, patients, and family members. Even medical students are eager to participate. Stanford students, feeling that sexuality was not adequately covered in their schedule, arranged an evening course taught by a professor from a science department on the university campus. It was well attended and subsequently became part of the curriculum. Yale second-year students, eager to help the nearby poor community, organized a Saturday clinic backed by professors impressed by their desire to help. It went well, and by year's end, they presented the dean with a full roster of students ready to take over the following year.

Palliative Care

"Palliative care" once was thought of as a consolation prize when there was no more treatment to offer. It was more an announcement than a treatment. It has, however, undergone a welcome change. Like many important social changes, the current interest in palliative care goes back a long way. Two popular innovators contributed to a

sea change. In 1969, Elisabeth Kübler-Ross published a very popular book, *On Death and Dying*, which vividly described the psychological experience of dying patients. Suddenly, they became people with an inner life, a meaningful journey, and important intrapersonal and interpersonal experiences. Psychiatrist Viktor Frankl argued that people can experience a sense of meaning in life until the last breath. Next, the work of Dame Cecily Saunders at St. Christopher's brought a fully elaborated model of good palliative care to world attention in the 1970s. Her insistence on the use of opiates at whatever dose was needed to relieve patient suffering met with widespread public approval (despite frequent medical disapproval), leading to the expansion of the hospice movement in the United Kingdom and a lively grassroots movement in the United States.

Since then, there has been a steady stream of dedicated physicians who devoted themselves to developing palliative care within hospitals, such as Katherine Foley, who pointed out that "competence by itself is not enough, it must be paired with compassion." The value of palliative care was quickly recognized, especially since it enhanced the quality of life for patients of any age, with any kind of diagnosis, and during curative treatment as well as terminal care. It became established as a subspecialty of medicine in 2006 and trained physicians, psychologists, advance care nurses, social workers, and clergy, as well as many other dedicated specialists and volunteers. The demand for them has become so great that there is a shortage of them. The need became particularly acute during the COVID-19 epidemic. In one study of New York City area hospitals, palliative care consults increased by 59% compared with pre-pandemic requests 2 months earlier.

The Introduction of Medical Ethics into Hospitals

The initial rapprochement between ethicists and hospital physicians was difficult without at least one of them already able to function as a bridge. However, in keeping with the flexibility of the era, ethics committees did become well integrated into their hospitals and are now mandated by law. A great strength of these committees is their

multidisciplinary nature. Committee chairs are selected for extensive and appropriate medical or nursing experience, a thorough knowledge of the ethical issues, and a high level of experience. They continue to keep the members up to date and bring in speakers as needed.

Most important, they staff a highly valued consultation service that can support a physician in demanding conditions. The ability to prolong both life and the dying process in the context of individual patients' and family members' disparate values, goals, and levels of capacity can put physicians into an ethical bind, which also has psychological consequences for their own well-being. Doctors must recognize that managing them is a collaborative effort. In addition to nurses, there are also ethics committees that can mentor them about the various ethical issues involved.

The ethics consultation consists of a set of services provided by a group of individuals assigned by their institution who seek to resolve conflicts regarding specific ethical concerns. This group can identify and analyze conflicting values when it comes to decision making. One of the most common issues requiring consultation is end-of-life care, for example, whether the decision to withhold cardiopulmonary (CPR) attempts may be made without involving a patient surrogate.

Since terminal situations are the most tragic, the consultation service is often called and may support both family members and members of the team. That support may be a greater factor in resolution than any ethical argument and confirms the value of pairing competence with compassion.

PSYCHOLOGICAL REACTIONS OF PHYSICIANS

All humans are equal in the face of death, but physicians are expected to put aside their personal reactions to remain focused on the care of any dying patient, as well as the family. Yet, there is evidence that doctors may have more death anxiety than others and that some become physicians to conquer that fear. Regardless, long exposures to disease and death can breed anxiety, despite the appearance of familiarity, and, since patients and families cannot see

their doctor falter, the practice of medicine demands high intellectual coping skills. Fortunately, this work is profoundly rewarding for most seasoned physicians, who had enough resilience and compassion to get through all the hard moments and benefit from the learning opportunities. Time and experience also facilitate resilience.

However, today's physicians, especially those still in graduate training, are dealing with a society with increasing expectations. Patients and families read a wide range of medical articles—sometimes useful, sometimes inflammatory—and may demand more ineffective treatments. Others may manifest uncontrolled grief or anger, sometimes becoming threatening. In the middle of the hectic pace and complex demands typical of today's hospitals, facing many such confrontations with death can arouse threatening emotions, especially in younger physicians. Rare, but perhaps deepest, is an inchoate fear that can be so rapidly submerged that it is barely experienced, much less explored! Basic self-protective behaviors such as tamping down one's emotional responses are inevitable. If recurrent, they will eventually lead to feelings of inadequacy and anxiety, which may feed upon themselves.

Also, when facing "bedrock" human pain, tired physicians may suddenly realize that some personal experience has been awakened. They tamp that down as well and correctly focus on tackling the situation at hand. However, recurrent experiences like this can ultimately impede their ability to be truly present with their patients. In all these cases, if physicians in this position avail themselves of supportive resources, constructive discussions can liberate them and help them feel strong.

This kind of denial is not universal. Many rise to the demands of their life choices to the benefit of patients, trainees, and colleagues. However, until recently, many of today's students have not previously been exposed to this kind of suffering since death had moved out of the home and into the hospital. This is why it is particularly important for institutions to support young physicians as they navigate this difficult terrain. Even those who usually navigate it well might need help from time to time. Fortunately, the last 25 years have seen

welcome developments in the profession's awareness of the need for support and training of staff.

INSIDE THE MAELSTROM: PSYCHOLOGICAL REACTIONS OF PHYSICIANS DURING AN EPIDEMIC OR PANDEMIC

As of this writing, today's students, trainees, doctors, and all hospital staff are receiving the kind of education in death and dying that comes once in a lifetime, perhaps once in a century. This education is forced on them—as it is forced on everyone around them—during times of epidemics and pandemics, an education that is relentless, particularly in its special attack on our common humanity. The fight against COVID-19 has rightly been described as a war, turning doctors, nurses, and all health care staff into frontline soldiers. The psychological toll on them has been great, personally, professionally, even morally. Some physicians describe the pandemic as the greatest threat to the intimacy of the doctor-patient relationship they have ever known. They complain about how little time they have to grieve their losses when there are so many very sick people who need their attention. In the early days of a novel pandemic, an added burden is the fact that the health care team is still learning what helps and hurts their patients, who serve as involuntary subjects in an experiment for which they hadn't signed up. Themes common to health care workers' descriptions of this toll can be found in Table 27.9–1.

As of this writing, 3,000,000 people have already died around the world of this disease, with many more to come before vaccinations are able to subdue it. Medical staff can be overwhelmed by the sheer massiveness of the scale, sometimes to the point of having to turn away patients who need their help and who may be going home to a very lonely and terrifying death. This may also be the case for patients dying of other illnesses, for whom there is no room.

Fear is everywhere during such times, in grocery stores, in dentists' offices, but it is greatest on the hospital floor, where every

colleague and every patient is both utterly vulnerable and a potentially lethal threat to everyone else. This situation gives rise to a feeling of dehumanized interactions between patients and the staff caring for them, who must be shielded from them by multiple layers of protective clothing, masks, and face shields so tightly sealed that they leave lines etched into faces long after they are removed. And yet, these same health care personnel must act as the human go-between between dying patients and the family members who would wish to be with them at the end. And they also inform the family when their loved one has died.

Table 27.9–1.
Common Themes in Health Care Workers' Reactions to the COVID-19 Pandemic

Lack of control and a sense of futility

Relentlessness

Unresolved grief over patients dying at an unprecedented pace

Emotional and physical exhaustion

Guilt:

- Learning on the job how to best treat patients for a new disease
- The feeling of failing their patients morally when forced to make triage decisions they wouldn't make under normal circumstances, like sending people home to die because there is no room for them in the intensive care unit
- Being afraid of patients and colleagues who might infect them

Feeling isolated from the community, particularly the feeling of working in a "war zone" while many members of the outside community don't heed public health advice

Fear of contracting and potentially spreading disease, particularly to family members and loved ones

Anger

- Shortages of personal protective equipment
- Denial by others of the seriousness of the disease

Dehumanization in the doctor–patient relationship

- The need for personal protective equipment hides faces
- Fear of contagion and the intense pace of work lead to spending less time with individual patients

Feeling emotionally numb or fearing becoming so

The fear stays with medical staff as they return home, sometimes isolating themselves from the family in order to protect them from themselves until they return to work the next day to start it all over again, sometimes while mourning patients they have lost, but also friends, family, or colleagues as well.

Helping the Helpers

Help for medical professionals and staff must address environmental, interpersonal, and intrapsychic dimensions, especially in wards with prolonged illness and high mortality.

A supportive environment acknowledges the stressors and provides:

- Leaders who validate emotional realities and make clear but understandable demands
- A team approach that provides backup prevents isolation and precludes feeling too irreplaceable
- The use of practice interviews for a range of difficult situations, with a trained leader using actors or real patients
- The presentation of seminars and case conferences to discuss difficult cases, the ethical and existential issues that they arouse, or any reaction that a trainee wishes to discuss
- The use of a group for first-year trainees with an outside leader familiar with the hospital environment they face
- The availability of confidential psychological support without prejudice

Doctors can be more authentic with patients if they are allowed to be authentic with themselves and each other within the proper bounds of the workplace. This extends across wider groups as long as they have shared goals, as proven by some of the many humanistic programs offered to the wider hospital community in many medical centers, such as Memorial Sloan Kettering's *Art of Medicine* series. The result is a more comfortable atmosphere, easier relationships, and, above all, patients and families who benefit from the staff's ability to affirm shared goals.

The trainee, or any physician who is troubled or under-functioning in any way, should be approached for an individual discussion with a trusted supervisor and, if indicated, referred to a seasoned psychiatrist who is familiar with the setting.

One approach, originally introduced by hospices, is to hold staff memorial services at regular intervals, during which all patients who

had died in the interim are named and remembered with stories, tears, and chuckles. These have now been instituted on many hospital services and are highly valued by staff. Some wards invite family participation, which is deeply valued.

Helping the Helpers During an Epidemic or Pandemic. A supportive environment during an epidemic or pandemic must remain particularly flexible and attuned to the many types and intensities of emotional assault on health care workers and provide:

- Different modalities of support as needed, including one-on-one sessions, support group sessions, or others using videoconferencing and telephone support when face-to-face interactions are dangerous.
- A chance for health care workers to choose which modality best suits them at a given time. For example, using a teleconferencing method such as Zoom, but allowing participants to mute their own computers or turn off their cameras if they want. They may prefer to listen than to speak. In one group for New York City area hospitals, for instance, nurses all preferred a telephone-based intervention rather than one mediated by videoconference.
- An environment in which facilitators remember that what they say to participants—whether individually or in a support group—is often less important than how well they listen to them.
- A chance for medical staff to grieve for all the losses they experience day in and day out.
- Consistent reminders to the medical staff regarding the importance of self-care. Proper self-care helps not only the staff members but also helps them to help their patients and colleagues and decrease the chance for burnout.
- Giving health care workers room to express their feelings while listening to others express theirs offers validation and respite, and sometimes, even helpful advice about how others get through their day. Perhaps the most important element of a support group or session is the reminder to medical staff that, even in the midst of so much isolation and intense feelings of dehumanization, they are all in it together, expressing their

common humanity by taking care of their patients and of each other.

COMMUNICATION BETWEEN DOCTOR AND PATIENT

Good communication skills are essential to the success of any clinical encounter. Poor skills can create vicious cycles; when physicians cannot identify the patient and family values that should influence medical decisions, it becomes hard to develop a solid treatment plan or to assuage uncertainties. This generates chronic anxiety and dissatisfaction in patients and family and increases the likelihood of inconsistent information from other members of the team. Finally, without effective communication, the patient and family experience the inconsistencies that often accompany their sense—right or wrong—of vague treatment goals, which lead them to demand yet more end-of-life health resources.

Guidelines to Good Communication

Communication skills can be learned in many ways, including experiential exercises, retreats, and workshops. Physicians who undergo training in this area report greater comfort and increased feelings of self-worth as they provide terminal care. Interactive teaching modules with role-plays are particularly effective. The experiential, interactive, and group aspects help clinicians detoxify their own insecurities and find support in one another. There are also didactic teaching modules and articles with clear and useful guidelines about breaking bad news. Despite the challenges posed by these tasks, the literature indicates that the courses increase confidence and improve communication. For an immediate example, a scenario follows:

What does the patient know? Always inquire about what the patient and family know before providing new information. “We are here to discuss the further plans for your care, but, before that, do you have any concerns or questions about your illness and the way

things are going." Physicians are often startled to see gaps shaped by lack of information as well as culture, education, socioeconomic class, and religion. When such gaps are ignored, serious misunderstandings are likely to follow. Clarify cultural expectations if indicated.

How much does the patient want to know? Historically, families have generally "protected" loved ones from hearing bad news. This practice has been slowly changing in some parts of the world. Most western countries now view it as abuse. Patients have the full right to receive all information but are not deprived of the right *not* to know. The corresponding legal terms in the United States are *informed consent* and *informed refusal.* The language used in medical care is more detailed than for the legal system:

Full Disclosure is for alert, expectant patients, who may pay a psychological price for their knowledge, but will keep up an active dialog and maintain good access to the doctor.

Nondisclosure: Total nondisclosure applies to the very frightened, dependent patient or an incapacitated one; both will need various supports, management, and a proxy.

Individualized disclosure is for patients who only want to know so much. They should be given the right to *informed refusal,* which should be documented, and they should be asked to name a surrogate or a health proxy. "Are you saying that you would rather that I did not discuss the details of your illness with you?"

Sharing the information: The physician should make no more than a few selected points, as patients have difficulty processing too much information when stunned by painful news. "I have given you a lot to process all at once. We can talk tomorrow when you have had a chance to think more about it." When continuing earlier discussions, the focus should be on adapting the goals of care to a changing situation. "We cannot cure the cancer, but we have some treatments that may slow its growth." It is helpful to include familiar staff members. The tone must be one of openness and realism but must always contain a message of hope, even when the situation is so dire that hope lies in the promise of continued caring, support, and symptomatic care. "It is true that the treatment is no longer

working, but there are many other measures to discuss, and, no matter what you choose, we will work closely with you to keep you comfortable." Feedback must always be obtained to ensure that the patient has understood and agrees. Patients should be encouraged to express their feelings and explore their level of understanding. "Before we end, I want to make sure that we all agree about the next steps."

Responding to patient and family feelings: The physician should be prepared for possible outbursts of intense emotion, especially in the wake of previous rosy promises. Alternatively, patients may have been given realistic information but subsequently comforted themselves with unrealistic hopes. The opposite is also heard: "You have taken away hope!" This can be minimized by an affirmative, engaged attitude about the many ways in which care will be continued to the end. Ambivalence is always present, and disbelief may predominate. It can be gently confronted, but there is no need to insist because the conversation will be resumed many times in the days to follow, and the passage of time will effect a change. Physicians must acknowledge the emotions, validate their normalcy, and reflect on the patient's and family's observed strengths while indicating an awareness of the difficulties that they are facing. "This is difficult news to hear, even with all of the support and comfort that I have seen you give each other."

Planning and follow-up: These are the keys to a successful interchange. Patient and family must be left with a clear sense of what care is being provided and why. Further meetings must be planned; end-of-life decisions are psychologically and morally so stressful that some repetition is essential. Their understanding and acceptance must be ensured, and multiple support sources must be explored. However, under so much emotional fear and pain, and in complex families, the responses may impair patient care, and psychiatrists may be consulted.

The tenor of these discussions will vary with each physician, but its understanding and respectful tenor should always be there.

Consultation: Communication is always enhanced by consulting with other members of the medical team. It is to everyone's benefit—

whether senior attendings or young physicians—to maintain good relationships with seasoned nurses, whose keen understanding of the patient's family situation helps greatly. Social workers are often sophisticated family therapists. Other resources available include psychologists, who are both therapists and have specialized skills, patient representatives, physical therapists, or any other staff playing a role in patient care.

Psychiatric Contributions

When asked for an inpatient consultation in a new ward, the psychiatric consultant must recognize that the ward is a complex interactive system that affects every patient case. Taking some time to learn the ropes while working on a case pays off for that day and on future consults. Staying in touch with staff is essential.

The consultant should evaluate a responsive patient alone first, then with input from family members. Next, sharing one's findings with the physicians and involved nurses will probably include additional questions and information exchanges on both sides. The results should be a manageable plan. With very difficult cases, the extra time is well rewarded. The psychiatrists must reframe family dynamics in ways the staff finds more understandable, or, if not more pointed, and open to different management.

The consultant is obliged to avoid unnecessary details, even—or especially—if they might become gossip. However, an anecdote that brings shared pleasure into the picture, like the patient's tennis prize, should definitely be shared. Turning to staff members, if psychiatric consultants observe something like exaggerated negative judgments, they can interpret some of the patient and family dynamics in a more understanding way. If consultants identify particular individuals who have become too involved positively or negatively, they must note this and review it privately with the individual. Over time, trusted psychiatrists may be called on by staff members for personal reasons, and obtaining the best referral for them is an important contribution to their work.

PHYSICAL AND PSYCHOLOGICAL SYMPTOMS IN PATIENTS WITH ADVANCED DISEASE

Studies have shown that dying patients experience more symptoms than they can describe. In a cancer patient study, outpatients averaged more than 9 symptoms, and inpatients had more than 13 symptoms, many of them unrecognized or undertreated. Unexpectedly, when psychological symptoms and existential concerns—such as nervousness, sadness, insomnia, fear of dependence, or loss of dignity—are included, they are significantly more prevalent than the physical ones. Many recent studies confirm that physical, psychological, neurologic, hormonal, and existential concerns interact with each other in ways that are only beginning to be understood. What this relationship indicates is that all symptoms must be attended to. Sometimes this needs to be emphasized with physicians untrained in palliative care.

Symptom Assessment

Any intervention must be examined in light of the patient's total illness and treatment goals. How does it relate to the general quality of life and the goals of care? For example, metastatic bone pain responds to radiation, but this should only be done if the benefit outweighs the discomfort of moving the patient and if the patient prefers this to intensified opiate treatment.

The use of validated instruments, such as the Memorial Pain Assessment Scale (MPAS), allows more reliable evaluations, making it harder to dismiss symptoms. It asks for the level of pain, from 0 to 10. Over time, patients serve as their own controls because their scores are internally consistent. Pain evaluation has become a vital sign used in routine reassessments, ensuring that the patient's voice is heard by overworked caregivers. Other scales that can measure distress and quality of life include the Hamilton Depression Rating Scale (HDRS), the Hamilton Anxiety Rating Scale (HADS), the Distress Thermometer, and the Quality of Life questionnaire (QOL). Internal consistency is true for them as well.

Assessment and Treatment of Pain

Incidence. Pain is common in dying patients but can be relieved or at least managed until the very end. However, the prevalence of pain at the end of life remains extremely high.

In cancer, its overall prevalence of 51% rises to 75% in advanced disease, of which 64% is moderate to severe, and 20% to 30% is said to be excruciating if untreated.

Unfortunately, cancer pain is commonly undertreated; about one-third receive suboptimal analgesia in proportion to their pain. Pain management should be individually tailored according to its pathophysiology as well as the patient's subjective experience. Cancer pain can be classified as either nociceptive or neuropathic and can be manifested as acute or chronic.

Pain is also frequent in AIDS and advanced multiple sclerosis (MS) and can be expected in almost any advancing illness unless patients slip into a coma, as seen in hepatic failure or untreated hypercalcemia. Pain specialists are widely available. In the hands of a skilled physician, adequate relief should be obtainable in the majority of cases, and some alleviation obtainable in the rest, but there are often significant side effects. Many of them can be corrected or minimized, but patients and physicians must decide together which symptoms or side effects are most acceptable.

The psychiatrist can work with psychological symptoms now known to be intimately connected to the experience of pain.

Types of Patients. The management of pain should be addressed first by distinguishing its intensity using a 0 to 10 numerical scale, and it must be individualized to address the patient's specific goals in terms of comfort and functioning. It is useful to recognize patients in several categories.

Acute pain patients respond well to treatment but can develop tolerance to any analgesic, requiring more medication if the pain lasts beyond a few days or weeks. This needs to be explored without prejudice or judgment in very ill or dying patients. Nor should patients who will live long enough to improve and continue to use the

medications be viewed prematurely as *addicted* or *drug-seeking*. While the very success of recent treatments (bringing more cures or longer survival) has been accompanied by increased addiction and all its problems, this does not warrant decreasing pain treatment. Patients presenting with an acute pain crisis may require hospitalization for appropriate management or may be an appropriate candidate for hospice care.

Chronic pain patients: The treating physician should be careful not to minimize the severity of patients' pain over time or lose sight of the progression of the disease, even if it is slow. The use of opiates in chronic pain is still controversial, especially in nonmalignant pain. However, regardless of controversy, there is no justification for withholding relief in a patient with a predictably limited future, even one that may extend over many months.

Chronic pain patients in palliative care are already dependent and may begin to use opiates as a release from existential suffering, as well as from physical pain. This should not be denied to a dying patient. However, if indicated, a psychiatric consultant can help explore and differentiate between these conditions and can recommend specific interventions. Improved spiritual and psychological well-being occasionally results in less opiate use, but the guiding principle should always be effective relief of distress.

Palliative care patients with a substance abuse problem: If actively abusing or on methadone (Dolophine), these patients are already tolerant and must be given a correspondingly larger amount of medication for adequate pain control. Prejudices about such individuals must be put aside, and they should receive the same compassionate pain relief as others.

Multiple Pains. Patients with advanced disease commonly experience several different kinds of pain (Table 27.9–2). The distinctions are important because they call for different treatment strategies: somatic and visceral pains are more responsive to opiates, while neuropathic and sympathetically maintained pain often responds better to nonopioid adjuvant medications. If neuropathic pain is an integral part of the condition, it may respond poorly to

treatment. Treatments to consider are glucocorticoids (dexamethasone) or specific anticonvulsants and antidepressants such as pregabalin (Lyrica) or gabapentin (Neurontin). A comorbid depression may be helped by analgesic antidepressants, for example, a tricyclic drug such as desipramine (Norpramin), or a serotonin-norepinephrine reuptake inhibitor such as duloxetine (Cymbalta). Therefore, the psychiatric consultant should seek out a sophisticated pain history and ensure that all of the patient's different pains receive individual attention until the last breath. Again, pain consultants should be consulted as needed.

Diagnosis and Prognostication. A careful evaluation may require an etiologic work-up; certain pains can be eradicated even in terminally ill patients. Even so, it is critical to always weigh the benefits of better pain relief against the pain and intrusiveness of diagnostic procedures. Clinical decisions are hindered by the inaccuracy of medical prognostication at the end of life. Studies show that the majority of DNR orders were written within less than a week of death. This over-optimism leads doctors to be more proactive with treatment and, often, less generous with opiates. It also worsens the family's ordeal and increases their later regrets, which can create lasting wounds. A consultation with the Palliative Care team may help to disentangle these thorny treatment issues.

Table 27.9–2. Types of Pain

Nociceptive Pain	
Somatic pain	Usually, but not always, constant, aching, gnawing, and well localized: for example, bone metastases
Visceral pain	Usually, but not always, constant, deep, squeezing, and poorly localized, with possible cutaneous referral: for example, pleural effusion leading to (1) deep chest pain and (2) diaphragmatic irritation referred to the shoulder
Neuropathic pain	Burning dysesthetic pain with shock-like paroxysms associated with direct damage to peripheral receptors, afferent fibers, or the central nervous system, leading to loss of central inhibitory modulation and spontaneous firing: for example, phantom limb pain; can involve sympathetic somatic afferents
Psychogenic pain	Variable characteristics, secondary to psychological factors in the absence of medical factors: vanishingly rare as a pure phenomenon in patients with advanced conditions, in which pain is often present, but often is an additional factor in the presence of organic pain

Treatment of Pain. Aggressive multimodal treatment should be the norm. Drugs are the mainstay but must be part of a broader approach, including ancillary programs such as relaxation, guided imagery, massage, hypnosis, acupuncture, use of splints, and exercises. Music has always been soothing, to the point of helping

regulate breathing in semicomatose patients. Unfortunately, there are multiple significant barriers to pain relief in cancer stemming from system obstacles, patients themselves, family members, and clinicians.

PHARMACOLOGIC TREATMENT OF PAIN. The World Health Organization's (WHO) three-step ladder for cancer pain control is a drug-treatment method known to be effective in many cultural and national settings. The use of drugs begins with nonnarcotic analgesics, moves to the opiates used for moderate pain, then to opiates used for severe pain, culminating in a continuous drip with adequate *rescue* doses for breakthrough pain. Many opiates can be escalated without any upper limit, as long as side effects are well managed. Nonnarcotic analgesics and other adjuvant medications should be used as adjuncts to narcotics at any stage.

CLASSES OF PAIN MEDICATION

Nonopioid Analgesics. Nonnarcotic analgesics include nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen. The latter is a good analgesic for mild-to-moderate pain, with few side effects, except rare hepatotoxicity, especially in the presence of alcohol abuse or hepatic disease. All NSAIDs have a ceiling effect; hence, their use in fixed combination with a narcotic means that the narcotic cannot be used to maximum effect unless more of it is added separately. NSAIDs produce analgesia by blocking the biosynthesis of prostaglandins, inflammatory mediators that initiate pain. They are said to help bone pain and are good anti-inflammatory agents, but side effects often limit their use in patients with advanced disease. Contraindications include renal disease, a history of peptic ulceration, hypertension, bleeding diathesis, and encephalopathy. When appropriate and available, use patient-controlled analgesia.

Opioid Analgesics. Some narcotics are effective for moderate to moderately severe pain and should be used until they are no longer

effective. Opioids include morphine, fentanyl oxycodone, hydromorphone, oxymorphone levorphanol, and methadone. Morphine, hydromorphone, hydrocodone, oxymorphone, and codeine should be used with caution in patients with fluctuating renal function. Their main side effects are sedation, dizziness, and nausea, which can be dose-limiting, but confusion, delirium, and hallucinosis are also seen. The narcotics that work for severe to very severe pain are divided into pure agonists and mixed agonist–antagonists. Pure agonists have no ceiling effect and can be increased indefinitely, as long as side effects are controlled. Somnolence responds to stimulating agents such as dextroamphetamine methylphenidate and amphetamine and dextroamphetamine in both immediate- and delayed-release preparations. Modafinil, a non–stimulant-activating drug developed for use in narcolepsy, is effective in medically ill patients. Confusion, delirium, and organic hallucinosis respond to antipsychotic agents, and nausea can be helped by a variety of antiemetics (e.g., prochlorperazine). Mixed agonists–antagonists should be left in the hands of skilled practitioners because they have a ceiling effect, can reverse positive effects, or can precipitate an abstinence syndrome in patients already dependent on pure agonists. They also have a higher incidence of psychotomimetic effects, such as confusion and hallucinations. A frequent mechanism of psychotoxicity is the accumulation of drugs or metabolites whose duration of analgesia is shorter than their plasma half-life, notably morphine levorphanol and methadone. Using drugs such as hydromorphone with half-lives closer to their analgesic duration can relieve the problem without loss of pain control. Cross-tolerance is incomplete between opiates, so patients should be tried on several drugs, and the dosage should be lowered when switching drugs. Knowing equianalgesic doses of drugs and different routes of administration (Table 27.9–3) is important so as to avoid accidental under medication or overmedication. For example, to change a patient from intramuscular (IM) to oral morphine, one should multiply the IM dose by two to six times (depending on the chronicity of usage) to avoid causing the patient pain and provoking what others will call drug-seeking

behavior. Dying patients who must choose between pain and alertness face a poignant dilemma, but somnolence can be countered by several safe psychostimulants and can be used in ways that meet shifting needs.

Dosing Instructions. The need for regular *by-the-clock* administration, as opposed to *as-needed* (PRN) administration, cannot be overemphasized. It is counterintuitive, but a maintenance schedule achieves faster and better pain control with a smaller total dose because it is an early and often pre-emptive response. PRN orders only provide a slightly or very delayed response. The patient may wait until the pain is significant before calling for medication and then wait again for it to be given, during which time increasing pain is worsened by anxiety and growing resentment. The patient starts to ring repeatedly, often annoying overburdened nurses. The patient has been set up! To some extent, so have the nurses.

Rescue doses should be directly available to the patient for breakthrough pain. Their repeated use should signal the need to raise the maintenance dose. Any patient on breakthrough doses should always be sent home or to a hospice with the same prescriptions since new doctors may not realize the patient's condition.

Adjuvant Drugs. Adjuvant drugs should be used simultaneously throughout. Many of them are psychotropics well known to the psychiatrist, but their analgesic effect has often been shown to be separate from their primary psychotropic effect. They are particularly important in neuropathic and sympathetically maintained pain, where they can be the mainstay of treatment, but they also introduce new side effects that need to be recognized.

Surgical and Anesthetic Modalities. Other modalities include palliative radiation and anesthetic and neurosurgical techniques that can all give regional relief where other methods have failed. Their intrusiveness is only warranted if they are painless once installed

and can provide significant relief, as they often do. Other methods should be considered in imminently dying patients.

Coexistence of Pain and Psychiatric Symptoms. Patients with pain have a significantly higher incidence of depression and anxiety. It had been suggested that: (1) chronic pain may be a depressive equivalent, (2) pain may cause psychiatric syndromes, and (3) pain may coexist with psychopathology in vulnerable subjects. Given the steady stream of interactions now recognized as integral to the human organism, it can be said that *all* suffering patients are vulnerable, and treatment should proceed from *any* angle. Psychiatric interventions, along with primary medical ones, selected integrative medicine options and thoughtful, personal care all play a role. The result will be more than the sum of its parts.

Table 27.9–3.
Routes of Opioid Administration

Route	Comment
Oral	Preferred in cancer pain management.
Sublingual	Buprenorphine (Buprenex) is effective but SL buprenorphine is not indicated for pain. Efficacy of highly lipid-soluble drugs, such as fentanyl (Actiq), is likely, but there are no studies and little clinical experience. The efficacy of morphine (Duramorph) is controversial.
Rectal	Available for morphine, oxymorphone (Numorphan), and hydromorphone (Dilaudid). Customarily used as if the dose were equianalgesic to oral dose. Absorption is variable, however, and relative potency may be higher than expected.
Transdermal	Available for fentanyl. Dosing interval is 2–3 days. Empirical indications include problems with oral drugs, desire to offer a trial of fentanyl, compliance problems with oral dosing, or the possibility of improved quality of life if oral therapy is avoided.
Oral transmucosal	Formulation using fentanyl is currently undergoing trials for breakthrough pain.
Subcutaneous	
Repetitive bolus	Ambulatory infusion pumps can

Continuous infusion Continuous infusion with patient-controlled analgesia	provide continuous infusion with any parenteral opioid formulation. More advanced pumps can also provide patient-controlled analgesia. The clearest indication is an inability to tolerate the oral route.
Intravenous	
Repetitive bolus Continuous infusion Continuous infusion with patient-controlled analgesia	Continuous infusion is possible if a permanent venous access device is available.
Epidural	
Repetitive bolus Continuous infusion using percutaneous or implanted system	The clearest indication is pain below the arms and dose-limiting side effects from systemic opioids. Often co-administered with a local anesthetic.
Intrathecal	Usually administered via a totally implanted infusion pump. May be cost-effective for those patients with a clear indication for intraspinal therapy and long life expectancy.

Adapted with permission from Portenoy RK, Osta BE, Bruera E. Physical symptom management in the terminally ill. In: Chochinov HM, Breitbart W, eds. *Handbook of Psychiatry in Palliative Medicine*. 2nd ed. Oxford University Press; 2009.

Furthermore, in the face of advanced disease, the role of personality factors and pre-existing diagnoses becomes less and less significant. While psychiatrists mention them in their notes, they must also comment that *these issues are no longer in play*. This is important in preventing the staff from psychologizing the patient's delirium and related behaviors.

However, there are some patients who manifest clear psychopathology, are more difficult to evaluate, and whose complaints are more easily disqualified. Hence, the consultant must remain attentive and help the staff treat their pain as aggressively as that of other patients. The psychiatric diagnosis and its impact on illness must be explained and treatment recommendations made while generating as much genuine sympathy for the patient as possible.

Undertreatment of Pain. The incidence of psychiatric complications is particularly high when pain is undertreated by the staff, which happens for many reasons. The daily use of the pain scale was driven by studies showing that when doctors and patients were separately asked to rate pain, their responses matched well for mild and moderate pain, but the higher the patient's pain rating went, the slower the physician raised theirs. Inadequate management and unawareness of resources are both possible reasons, but often it appears to be an unconscious avoidance of the treater's own helplessness in the face of the patient's complaints. Nurses and aides might also share it, especially if the patient is genuinely unlikable, but they may tend to recognize it sooner because of their more frequent and intimate interactions.

However, it can also be patients and/or their families who have false beliefs about medications, such as destructive effects of drugs or side effects, or addiction. These misconceptions are often a metaphor for fear of death. In its most severe form, a dependent spouse whose mate is suffering but not yet moribund, or the mother of a young child who is still conscious but exhausted, cannot tolerate the loss of reactivity that comes with pain relief. They cannot allow the patient much-needed relaxation or sleep, as they experience this separation as the beginning of their final loss. Psychiatrists can be called in, but familiar trusted physicians can often handle similar situations.

Medical Staff Vulnerabilities. Medical staff barriers to pain treatment can be better managed if better understood. At an

unconscious level, doctors, and nurses, living through many patient experiences, develop an incompletely acknowledged, internal standard of how much pain is *expectable* in a given situation. The standard is personal, not universal, but tends to lean toward the so-called “good patient,” that is, the brave and uncomplaining one. Each patient’s complaints are unconsciously measured against both other patients’ behaviors and the caregiver’s own standard; many come up wanting. Nurses are more likely to make a correction for each other, but young, untested doctors who may still feel immortal may have more difficulty. They will not have the same understanding as a mature physician who has had a hard turn at being a patient or a senior physician who just lost a spouse after a long illness. In the final analysis, the tendency to underestimate pain is intimately related to every physician’s personal history and stage of life, as well as their deepest motivation and coping mechanisms in doing this difficult work. They are capable of learning, but attention should be paid to it. They must also protect themselves against too much empathic identification, as well as guilt. An occasional lapse into ignoring or blaming the victim is an all-but-irresistible response to so many difficult situations and another good reason for close teamwork and the support and insight that come with it.

PSYCHIATRIC INTERVENTIONS. Psychiatrists can help optimize pain management by reorienting staff responses in a supportive, nonjudgmental way, emphasizing the need to respect the patient’s statements, and reaffirming the now well-accepted importance of daily review of patients’ pain scales. Psychiatrists can give the team insight into the patient’s psychological state, emphasizing the patient’s problems in ways that undermine a team’s unconscious pain biases. They can sympathize with the team’s difficulties and uncertainties, normalize their feelings, ensure adequate pain management, and re-educate them about the low addiction risk and its now irrelevant role in dying patients.

Table 27.9–4.
Therapy in the Terminally Ill Patient

Psychotherapy (individual, family, or group)
Crisis intervention
Family-focused grief therapy
Group supportive psychotherapy
Meaning centered psychotherapy
Dignity therapy
Cognitive-behavioral therapy
Behavioral therapy
Supportive–expressive therapy
Provision of information
Life review
Facilitating communication
Addressing unfinished business
Leaving a legacy
Provision of information
Reframing
Focusing
Problem-solving
Relaxation
Meditation
Mindfulness-based stress reduction
Hypnosis
Desensitization
Rehearsal
Music therapy

Psychiatrists' role in bringing about optimal pain relief is a powerful intervention in itself, but it is not complete unless integrated into a multipronged program that includes supportive psychotherapy and some of the many focused therapies that deal with terminal care (Table 27.9–4). Patients using behavioral interventions report a

greater sense of control and decreased anxiety and pain. In one study, doctors underestimated the value of these methods compared to the patient's own estimate. Hence, it is useful for psychiatrists to recommend them. Psychotherapy must help the patient differentiate between pain and suffering (which includes psychological symptoms but also prominent religious and existential concerns!) and must facilitate appropriate responses to each. Most hospitals have chaplains, but a trusted religious familiar is also desirable.

Fatigue

Fatigue is one of the most common symptoms reported by patients, and its effect on the quality of life is profound. In one study, 62% of cancer patients rated it as worse than pain, 12% said that it made them want to die. Yet only 27% reported that their doctor had suggested a treatment. Unfortunately, fatigue is hard to define, even harder to measure, and often goes unnoticed. It is a multidimensional concept with physical, cognitive, affective, and motivational components that differentiate it from symptoms such as weakness, somnolence, and tiredness after exertion. It is integral to acquired immunodeficiency syndrome (AIDS), cardiac, respiratory, hepatic, renal, and neurologic end-stage disease.

If internists accept fatigue as an inevitable correlate of major illness, psychiatrists may over-psychologize it. Fatigue is, after all, a defining criterion of the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* diagnosis of depressive and anxiety disorders. Psychologically driven fatigue may be incapacitating and is known to amplify somatic symptoms. Furthermore, the incidence of psychological disorders in very ill patients is high. However, as mentioned before, these distinctions are no longer clear; hence, teasing out psychologically from physically determined fatigue may not be possible because the two coexist with such regularity.

Table 27.9–5.
Possible Etiologies of Fatigue in the Medically Ill

I. Medical/physical conditions

- Associated with the underlying disease itself
- Associated with treatment for the disease
- Chemotherapy
- Radiation
- Surgery
- Biologic response modifiers
- Associated with inter-current systemic disorders
- Anemia
- Infection
- Pulmonary disorders
- Hepatic failures
- Renal insufficiency
- Malnutrition
- Neuromuscular disorders
- Hypothyroidism
- Hypogonadism
- Hypoadrenalism
- Associated with sleep disorders
- Associated with immobility and lack of exercise
- Associated with chronic pain
- Associated with the use of centrally acting drugs (e.g., opioids)

II. Psychosocial factors

- Associated with anxiety disorders
- Associated with depressive disorders
- Stress-related
- Related to environmental reinforcers

Adapted with permission from Portenoy RK. Physical symptom management in the terminally ill: An overview for mental health professionals. In: Chochinov HM, Breitbart W, eds. *Handbook of Psychiatry in Palliative Medicine*. 2nd ed. Oxford University Press; 2009.

Table 27.9–5 outlines some causes and interventions for end-of-life fatigue. It should be evaluated in multiple dimensions before deciding on treatment. It can be cruel to require a dying patient to move, but this can improve the quality of life in a patient who has more time left. Both patients benefit from being taught energy-conserving techniques. Psychostimulants used purely for fatigue have been observed to be helpful and can interrupt a vicious cycle of fatigue and despair, although different patients will have different risks from side effects.

Non–stimulant-activating drugs, such as modafinil and dextroamphetamine/amphetamine, are increasingly used in ill patients, although they are not, at this time, FDA-approved indications.

Insomnia

Sleep hygiene is important to the healthy and the sick, and yet hospitals can be blatant offenders in their lack of concern for patients' sleep. Dying patients may be desperate for the blessed release of "getting away" for a few hours. Of course, very ill patients may require care and procedures at any time of day, but such simple measures as minimizing noise and maintaining optimum light are neglected in environments that are otherwise attentive to patient needs. Patients and their caregivers need education about maintaining as close to a normal circadian rhythm as possible and preceding sleep time with a quiet routine. Long-acting pain medication is critical to prevent middle-of-the-night breakthroughs, and many patients need help in understanding the use of sustained-release preparations, such as morphine or oxycodone. Despite recent publicity about abuse, these long-acting pain medications are not as readily abused by very ill patients as by patients who may get better for some time. They have an important role to play in late-stage patients and should not be avoided because they are too long-lasting. Sedatives are equally important. Zolpidem and zaleplon are well tolerated, and the latter is short-acting enough that it can be taken in the middle of the night. Benzodiazepines have an

antianxiety effect as well, which often makes them the drugs of choice in nondelirious patients but are contraindicated in delirious ones. Several antidepressants are so predictably sedating that they are often used as hypnotics even in the absence of a diagnosis of depression. They include trazodone, nefazodone, mirtazapine, amitriptyline, imipramine, and other tricyclics. Antipsychotics, such as olanzapine, quetiapine, and risperidone, can be used the same way. The side effects of all the psychotropics should be evaluated, but generally, the habituation that accompanies the use of many hypnotics does not occur.

Terminal Anorexia and Cachexia

Anorexia and the wasting state known as cachexia are common near the end of life, but, in some conditions, such as cancer and AIDS, they appear well before the end of life, causing great distress to family and friends. If they have not been educated about its involuntary nature, unprepared family members become angry that the medical staff does not share their intense concern. They may try to relieve their sense of helplessness by fixating on making the patient “try a little harder” to eat. This generates guilt and anguish in the patient at a time when peaceful human contacts are the most precious. Families have been known to request a psychiatry consultation for an eating disorder, wanting to believe, against all evidence, that better nutrition would change the inevitable. This example of making patients responsible for their illness is one of the most poignant and frequent demonstrations of love and desperation going awry. Families, and indeed the public as a whole, need to understand the involuntary and overwhelming nature of terminal anorexia and, even more importantly, that the patient is not experiencing hunger and will not benefit from forced nutrition.

In fact, the opposite is often true. When anorexia is part of the active dying process, total parenteral nutrition (TPN) has been shown to worsen the patient’s quality of life. However, in cases in which the patient can still experience hunger—for example, in ovarian cancer in which a nonfunctional GI tract may exist in the

presence of functional liver and kidneys—TPN is available and has been known to sustain patients for long periods. (Its wisdom can be disputed, but that is a different issue.) Thirst, another family concern, is more related to dry mucous membranes and can be relieved with frequent small sips of water. Intravenous (IV) hydration and transfusions are counterproductive in the face of failing hearts or kidneys. Table 27.9–6 outlines some recognizable causes and the treatment of anorexia for patients who are not yet actively dying. The treatment plan should address multiple etiologies.

Other GI Symptoms

Nausea and Vomiting. Nausea is near the top of lists of unpleasant symptoms, and unfortunately, is one of the most common. Many patients say, “I would be okay if it were not for nausea!” The act of vomiting itself, although it gives temporary relief from nausea, is unpleasant and can be painful in certain conditions. It can be difficult to eradicate even when its etiology is known and all the more so when one cannot pinpoint the cause—a not infrequent event.

Available antiemetic medications are helpful in controlling more vomiting and nausea. A careful assessment may help to establish the best approach and most effective treatment for both. Asking the patient-specific questions, such as onset, frequency, time of the day, quality of content, and its association with other symptoms, will help the clinician to choose a more effective medication. For instance, escalation of pain medication could be associated with nausea as well as medical interventions, procedures, and certain treatments such as chemotherapy or radiation. Common causes of nausea and vomiting in the medically ill are related to opioids, NSAIDs, and centrally acting drugs. Intra-abdominal neoplasm and antineoplastic medications are common causes of nausea and vomiting, as are intracranial neoplasm and leptomeningeal disease. Other causes include psychological processes and metabolic disturbances such as hepatic failure or renal failure and electrolytes abnormalities.

Table 27.9–6.
Causes and Treatment of Anorexia

Causes

Disease-related

Nausea, fever, anemia, weakness, dehydration, pain

Sepsis, other acute malaise, electrolytes abnormalities

Weakness or damage in muscles of deglutition

Altered cognitive states

Altered metabolism: Uremia, hepatic failure

Abnormal response to nutritional intake

Treatment-related

Chemotherapy or other drug effect (nausea, diarrhea, altered taste or smell)

Surgery

Radiation therapy effects

Dialysis side effects

Transplant rejection, graft-versus-host disease

Cancer-related symptoms

Psychological

Anxiety syndromes, depression, delirium, specific phobias

Pre-existing or relapsed psychiatric disorders

Nonpharmacologic interventions

Education

Dietary management

Discuss etiology (often multifocal) and characteristics (involuntary) and with patient and family

Reassurance

Increase physical activity and psychosocial intervention

Alternative therapies (massage, muscle relaxation, mindfulness-based therapy, yoga)

Pharmacologic intervention

Megestrol acetate (Megace)

Steroids

Appetite-inducing psychotropics (olanzapine, quetiapine)

Psychostimulants (methylphenidate, dextroamphetamine)
Wakefulness-promoting agents (modafinil)
Selective-serotonin reuptake inhibitors (fluoxetine, paroxetine, citalopram, escitalopram, sertraline)
Selective-norepinephrine reuptake inhibitors (venlafaxine and duloxetine)
Norepinephrine-dopamine reuptake inhibitor (bupropion)
Alpha-2 antagonist/5HT2/5HT3 antagonist (mirtazapine)

Diarrhea and Constipation. Diarrhea is common in AIDS and in certain cancers. It is usually associated with local pain, burning, and often abdominal cramping. It also leads to fecal incontinence, one of the most humiliating and unpleasant symptoms a patient must endure. Rapid cleaning and good skin care by a relaxed, well-related person is important to shorten the experience and minimize pain, skin irritation, and breakdown. Drugs that slow down intestinal motility can be helpful, so the anticholinergic side effects of many psychotropics are welcome. However, it can be a very resistant symptom when caused by opportunistic organisms and/or *Clostridium difficile*.

Constipation is also common and can cause significant abdominal cramping, bloating, distention, nausea, and vomiting. Ideally, it should be prevented or aborted by adequate hydration, optimal mobilization when possible, and, most of all, early institution of an aggressive and consistent bowel regimen. The use of pain medications could contribute to constipation if not given with stool softeners. Enemas or disimpaction may be instituted if the patient desires. However, in someone close to death, increased opiates may be preferable, especially as normal bowel function is frequently absent during the terminal phase.

Respiratory Symptoms

Respiratory distress is one of the most difficult symptoms to endure —and to watch. Although measures have been developed to assess dyspnea, assessment of the ill patient should be based on self-report

because objective measures, such as oxygen saturation and arterial blood gas measurements, do not often correlate with subjective experience. It is easy to treat because opioids and benzodiazepines decrease the anxiety and the urge to breathe within minutes, allowing the patient to rest and relax. However, in the actively dying patient, a significant decrease in the effort to breathe is associated with increased hypoxia and eventual carbon dioxide (CO_2) narcosis. Parenthetically, this is one of the most painless ways to die and is the subject of debates about the "double effect," in which an action has an intended (patient comfort) and an unintended effect (hastening of death). If dose escalation is too sudden, it may hasten the moment of death, but when the drugs are prescribed appropriately, respiratory depression is gradual; death still comes gradually but more comfortably.

As with pain patients, the dyspneic patient is anxious and hyper-alert and may have already been exposed to opiates or benzodiazepines (the latter is now contraindicated). Therefore, the gradual escalation of drugs to give consistent relief of dyspnea does not result in sudden death. In fact, family members who have waited at a dying patient's side comment on "how long it takes for a heart to give up." One of the more common signals that the end is near is agonal breathing, where one hears only acute gasping breaths that become less and less frequent. If family members are keeping a long watch, it is useful to check on them and explain what is and will be happening. The dying patient can still display involuntary movements that are experienced as communication by a watching grieving spouse or child. These last moments should be managed with kindness and delicacy because they will never be forgotten.

Distress due to persistent coughing is exhausting and interferes with communication. Opioids turn off the cough reflex promptly, and if the patient is strong enough to cough repeatedly, opioids can and should be used without risk of respiratory depression.

Sedation of Patients. Neuromuscular blocking agents are used routinely in intubated patients to prevent them from fighting the respirator. Agitation can precipitate accidental extubation, leaving a

conscious patient without any ability to breathe, a terrible experience. For that reason, patients in critical care units (CCUs) are often kept sedated while on the ventilator. When the patient is receiving only comfort measures, such a condition must be re-evaluated, but, whatever the case, *the planned withdrawal of life supports must always include adequate pre-sedation.*

This needs affirmation because, currently, there are more CCU patients stabilized on respirators who must be transferred to intermediate units to allow the treatment of newly acute patients. This is where final controversies may play out. There have been times when end-of-life management occupied the time of politicians whose duties lay elsewhere or when individual caregivers did not yet understand that the rule of care took priority over their personal convictions while it was being argued in appropriate venues. All of these scenarios with patients in pain and respiratory distress involve the double effect. This partly describes every drug ever given to any patient, but if the side effect is hastened death, the controversy should be brought up and carefully reviewed before proceeding. This will be discussed further in the section on ethical issues.

PRIMARY PSYCHOLOGICAL SYNDROMES AND SYMPTOMS IN TERMINALLY ILL PATIENTS

Psychological symptoms are nearly universal at the end of life. Psychiatric syndromes occur with an increased, definable frequency and may have different age and gender distribution. For example, anxiety and depression are as common in men as in women. The DSM-5-TR classification remains an important framework on which to base clinical observations, but it was not designed with dying patients in mind. Hence, for terminally ill patients, it is pragmatically useful to focus on three major conditions: anxiety, depression, and confusion—which, in fact, frequently coexist and overlap. Rarely, specific phobias of needles, enclosures, and the like may interfere with comfort into the terminal period and should be addressed to ease the patient's experience. The consultant should remain alert to

any precipitant factors that can cause new discomforts and work to defuse them. Major psychotic disorders may become submerged under the increasing symptomatology of the active dying process. However, they require specific attention when the patient is not actively dying and when the psychotic symptoms are clearly separate from and superimposed on the symptoms of either the disease or the treatment.

Prevalence

Much of the research on prevalence has been done in cancer and AIDS and shows a marked increase of psychiatric conditions near the end of life. Severe depressive symptoms rose from 25% to 77% in a sample of hospitalized cancer patients, although stricter criteria find 15% with major depression and another 15% having severe depressive symptoms. The prevalence of delirium rises from a range from 25% to 40% to as high as 85% with increasingly advanced disease. The association of psychiatric symptoms with pain was demonstrated in one of several consistent studies in which 39% of patients with a psychiatric diagnosis reported significant pain, compared to 19% for those without a psychiatric diagnosis. In a sample of AIDS inpatients, 65% had an organic mental disorder, and 27% had major depression. The financial cost of psychiatric disorders can be inferred from a study in which patients with a psychiatric diagnosis remained in the hospital 60 days longer than those without a psychiatric diagnosis.

General Treatment Principles

Improved quality of life is the *immediate* goal, so all available modalities that can bring symptom relief should be instituted rapidly while a plan for psychological and family interventions is designed and set into motion. Since psychiatric syndromes are intertwined with medical conditions, understanding the medical condition is necessary. Good communication with the treating physician yields a fuller analysis and better coordination with medical treatment goals.

Most commonly, terminally ill patients demonstrate an intertwining of anxiety and depression. These are difficult to tease apart, and the term *negative affect* has been suggested to define them as a symptom complex. It is hard not to feel grief at so much loss and fear about the dark unknown ahead. Individuals whose deep faith in an afterlife that animates their spirit are an exception, but, even among them, many describe coexisting regret at the loss of their temporal life with its rich palette of life events.

However, current symptoms may be an exacerbation of a pre-existing disorder, in which case, symptom control still remains the primary response. Other than medical complications, a personal or family history is the best predictor of psychiatric problems in advanced disease.

Death Trajectories

There are many different death trajectories with different conditions, of which a few will be briefly mentioned. Death from pulmonary insufficiency is slow and is terrible for both the patient and the family. Mild sedation eases the pain and may let the patient rest while slightly shortening the time to death (the so-called double effect). Psychiatrists may be needed when there is debate among participants, as might the Ethics Committee.

Neurologic disorders are multiple. Many cause a slow decline until, far into the disease, only shreds of the patient's sense of self remain intact. In such cases, both patient and family caregivers should be offered early support, the patient some tranquilization, and the family a chance to speak about their reactions. Under such conditions, there may be no previous psychopathology, but the late events can create it, as happens in accidents and disasters.

Every cancer is an unpredictable disease and can have a long and complex course, hence an unpredictable mode of death. It is also characterized by presenting several possible options, not only throughout the course but often during the final months. Families live through this unpredictability at a cost. Complications and disagreements cause stress for everyone, including medical staff. In

addition to the usual chart review and examinations, it is useful for psychiatric consultants to also learn from the staff the “story” of the course of treatment. This often opens routes for improvement.

Anxiety in Patients with Advanced Disease

Characteristics. Anxiety can be the presenting symptom for almost all medical disorders and is often a side effect of medications. However, in patients with advanced disease, it usually presents somatically, such as restlessness, hyperactivity, tachycardia, GI distress, nausea, insomnia, shortness of breath, numbness, or tremor. It lowers the threshold for pain, worsens functional impairment, and increases distress. Anxiety often interferes with the patient’s ability to cooperate with other treatments or to relate optimally with loved ones. Patients are more likely to refer to fear, apprehension, or ruminations rather than to anxiety itself. It is also associated with deep existential concerns, as outlined in Table 27.9–7. Individuals with pre-existing anxiety disorders commonly have an exacerbation.

Mr. S, a 50-year-old physical therapist with newly diagnosed unresectable lung cancer, had panic symptoms when his wife left his bedside to attend to other needs. He hyperventilated, felt short of breath, became restless, was unable to concentrate, and felt overwhelmed with morbid ruminations about his future. His symptoms were exacerbated by his discomfort about his dependence on her. Mr. S. was taught special breathing and relaxation exercises and given clonazepam, which brought about a marked resolution of his anxiety. He felt calmer, more resilient, and able to handle periods of solitude with less difficulty.

Treatment. Anxiety is so common that it is sometimes discounted, but an etiology should be sought, and treatment should be instituted promptly. Anxious patients are more likely to be aroused enough for supportive therapy, cognitive-behavioral techniques, and

complementary modalities, such as deep relaxation, meditation, and adapted yoga. If a patient brings up an issue that had never been resolved, discussing it is not only appropriate but a major gift, contrary to some therapists' feeling that "the work won't go anywhere." Bearing witness to one's life, especially in the company of another person, is a poignant and meaningful act. Patients' inner lives are their last personal possession; sharing and enriching them is a powerful intervention, one of the last times they will reflect upon themselves in a meaningful dialogue with another human being. It is perhaps the most meaningful of all.

Table 27.9–7.
Causes and Treatment of Anxiety

Causes	Treatment
Medical causes (psychiatric diagnosis: Anxiety secondary to a medical condition)	**Search for an etiology**.
Untreated delirium	If a medical etiology is present, treat it or minimize it.
Central nervous system pathology	**Use a multimodal approach**.
Hormone secreting tumors	Should always include the provision of immediate relief along with other interventions.
Metabolic or electrolyte abnormalities	**Anxiolytic drugs**
Pulmonary embolus	Benzodiazepines
Respiratory insufficiency, hypoxia, dyspnea	Lorazepam (Ativan), oxazepam (Serax), and temazepam (Restoril) are metabolized through conjugation and hence are more usable in hepatic insufficiency.
Sepsis	Alprazolam (Xanax), clonazepam (Klonopin), diazepam (Valium), chlordiazepoxide (Librium) are benzodiazepines that are metabolized through oxidative pathways and can be used with renal impairment.
Poor pain control	Nonbenzodiazepines (beware of drug interactions)
Side effect of bronchodilators, steroids, β-adrenergic drugs, and other medications	Selective serotonin reuptake inhibitors
Substance withdrawal	Escitalopram (Lexapro)
Psychiatric disorders	Serotonin and norepinephrine reuptake inhibitors
Acute stress response	Venlafaxine (Effexor) and duloxetine (Cymbalta)
Adjustment disorder with anxiety	Neuroleptics (alone or with a benzodiazepine)
Adjustment disorder with mixed anxiety and depressive mood	
Panic disorder[a]	
Phobic disorder[a]	
Generalized anxiety syndrome[a]	
Depressive disorders[a]	

Existential causes	Haloperidol (Haldol), olanzapine (Zyprexa), quetiapine (Seroquel)
Awareness of oncoming death	Tricyclics
Fear of death itself	Hydroxyzine (Atarax)
Fear of the dying process	Buspirone (BuSpar)
Mourning of losses	**Nonpharmacologic interventions**
Interpersonal regrets	Behavioral methods
Continuing conflicts	Hypnosis, meditation, deep relaxation, with or without guided imagery (selected for induction of peacefulness)
Guilt over abandonment	Supportive psychotherapy
	Explores patient fears, reduces cognitive uncertainty, and reassures about accompaniment
	Family sessions
	To improve communications, to reduce tensions, and to say goodbye
	Spiritual counseling

[a]Often exacerbations of pre-existing symptoms.

MEDICATIONS. Several classes of effective antianxiety medications can and should be used even in the presence of hepatic or renal impairment, given careful drug selection, dosage adaptation, and ongoing monitoring. Benzodiazepines add to the depressant effects of other sedating drugs and can worsen the symptoms of confusional states, making them a poor long-term choice for the older adults. However, if the patient has been taking them for a long time with good effect, continuing them is desirable because their action is immediate and, with careful dosage, generally beneficial. They must be chosen with the patient's hepatic function in mind. All are metabolized by the liver, except for lorazepam, oxazepam, and temazepam, which are metabolized by conjugation and, hence, less

dependent on liver function. Lorazepam and diazepam can be given parenterally and sublingually. The first is short-acting and is preferred by patients who want more control over their ability to interact. The second is long-acting and tends to accumulate unless monitored carefully, but it is effective and has the added benefit of being an excellent muscle relaxant, which, for some patients, gives significant pain relief in itself. Clonazepam lasts 12 hours and does not accumulate. Habituation can require dosage escalation of all benzodiazepines, but this is acceptable if the drug improves the quality of these patients' limited life.

Table 27.9–8.
Causes and Treatment of Depression in Terminally Ill Patients

Causes	Treatment
Medical causes: Resulting in mood disorder secondary to a general medical condition	Search for an etiology; if a medical etiology is present, treat it, or minimize it
Medications	Psychopharmacological management
Steroids	
Interferon and interleukin-2 (Proleukin)	Choose an antidepressant based on the patient's review of symptoms
Methyldopa (Aldomet)	
Reserpine (Serpalan)	Tricyclic antidepressants in depressed patients with pain and insomnia
Barbiturates	Monoamine oxidase inhibitors
Propranolol (Inderal)	
Some antibiotics (amphotericin B [Amphocin])	Mirtazapine (Remeron) in depressed patients with insomnia and anorexia
Some chemotherapeutic agents	
Disease conditions	Bupropion (Wellbutrin) in sedated depressed patients
Metabolic and electrolyte abnormalities	
Endocrine abnormalities	Psychostimulants effective in treatment-resistant depression and sedated patients
Hormone secreting tumors	
Nutritional deficiencies	Selective serotonin reuptake inhibitors in depressed patients

	with cardiac risk factors
Anemia	
Uncontrolled pain	Serotonin norepinephrine reuptake inhibitors
Psychological causes	
Adjustment disorder with depressive mood	Mood stabilizers Nonpharmacologic interventions
Adjustment disorder with mixed anxiety and depressive mood	Individual psychotherapy
Comorbid with various anxiety disorders	Supportive psychotherapy Cognitive-behavioral therapy
Depressive disorder not otherwise specified	Family therapy
Existential causes (all held with morbid intensity impervious to reassurance)	Group therapy
Awareness of oncoming death	Spiritual counseling
Mourning of losses	
Interpersonal regrets	
Continuing conflicts	
Guilt about burdening family	
Guilt about betraying loved ones	
Decreased self-worth	
Self-criticism about perceived failed relationships and life achievements	

Depression in Patients with Advanced Disease

Prevalence. Depressive symptoms are also common in advanced disease and associated with the same existential factors as anxiety. Studies have found a prevalence ranging from 9% to 58%, depending on criteria strictness. Risk factors again include previous episodes or family history. Table 27.9–8 outlines the common causes and treatments for major depression.

Diagnosis. Differentiating somatic effects of disease from the neurovegetative criteria of major depression is especially daunting in the terminally ill. Since the DSM-5-TR criteria (developed for primary psychiatric patients) include somatic symptoms that may be due to their medical disease, a *substitutive approach* has been developed, which replaces physical symptoms with nonsomatic symptoms. Table 27.9–9 describes the Endicott Substitution Criteria, which is the substitutive approach in primary use because it has been found to perform as well as the DSM-IV-TR criteria and the stricter Research Diagnostic Criteria. It also highlights the important clinical observation that classically described depressive thoughts and feelings are not universal in terminally ill patients and, when present, reflect depression just as they do in physically healthy patients.

Treatment. Current studies and a large body of clinical experience with medically ill patients have shown that the pharmacologic treatment of depression can be useful through the last days of life, even in the face of definable medical causes.

Table 27.9–9.
Endicott Substitution Criteria for Depression

Physical-Somatic Symptoms	Psychological Symptom Substitute
Change in appetite or weight, or both	Tearfulness, depressed appearance
Sleep disturbance	Social withdrawal, decreased talkativeness
Fatigue, loss of energy	Brooding, self-pity, pessimism
Memory and concentration deficits, indecisiveness	Lack of reactivity

Mrs. V, a diabetic patient with end-stage renal disease, was on dialysis for 2 years and was diagnosed with depression and severe insomnia. She started on a daily oral dose of 15-mg mirtazapine and immediately slept better and felt less depressed within 3 weeks. Four weeks later, she was admitted to the hospital with congestive heart failure for what would be her terminal admission. She did not wish to give up the antidepressant but now felt oversedated and wished to be more alert during the day to interact with her family. Twice-daily 5-mg doses of methylphenidate made her more engaged and communicative. After her death, her family expressed deep gratitude that they could continue to feel so connected to her until the end.

Antidepressants are the first line of treatment in patients who can be expected to survive long enough for the delayed onset to take effect. If there is no time or if increased energy and ability to interact with loved ones are urgently desired, patients can be treated with psychostimulants. Because the side effects of antidepressants can

be very variable, including sedation and excess energy, they should be used empirically, and their side effects monitored carefully.

Cognitive-behavioral techniques are often less relevant because very ill patients often cannot concentrate well enough. However, for those who can, deep relaxation associated with guided imagery can be powerful enough to transport them, even briefly, to a better place.

Ms. D was a 17-year-old high school student with recurrent, unresponsive acute lymphocytic leukemia (ALL). Her loving parents encouraged her to do more than she could and were counseled separately to lower their expectations. When seen alone the first time, she was very aware, thoughtful, and saddened by her parents' requests, yet showed remarkable understanding and maturity. She gladly selected deep relaxation and guided imagery instead of further "talking" and mentioned that she loved hiking. The therapist saw her several times before she died, "taking her" on several favorite hikes. This created safe moments for Ms. D, who described them as "really peaceful." Relaxing this way enabled her to stay connected to her own strengths.

Supportive therapy of depressed terminally ill patients is one of the more difficult therapeutic tasks. Every therapist has moments of frustration instead of empathy with the imperviousness of depressive thinking and affect. When found at the door of death itself, the therapist's own feelings of helplessness and fear may generate the urge to flee. Taking an active role in symptom control, psychopharmacological treatment, and behavioral interventions can relieve the doctor and help the patient. Beyond that, if the patient seems to welcome the therapist's presence, then staying with the patient is paramount; a faithful presence at the end is profoundly meaningful to someone who is dying. Some therapists experience such moments as gifts to them as well.

Confusional States in Patients with Advanced Disease

Prevalence. The prevalence of delirium rises to 85% in patients with advanced disease. If one includes the last hours of life, it nears 100% unless the patient lapses rapidly into a coma or dies of an acute event, like pulmonary embolus. It is always unexpected and traumatizes the survivors, despite knowing full well that the patient was near death. Some patients slip into an irreversible coma, leaving families in a bedside vigil, which, while they can be exhausting, may actually give them a period of adaptation before the final moment of death. However, these events only occur 15% to 25% of the time.

Table 27.9–10.
Subtypes of Delirium

	Hyperactive	Hypoactive
Type	Hyperalert, agitated	Hypoalert, lethargic
Symptoms	Hallucinations, delusions	Sleepy, withdrawn
	Hyperarousal	Slowed
Examples	Withdrawal syndromes: alcohol, benzodiazepine	Hepatic, renal encephalopathies; benzodiazepine intoxication
Pathophysiology	Elevated or normal cerebral metabolism	Decreased global cerebral metabolism
	EEG: fast or normal	EEG: diffuse slowing
	Reduced activity in GABA systems	Overstimulation of GABA systems

EEG, electroencephalogram; GABA, γ-aminobutyric acid.

Diagnosis. Patients frequently experience some disorientation, impaired memory, concentration, and altered arousal as they become increasingly ill, especially if they are older adults. These symptoms may remain mild or may be the harbingers of a full delirium, as described in Tables 27.9–10 and 27.9–11 summarize the causes and treatment of delirium.

The DSM-5-TR diagnosis excludes the presence of dementia as an etiologic factor, but, in the growing older adult population, not only is pre-existing dementia common, it is a strong risk factor for a superimposed delirium and makes the delirium much more resistant to treatment. While it is harder to tease out how much symptomatology is reversible, this does not alter the management.

Since Paula Trzepacz's important paper, delirium is now divided into:

- A *hyperactive hallucinatory delirium*, easily recognized by both physicians and families, although the early symptoms are often mistaken for depression, anxiety, and poor coping. They may not get the diagnosis right, but they do bring a real problem to medical attention.
- A *hypoactive delirium* must be differentiated from the more easily recognized hyperactive state (Table 27.9–10). These patients are hypoactive, withdrawn, with varying levels of somnolence and unresponsiveness. They are quiet and undemanding, making it easier for this reversible condition to be long overlooked by the team. This is highly regrettable; one recent group of patients who recovered after treatment described their continued awareness and had acutely unpleasant memories of the experience. Hence, physicians should remain alert to diagnosing hypoactive delirium and treat it as aggressively as the hyperactive form.
- A *mixed delirium* includes patients with fluctuating activity levels. They may also have normal levels of psychomotor activity, but their attention and awareness are disturbed.

A psychiatric consultation was sought to evaluate depression in Mr. K, a 56-year-old practicing attorney with pancreatic cancer. His moderately severe back pain was apparently responding to morphine, but he was noted by the inpatient staff to be more withdrawn, disengaged, quiet, with poor eye contact, and somnolent throughout the day. The consultant found Mr. K to have disturbed arousal, with mild confusion and disorientation, slow speech, and disorganized thought process. Mr. K admitted to intermittently experiencing visual hallucinations that he had been too embarrassed to report to nursing staff. Diagnosed with a hypoactive delirium secondary to opioid medications, he was treated with a low dose of olanzapine, 2.5 mg at bedtime, improving his sensorium dramatically. He became alert, fully oriented, better related, and without perceptual disturbances or thought disorder, all without decreasing his much-needed pain medications.

Table 27.9–11.
Causes and Treatment of Delirium in Terminally Ill Patients

Causes	Treatment
Opioids	Medications commonly used in managing delirium
Some hallucinatory drugs such as LSD and PCP	Typical neuroleptics
Benzodiazepines	Haloperidol (Haldol)
Anticholinergic drugs	Chlorpromazine (Thorazine)
Sedative-hypnotics	
Steroids	Atypical neuroleptics[a]
Cardiac glycosides, antihypertensives	Olanzapine (Zyprexa)
Anticonvulsants	Risperidone (Risperdal)
Antihistamines	Quetiapine (Seroquel)
Bronchodilators	Ziprasidone (Geodon)
Benzodiazepine and alcohol withdrawal	Aripripazole (Abilify)
Metabolic and nutritional deficiencies	
Hypoxia	Benzodiazepines may be combined with neuroleptics to calm severely agitated delirious patients.
Fluid, electrolyte, osmolarity imbalance	
Vitamin deficiencies (thiamine, folate, vitamin B_{12}, niacin)	Lorazepam (Ativan)
Infections	Midazolam (Versed)
Liver and renal failure	
Vascular disorders	Anesthetics

Endocrine and hormonal disorders	Propofol
Endocrine tumors	
Carcinoid tumors: mainly ovary and lung	
CNS disorders, metastatic disease, and neoplasm	

Management. In a preterminal delirium, multiple etiologies are the rule and should be pursued. However, when a patient develops a terminal delirium in the last days of life, symptom control must again be the primary goal. Its general management includes security and orientation measures, pharmacologic management, and a search for treatable etiologies. Eighty to 90% of delirious patients respond to symptomatic treatment, even when close to death.

Haloperidol and chlorpromazine are the main IV medications, but the atypical antipsychotics are effective in patients who use other routes of administration. Drug companies are actively devising new routes of administration for several of them. If given alone, benzodiazepines worsen delirium and are contraindicated, but they are useful adjuncts to antipsychotic drugs, providing sedation for persistently agitated patients. When cognitive impairment and early delirium are present, antipsychotics alone can be effective in controlling symptoms. The weight gain and type 2 diabetes seen in chronic psychiatric patients are not a problem here, but dyskinesia, akathisia, tremors, parkinsonian rigidity, and, rarely, tardive dyskinesia does occur. Parkinsonian symptoms can occasionally affect muscles of deglutition and intercostal muscles, leading to impaired swallowing and respiration that are mistakenly ascribed to other causes.

Delirium is so common that medical staff deal with it quite matter-of-factly. However, a hyperactive one can frighten family members, who see it as a drastic change for the worse. They fear a permanent change in the patient, an especially upsetting one, given the content of hallucinations, their commonly paranoid cast, the appearance of

anguish and terror, the frequent aggressiveness, and the loss of dignity associated with many delirious behaviors. In such situations, family education is critical; in fact, explanations and reassurances should be routinely given at the first hint of any symptoms to minimize their trauma. It usually falls to the nurses, who are well acquainted with it, closest to the patient's condition, and well aware of the needs of the family and visitors. Hypoactive deliria, however, are sometimes mistaken for depressions.

PSYCHOLOGICAL ACCOMPANIMENT OF THE DYING PATIENT

When facing a bedrock human experience with an imminently dying patient, the usual language of therapy should be altered so as to avoid pathologizing tragedy. Accompaniment is the goal of interactions with dying patients, even those who are less distressed, and even while aggressive efforts are made to treat all treatable diagnoses and symptoms. The psychiatric consultant must be familiar with the patient's medical condition. The patient–psychiatrist boundary should not be as well defined with terminally ill patients as with healthier ones. The doctor should be alert and responsive to signs of increased discomfort. Touching bedridden terminal patients calls for judgment but need not have negative connotations. If a patient is weak and sometimes unheard and unable to call for help, then helping the patient call for assistance is itself a strong intervention. Untangling or pulling up a sheet the patient cannot reach can be offered casually, as is helping to contact the nurse for more complex needs. Psychiatrists are well trained to respect boundaries, but this is a time when some flexibility is indicated.

Family involvement must be explored and encouraged, and staff members queried for their views. The latter group is, especially at this time, a part of the operant group and must be included in understanding and resolution of difficult situations.

The special case of the epidemic/pandemic amplifies and complicates all of these interpersonal dynamics. In such cases,

every person is a possible vector for everyone else. This may also be true for patients dying of other illnesses, whose visitors could be vectors.

The predominance of protective clothing and equipment among both staff and visitors serves to highlight any sense of isolation already being experienced. As do extreme restrictions on visitors, as may happen at some points during epidemics. At such times, it is not uncommon for family members and patients to exchange last words through an iPad or other electronic means, a wrenching experience for all, including medical staff who serve as the family's stand-ins for physically accompanying the patient until death.

Every avenue to lessen isolation and increase the feeling of human connectedness should be explored, for example, having staff wear photos of themselves on their protective garments in case patients can't see their faces or making a point of holding a patient's hand through gloves. Family members must be given clear information about what to expect, including an understanding of the level of uncertainty about those expectations. And, while visitation restrictions might be necessary, the team must take all steps possible to enable family members to physically stay with their loved ones in some manner, as safely as possible. This would be a kindness to everyone, patient, family, and staff.

Sharing the Patient's Subjective Experience

Dying patients should be engaged for as long as they are able to respond. Giving them a chance to share feelings, memories, and achievements honors their existence and is a precious gift to them. A patient who is talking with an empathic listener feels themselves as *still living*, not dying, during that conversation. Eliciting and listening are more important than anything that the interviewer has to say. Although supportive responses are appreciated, unrealistic reassurance aborts authentic conversation and is cruelly isolating.

Many dying patients are deeply troubled by unresolved personal issues and often keep silent in response to covert messages from those around them. The therapist should try to help them explore

these issues with as much care as with any other patient. Besides the painful presence of their disease, they may be still full of thoughts about the meaning of their lives, the values by which they have lived, the relationships that they feel they have honored (or betrayed), about death, about life after death, about their faith or lack of it, and about their relationship to God. The conversation opens the door to sharing burdens and shedding tears. The relief it can bring is like letting fresh air into the room.

Patients may also be grateful for help reconnecting to happy memories, meaningful achievements, joys, and laughter. Consultants may ask for permission to share some achievements with the team, who will be glad to discuss them with the patient, rather than only drug doses. Patients close to death can still enjoy mundane activities that bring them closer to loved ones or to treasured aspects of themselves. A late-life review may help patients see the totality of their lives, revealing positive meanings and connections and giving them a chance to value their lives with more depth, solidity, and self-esteem.

Some patients may have late emotional changes of desires or feelings. It has been shown in several settings that, as patients become sicker (than at the time of their decision making), they accept an increasingly limited quality of life as worth living and opt for more onerous, less promising treatments if they offer even a small chance of help. It is reassuring that IRB committees make sure that only procedures with some potential are allowed at such desperate times.

Disease-Specific Considerations

Different illnesses routinely bring special issues. For example, a patient on dialysis can opt for death rather than treatment three times a week and is more vulnerable to acting on feelings of depression, anger, hopelessness, and reactions to family neglect or conflict. The cancer patient must acknowledge possible death during complex treatments while hoping for a cure or remission. Treatment decisions in the face of a disease that is less and less treatable

become increasingly difficult and can cause acute anxiety. Stem cell transplant patients experience high levels of anxiety and depression because they are getting a last chance with high stakes and high risks. The availability of organ transplants has created a large population of patients who know they may die while waiting for a cure that could be just around the corner. A patient who ignores medical advice to amputate a limb, and is later diagnosed with metastasis, suffers a great deal and benefits from added support and understanding. Other patients who have lost limbs may have lost a very important part of their identity. Neurodegenerative disorders are associated with increased physical disability and dependence. If cognition is maintained, a number of patients and their caregivers can manage well until the end. When loss of cognitive faculties is present, the problems can be difficult for the caregivers.

When a patient is dying during an epidemic, in addition to any family issues predating the onset of the illness or epidemic, are the myriad responses each person in the family unit may have toward both the illness itself as well as toward the patient dying from it. These may include guilt, either reasonable or unreasonable, over possibly having infected the patient, or anger at another family member for perhaps having done so, especially if reckless behavior was involved, or even anger at the patient themselves. A further complication is the large range of possible attitudes toward the disease itself. In the case of COVID-19, for example, attitudes may range from panic all the way to denial and referring to it as a hoax; behaviors may range from going to great lengths to avoid the disease—such as washing one's grocery bags for fear of fomites—to refusing to wear masks, physically distance, or avoid crowds as recommended by public health officials. In such cases, family members must be helped to focus squarely on the patient's experience and comfort, regardless of who did what to whom and leave family quarrels outside the hospital room door.

Group Therapies

Given enough survival time, group interventions for patients with advanced disease are helpful. They provide a forum in which patients can “detoxify death” by relating to each other’s concerns, talking about dying without fearing that they are upsetting loved ones, and practicing getting acquainted with dying. Many other kinds of approaches have been developed, including groups that use rational–emotive therapy, *meaning-based* groups based on Viktor Frankl’s work, *spiritually based* groups that use a nonsectarian but more faith-based vocabulary, groups that use mindfulness-based meditation techniques, and many free support groups run by nonprofit organizations, each focused on a particular condition. Various kinds of family involvement and support have also been given of benefit to both family and patient. While this subject deserves further attention, it goes beyond the scope of this chapter and is well documented elsewhere.

Other Modalities

Hypnosis, guided meditation, deep relaxation techniques, meditation, minimal movement yoga, music therapy, and techniques that address body and spirit, such as soothing the body and mind with forms of touch and gentle massage, are all helpful to patients who can participate. The consultant can make a personalized tape for the patient during which gentle relaxation and breathing are followed by a detailed evocation of a place or experience chosen by the patient. If the result is relaxation or peaceful sleep, the patient will continue to use it at home. Music therapy in skilled hands that follow the patient, not the score, has been observed to ease respirations and calm agitation in very ill patients. All of these methods deserve the growing attention they have been getting.

SPIRITUAL CONCERNS

More than 70% of patients turn to religious beliefs for comfort, and many others yearn for spiritual sources of meaning. The therapist must engage this side of the patient’s inner life in a comfortable,

respectful way. The consultant should not presume to replace a chaplain but should integrate this aspect into psychological concerns, as most patients have learned that their religious or spiritual concerns do not find a home in the medical environment. Does the patient have religious beliefs? Did they have them in youth? What is their relationship to them? To a personal God? To a sense of a transcendent reality? Ned Cassem suggests that the patient's relationship to God be viewed as one of the patient's many important relationships. Some patients describe themselves as not religious but spiritual. If so, can they describe how they experience their spirituality? Can it be expressed through the values by which they have defined themselves? Through belief in a greater power or life force? For people with environmentalist convictions, the unbroken chain of life in nature may be a link to immortality.

The psychiatric consultant—and everyone else—should facilitate a connection to appropriate religious guides for any willing patient. Their presence can offer healing that no layperson can duplicate. Patients may lack the energy or the will to ask for them, and many do not know that they are available.

As mentioned earlier, patients with a well-elaborated faith, especially one that includes a reunion with God in the afterlife, tend to do better at the end. They may experience the illness as a test of their faith, may view suffering as having redemptive value, and may gain strength from a belief that God will not send them more than they can handle. However, they also often ask, "Why me?" and may struggle with anger, fear, a sense of betrayal or abandonment, disappointment, self-imposed guilt, and, at worst, a loss of faith that leaves them truly desolate. If the patient wants to continue to speak with the therapist, it is appropriate, but referral to an experienced religious authority should also be on the table.

Decision-Making Issues

Many patients base medical decisions about life-sustaining interventions on religious beliefs. The belief that life belongs to God and must be nurtured as long as possible, or a belief in miracles, or

both, are often the reason given for demanding aggressive life-prolonging measures. This may be quite sincere, but patients and families may use religion as camouflage for dynamic conflicts or as a way to control end-of-life treatment decisions because they lack trust in the staff or are unable to face death. Mistrust is a frequent reason for rejecting medical recommendations and often crystallizes around inadequate DNR discussions. Today's clinicians are trained to respect religious beliefs and can also recognize multiple agendas, but it may still take psychiatric input to untangle them and promote conflict resolution.

PATIENT–FAMILY UNIT, THE FUTURE SURVIVORS

The intensity of family relationships becomes even greater during the terminal period. Yet, that is also when one may see conspiracies of silence. With an unconscious patient, it is less necessary to intervene, but the saddest silence is that of a loving family, tense and quiet at the bedside because they are protecting the patient by not talking about dying, while the patient remains quiet for fear of upsetting them. Instead of closeness, expressions of gratitude, apologies, reminiscences, and farewells, there is distance. Although surrounded, such patients feel as though they are dying alone.

Family-Focused Grief Therapy

The stakes go beyond the patient. The last days of a dying patient are indelibly imprinted on the memories of the survivors. Events perceived to have gone wrong can resonate for years. Research has shown that families with good communication endure the experience better and have a more normal grieving process. Later, they are better able to function as a family, with better outcomes for individual members too. In one study, families that had openly discussed dying were initially more upset but, in the end, were less distressed than families that had been more protective. It is likely that the patient died still feeling loved and valued.

Psychiatrists can use family sessions to open patient–family dialogues that can identify discrepant views of the illness or treatment and explore concerns regarding an absent member, which may be undermining patient support and medical management. A major crisis, such as the imminent loss of a member, destabilizes the family structure, creating an opportunity for the psychiatrist to promote adaptive change and reconstitution. For example, family-centered grief therapy, which includes the patient and continues after the patient's death, provides a natural setting for such interventions.

When an older adolescent dropped out of college to take over her dying mother's duties with greater effectiveness, the family subtly discouraged her return to school after her mother's death. Psychiatric intervention while the mother was still alive allowed the patient to play a part in reorganizing family roles in a way that made it more possible for her daughter to continue her studies without facing too much hostility. The patient herself had wanted it settled, and the family responded lovingly.

The Last Vigil

As patients sicken, their consciousness waxes and wanes. It cannot be known how aware they are of their surroundings, but families usually keep watch, and the patient's comfort measures should not be changed unless it is clear they have become counterproductive. As patients fade, family members often feel as though they are being abandoned. This can be unexpectedly painful, even in relatives who had felt prepared for the event. Involuntary movements are often overinterpreted as last messages. The consultant should appreciate these dynamics, help the family grasp the reality, and prevent inappropriate requests for ever more life-sustaining measures. Comatose or moribund patients may look uncomfortable during agonal breathing, but their level of awareness is minimal. It is difficult for exhausted family members, who may feel guilty for wishing it was over. *These negative feelings should be recognized, validated, and*

normalized. Taking turns can be encouraged. As death becomes imminent, the nursing staff will be attentive, calling for a physician and supporting the family.

During times of epidemic, the last vigil may, in fact, occur at home, punctuated by electronic visits via tablets or other technologic devices, often mediated by a nurse, who may, for instance, touch the patient as directed by the family. Such moments can be filled with guilt for not being able to be with one's loved one. Medical staff may be able to help families make the most of these "visits" by helping them think ahead of time what activities might be most comforting to their loved one, whether music, prayer, reminiscences, or, if their loved one can speak, by simply being present and listening.

After Death: The Final Farewell

Responses range from dramatic to subdued. The family is given time alone, crying and comforting each other, sometimes singing hymns or songs. Sometimes a spouse or parent clings to the body and refuses to leave. Private leave-taking should be respected, and the grievers are usually ready to separate before institutional post-death routines are interfered with. Some surveillance always continues by nursing staff, who will call psychiatry if an occasional acutely distraught member refuses to leave, if suicide is mentioned, or if anything else concerns them.

All of the patient's doctors should be informed about the death so that they can respond personally. A phone call or a handwritten note is highly valued by family members. The consultant should offer bereavement counseling as needed. Family members sometimes call back years later. Hospices automatically provide bereavement counseling. Some hospitals also have bereavement programs, sending letters to the family at intervals during the first year, with condolences and information about bereavement groups. The response is usually very positive.

Unattended Deaths

Many traumatic or unexpected deaths become known from a catastrophic phone call. The patient is gone, but the traumatized family needs help to absorb the loss, cope with the circumstances, and come to some kind of closure. An unexpected death, even an understandable one, such as a heart attack in a cardiac patient, leaves an aching sense of unfinished business over and above the expected grief. If the person was the victim of a crime, obsessive thoughts might be difficult to repress, and grief may turn to rage, with profound psychological disruption. It is also difficult, if not impossible, for survivors to fully make peace with suicide.

The absence of a body or a locale is also troubling. Soldiers take enormous risks to retrieve bodies. Families clamor for remains or a shred of irrefutable knowledge or proof. Emergency rooms, police departments, and religious and community institutions should be equipped with a list of resources to help survivors of traumatic deaths. Psychiatric input can include program development and consultation to a wide range of professionals and individuals. Families must be helped to construct their own ritual whereby they acknowledge to themselves and others the finality of their loss and perhaps create a place, if not a grave, around which to center their memorializing. In the case of a pandemic, the family may live stream services. If they prefer a more intimate way to say final goodbyes, they might wish to also plan for a memorial service to be held after the dangers have passed.

Attended Deaths

Patients can die in an acute hospital, in nursing homes, in hospices, and at home, with or without hospice support. Most patients still die in acute care hospitals, having received active care until shortly before they die. This may occur because death is sudden or because the family or patient needed to be in a place where “everything is being done.” Fortunately, a growing number of hospitals have palliative care teams that provide appropriate care in the acute hospital setting, and home care programs are still

increasing. Many patients die in nursing homes without the benefit of special care.

This unfortunate situation could be remedied by bringing formal hospice care into nursing homes, but funding sources and turf issues need to be settled before it can if ever, become routine practice. Inpatient hospice care was the first model of care to be developed and is warmly remembered by grateful families whose multiple human needs and those of their loved ones had been met in ways that they had not been trained to expect. As hospice care has gained acceptance, the insufficiency of inpatient beds has encouraged the development of home hospice care. This has, in turn, encouraged more families to elect to keep dying loved ones at home.

In a home hospice program, the patient is evaluated and accepted in the usual manner but stays at home. The patient and family receive extensive instruction about what to expect, including the possibility of readmission to the hospital if they become truly overwhelmed. They are helped to obtain necessary materials, taught how to use them, and get as much home help as they need. All the while, they receive medical supervision, nursing care, and emotional support with 24-hour phone availability and routine daily contacts.

Without this kind of help, a good death at home can be difficult to achieve. With it, patients feel safe from the abandonment they commonly fear, and families feel safe from the terror of an unmanageable event. The families of these patients work hard but are more likely to feel competent and in control.

However, this rosy picture should not become a guilt-provoking expectation. Some families feel unable to manage at home, and, indeed, many do lack the physical and emotional resources. When a patient wishes to die at home, the family may concur while harboring serious qualms. When a patient pleads and a family refuses, the clinician must resolve a painful conflict. Sometimes a visit to a hospice or an interview with a hospice worker eases the impasse, leaving the patient more willing to go into a hospice or the family more willing to take a chance at home, as long as transfer to inpatient hospice is a guilt-free option.

SURROGATE BURDENS AND FAMILY COPING DURING THE END OF LIFE

The difficulties faced by family surrogates are sometimes discounted by the medical staff because the need for their decisions may displace other concerns. However, end-of-life decisions are momentous, and their memory remains as permanently vivid as classic traumatic memories. Laypeople severely overestimate the practical consequences of end-of-life decisions. Proxies feel that they had decided the “when” of a patient’s death, while all they did was to minimally alter the “how.” Health professionals should be sensitive to these distortions and should educate and support surrogates well before the actual moment of decision. Early, extensive communication can positively impact the surrogate’s ability to grieve and to reach a healthy sense of resolution.

Three months after her 83-year-old demented father's death, Mrs. X consulted the hospital psychiatrist because she was haunted by the decision that she had been asked to make about stopping antibiotics during his terminal pneumonia. His baseline pulmonary function was getting poorer, which led the physician to ask the question in good conscience, but she experienced her final act on her father's behalf as a betrayal.

Grief counseling focused on two areas. The first area was her relationship with her father before and during his years of dementia and how they led to the final decision. Had her family relationships been seriously dysfunctional, or had she been more vulnerable, the counseling might have required a longer course. This bifurcation is a common technical issue for psychiatrists dealing with cases of complicated bereavement. If the physician wishes to make the option available, it should be openly discussed, and the goals of treatment should be altered through a mutual decision process. The second area was her relationship with his caregivers, who, while generally supportive, had underestimated her vulnerability and her need for their affirmation of any decision she made.

Medical caregivers may not realize how little some families know and how much their words and behaviors are overvalued. Family members bring intense feelings and possibly contradictory agendas to the bedside. There may be jostling for authority or determination to replay an important family scenario one last time (e.g., favorite child, supportive sibling, or patriarchal authority) or confrontations previously held at bay. Formal proxy or informal surrogates are at added risk for being either criticized by family members or pressured for decisions by the staff. Psychiatric consultation should be called as early as possible when this constellation is identified.

Primary Caregivers

Primary caregivers are a special case. Their physical and psychological distress has been found to be, in some cases, as great or greater than that of the ill, but not dying, patient. Studies have shown that they experience a 25% to 30% incidence of job loss, and more than half move to lower-paying jobs to accommodate the need for flexibility. When the patient nears death, some caregivers feel ready or even eager to let go, which may cause some guilt. Sometimes they cling desperately to an individual whose continued existence has become the raison d'être for their own. This should not deny the finding that almost all caregivers also describe feelings of joy and transcendence while carrying out their task, as described in a study of HIV patients and their partner caregivers. However, they still come to an end in a state of depletion, and their welfare should be of concern to clinicians.

Ms. T and Ms. M were sisters who had lived together after they were widowed, although both had children. Ms. T had cared for Ms. M as the latter's coronary artery disease had worsened and was the health care proxy. When Ms. M suffered a stroke and became comatose but not brain dead, her son began to discuss goals of care with the physician, who had to remind him that it was not his decision. At the same time, she had to urge Ms. T to overcome her reluctance to confront the severity of her sister's condition and to protect her from her nephew's growing resentment. Aware that the closeness between the sisters had created a distance from the next generation, the physician-focused on fostering rapprochement between them. As the son acknowledged his appreciation for the care that his mother had received, his sister felt more supported and could begin processing her imminent loss.

LEGAL ISSUES: ADVANCE DIRECTIVES, PROXIES, AND SURROGATES

This section reviews information that does not always affect an end-of-life case but needs to be familiar to physicians and other staff.

Advance Directives

Advance directives (ADs) are instructions left by patients about their wishes regarding medical interventions once they can no longer make their own decisions. Legally binding in all 50 states, they are dictated by the Federal Patient Self-Determination Act of 1992. ADs refer to the right to *refuse*, not to demand, treatment. This distinction is sometimes lost on patients and even more on families, opening the door to stressful confrontations. Although the use of ADs is increasing, the majority of patients still do not have them, leaving family members to make decisions.

Living Will. Patients may leave instructions about what care they do or do not wish to receive after they become incapacitated. These can be extremely helpful to family members and medical caregivers. However, they are often vaguely worded and cannot predict the exact form that terminal events will take, so there is often an element of uncertainty about their interpretation. This can be lessened if there have been family discussions and/or legal advice.

Health Care Proxy. Patients may formally designate any individual to function as a health care proxy and make any and all health decisions on their behalf. The law dictates that choices be made according to the following hierarchy: (1) the patient's own wishes; (2) if the patient's wishes are unknown, the patient's best interests; (3) if that is ambiguous, the decision can be justified as being the most reasonable one; and (4) last, state interest can be invoked; the latter is currently applied mainly to pregnant women, in which case the welfare of the fetus has increasingly been seen as competing and having priority over that of the mother, but that is another story. The proxy cannot overrule any patient's written instructions, especially with respect to life-sustaining measures, such as feeding, hydration, and life supports.

Family members are believed to have the most reliable knowledge of patients' wishes and are deemed natural surrogates. Yet, numerous studies have found that agreement between patients and their family members about end-of-life decisions is no better than random. Indeed, their intimacy with the patient creates ambiguous motivations. Some proxies approach the task without any previous discussions with the patient and do not feel confident about understanding the patient's wishes. Others harbor different opinions and carry out their own wishes, despite legal instructions to the contrary. Both scenarios engender significant guilt, which endures long after the patient's death. In general, the psychological and ethical burden of proxies, as well as their need for ongoing education and support, is profoundly underestimated.

Surrogate Decision Maker. When patients have left no formal instructions, the nearest relative becomes the decision-maker by custom and by default. It is usually the one who is most involved, but, occasionally, the lot falls to one who is emotionally or geographically distant, uninformed, or unwilling. This leads to the problems mentioned above.

Durable Power of Attorney. A durable power of attorney is a broader legal power that includes the health proxy along with financial powers. It has been legally available for a long time but was less widely used.

Brain Death Determination. Brain death is defined as two successive determinations of a flat EEG at least 6 hours apart and is accepted as a legal alternative to death by cardiac arrest. Many families have difficulty accepting that a loved one with warm flesh and a beating heart is truly dead. Often, life supports are continued for a period of time while the family is helped to come to terms with the situation. Some families invoke religious beliefs to refuse it altogether, creating stalemates that often go to institutional ethics committees with unpredictable results. The growing use of organ transplantation has been a factor in the legal acceptance of brain

death because it enables a better chance for the transplanted organ to work well.

Table 27.9–12.
Advanced Directives

Directives	Patient	Family
Medical decisions		
Living will	Often causes problems if lacking details about withholding and withdrawal of life supports, feeding, nutrition, dialysis, total parenteral nutrition, blood products	Changing circumstances are associated with ambiguities; the family may deny the current applicability of the living will
Health proxy (or durable power of attorney)	Same problems as with living wills	
Legal guidelines		
Substituted judgment Best interests Reasonable decision State interest		If there are no written instructions, the proxy may act freely but can be opposed by the medical staff
De facto proxy behaviors		Conflicts may be referred to:
Proxy desires		An ethics committee
Staff desires		The courts (rare)
Brain death determination	Legally defined	Families may still demur on vaguely worded religious grounds
Autopsy	Usually no patient	Family demands are

	instructions	respected
Organ donation and transplantation	Patient's desires should be honored	Patient's choice may be overridden by family, absent formal directives; none of these decisions can be overturned without recourse to legal intervention
Financial and legal decisions	Formal documents are binding	

Autopsy and Organ Donation. A patient's advance interdiction of autopsy or organ donation will not be overridden. However, in the absence of instructions, families are asked to make the decision. It can be upsetting for some families, especially the process of harvesting organs from a body that is brain dead and still appears alive. Even without pre-existing religious objections, some families find it difficult to allow. Ethicists have weighed concerns about the moral acceptability of pre-death procurement as decided by surrogates in the absence of clear patient instructions. Although there is an appropriate firewall between those with a stake in organ transplantation and those with direct responsibility to the patient, more and more people are aware that refusal deprives unknown individuals of a chance to live. A few sensitized family survivors may experience painful conflicts and may harbor residual guilt.

Table 27.9–12 summarizes this information and points out the extent to which all of these categories are subject to interpretation and argument. True to current society, only the instructions about financial and legal matters are unequivocally binding. The thicket of decisions confronting families today would bewilder a time traveler from as little as 50 years ago, who would glance at the patient and know it was time to mourn—nothing more, nothing less.

CULTURAL, SPIRITUAL, AND RELIGIOUS ISSUES

Culture and religion help shape the ways in which people make meaning out of suffering, loss, and death, and the ways in which they understand the sick role, the caregiver role, and every other basic role, such as a parent, partner, child, or sibling. When clinicians share the same unconscious assumptions, decisions can be negotiated more easily. Major differences still occur but play out against the same background music. The consultant should be attuned to the differences—not only intercultural differences but also the ways in which given patients, or family members deviate from their intracultural norms. It is a tall order but well worth the effort in decreased psychological stress, smoother decision making, and improved care. Furthermore, the knowledge gained in one case later eases the management of other cases with the same background. Many institutions have formal seminars or protocols to educate staff about recurrent cultural or religious scenarios. Table 27.9–13 describes a model for the evaluation of cultural issues.

Cross-Cultural Barriers

Cross-cultural problems can be manifested in multiple ways, the most important ones of which are discussed here.

Trust. It is more difficult to establish trust across wide cultural barriers. Some minority groups are thought to want more aggressive care, use fewer DNR orders, and participate less in organ donation and research because they do not trust medical caregivers to treat them as well as they treat the majority group. Some mistrust is justified. There are significant differences in quality of communication, access to care, and quality of care that result in well-documented poorer health outcomes for minority populations. However, when trust is present, the differences are often minimized.

Table 27.9–13.
Evaluation of Cultural Issues: The ABCDE Model

*A*ttitudes: Elicit *a*ttitudes about illness, family care, and responsibilities.

*B*eliefs: Explore *b*eliefs and ritual practices.

Ask direct questions about faith and religious experience; follow up on cues. “What does that mean to you right now?”

Do not respond to statements of religious and spiritual values with facts.

Reflect them respectfully.

Do not deny or pretend to go along with expectations such as miracles but use “I hope” or “I wish” statements that indicate a shared desire for the best outcome that can be arranged.

*C*ontext: Inquire about the cultural *c*ontext in which the patient and family operate.

*D*ecisions: Determine their *d*ecision-making style.

*E*nvironment: Learn about their current *e*nvironment.

Data from Koenig BA, Gates William J. Understanding cultural difference in caring for dying patients. *West J Med.* 1995;163:244.

Truth Telling. The requirement for truth-telling is so embedded in U.S. law and custom today that it may be hard to remember how foreign it can be to other cultures. Surveys of Chinese, Korean, Japanese, Ethiopian, Mexican American, and Native American groups found that only 35% to 52% saw end-of-life truth-telling as desirable. Furthermore, truth in prognostication is not well practiced even in western medicine. Not all physicians prognosticate truthfully, and some may be using good judgment by respecting a strong family culture. It is also useful to remember that nonverbal communications are more highly valued in other cultures. The ability to intuit what the other person is thinking, and to address concerns without too direct a confrontation, is appreciated.

Family Involvement in Decision Making. Families are always involved in decision making but, in some cultures, there may be a strong duty to completely relieve the patient of that burden. This custom is independent of socioeconomic status. In a study of Japanese American families, the custom was independent of the degree of acculturation as well. A family whose request for nondisclosure is ignored may feel upset, angry, and disrespected. If the patient gives informed refusal, the family can be accommodated. However, if the patient is ambivalent or appears interested, psychiatric consultation should be requested and must include an evaluation of cultural and religious factors as well as patient and family dynamics. The family should be educated about the patient's situation, and their concerns about disclosure should be explored nonconfrontationally with indirect questions about the consequences. "How will you feel if you cannot answer your father's questions?" "What will your mother think as she becomes sicker?" When the physician feels strongly that the patient must be asked to participate, it may be wise to also call an ethics committee consultation, for which the consultant's analysis is a useful document.

Mrs. M came from a traditional Chinese family and did not speak English. When she was found to have advanced carcinomatosis, her son and husband refused to tell her about it and were indignant at the thought that anyone would upset her with this information. Consultation with an acculturated Chinese physician from the same subgroup confirmed that their reaction was the standard one. He interviewed the patient and found that she had decisional capacity, had no interest in her medical condition, and shared her son and husband's views on the nature of family support. This was considered an adequate informed refusal and, although she was periodically revisited by the same physician, her demeanor never altered.

Such cases arouse discomfort in medical staff well indoctrinated in the rules of informed consent. However, assuming that a westernized moral climate applies to everyone has its dangers. It is sometimes wiser to respect family mores.

Religious Issues

Every religion has beliefs about death, and every culture has highly valued rituals to honor them. They play a major role in family expectations and reactions. Every hospital or hospice staff should be familiar with such customs in the major religions that they will encounter. They should have access to consulting appropriate clergy to enable them to understand and respect family reactions. The humanizing trends described above have made this more commonplace.

STAFF–FAMILY INTERFACE

In any inpatient setting, medical caregivers are an integral part of the terminal scenario. Their words and nonverbal cues are scrutinized, giving their conscious and unconscious biases an exaggerated impact on events. Staff members can become overinvolved with a patient and family, can scapegoat them, or can overestimate or

underestimate their coping abilities, all of which negatively impact care.

In the hospice setting, patients, families, and staff are already all aware of the outcome and do not bear the burden of the many transitions and secrets that characterize the modern death trajectory in hospitals. Nevertheless, continued motivation without burnout and without developing dysfunctional norms requires vigilant attention, and hospices have had built-in psychological support from their inception, which probably explains their lower turnover rate of personnel.

In hospital settings, however, staff members must make constant transitions from day to day and from patient to patient on a given day. They must repeatedly shift set and help patients and families struggle through painful changes. Fortunately, in today's setting, psychological support is available to staff as well as patients, often within case discussions that now include psychological as well as medical issues.

PEDIATRIC END-OF-LIFE CARE

The death of a child always feels like a crime against nature. The biologically determined instincts that drive some adults to care for sick children may endow pediatric wards with a particular intensity that must be channeled with experience and training, but it also provides the children with the responsiveness they need. Medical caregivers must also be aware of the child's level of development and request psychiatric help early if there is a question of cognitive or emotional problems since they will interfere with the child's ability to handle the treatment and further course.

Their parents will remain distraught, although some may acquire strength in the process, while others will require ongoing attention. In all cases, *a cooperative, supportive connection between caregivers, the family members, and the child must be maintained throughout.* This tripartite connection helps the child feel more secure, while the family appreciates the consideration and support, and the caregivers can be, and feel, more effective.

ETHICAL RAMIFICATIONS OF THE TRIPARTITE CONNECTION

The requirements of the tripartite connection define the entire course of treatment and hinge on three values that must always be present: *trust, honesty, and confidentiality*. Their importance revolves mostly, though not exclusively, around three main issues: (1) The parents are facing the loss of a child to whom they gave life, which, along with grief, induces a sense of irrational guilt that cannot be fully erased and may drive them to make extreme demands against the child's interests. (2) Legally, pediatric patients are always third parties, ranging from helpless infants to 18-year-olds who may be wiser than their parents yet not free to make their own decisions. (3) The medical world had, until recently, not focused much on the fact that adolescent maturation is as relentless as breathing and continues its struggles to survive under a dark sky. Parents able to help younger children may find it more difficult to honor the adolescent's needs and require more information, explanations, and support.

Trust and Honesty

This creates the need for what was well characterized in this quote: "The goal from the outset is to establish a dual treatment relationship with both parent and child with a common goal of understanding the child's thoughts and feelings and improving the child's well-being. *It is necessary to establish a three-way message of trust."* (see Kearney J.) Physicians who regularly interact with the parents and child carry a special burden. The situation demands that they earn everyone's trust and honesty when meeting with children and parents, separately or together.

Confidentiality

Negotiating confidentiality is a delicate matter and is dependent on doctors' communication skills. Having addressed the need for full honesty, they are obligated to begin by explaining to the parents the

legal limits to confidentiality when safety is at risk. Next, they must show the kind of understanding and support that convinces parents to trust that they will not lose touch with their child, even if they are not told all the thoughts the child has shared. Physicians must further explain that they *need* that trust because the child will only trust them if they can promise to use appropriate discretion when talking to the child's parents. Finally, doctors should describe their own determination to always keep in mind the priority of sustaining the parent–child relationship.

These meaningful issues must be addressed from the beginning of treatment, as gradually as necessary, when there is time for the parents to adapt incrementally to the more difficult times that lie ahead. It may require a psychiatrist since parents are such an important part of the patient's treatment that they need the same level of attention for the good of the child. Another potentially difficult position arises when parents, who have the legal right to make many decisions, are obstructing the best course. This is one more reason why it is critical to create a trusting collaboration from the beginning.

DEVELOPMENTAL STAGES

Infants and Toddlers

It is hard for anyone to watch the suffering of infants and toddlers, but while staff can move on more easily, the pain of parents is inherent in their parenthood. Giving birth implied giving life, and they are now failing and helpless. They need support to remain stable and keep providing the loving presence the child expects and needs. The medical team will do their part for the child's comfort and will continue to sustain the parents, although further help is often needed.

School-Age Children through Preadolescence

Within this age limitation, children vary widely in their capacity for absorbing what is happening. Adults often underestimate children's understanding, particularly in a crisis that draws out their most

protective responses. However, the reality is that, like sponges, children listen intently to what they hear, soak up the emotions that flow around them, and subject everything to an active process of interpretation, organized around finding out why they are being left out. Punishment is often their frame of reference, which they may elaborate on in various ways. When this happens, the child has unwittingly been made to carry what should be the parents' burden.

These suffering parents should be helped gently from the beginning to understand more about their child's response to their situation and should learn to speak to the child in age-appropriate ways, surrounded by reassuring affection. A knowledgeable individual must review the child's level of understanding so as to acquaint parents with appropriate ways of responding, explaining to them that these interactions are as fundamental to parenting as the care they had given their infants. On today's wards, parents must be given special support, which is one reason why many pediatric wards have their own support staff, including psychiatrists and psychologists.

The Child's Cognitive Understanding of Death and Dying

Understanding children's developmental stages and their level of insight about terminal illness has practical implications for the clinician. It provides a basis for effective communication with children about their illness and guidelines for improving their coping skills. Although children's reactions depend on their personality and level of development, they are also strongly influenced by their emotional family milieu and must be understood within that context.

Children's reactions to their own dying or to the death of others follow a developmentally determined conceptual framework, enriched at times by their own interpretations of familial conversations. Accurate comprehension of death requires the mastery of four basic concepts: irreversibility, finality, causality, and inevitability (or universality). These are detailed in Table 27.9–14 and should be familiar to adults dealing with children facing severe illness

and death because the children’s attempts at self-explanation make their course worse than it needs to be.

Table 27.9–14.
Concepts of Death and Implications of Incomplete Understanding for Adjustment to Loss

Irreversibility: Death is seen as a permanent phenomenon from which there is no recovery or return.

Example of incomplete understanding: The child expects the deceased to return as if from a trip.

Implication: Failure to comprehend this concept prevents the child from engaging in the process of detachment from the deceased, a necessary first step in successful mourning.

Finality (nonfunctionality): Death is seen as a state in which *all* life functions cease completely.

Examples of incomplete understanding: The child worries about a buried relative being cold or in pain; the child wishes to bury food with the deceased.

Implication: May lead to preoccupation with the physical suffering of the deceased and may impair readjustment.

Inevitability (universality): Death is seen as a natural phenomenon that no living being can escape indefinitely.

Example of incomplete understanding: The child views significant individuals (i.e., self, parents) as immortal.

Implication: If the child does not view death as inevitable, they are likely to view death as a punishment (either for actions or thoughts of the child or the deceased), leading to excessive guilt or shame.

Causality: The child develops a realistic understanding of the causes of death.

Examples of incomplete understanding: The child who relies on magical thinking is apt to assume responsibility for the death of a loved one by assuming bad thoughts or unrelated actions were causative.

Implications: Tends to lead to excessive guilt that is difficult for the child to resolve.

Adapted from Schonfeld DJ. Crisis intervention for bereavement support. A model of intervention in the children's school. *Clin Pediatr (Phila).* 1989;28(1):29. doi: 10.1177/000992288902800105.

During the first few years, children have almost no concept of death other than a disappearance or separation. Most children under the age of 5 years do not think of death as final and believe that the departed person is somewhere else. The most commonly offered explanation is heaven. Worried about being separated from their caregivers, young children may ask, "When I die, will Mommy come with me?" However, even children under the age of 5 years develop a precocious understanding of death if they experience a traumatic event like the death of a parent or sibling or any event exposing them to death. Children between the ages of 6 and 9 years understand that death is final and entertain concrete thoughts about the process of death and dying. For example, an 8-year-old child may conceptualize death in terms of damage to a particular injured body part. Stories of devils and ghosts may frighten children, and they may have vague ideas about the soul continuing to live on after death. A 7-year-old child suffering from terminal Ewing's sarcoma asked his mother, "When I die, will my leg fall off and stop hurting?" Children aged 10 years and older have a fairly good understanding of death. They begin to see patterns in nature, recognize life cycles, and often become aware of their own mortality. Some are quite precocious and could qualify as young adolescents.

Younger children may resort to themes of retribution and magical thinking when reacting to their illness. Perceiving their suffering as a punishment for real or imagined misdeeds, they accept the burden of personal shame or guilt to account for it. They view their illness in an egocentric manner and express their fears accordingly: "Did I cause it? Who is going to look after me? Am I going to be abandoned?" An older child or adolescent, aware of the irreversibility of death, may exhibit anger, anxiety, and depression while trying to cope with the

terminal illness. However, some children inspire respect by their courage and stoicism in the face of death.

Communication with Severely Ill Children

Children quickly learn to whom they can trust and confide. Whether or not individual children should be told about their prognosis is not a simple matter. Parents have psychological, moral, and legal authority. Their wishes must be explored earlier rather than later. Some parents do not want their children to be told they are going to die. It is useful to ask them *how they would respond if the child asked them if they were dying.* It should be the opening of an ongoing conversation, aiming to help them understand more about their particular child's response, the fears, the sadness, and the need for *authentic* reassurance. When some families are willing to tell the child, one individual should be selected to talk to the child, but only after discussions with the physician. Sometimes, the physician will be asked to be present during such conversations or might even be asked to be the one to speak to the child. The same information must then be conveyed to everyone close to the child because inconsistent explanations are confusing and even emotionally crippling. In such cases, an experienced child psychiatrist or psychologist can be helpful early in the process.

When the child asks a question about death, it is very important to first clarify what the child already knows and the reasons behind the question since they may be very different from what adults expect. Some children are responding to the anxiety and grief projected by their parents; others are preoccupied with pain, discomfort, mutilation, abandonment, and loneliness. The child should be given ample time and opportunity to express concerns, and any frightening misconceptions should be clarified. Even when children are told their illness is fatal, they should be comforted and reassured that the physicians will do everything possible to keep them comfortable and that they will always be loved and cared for. If the physician expects a difficult session, it may be useful to ask a child therapist to attend. In fact, early referrals are frequent and desirable.

Communication with Parents

Communicating with the parents of a very sick child follows the principles used in families of adult patients, save for one crucial difference: the parents' deep sense of responsibility for the child's welfare and the attendant feeling of failure. Some parents are too overwhelmed to function. Others throw themselves into research, taking the child for multiple opinions and treatments. Still, others never leave the child's bedside, which is helpful for younger ones but may dominate the child's relationships with other caregivers. Constant tasks leave them little time for thinking or feeling. A few may actually remove themselves. Fortunately, pediatric wards still witness remarkable feats of loving accompaniment in the face of increasing grief and exhaustion.

Parents often need guidance and support, particularly about whether they should treat the child normally or with special attention, especially when they have other children. Intensely protecting a young child beyond what the illness requires confuses the child, who has no framework to explain this novel behavior. The older child and the adolescent understand its basis; some welcome this protection, and some crave and require it. Others prefer more freedom and privacy, often acting out a fantasy of being well or finding a means of denying the fatality of their disease. The advice and support of an experienced child psychiatrist can help parents strike the right balance.

Parents may demand aggressive medical treatment because they cannot bear the thought of future regret over any omission. These feelings may not be openly voiced to the physician. They should be sought for and discussed openly if any other option is to be considered.

Finally, as parents learn to accept that their child will die, they reach a state of resignation that spares them the previous bouts of activity, ushering in a different kind of suffering and anticipatory grieving. In this exhausted state, one or both parents may find themselves wishing the child dead. These unacceptable secret thoughts burden them with excruciating guilt. They should be *sought*

for and clearly normalized. It is a major gift to relieve them frequently of these attacks against themselves.

PSYCHIATRIC SYNDROMES IN THE TERMINALLY ILL CHILD

Although psychiatric problems in dying children are similar to those seen in adults, their presentation varies depending on the child's stage of development. The young child's ability to report symptoms of physical or emotional discomfort is generally undeveloped or unreliable. Other young children may not wish to disclose their suffering out of unwarranted shame or guilt from real or imagined wrongdoing. Clinging to magical thinking, these children may fear that voicing their complaints will worsen their symptoms. Others may be the opposite and will use a lot of energy on loud complaints, in which the line between physical and emotional is hard to distinguish. A few children may assume that if they wish to be healthy and think "good thoughts," the problems will go away. All this leads to withholding of information and compromised care. Older children may not be much more forthcoming. An astute physician knows to look for symptoms even if the child is not vocalizing them. Consulting with child therapists is useful in such cases.

Symptoms of delirium, depression, and anxiety occur in children with a terminal illness, and their causes are physiologically the same as in adult patients. Children with pre-existing psychopathology are more vulnerable to developing psychiatric syndromes as they confront terminal illness, but the symptomatic treatment is still evaluated the same way as with adults.

Delirium in Terminally Ill Children

As in adults, symptoms of mild delirium may be overlooked or mistaken for regressive behavior in a young child. Because a young child's world normally fluctuates between fantasy and reality, symptoms of visual or auditory hallucinations may be viewed by the parents as the child's fantasy rather than as a delirious state of

altered perceptions. Disoriented states may be overlooked or minimized because children's attention to the items measured is variable at best. In response to this, Paula Trzepacz has adapted her delirium scale to children and adolescents.

As with adults, treatment of delirium requires an immediate institution of symptom management, along with a search for the etiology and correction of the underlying cause if possible. Neuroleptics, such as haloperidol or droperidol (Inapsine), as well as the newer antipsychotics, may be used to treat the symptoms. Benzodiazepines are usually avoided because of the associated disinhibition. In addition to this treatment, reassuring and reorienting the child by placing familiar objects and people in the room is helpful. Psychoeducation of parents can relieve fears and misconceptions and allow them to better support the child.

Depression in Terminally Ill Children

Depressive symptoms are expected in children battling a life-threatening illness. One may see anticipatory grief and mourning for the perceived loss and impending death or behavioral problems, such as regression, opposition, aggression, withdrawal from family and friends, and noncompliance with medical care. Very few children develop a full-blown major depressive disorder that requires pharmacologic intervention. As with adults, vegetative symptoms, such as fatigue, anorexia, and insomnia, are so common in terminal illnesses and major depression that it is impossible to tease them apart.

With adolescents, it is important to explore suicidal ideations and fantasies overtly. In their struggle with a bleak and uncertain future, some harbor suicidal thoughts as a means of gaining control over their destiny. To judge the level of risk, the consultant must explore the youth's understanding of what suicide means, the personal motivation for it, and the presence or absence of a plan. Known risk factors include the presence of previous or comorbid psychiatric disorders, persistent and intractable pain, and poor social supports.

Treatment of depressive symptoms begins with helping the families make the children feel confident that they will not be abandoned and that their comfort will always be a top priority. Maladaptive behavior patterns can be explained to the family as the child's way of coping with anger and grief. Some parents can help the child process the myriad emotions that assail them in the face of impending death. Exploring the child's feelings through play or drawings can be liberating. Providing children with an open forum to talk about their concerns, beliefs, and fears about death helps them emotionally process what is happening and feel less alone. Some courageous children decide to whom they want to leave their belongings and say personal goodbyes to friends and family in a variety of ways. This authentic and generous engagement can be empowering, but it *must* come entirely from the child, suggesting it could be very upsetting to an unprepared child.

Antidepressants may be necessary for a minority of children with major depressive disorder, but children should also be receiving active treatment for pain, fatigue, insomnia, and any other treatable symptoms. The etiology should be sought while treatment is instituted.

Anxiety in Terminally Ill Children

Anxiety in the face of death is ubiquitous. It may stem from physiologic issues such as intractable pain, compromised respiratory state, or medications, as well as from psychological issues such as separation from parents, the unfamiliarity of the hospital environment, and fear of death. One should always treat physiologic symptoms while helping parents treat the symptoms due to the child's own observations, experiences, and interpretations. Ensuring consistent contact with parents, avoiding prolonged separation, addressing the emotional states of caregivers, and making the hospital milieu more child-friendly go a long way toward assuaging the child's anxieties. More severe symptoms may require the use of anxiolytics. Short-acting benzodiazepines are preferred to minimize

sedation, respiratory compromise, and disinhibition. Child psychiatrists and other child therapists should be effectively used.

Pain Management in Terminally Ill Children

Pain assessment in children is more complicated than in adults. Children who lack verbal skills cannot communicate pain to caregivers. Young verbal children may distract themselves from pain with play, some recoil into sleep, and some remain withdrawn and anxious. Adolescents may not be forthcoming about pain due to the belief that they are invincible or due to a misplaced fear of addiction.

Yet, with the use of appropriate rating scales, children can be reliable reporters. Age-appropriate and validated scales do exist, and more physicians are now familiar with them. As with adults, it has been found that professionals using clinical judgment assess the child's pain level as lower than do both the parents and the child. Worse yet, the greater the child's pain, the greater the discrepancy.

Most parents recognize their child's pain and are eager to see it relieved, but a few mistrust the medication to the point of forbidding it. Some are worried about addiction but accept education and support. A few are unable to tolerate seeing their child relax and become less related because they do not experience it as relief for the child but oncoming loss for themselves. With PCA, they express fear of overmedication. Yet, it has been demonstrated that children old enough to understand the technique showed significantly diminished use of opioids with PCA. Family education around these issues is important, but often a consultant must ease the parents into realizing how much their reactions are a way of avoiding the truth of their child's condition. Only after they confront the reality can they wholeheartedly cooperate with optimal pain management.

COMMUNICATION WITH ADOLESCENTS AND YOUNG ADULTS (AYA)

Introduction

One of medicine's strengths is its focus on the individual and the positive attention it brings to each patient's care. The earlier discussion of the close interaction between medical and psychological management for children and adults need not be repeated here because adolescence overlaps both categories, as will be discussed below. This section will discuss recent developments that specifically focus on adolescents and young adults.

Current Interface of Hospitals and Adolescents

Only in the last few decades have medical hospitals thought about special arrangements for adolescents since they could still be assigned to either pediatric or adult wards. Yet, human societies have always been aware of the adolescent trajectory as a meaningful period for them and society. There have been increasing numbers of specialists over time, but only in the last two decades have hospitals introduced dedicated spaces and trained individuals to work with them. They have been well utilized by terminally ill adolescents who suddenly have to integrate the most profoundly threatening experiences while still making meaningful relationships in the process.

AYAs' Development during Their Illness

Adolescents and young adults, now referred to as "AYAs" by researchers, are a group of patients that should not be defined solely by age but by the level of development. It could include a precocious 12-year-old or a solitary 25-year-old. An early hospital study found that parents' protective instincts were as powerfully aroused with older as with younger children, which made them cling more strongly to their parental decision making. This observation encouraged caregivers to help parents understand and respect their adolescents' growth. It confirmed what was being increasingly noted, that relentless exploration toward adulthood continued throughout their illness to the very end. This means recognizing that their grim situation does not stop them from thinking about making new peer

relationships in the hospital, still focusing on sexuality or at least intimacy, evaluating the life goals lost, maybe finding an appropriate new one, and last, despite—or because of—their misfortune, sometimes achieving unexpected levels of intellectual and moral development.

Adolescent psychiatry now plays a well-established role in medicine. Large medical centers provide gathering places where only adolescents, including gravely ill ones, can share their experiences with each other and where adolescent psychiatrists, psychologists, and teachers have roles to play. The main purpose is to allow adolescents, including dying ones, to still experience adolescent development. This is an excellent change, but it still is not always available in small hospitals and rural areas, where the smaller number of patients might require a different approach.

It is best to begin as early as possible to help AYA parents help their children to remain themselves. This help includes assessing AYA patients' readiness to discuss their disease, with a plan to help them understand and participate more and more—to the extent that they wish. Over time, their ability or willingness to confront their impending death should be assessed and explored, and if any of them show any ability to deal with it, they should be helped and encouraged. For some adolescents, it is deeply meaningful to write letters, leave gifts, or give instructions about future events such as funerals and posthumous remembrances of their birthday. Others simply hang on to close connections, leaving life on a note of fundamental love and attachment.

A group supported by the National Institute of Mental Health has been studying this area at length. They published the document *Voicing My CHOiCES* based on their research as well as feedback from AYA patients themselves. It guides health care providers to help patients and their families navigate this painful and complex process, using individual sections which AYAs can fill out with the support of health care providers, according to their comfort level. *Voicing My CHOiCES* provides a thoughtful and thorough discussion of how AYA patients can be helped to explore the important issues, although it also makes them aware of options at every point. When queried,

over 90% of patients reported feeling positive about participating in the process.

PSYCHOLOGICAL ISSUES OF HEALTHY SIBLINGS

Studies of healthy siblings have found increased levels of regressed behaviors, somatic complaints, altered peer relations, and a drop in scholastic achievement. They have also found higher anxiety levels and lower self-esteem. Children are at the mercy of their environment, and it is easy for anguished adults to forget that siblings still require the same nurturance and now also have additional needs. Caregivers who notice any problems should help parents develop constructive responses. Professional consultation may be required for complicated situations or dysfunctional families.

Parental Response to Healthy Siblings

The illness and death of a sibling is a world-transforming event. It permanently changes family dynamics and sometimes leaves the family in financial straits that diminish the surviving child's future opportunities. Acutely, it profoundly disrupts the family routines and captures the adults' time and attention, leaving them emotionally depleted. Some parents are strong enough to remain available to their other children, but many react by protecting them (i.e., keeping them uninformed and away from the family tragedy). Sadly, the patient's siblings are marginalized at a time when they most need to feel like integral members of the family. Keeping healthy children engaged in the family drama requires an understanding of the child's developmental level and emotional state so as to know what will help them feel loved, trusted, and included. Optimally, the staff caring for the patient will help parents maintain a closer and more open relationship with their other children throughout the illness.

Children's Understanding of a Sibling's Terminal Illness

Siblings 5 years old and younger do not understand the terminal nature of the illness and may react negatively to the parent's emotional state. If they sense withdrawal and sadness, they become frightened and may regress or act out, hoping to gain parental attention. Children between the ages of 5 and 10 usually understand their sibling's condition but may become anxious about being abandoned by a distraught parent as well as fearing that harm will befall them. Some children are plagued with guilt because they have been jealous and angry about the attention given to the patient and remember past times when they harbored angry feelings and even wished the sick child was dead. Younger children may believe that this wish was magically fulfilled and thus blame themselves for the course of events. On the positive side, given both reassurance about being loved and age-appropriate information such as well-related options on how to relate to the ailing sibling, many children become eager to show their support by making drawings, bringing special toys and treats to the hospital. With parents' approval and affection, this fruitful participation in family events significantly enhances the sibling's self-esteem and sense of security and may help the sick child as well.

Adolescent siblings can become supportive, to the point of assuming parental roles toward younger siblings and taking over household tasks. When the family members begin to take it as a given, it may put these youngsters in a position that will interfere with their development. However, in today's world, it is increasingly likely for adolescents to withdraw from the family, acting out or devoting more time to being with their friends or just spending more time with their eyes glued to a screen. In any case, they too will need help, whether to prevent them from continuing their parentified role beyond the death or to help them return into the family fold in time to manage their feelings toward their dying siblings (with help, if needed), and experience the shared affection as well as the grief.

STAFF DYNAMICS IN END-OF-LIFE CARE

The family–staff interface in pediatrics and the associated trust and communication needs are the same as with adult patients, but there are a few special issues associated with the staff. Pediatricians and nurses choose to work with children because they love them. During an increasingly severe illness, they come to know the child well and may become very attached. The expression of affection toward a pediatric patient by caregivers need not have the inappropriate implications it has for adults, as long as the medical judgment is unimpaired. Ideally, the staff and the family remain united by their common dedication to the child, but occasionally the attachment is so strong that it creates conflicts. For example, a nurse's maternal instincts can engender an unstated competition with the child's mother, which makes her less supportive and affects other staff as well. The mother is usually keenly aware of it but sometimes afraid to mention it. This situation requires a change of assignments for the nurse, with special support and training to prevent recurrences.

Sometimes, staff members are quick to pass judgment on families that are not meeting their expectations. Once crystallized, these judgments can be very hard to revise. Negative stereotypes and competitive feelings are very destructive. They cannot be hidden from parents, who are exquisitely sensitive to staff behaviors and utterances. It is critical that team leaders set the tone and create a culture in which children and parents are *both* treated with equal empathy. Consultants must remind the staff how much the children want to feel securely embedded in their families at all stages of illness. Children's profound dependency on their families is such that they are enslaved by faithfulness, even in the face of parental indifference or abuse. *Any staff behavior that threatens family unity is unacceptable, no matter how well-intended*.

Staff overinvolvement also creates Intra staff rifts. In one case, an oncology fellow became so involved with a child that he argued heatedly over the attending's choice of treatment. In another case, two nurses became so attached to a patient that they arranged their work schedule to have one of them on duty every day because they felt their colleagues would not care for him well enough. It is not that unusual for young pediatricians to share some of the parents'

feelings and, occasionally, to become more involved than they had intended. These doctors must learn to exercise control with the parents and would benefit greatly by sharing their feelings with a trusted colleague. In general, this is why group work and open discussions have become a larger part of the climate when working with terminally ill patients.

END-OF-LIFE DECISIONS IN PEDIATRICS

Assent and Consent

As children mature and are better able to process information about their illness, they can play a more active role in decision making. However, with the exception of emancipated minors, the child can only assent, while it is the parent who can give legally binding consent. This is usually not a problem because most parents respect the wishes of the dying child, but there may be times when discrepancies arise.

One scenario is that of adolescents refusing treatment that their parents, and sometimes their physicians, would like to administer. This situation calls for psychiatric consultation to allow all participants to explore their feelings and to help achieve consensus about the care plan. Consultation with an ethics committee may be necessary when an agreement cannot be reached.

Another scenario is that of an exhausted or frightened parent who refuses treatment that the staff believes a child would accept were they not afraid to disagree with the parent. It is more likely to happen if the staff has not achieved an easy, supportive relationship.

The single mother of a 9-year-old boy with relapsed leukemia refused a bone marrow transplant on religious grounds. The nursing staff dealing with the child felt that, at age 9, he was aware and would not have minded the treatment but was afraid to disagree with his mother. The consulting psychiatrist found that the mother felt overwhelmed and unsupported by the staff. Her religious feelings, although genuine, were also a way for her to escape the situation. The consultant urged the physicians and nurses to hold off on requesting any decision while being very supportive of the mother and validating her apprehensions and pain. Within 3 days, she was ready to proceed with the treatment, which the child accepted readily.

Neonatal and Infant Issues

Neonatologists can now save premature babies who weigh little more than 1 lb and are at high risk for intracranial hemorrhage or respiratory insufficiency. They can also salvage severely handicapped newborns who will always need intrusive medical care and whose quality of life will remain poor. Some people believe life-sustaining interventions should always be used, others believe they should never be used, and a large group thinks that it depends on circumstances. Among physicians who are not absolutely opposed to withholding life-sustaining measures, the relevant quality-of-life issues are: (1) the extent of physical impairment, such as severe neurologic damage; (2) the burden the child will place on the family; and (3) the ability of the child to derive pleasure from existence, such as having an awareness of being alive or being able to form relationships. From a philosophical point of view, these are very disparate arguments, but they derive from the pragmatic and casuistic method that has characterized valid medical thinking.

WHERE WE STAND NOW

Decision Making

Truth-telling and obtaining informed consent are legal obligations. The intellectual requirements for having the capacity to consent are well elaborated. First, the patient must be provided with information about the diagnosis, prognosis, and treatment options, as well as a review of the risks, benefits, alternatives to treatment, and the consequences of no treatment at all. Processing this information can be difficult, especially under the dual burden of severe disease and the nearness of death. Given the high incidence of cognitive clouding in very ill patients, every dying patient's right to make decisions might be imperiled if one focused only on cognitive criteria when establishing decisional capacity. Consultants must come when patients are most alert and lucid and *must look for an internally consistent sense of self and general awareness of their condition*. If present, these should weigh more heavily than the patient's ability to perform a standard mental status examination. This is not to imply that the consultant should be less aggressive in correcting the patient's cognitive state by all the usual means.

Informed Consent for Experimental Treatment. It is difficult for patients in relatively good health to absorb the basic facts about clinical trials. They may agree to the trial to please their physician or may believe that the physician is offering them a place in the trial because it is good for them. Reality #1: doctors continue to have a personal duty to the patient even if they enroll them in a trial; they must remove the patient from the trial if the patient's welfare is incompatible with the demands of the protocol. Reality #2: patients need to keep believing their doctor is serving their needs whether they are in a trial or not; this is even more intense for terminally ill patients who have become known as *desperate volunteers,* and who enter trials "because" it is their only chance—and indeed, their desperation cannot be assuaged! Its presence places an even greater ethical burden on both physician–researcher and Institutional Review Board (IRB). If both parties do their jobs, the psychological and ethical ambiguities inherent in working with desperate volunteers should not deprive the patients or society of the potential benefits of valid research.

An article on the ethics of phase I oncology trials observed that the risk–benefit ratio of phase I trials is not significantly worse than those approved by the FDA for clinical trials of chemotherapy. It identified three important issues relating to informed consent in terminally ill volunteers: (1) disclosure, which available data show to be adequate; (2) understanding, which also has been found acceptable in more than 70% of patients; and (3) voluntariness, which was initially strongly denied by moral philosophers. The authors argued convincingly that patients with advanced cancer have a different perspective than the healthy bioethicists who worry about them and feel they are being abused. Many dying patients are known to be truly yearning to try more low-yield treatments the closer they are to death.

Ethical Issues about End-of-Life Treatment

There are possibilities of management that are unique to end-of-life care. They include withholding treatment, withdrawing treatment, and invoking the double effect.

All of these were legitimized in 1982 when the Belmont Report, produced by a presidential commission and supported by major Catholic and Protestant doctrinal statements, affirmed the moral acceptability of withholding extraordinary measures or of stopping them later. It also described acceptable uses of the double effect.

However, it has proved to be surprisingly difficult to define *extraordinary* versus *ordinary* measures in the context of withholding or withdrawing treatment. If food and hydration are *ordinary*, what of nasopharyngeal tube feedings? What of IV fluids or percutaneous feedings? Perhaps everyone can agree that TPN is extraordinary. Cardiopulmonary life supports are generally accepted as *extraordinary*, but what of intubating a patient in worsening respiratory distress without cardiac arrest? What of raising vasopressors? What of the so-called temporary addition of dialysis? What of blood products? The persistent controversies can be understood better if one asks two fundamental questions:

1. *From what do patients die?* Do they die from their disease? Or because dialysis was discontinued? Or because they received morphine to relieve respiratory distress? Or because they were not resuscitated? Or because life supports were discontinued in the face of irreversible organ failures?
2. *To whom does life belong?* If it belongs to a higher being, many believers feel that it is held in trust and cannot be shortened. The most extreme of these vitalists feel that all available methods of treatment must be used, even when survival would be miraculous. However, if it belongs to the individual, or even if the family, tribe, or state has a claim, decisions can be made according to personal preferences, social mores, or legal criteria.

Table 27.9–15.
Range of Terminal Care Treatment Decisions

Never diminish comfort measures unless they have become uncomfortable!

Stopping

Curative treatment

Invasive procedures and treatments

Withholding

All diagnostic procedures

Blood products

Antibiotics

Total parenteral nutrition or dialysis, or both

Cardiopulmonary resuscitation

Invoking the double effect, if indicated

Withdrawing

The previously mentioned treatments

Life supports

Tube feedings

Intravenous hydration

Oral feedings

The fundamental incompatibility between these views is illustrated by looking at the range of end-of-life measures in Table 27.9–15. The vitalists may object to every measure, whereas those who believe that life belongs to the bearer may view them all as a matter of individual choice. A dedicated vitalist will believe that death resulted from the immediate action, such as discontinuation of dialysis, rather than from the irreversible disease process. They would refer to withholding treatment as *passive euthanasia* and to withdrawing it as *active euthanasia*. On the other hand, the nonvitalist would be comfortable with the use of slowly escalating doses of morphine to relieve terminal distress, even if it hastens death.

As the debate has become more heated, loaded terms have been used, such as *slow euthanasia*, which has been used to describe opiates for effective pain control, or *passive euthanasia*, which has been used to describe the withholding of invasive life-sustaining treatments. Thus, the vitalist position blurs the distinction between assisted death practices and good palliative care as it is currently understood. On the other side, dedicated proponents of assisted death have supported actions and policies that cause uneasiness even in those who are sympathetic to their point of view. Because physician aid in dying is being legalized in a growing number of jurisdictions, it is crucial to avoid polarization of a debate in which good palliative care is ultimately the casualty.

Physician Aid in Dying

The nature of patients' desire for death, outlined in Table 27.9–16, ranges from transient passive thoughts of suicide, through the suicidal preoccupations of major depressive episodes, to active requests for physician aid in dying. Physician aid in dying addresses only the last category, patients whose pain is uncontrolled or whose suffering is intolerable and who ask for help in ending their lives. However, it has been demonstrated that, indeed, many patients requesting help are clinically depressed and must be given the benefit of consultation and attempt at treatment.

Table 27.9–16.
Desire for Death in Terminally Ill Patients

Transient passive thoughts of death
Easily dissolved with improved quality of life
"It would be OK if I did not wake up"
Suicidal ideation in the context of major depression
Persistent, obsessive thoughts of dying and desire for death, associated with excessive guilt, feelings of self-hatred, and worthlessness
Not necessarily associated with a plan
Not responsive to medical and environmental measures
Request for physician aid in dying: assisted suicide and euthanasia
Commonly associated with fear and with hopelessness, with and without depression
Often has a strong component of more or less conscious anger

Physician aid in dying includes physician-assisted suicide (the provision of enough medication to enable a patient to commit suicide) and active voluntary euthanasia (bringing about the death of another person with their consent). Involuntary euthanasia (bringing about the death of another person without their consent) is murder in the United States.

Physician-assisted suicide and euthanasia were legalized in the Netherlands after a long period of having been openly tolerated and regulated. Opponents have pointed to longitudinal studies that show the incidence of euthanasia rising in proportion to physician-assisted suicide and found some cases of euthanasia of unconscious patients in which overt patient requests were not documented, leaving one to wonder about the dangers of the so-called slippery slope.

In the United States, two federal Circuit Courts of Appeals supported assisted suicide, one on the basis of equal protection under the law, equating it to the available right to discontinue life-preserving treatment, and the other on the basis of liberty and

privacy rights. Both decisions were halted by injunctions and were reviewed by the U.S. Supreme Court. In June 1997, the Court refused to affirm a constitutional right to assisted suicide but stated a need for further social exploration. In particular, Justice Sandra Day O'Connor emphasized a positive right to excellent pain and symptom management, giving hope to many that palliative care would gain impetus, as indeed it has since then.

While euthanasia remains unacceptable, physician-assisted suicide was legalized in Oregon in 1997 after angry voters and attorneys general faced off over this issue. In response to physicians' reasonable fear of harassment, the California Board of Professional Medical Conduct was one of the first states to publish guidelines to protect physicians. Other professional bodies have done the same. Subsequent history in Oregon has not borne out the fears of a slippery slope. As of this writing, there are at least eight states and Washington, D.C. that have enacted *Death with Dignity* laws, with more potentially on the way. A list of current *Death with Dignity* laws can be found in Table 27.9–17.

However, it is important for physicians to be aware of psychiatric and medical issues which are sometimes overlooked. Delirium, for example, is associated with impulsivity and must be treated. Also at risk are patients with poor pain control, a sense of helplessness and loss of control, and a previous psychiatric diagnosis. Hopelessness as part of a pessimistic coping style has been found to be a better predictor of suicidal wishes than depression without hopelessness. To complicate matters, the *will to live*, as measured with a visual analog scale, was found to fluctuate rapidly, correlating with anxiety, depression, shortness of breath, and other painful or frightening symptoms. Treatment of pain and other symptoms often diminishes or dissolves the desire for help in dying. Provision of social and spiritual support is also powerful. Understanding these issues is more important to the patient's welfare than public hand wringing about the slippery slope.

Table 27.9–17.
Current Death Dignity Laws

States	Death with Dignity Statutes	Year Approved/in Effect
California	End of Life Option Act	2015/2016
Colorado	End of Life Options Act	2016
District of Columbia	D.C. Death with Dignity Act	2016/2017
Hawaii	Our Care, Our Choice Act	2018/2019
Maine	Death with Dignity Act	2019
New Jersey	Aid in Dying for the terminally Ill Act	2019
Oregon	Death with Dignity Act	1994/1997
Vermont	Patient Choice and Control at the End of Life Act	2013
Washington	Death with Dignity Act	2018

Voluntary Refusal of Food and Water

An Oregon report from Dr. Linda Ganzini found that almost one in three nurses had cared for patients who died a peaceful death after refusing food and water. Compared to the assisted suicide group, these patients were less likely to have cancer, in less acute pain, less preoccupied with control, a decade older, and more ready to die. This interesting study highlights a mode of death that is universally available to any competent patient. However, many patients requesting aid in dying feel out of control and are afraid to die in acute pain and solitude. They are anguished and yearn for loving care to heal both pain and suffering. Lacking that, they demand an ultimate act of nurturance that heals by bringing oblivion. By placing a heavy burden on others, they may express both yearning and

resentment. Others, however, plan ahead, discussing those plans with loved ones, and finding physicians with whom they negotiate their request in a cooperative mode. Additionally, one should not ignore cases in which patients are driven by the realistic fear of losing the ability to express their wishes.

Caregiver Responses

In the same study, nurses stated that all staff members found it difficult to care for patients who elect to forgo fluids and nutrition. Similarly, Oregon physicians who had responded to a request for physician-assisted suicide described feeling very uncomfortable. They had discussed technical issues with colleagues but kept their conflicted feelings to themselves. They usually concluded that they had no regrets and believed that they had become more comfortable in dealing with end-of-life issues. Some may wonder whether this represents improved palliative care skills or desensitization to death. In any case, the development of palliative care has given physicians an option to deal with such patients to their professional and ethical satisfaction.

Societal Implications

Proponents of legalization emphasize dignity and autonomy, pointing to Dutch studies that name this as the most frequent reason for help-in-dying requests. Opponents point to the lack of good pain management and other palliative care, citing American and Canadian studies that found depression and poor symptom control as the major factors underlying patient suicidal tendency. Given severe retrenchment of health care expenditures, with politicians, insurance companies, and managed care corporations setting the policies, there is cause for concern even among individuals who have no philosophical or moral objection to assisted suicide. African Americans and other minorities—groups that have historically known inferior medical treatment or inferior representation in medical studies—tend to be far more opposed to legalizing assisted suicide than the rest of the population. Associations of disabled individuals

also oppose it because they believe that many of them would not be alive had it been acceptable to terminate lives deemed not worth living. All of these groups insist that moral opprobrium and legal sanctions are essential to hold dark human tendencies in check. Independent of religious or philosophical convictions, historical and contemporary examples demonstrate that they cannot be ignored. But the authors do experience relief at the wholehearted adoption of palliative care and the gentle invasion of humanizing trends in medicine today.

The Moral Burden of Physicians

Medical training is inherently casuistic and teaches that each case must be decided on its own merits. Primary care physicians and hospitalists have depended on their professional values to guide them and to prevent abuse more often than not. However, this process worked as well as it did because it was buttressed by a social climate that protected individual life. Many of the choices physicians made were transparent. Decisions about withdrawing treatments and about nutrition and hydration were de facto shared by family members and other caregivers, giving social morality an opportunity to mold physician behavior. Medicating dying patients with drugs that invoke the rule of double effect is less controllable and presents doctors with the easiest opportunity for assisted suicide. Contrary to public myths about doctors' enjoyment of power, most physicians have not welcomed it and are delighted with an unambiguous mandate for good palliative care, free of moral and political shoals.

Given the complex motives of terminally ill patients and the fact that palliative care specialists are still in short supply, it seems dangerous to risk desensitizing medical caregivers in particular, and society in general, to the inadequacies of palliative care and, ultimately, to the complexities of helping a patient die. Yet, the legalization of physician-assisted suicide could lead to such a development. Palliative care specialists *are still in a race against time*, as they try to educate the medical profession *and* the public

about the provision of state-of-the-art care before the legalization of aid in dying provides excuses for the avoidance of faithful attention to the needs of dying patients. The fact that state-of-the-art palliative care for suffering patients is not yet routine and that, even when it is available, can become mired in political controversy is tragic.

Whatever the outcome of the debate, psychiatrists should remember that there is no room for political or philosophical controversy at the bedside. There is just one reality that they and their medical colleagues should keep uppermost in their minds: a dying human being whose physical, social, emotional, and spiritual needs are all being effectively attended is far less likely to request help to commit suicide, and the family members—given proper help and support—derive a deep sense of peace from having helped their loved one to die feeling loved and secure.

ACKNOWLEDGMENTS

We'd like to pay tribute to the original author of this work, our colleague, Dr. Marguerite S. Lederberg, who has since died. At the time we prepared this chapter for the 50th-anniversary edition, Dr. Lederberg knew it would be her last work, and, in addition to her prodigious intellect and unparalleled clinical acumen, she put heart and soul into every page. She did so not only for the edification of the psychiatric community but also to leave a legacy for her co-authors to continue after she was gone. We are honored both to receive that legacy and to continue the work she started.

27.10 Stress and Psychiatry

Traci J. Speed, M.D., Ph.D., Paul S. Nestadt, M.D., and Elizabeth J. Prince, D.O.

Before the 1930s, the term "stress" was primarily used in engineering and simply referred to the physical strain on a material object. The modern psychological construct of stress was formulated in the 20th century but has rapidly become a fundamental concept of psychiatry. Patients will readily describe their chronic and acute stressors without much prompting, and much can be learned from their particular way of recounting, prioritizing, and reportedly overcoming (or succumbing to) each instance of stress. All people share an existential vulnerability to life's difficulties; as the classical Greeks would have it, "we are all but a heartbeat away from disaster." Stress has been invoked as a cause of major psychopathology, a precipitator or trigger of psychiatric illness, and a contributor to considerable mental anguish. Similar roles have been cast for stress due to illness throughout medicine. Many of the suggested links are intuitively appealing. After all, who has not experienced somatic distress in the face of unpleasant events and thoughts? Such associations between stress and diverse symptoms are obvious. Whether stress causes, an illness is much more difficult to demonstrate.

The slipperiness of the term stress is both an advantage and a disadvantage. It is an advantageous term because it is all-embracing and synthesizes many aspects of life's experience. It is disadvantageous because its referents are diverse. Stress refers both to a subject and a predicate, an event, and the consequences of that event. For clarity, it is probably wise to eschew the word stress altogether and use different terms for its various meanings. Thus, it is much clearer to refer to "stressful" events or "stressors" and the resulting "distress" or "stress responses" incurred. Such terms will be utilized throughout this section, but occasionally, the broader term of stress will be referenced.

HISTORY

The term *stress* was coined by Hans Selye (1907–1982). He observed that many highly diverse ways of perturbing the organism resulted in common physiologic responses. The concept was unusual because the prevailing ideology of medical research emphasized specificity, that is, that specific pathogens elicited unique pathologic responses. Selye found that highly diverse stimuli seemed to result in common changes. From animal studies, he reported that there is a “general adaptation system,” a systemic well-orchestrated adaptive response to diverse stressors. Selye invoked the adrenocortical system as the crucial responder to stressful stimulation. He observed that any novelty or perturbation was associated with an elevation of adrenocortical activity, at least transiently, and that if stressors were unremitting, diverse pathologic changes would be evident.

Like all pioneers, Selye was guilty of oversimplification, a weakness that has become abundantly clear with the accumulation of additional empirical data. Not all organisms respond to all perturbations with the general adaptation system. However, his insights were important in shaping the field. As a result of his prolific scholarship, the field of psychology has been blessed (or cursed) with the term stress, which has become so popular that it is used constantly, even when researchers would prefer more precision. Stress is a term like neurosis or hysteria, ripe with years of reference, conveying both information and vagueness.

The other groundbreaker in stress research was Walter Cannon (1871–1945). Although he made major contributions in gastroenterology and roentgenology, his long-abiding interest was in the physiology of emotion and the autonomic nervous system. If Selye is known for his explorations of the adrenocortical system, Cannon is acclaimed for his methodical investigations of the other great pathway of stressful responses, the sympathetic nervous system (SNS). Cannon also focused on more immediate or short-term responses to stressors.

Whereas the term stress and the accumulating empirical research reflect the 20th century and the intellectual progeny of Selye and Cannon, there are earlier referents for the concept. For centuries physicians and patients have associated adverse life events and illness. In law, for example, there is a long history of tort cases alleging that emotional arousal secondary to a stressful event causes miscarriage. The links between emotion and sudden cardiac death have been noted in sources as diverse as the Bible, anthropology, and clinical experience. These types of links were repeatedly observed by crucial figures in the history of

medicine. William Harvey in the 17th century and William Osler in the 19th century frequently alluded to the relationship between adverse life events and illness onset. Many contemporary cultures regard illness as the outcome of being “out of balance” with the environment and its demands, a manifestation of inadequate coping with diverse stressors.

The confusion between stress as a “cause” versus “trigger” of illness has hindered progress. The allegation that a stressor caused an illness is difficult to demonstrate in most human studies, which impose a short-term stressor and examine the resultant physiologic changes. Illnesses such as myocardial infarction usually become evident only after a long accumulation of coronary artery disease. As a result, how can one assert that “stress caused a myocardial infarction”? However, there is an alternative hypothesis that provides very strong evidence for a link between stressors and illness. That argument emphasizes that stressors trigger illness in individuals whose underlying illness is latent or subclinical. This sort of case is demonstrated routinely in psychophysiology and psychosomatic medicine studies. For instance, studies of the physiologic response to stressors in normal individuals demonstrate large amplitude changes in physiologic levels of blood pressure, gastric motility, and hormonal levels. When such psychophysiological studies are extended to patient groups, one sees breathtaking evidence for the role of stressors as trigger events in eliciting pathophysiologic phenomena. For example, even discussing emotional conflicts can elicit life-threatening arrhythmias in vulnerable individuals, and exposure to a catastrophic stressor can be accompanied by unique and reversible cardiomyopathy (Fig. 27.10–1). Similar effects of stressors on blood pressure have been repeatedly demonstrated in warfare and natural disasters.

A 54-year-old man whose office was in the vicinity of the World Trade Center had his blood pressure recorded twice a day from September 4 to September 21, 2001. His blood pressure dramatically increased during the week after the World Trade Center attack (Fig. 27.10–2).

The COVID-19 pandemic provided the 21st century’s first worldwide stress test. Studies into the differential impact of this universal stressor have found increased levels of self-reported distress and depressive

symptoms in the context of infection risks and the mitigation measures required to stem the pandemic. However, more objective measures of severe psychiatric illness such as hospitalizations and suicides have demonstrated no such increase and, in some cases, have decreased outside of specific vulnerable populations. Studying the responses to both natural and contrived experiments will further elucidate the complex relationship between stress and psychiatric sequelae. In the future, we will continue to broaden our understanding of the human stress response at the cellular, organ system, individual, community, and population levels to best understand stress's role in mental life.

FIGURE 27.10–1. Impact of stress on cardiac function. A reversible cardiomyopathy can be elicited by psychologically stressful events. This is characterized by systolic dysfunction affecting the distal left ventricular chamber. (Reprinted with permission from Sharkey SW, Lesser JR, Zenovich AG, et al. Acute and reversible cardiomyopathy provoked by stress in women from the United States. *Circulation.* 2005;111(4):472–479. doi: 10.1161/01.CIR.0000153801.51470.EB.)

VULNERABILITY AND RESILIENCE

Parallel to confusion between stress as a trigger and stress as a response, another key conceptual problem revolves around the issue of

vulnerability versus resilience or stress versus coping. The conceptual origins of resilience, like stress, are outside psychiatry and medical science in diverse fields from engineering to ecology. Resilience focuses on the recovery, adaptation, or even transformation of a system following exposure to stress. In psychological resilience, the system at the center of the process is a person.

FIGURE 27.10–2. Impact of stress on blood pressure (BP). *DBP*, diastolic blood pressure; *SBP*, systolic blood pressure. (Reprinted with permission from Lipsky SI, Pickering TG, Gerin W. World Trade Center disaster effect on blood pressure. *Blood Press Monit.* 2002;7(4):249. doi:10.1097/00126097-200208000-00008.)

Researchers initially focused on the stressor, treating it like a virulent pathogen that would infect all individuals despite varied life experiences. Thus, the initial stress research primarily focused on the physiologic consequences of stressor imposition. The variability in response patterns then motivated investigators to study the subtleties of how people interpreted the stressful challenges. These interpretations were framed as "defensive" styles, how individuals guard themselves against painful emotional stressors. Subsequently, however, the inquiry broadened, and investigators examined individuals' defensive behaviors, information-seeking behaviors, affiliative behaviors, and all-around problem-solving

behaviors. This heterogeneous combination is referred to as *coping behavior*.

FIGURE 27.10–3. A systemic model of resilience comprised of interacting scales. The Xs represent promotive and protective factors at different scales. The dashed ellipse represents a single multilevel system. (Reprinted from Ungar M, Theron L. Resilience and mental health: how multisystemic processes contribute to positive outcomes. *Lancet Psychiatry.* 2020;7(5):441–448. doi: 10.1016/S2215-0366(19)30434-1.)

Beyond behavior, genetic and environmental factors are also being studied for their impact on response to stress. For instance, a New Zealand study prospectively followed approximately 1,000 subjects aged 3 to 26 to learn more about stress effects on the onset of major depression. The promoter region of the serotonin transporter gene had a powerful effect on vulnerability to stress. Individuals who were homozygous for the short allele of the promoter region of the serotonin transporter gene were more likely to become depressed and suicidal in response to stressors. The role of the environment in stress is also being studied. Further research demonstrated an association between the short

allele and increased vulnerability to stress in studies of childhood maltreatment and certain medical conditions.

As stress-related psychiatric disorders are influenced by genetic predisposition and environmental factors, researchers have begun studying epigenetic mechanisms that may account for environmental influences on the development of stress-related disorders in recent decades. Recent research shows that prenatal factors such as stress or mood disorders in mothers are risk factors for psychiatric disorders in offspring. These different influences on trajectories of response to stress suggest resilience is a process of multiple interacting scales rather than simply a trait possessed by an individual (Fig. 27.10–3).

MEASURING STRESS PSYCHOLOGICALLY

Regardless of whether stress is a cause or trigger, or whether one focuses on stress or factors that affect resilience to stress, the key step is to recognize and in some way quantify its extent. Doctors have always asked about the stressors in their patients' lives. Obtaining such information is, after all, at the core of history taking. "What types of things aggravate your symptoms? Are you facing any unusual burdens or challenges"? With certain symptoms such as angina, the link between stressor and illness is immediately obvious. However, it appears that stressful conditions aggravate many illnesses not traditionally thought of as "stress-sensitive." As will be discussed later, the mechanisms for this link are complex.

In the early 20th century, Adolf Meyer suggested that psychiatrists employ a "life chart" in evaluating their patients. The idea is elegant in its simplicity. The psychiatrist plots a patient's life on a line, beginning with birth and ending in the present. He or she then pencils in when various important life events have occurred and indicates the onset or worsening of health problems. The life chart turns out to be a very effective way of eliciting a clinical history. Sometimes, recurrent patterns of association between life events and illness episodes are suggested (Fig. 27.10–4).

The next step in the evolving field of life events was developed by the fruitful collaboration of Thomas Holmes and Richard Rahe. They felt that a list of commonly encountered stressors would be more useful than taking an unstructured history. After considerable research, they developed a list of roughly 40 life events ranging in severity from the death of a spouse to

receipt of a traffic ticket. The checklist or schedule of recent events can be self-administered and requires very little time to complete. It is noteworthy that the form tallies both positive and negative life events. The underlying assumption is that all life events, be they positive or negative, impose a demand for adaptation and that such demands are stressful. While at first blush this may seem counterintuitive, positive life events are not totally benign; getting married brings with it a host of stressors. Another characteristic of the Holmes–Rahe approach is that the items are weighted in their adaptational demand. Most people rank order stressors similarly, and thus it is possible to assign a specific "number" of life-change units to the occurrence of each specific stressor. This technique has been used in hundreds of studies and has demonstrated that numerous illnesses follow on the heels of increases in life stress. It is not that the high-scoring individual is at risk, but rather that the individual with an *increase* in life stress units is at risk for any number of health consequences.

There are many criticisms of this approach and, of course, alternative ways of measuring stressful life events. Some investigators feel that negative life events carry with them *far* greater anguish and adaptational pressure and that the positive life events may be ignored. Some question the utility of adding all the life-change units together and coming up with one number to represent the total stressful exposure of the individual. Whereas the Holmes–Rahe approach may be extremely useful for epidemiologic research, for clinical use, it may be more helpful to have subscales that list, for example, the stressor scores associated with job pressure, home pressure, and so forth into separate categories. Some theorists feel that inventories of relatively rarely occurring stressful events are of limited utility and that more is to be gained by measuring the accumulation of the more common microstressors that individuals encounter frequently. Other investigators doubt the validity of a universal weighting of stressful events and favor allowing individuals to apply their idiosyncratic assessment of emotional travail elicited by events. Finally, common to all scales that measure stressful events is the problem of retrospective distortion. Patients forget, disavow, deny, and repress—all words that reflect a splitting off of accurate recall. As a result, when patients are asked to retrospectively report life events, they tend to forget events shrouded in the past. On the other hand, patients' beliefs

sometimes cause them to attribute symptoms to stressful events instead of disorders.

FIGURE 27.10–4. Line drawing of the life chart by Adolf Meyer. (From *Contributions to Medical and Biological Research, Dedicated to Sir William Osler, bart. M.D., F.R.S., in Honour of his Seventieth Birthday, June 12, 1919,*

SELECTED PHYSIOLOGIC RESPONSES TO STRESSORS

The body's reaction to a stressor (be it real, symbolic, or imagined) is to initiate a set of responses that seek to diminish the impact of the stressor. A stressor disrupts an organism's equilibrium, and the *stress response* consists of initiating physiologic adjustments that seek to react to the stressor, bring about an adaptive response, and restore homeostasis. Much is known about the physiologic response to *acute stress*, and considerably less is known about *chronic stress*. This represents a major gap in physicians' ability to relate the effects of stress to the occurrence of psychiatric illness in humans. One such example is disparate exposures among racial/ethnic minority populations and those with low socioeconomic status who may experience more lifelong stressors (e.g., discrimination, finances) than their more well-off counterparts. Many stressors occur over a prolonged period or have long-lasting repercussions (e.g., losing a spouse is followed by months or years of loneliness; a sexual assault is followed by years of apprehension and worry). Animal models that can capture this reverberation or "echo" of stress are limited. Still, what is known about the neuroendocrine and immune response to laboratory stressors is expanding and will ultimately inform the understanding of why and how stress harms humans.

Neurotransmitter Responses to Stress

Stressors activate a release of catecholamines from the autonomic nervous system, including noradrenaline, dopamine, and serotonin. The stressor type influences the brain regions and mediators that engage in the adaptive response. Physical stressors (e.g., blood loss, trauma, hypothermia) recruit the brainstem and hypothalamic brain regions. Psychological stressors (e.g., embarrassment, work-related stress) engage brain regions involved in emotion (amygdala), learning and memory (hippocampus), and decision-making (prefrontal cortex). The timing of stress affects neuronal pathways differently. For instance, early life stress affects neurotransmitter release in the prefrontal cortex, producing persistent changes through adulthood. Furthermore, emerging

research demonstrates sex-specific effects of early life stress on the prefrontal cortex catecholamine response. While catecholamine response varies depending on the time of stress relative to developmental stage and the type of stressor, consistently male rats, have greater variability in neurotransmitter response to stress than females despite conventional views that females are more vulnerable to life stressors. At present, we have a rudimentary understanding that the nature of the interaction between sex and stress is complex. The sexually dimorphic responses to stress as seen in animal models may have implications for the pathophysiology of stress-related disorders, including major depression and anxiety. Further understanding of the molecular underpinnings of sex differences in response to stress may advance the development of efficacious treatments for these disorders. Duration of stress also plays a role in catecholamine signaling. Compared with acute stress, which evokes rapid transient alterations in catecholamine release, chronic stress induces sustained effects on neuronal firing and gene activation. Although this area of research remains novel, epigenetics provides insights into the pathogenesis of response to chronic stress, as DNA methylation, histone modifications, and microRNA activity mediate dynamic molecular adaptations of the central nervous system (CNS) to chronic stressors

Endocrine Responses to Stress

It has become clear that amino acid and peptidergic neurotransmitters are also intricately involved in the stress response. Endocrine response to stress is secreted from the hypothalamus into the hypophysial–pituitary–portal system in response to stress. Corticotropin-releasing hormone (CRH) acts at the anterior pituitary to trigger the release of adrenocorticotrophic hormone (ACTH). Once ACTH is released, it acts at the adrenal cortex to stimulate the synthesis and release of glucocorticoids. Glucocorticoids themselves have myriad effects within the body. However, their actions can be briefly summarized as promoting energy utilization, increasing cardiovascular activity (in the service of the flight-or-fight response), and inhibiting functions such as growth, reproduction, and immunity.

This hypothalamic–pituitary–adrenal (HPA) axis is subject to tight negative feedback control by its end products (i.e., ACTH and cortisol) at multiple levels, including the anterior pituitary, the hypothalamus, and the hippocampus. It is now known that the HPA axis is also influenced by

multiple extrinsic systems, which should not be surprising given the co-ordinated nature of the stress response. For example, in addition to CRH, numerous secretagogues (i.e., substances that elicit ACTH release) exist that can bypass CRH release and act directly to initiate the glucocorticoid cascade. Examples of such secretagogues include catecholamines, vasopressin, oxytocin, and orexin. Interestingly, different stressors (e.g., cold stress versus hypotension) trigger different patterns of secretagogue release, again demonstrating that the notion of a uniform stress response to a generic stressor is an oversimplification.

A relevant feature of the HPA axis stress response is that it varies depending on whether the organism (most of these data come from rats and zebrafish) is exposed to the stressor on a single occasion, more than once, or over a prolonged period. Interestingly, it has not yet been possible to rely on a model that can predict whether "sensitization" (enhanced response to the same stress over time) or "desensitization" (a reduced response to the same stress over time) will occur for a given stressor. Nonetheless, the fact that the stress response can change dramatically depending on the frequency and duration of exposure highlights the necessity of specifying these elements when trying to understand the role of stress in clinical psychiatric illness.

PSYCHONEUROIMMUNOLOGY

Researchers have realized that the immune system is also a key player in stress physiology. There are numerous bidirectional interactions between the brain, behavior, and immune system, and these interactions are studied in psychoneuroimmunology. The immune system provides the body's defense against invading external pathogens such as viruses and bacteria and abnormal internal cells such as tumors. Innate immunity refers to the body's resistance to pathogens; this form of immunity operates in a nonspecific way without recognition of the different natures of various pathogens. Macrophages and granulocytes are nonspecific immune cells that induce immune activation by releasing proinflammatory cytokines (TNF-α; IL-6) and react to tissue damage by consuming debris and invading organisms. Specific immunity is acquired in response to identifying nonself-molecules called antigens. Each B-cell or T-cell is genetically programmed to attack a specific target by secreting antibodies (B-cell) or by killing cells of the body that harbor a virus (T-cell).

Interleukins or cytokine release from immune cells orchestrates both innate and specific immunity, and this cytokine network helps differentiate the immune response and the co-ordination of its magnitude and duration. However, the immunoregulatory processes cannot be fully understood without considering the internal and external milieu in which innate and specific immune responses occur, as well as the interactions of the brain, autonomic nervous system, neuroendocrine axis, and gastrointestinal microbiome with the immune system (Fig. 27.10–5).

Biologic Connections between the CNS and Immune System

Autonomic Nervous System. The CNS and the immune system are linked by two major physiologic systems, the HPA, and the autonomic nervous system, composed of sympathetic and parasympathetic branches. The SNS is a network of nerve cells running from the brainstem down the spinal cord and out into the body to contact various organs, including organs where the immune system cells develop and respond to pathogens. The sympathetic release of norepinephrine and neuropeptide Y, together with receptor binding of these neurotransmitters by immune cells, serves as the signal in this hard-wired connection between the brain and the immune system. In addition, sympathetic nerves penetrate the adrenal gland and cause the release of epinephrine into the bloodstream, which circulates to immune cells as another sympathetic regulatory signal.

Under both laboratory and naturalistic conditions, sympathetic activation suppresses the activity of diverse populations of immune cells. Sympathetic activation can also enhance other aspects of the immune response, such as the production of antibodies by B-cells and the ability of macrophages to release cytokines and thereby signal the presence of a pathogen. Additional studies indicate that sympathetic activation can also shunt some immune system cells out of circulating blood and into lymphoid organs (e.g., spleen) while recruiting other types of immune cells into circulation (e.g., natural killer [NK] cells). In general, SNS activation can reduce the immune system's ability to destroy pathogens that live inside cells (e.g., viruses) via decreases in innate and cellular immune responses while sparing or enhancing the humoral immune response to pathogens that live outside cells (e.g., bacteria). Together, these observations are a cornerstone for understanding fundamental neuroanatomic signaling between the autonomic nervous and immune systems.

Neuroendocrine Axis. Another way the brain can communicate with the immune system is via the HPA system. Cortisol influences the actions of various cells involved in an immune response by suppressing the cellular immune response. Indeed, a synthetic analog of cortisol is often used to suppress excessive immune system responses. However, cortisol can also prompt some immune cells to move from circulating blood into lymphoid organs or peripheral tissues such as the skin. It is important to note that immune cells can produce neuroendocrine peptides (e.g., endorphin, ACTH), which suggests that the brain, neuroendocrine axis, and immune system use the same molecular signals to communicate with one another.

Gastrointestinal Microbiome. Understanding the bidirectional link between gut physiology and brain function and how this link influences the immune system under normal and stressful conditions remains in its infancy despite wide acceptance of the "gut-brain" interaction (e.g., gut feelings, gut instinct, butterflies in one's stomach). The gut itself is an important immune organ that provides a defensive barrier against external pathogens, with gut-associated lymphoid tissues comprising 70% of the immune system. The brain acts on gastrointestinal and immune functions to shape the gut microbiome, while gut microbes produce neurotransmitters and metabolites that interact with the neuroendocrine and immune systems and control leakage through the intestinal lining and blood–brain barrier (Fig. 27.10–6). Animal studies show that exposure to acute and chronic stress alters the relative proportions of the main microbiota phyla, which influences host immune and stress responsiveness; peripheral administration of proinflammatory cytokines induces depressive- and anxiety-like behaviors. In humans, chronic gut disorders are associated with intestinal microbiome dysbiosis and behavioral changes, including increased responsiveness to stress and increased depressive and anxiety symptoms.

FIGURE 27.10–5. Model of human psychoneuroimmunology interactions and clinical implications. The model depicts the bidirectional interactions between the brain and the immune system, and the clinical implications of immune alterations due to stress, depression, or sleep disturbance. *CRH*, corticotropin-releasing factor; *SNS*, sympathetic nervous system; *HPA*, hypothalamic–pituitary–adrenal axis. (Reprinted from Irwin MR. Human psychoneuroimmunology: 20 years of discovery. *Brain Behav Immun*. 2008;22(2):129–139. doi: 10.1016/j.bbi.2007.07.013.)

Central Modulation of Immunity. This converging evidence of brain–immune system interactions suggests that the brain has a physiologic role in regulating immunity. Indeed, the release of CRH in the brain alters various immune processes, including aspects of innate immunity, cellular immunity, and in vivo measures of antibody production. Peripheral immune measures also change following lesioning of the brain (e.g., hypothalamus) or in response to the stimulation of certain brain regions. The brain controls immune cells in lymphoid tissue just as it controls other visceral organs through a complex series of coordinated autonomic and neuroendocrine pathways.

FIGURE 27.10–6. Model of the gut–brain axis. Normal gut physiology contributes to appropriate signaling to the central nervous system (CNS) and helps regulate healthy physiologic interactions. Intestinal dysbiosis alters gut physiology and leads to adverse consequences for CNS functions and results in disease states (*shaded area*). *CNS*, central nervous system. (Reprinted with permission from Cryan JF, Dinan TG. Mind-altering microorganisms: the impact of the gut microbiota on brain and behaviour. *Nat Rev Neurosci*. 2012;13(10):701. doi: 10.1038/nrn3346.)

Behavioral and Psychological Influences on Immunity

Given that psychological responses are expressed in neural activity with accompanying changes in neuroendocrine and autonomic function, it is not surprising that behaviors and emotions can alter immunity. One seminal example is classical conditioning of immune responses. Conditioned immune responses have also been found to retard disease progression in an animal model of autoimmune disease. In the clinical setting, immunosuppressive conditioning occurs in cancer patients who receive chemotherapeutic drugs, and conditioning processes are thought to contribute to the biologic effects of a placebo.

Stress and Immunity in Animals. In animals, acute exposure to stressors produces alterations of immunity that cannot be accounted for by the physical effects of the stress. Psychological components such as conditioned fear and uncontrollability induce altered immunity, and these effects are related in a dose-dependent manner to the severity of the

stressor. Almost every immune system component has been found to respond to stress.

Acute Stress and Immunity in Humans. Acute laboratory stressors (e.g., mental arithmetic) produce profound and rapid changes in the immune system due to redistributing immunoregulatory cells from lymphoid organs such as the spleen into the vascular space. Such acute stressors elicit decreases in cellular immune responses and increases in markers of inflammation (e.g., IL-6), which are thought to be mediated by the release of sympathetic neurotransmitters and β-adrenergic receptor activation. Individuals who are older adults or undergoing chronic stress show exaggerated immune responses to acute stress and are likely to take longer to recover from the administration of stress, which may put them at increased risk for infectious disease. Finally, among depressed patients, acute psychological stress leads to exaggerated increases in inflammatory cytokine activity and greater activation of the inflammatory signaling pathway, nuclear transcription factor-κB.

Chronic Stress, Depression, and Immunity. In contrast to the effects of laboratory stress, chronic or naturalistic stressors such as bereavement or caregiving and depression are associated with reliable decreases of cellular and innate immunity, along with increases in proinflammatory cytokine activity, due possibly to downregulation of glucocorticoid receptor signaling. When the stress remits or depressive symptoms resolve, natural and cellular immune function normalization occurs.

Proinflammatory cytokine activity is also produced in excess by senescent cells. Telomeres are repeats of DNA sequences at the ends of chromosomes bound by specialized protective proteins. Telomere shortening in immune cells, which is a sign of cell senescence and aging, predicts earlier onset of the diseases of aging even after controlling for confounders. Mounting evidence supports an association between chronic psychological stress, stress-related disorders (e.g., depression), and compromised telomere maintenance. These findings highlight one of the many mechanisms of immune dysfunction in response to chronic stress. However, while the association of stress, psychiatric disorders, and telomere length is well-established, a better understanding of the link between telomeres and stress in the development of stress-related disorders is necessary to improve diagnosis and treatments.

Heterogeneity in the effects of stress and depression on immunity can also be accounted for by factors such as age, gender, ethnicity, health behaviors (e.g., smoking, alcohol consumption), and coping. Depressed patients who have comorbid alcohol abuse or tobacco smoking show exaggerated declines in natural and cellular immune responses. Personal characteristics such as coping and personality (e.g., positive affect), which moderate neuroendocrine and sympathetic activity, also contribute to individual differences in immune responses to psychological stress and vaccine responses.

Sleep, Cytokines, and Immunity

Disordered sleep and loss of sleep are thought to adversely affect resistance to infectious disease and alter inflammatory disease progression. Studies show that sleep deprivation impairs influenza viral clearance and increases bacteremia rates. In humans, normal sleep is associated with a redistribution of circulating lymphocyte subsets, increases of NK activity, IL-2, IL-6, and the trans-signaling IL-6 receptor agonist (IL-6R), and a relative shift toward Th1 cytokine expression, which is independent of circadian processes. Conversely, sleep deprivation suppresses NK activity and IL-2 production and induces decreases in specific antibody production to infectious challenge (e.g., vaccination against influenza or hepatitis B virus). In contrast, innate immunity and proinflammatory cytokine expression measures, including cellular and genomic markers of inflammation, are enhanced following sleep loss. In clinical populations who show disordered sleep (e.g., as a result of depression, bereavement, alcoholism), natural and cellular immune function alterations coincide with sleep loss and disturbances of sleep architecture.

Furthermore, decreases in sleep continuity or increases in rapid eye movement (REM) sleep are associated with increases in the nocturnal and daytime expression of IL-6, possibly with consequences for daytime fatigue. Laboratory pain testing methods are now being used to understand individual differences in proinflammatory cytokines reactivity. One recent study showed greater pain-evoked IL-6 among older adults with insomnia disorder than among those without insomnia. Bidirectional actions of cytokines on sleep have also been identified. In animals, cytokines have both somatogenic and inhibitory effects on sleep, depending on the cytokine, plasma level, and circadian phase. In humans,

less is known about the sleep-regulatory effects of cytokines. Expression of the anti-inflammatory cytokine IL-10 prior to sleep predicts delta sleep amounts during the nocturnal period. In contrast, peripheral administration of the proinflammatory cytokine IL-6 reduces delta sleep, and nocturnal levels of both IL-6 and TNF temporally correlate with increases in REM sleep, particularly during the late part of the night.

Cytokine Influences on the CNS and Behavior

The nervous and immune systems convey information to each other, ultimately regulating neuroendocrine and autonomic outflow and the immune response. With peripheral immune activation, the inflammatory cytokines, TNF, IL-1, and IL-6, activate the HPA system via the central release of CRH. Immune activation leads to changes in peripheral physiology that are similar to a stress response. Coincident with these physiologic changes, animals show reductions in activity, exploration of novel objects, social interactions, food and water intake, and sexual behaviors, a response pattern known as *sickness behaviors.* Human studies have shown similar links between peripheral cytokines and behavioral changes. Healthy individuals develop anxiety and depression in response to low-dose cytokines. Even patients with the common cold show sickness behaviors such as fatigue, lack of interest, low mood, and cognitive impairment. Patients with chronic inflammatory diseases such as hepatitis C infection have increased rates of fatigue and depression with associated changes in the metabolism of central neurotransmitters in discrete brain regions. Large doses of cytokines, given as immunotherapy for cancer or hepatitis C, frequently worsen depressive symptoms, which can be attenuated by pretreatment with antidepressant medications.

Clinical Implications of Psychoneuroimmunology and the Cytokine–Brain Link

The links between stress and disease are bidirectional. Increasing evidence suggests that abnormalities in cytokine expression and regulation that occur during depression or stress might exacerbate the course of many chronic diseases. Research has primarily focused on the influence of stress exposures on the development and progression of disease, yet diseases can also serve as stressors. The following paragraphs provide several pertinent examples in which cytokines and

psychoneuroimmunology processes are thought to contribute to disease processes and how the disease process influences stress.

Cardiovascular Disease. Depression is associated with an increased risk of coronary artery disease and increased morbidity and mortality after myocardial infarction, congestive heart failure, or mitral valve replacement. Atherosclerosis is now thought to be an inflammatory process involving a series of steps, each of which can be impacted by stress or depression. Activated macrophages within the vasculature secrete proinflammatory cytokines such as IL-1, IL-6, and TNF, leading to the expression of cellular adhesion molecules. With the recruitment of immune cells to the vascular endothelium and the release of inflammatory cytokines, endothelial activation occurs, facilitating further binding of immune cells. Importantly, psychological and physical stressors lead to an increased release of proinflammatory cytokines and the expression of adhesion molecules that tether and bind immune cells to the vascular endothelium. Depressed mood, sleep disturbance, inflammation, and arterial repair might form a vicious cycle promoting cardiovascular disease. In a study of 1,794 Canadians, depression and elevated inflammatory markers predicted an increased risk of coronary artery disease. In another study of patients with coronary heart disease, the severity of depression was associated with elevated CRP and IL-6. This link was driven by behavioral health factors, including physical inactivity, smoking, and obesity, suggesting other mechanisms including epigenetic factors may promote the link between depression and cardiovascular disease.

Infectious Disease Risk. Compelling evidence has shown that inescapable stress, a putative animal model of depression, increases susceptibility to viral diseases such as herpes simplex and infection via alterations in immune function. In humans, prospective epidemiologic studies and experimental viral challenge studies show that persons reporting more psychological stress have a higher incidence and greater severity of certain infectious illnesses such as Epstein–Barr virus infections and the common cold. Moreover, experimental vaccinations have probed the disease-specific and integrated in vivo immune system action to psychological stress.

Atopic Dermatitis. Atopic dermatitis is a chronic and relapsing skin disease characterized by impaired epidermal skin barrier function, inflammatory infiltrates, and excessive pruritus. Psychological stress contributes to the course of atopic dermatitis through its direct and indirect effects on the immune response. Skin biopsies from patients with atopic dermatitis have elevated Th2 cells, cytokines, and eosinophils with elevated IgE production in response to stress. Patients with atopic dermatitis and high trait anxiety also have elevated levels of IgE. Numerous studies demonstrate that psychological stress aggravates pruritus. Both antidepressants and psychological interventions, including cognitive-behavioral therapy (CBT), improve pruritus and psychogenic itch.

Stress and Autoimmune Disorders. Stress has been found to precede autoimmune disorders and exacerbate symptoms. In a negative feedback loop, proinflammatory cytokines stimulate the HPA axis, resulting in the secretion of glucocorticoids, which suppress the immune response. However, in autoimmune disorders such as rheumatoid arthritis, it is thought that the counter-regulatory glucocorticoid response is not fully achieved. Rheumatoid arthritis patients show a relative hypofunctioning of the HPA axis despite the degree of inflammation. Data suggest that chronic stress provokes increases in the production of the proinflammatory cytokine IL-6, which correlates with disease symptoms, including fatigue, pain, and functional limitations. Moreover, the presence of depression in rheumatoid arthritis patients undergoing stress is associated with exaggerated increases in IL-6, a biomarker predictive of disease progression.

Cancer and Psychoneuroimmunology. In recent history, cancer has been reconceptualized from an acute disease model to a chronic disease with interest shifting towards intraindividual differences that affect clinical outcomes. In particular, researchers are beginning to conceptualize the psychoneuroimmunological pathways that affect the quality of life of cancer patients. Elevated levels of cytokines have been associated with cancer stage in melanoma, breast cancer, bone sarcoma, and post-treatment fatigue in breast cancer survivors. Recent data suggest that memory deficits in newly diagnosed breast cancer patients are related to an activated immunologic response. Stressful life events and depression are associated with higher mortality rates across various cancers. In a

study of ovarian cancer patients, those with a greater sense of social attachment were less likely to die. Furthermore, perceived social isolation or loneliness predicted morbidity and mortality risk across different ages. While data remains limited on psychoneuroimmunology's relationship to cancer, there is continued interest in discovering immune mechanisms to improve clinical cancer care.

Stress and Metabolic Syndrome. Stress during development, in the form of early life adversity, has been linked to subsequent development of metabolic diseases including obesity, insulin resistance, and type 2 diabetes. There are two primary proposed mechanisms for the association. First, direct biologic effects include stress-induced elevated blood levels of triglycerides, free fatty acids, glucose, and insulin, as well as permanent alterations in the HPA axis. Second, indirect effects through mental health and risk behaviors can lead to the development of the metabolic syndrome.

STRESS AND PSYCHIATRIC ILLNESS

Historical Conceptualization

Mental disorders have been ascribed to an imbalance in bodily humors, to the influence of external spiritual or other supernatural forces, and moral or somatic deficiency. In the early-to-mid-1800s, a school of thought emerged, led by Philippe Pinel (1745 to 1826) of the Salpêtrière in Paris and Amariah Brigham (1798 to 1849) in America, which held that the expression of mental illness was affected by life circumstances and, more broadly, by societal factors. These various influences converge in the biopsychosocial model proposed by Meyer. This orientation held that an individual's response to stress is modified by several intrinsic factors (e.g., genes, premorbid personality) and extrinsic factors (e.g., social support). The model incorporated individual temperamental and experiential characteristics, such as potential vulnerability (or resiliency) factors or stressful life events, as initiating or exacerbating factors, and a support network as a potentially modifying factor for the occurrence of mental illness. For the most part, this multidetermined model of mental illness dominates modern psychiatric thinking.

It is interesting to see how stress is handled in the diagnostic nomenclature of the fifth edition of the *Diagnostic and Statistical Manual of*

Mental Disorders (DSM-5). This classification does not emphasize the biopsychosocial model of the nature and genesis of psychiatric disorders because the decision to have the DSM-5 (similar to previous DSM editions) expound a *descriptive*, phenomenologic typology, one that theoretical or other subjective interpretations would least govern. Thus, in DSM-5, “major depression” is “major depression,” whether it appears in the context of job loss, divorce, war trauma, or for no apparent reason. Historically, there have been inconsistencies in this approach. Until the 2013 release of the DSM-5, major depression was not considered major depression if it occurred within 2 months of the death of a loved one. Such grief was somehow considered mutually exclusive from major depression, making it difficult to diagnose depression during bereavement, barring extreme symptoms such as suicidality or psychosis. The newest edition removes this bereavement exemption and replaces it with recommendations to consider true major depression even in the context of significant loss if the reaction is inappropriate to the stressor. In a welcome call for thoughtfulness, the text further allows the reader to exercise clinical judgment in assessing the appropriateness of reactions.

Stress can clearly contribute to pathology, so which diagnostic options are afforded by the DSM-5 to explain a depressive syndrome following a major stressor? For example, what if an individual becomes depressed following their parents’ divorce? According to DSM-5, if such a person develops a depressive syndrome, it might be considered an adjustment disorder (if short-lived), but if it is persistent, then a diagnosis of major depression applies. Following a traumatic stressor (e.g., sudden loss of a spouse in a motor vehicle collision), might one better diagnose post-traumatic stress disorder (PTSD)? Not necessarily. Although PTSD is another exception to the DSM-5 rule that the nomenclature should be atheoretical (it is one of the very few disorders in DSM-5 for which the occurrence of a stressful life event is pivotal for diagnosis), it has characteristic symptoms (e.g., re-experiencing symptoms) that are not equivalent to the depressive syndrome. However, comorbidity with major depression is extremely common in PTSD.

Further complicating this diagnostic dilemma is the suggestion that traumatic loss can result in a bereavement syndrome (suggested for further study in the DSM-5 as “persistent complex bereavement disorder”) that is not well captured by either the major depressive disorder (MDD) or PTSD diagnoses although it has elements of both. Thus, like those who

struggle to understand the influence of life events on the emotional functioning of their patients, the DSM-5 continues to struggle with the best way to classify and incorporate stressful life events into diagnosis. In the face of this ongoing turbulence, however, much research has been conducted to sharpen the thinking about the relationship between stress and psychiatric illness.

Stress and Psychotic Disorders

There is little reason to suspect that stress plays a role in the pathogenesis of schizophrenia. Most current etiologic theories of schizophrenia focus on genetic and prenatal environmental factors or a combination thereof. There is, however, ample evidence that adverse life events and stressful social or familial milieu play an important role in determining the course of illness in general and episodes of relapse in particular.

Chronic interpersonal stress, usually studied in the family context, is an important risk factor for relapse in schizophrenia. Studies of “expressed emotion,” a proxy for familial tumult, have demonstrated that persons with schizophrenia who reside in homes with high-expressed emotion tend to relapse at twice the rate of those who live with families who have low-expressed emotion. Other stressors that plague the lives of many patients with schizophrenia (e.g., poverty, homelessness, and criminal victimization) also powerfully affect the clinical course of their illness. Combined with evidence that schizophrenia renders the individual more susceptible and sensitive to the negative effects of even minor stressors, it is obvious that stress plays a major role in the course of schizophrenia. Numerous studies have examined the effects on relapse rates of psychosocial interventions that seek to enhance schizophrenic patients’ ability to cope with stressful events.

Affective Disorders

Stressful life events and affective illness share a complicated relationship. As discussed earlier, studies of stress face common methodologic challenges. This challenge is particularly clear in studies of stress and depression because there is a tendency for depressed patients to selectively recall negative life events and associate these events with their current difficulties. Nonetheless, there is evidence that depressed patients experience more negative life events than nondepressed patients. This

difference may be accounted for predominantly by an excess of "dependent" events (i.e., events that may conceivably have been *caused* by the individual's actions while depressed, such as losing a job due to poor performance or failure in school), as opposed to those independent of the depression (e.g., illness of a family member).

Another way of thinking about the relationship between stress and depression is to focus not on specific life events, per se, but rather on the effects of chronic stress. Studies in this genre are few (e.g., examining rates of depression in mothers of chronically ill children or in Alzheimer caregivers compared to control subjects), but those that exist tend to support a relationship between chronic stress and the propensity for major depression. To the extent that most animal models of depression (e.g., chronic restraint, forced swim) are subchronic or chronic stress paradigms, the study of chronic stress effects on depression in humans offers the possibility for convergence and translation between the preclinical, epidemiologic, and clinical knowledge bases.

There is a fundamental similarity between the neuroendocrine effects of stress on humans and the neuroendocrine abnormalities in major depression. For 50 years, major depression has been recognized as associated with overactivity of the HPA axis, as inferred by elevated cerebrospinal CRH levels, increased plasma cortisol and corticotropin (ACTH) levels, increased urinary free cortisol, increased cerebrospinal fluid cortisol, and cortisol resistance to dexamethasone suppression. There is also evidence that some features of psychotic depression, in particular, may be mediated by hypercortisolemia. Some studies suggest that childhood maltreatment, a strong risk factor for affective and other forms of psychopathology, leaves a neurohormonal "scar" that leads to CRH hypersecretion under stress and maybe a vulnerability factor for mood (and anxiety) disorders.

Biopsychosocial models posit that risk factors on different levels (e.g., experiential and biologic) could influence susceptibility to major depression. Although these models have held sway for many years, only recently has supporting data been reported. Researchers are beginning to discover genetic variants within the stress hormone system that increase the risk for depression and other psychiatric disorders. Dysfunction of the glucocorticoid receptor pathway is reported in MDD and individuals exposed to early stressors. Several studies have shown that genetic variants alter transcriptional responsiveness of glucocorticoid receptor

target genes to the glucocorticoid receptor and have further suggested that the risk of developing MDD after stressful life events may be influenced by an individual's sensitivity to cortisol release.

Increasingly, studies suggest that neither the gene nor the life stress alone significantly influenced risk; rather, the interaction of these factors explained the variation in depressive outcomes. Recent advances in epigenetics may specifically elucidate the mechanisms linking external stresses to affective psychopathology. Stress may affect gene expression through chromatin remodeling, histone acetylation, methylation, or DNA methylation. For instance, it has been noted that chronic social defeat stress in mice will increase the transcription of a particular DNA methyltransferase (*Dnmt3a*) in the nucleus accumbens, which in turn will increase depressive behaviors after mild social defeat exposures. This effect can be reversed by selectively blocking DNA methylation in that region.

Thus, contemporary genetic and epigenetic research yields empirical evidence of what has been viewed as a truism in contemporary psychiatric teachings: Genes and stressful life events operate in concert to elicit depressive episodes. However, it must also be considered that these types of gene-by-environment interactions may explain risk not only for major depression but also for an array of other stress-influenced mental disorders (e.g., anxiety disorders).

Anxiety Disorders (other than PTSD)

Compared to the voluminous literature on stress and depression, there is less empirical research on the relationship between stress and anxiety disorders. It is nonetheless apparent that panic disorder frequently has its onset or recrudescence in the context of stressful life events. In particular, there is evidence to suggest that either interpersonal conflict or serious illness (in a significant other) may trigger the onset of panic disorder in susceptible individuals. Given that patients with panic disorder are often somatically preoccupied and likely to interpret physical sensations as life-threatening, it is not surprising that the occurrence of illness in someone close to these patients might precipitate the onset or an exacerbation of their panic.

One difficulty in assessing the relationship between stressors, stress responses, and anxiety disorders may be that generalized anxiety disorder itself may include a pathologic prioritizing of stressors, distorting

reported stress burdens for study. That said, at least one major long-term study has identified recent adverse life events as a risk factor for late-onset generalized anxiety disorder. Another found that stressors in the domains of loss and danger were particularly prone to predict the onset of anxiety syndromes. In terms of the effects of early life stressors, there is growing evidence that certain adverse early life events such as childhood emotional, physical, or sexual abuse are risk factors for the later development of panic disorder, particularly in women.

Post-Traumatic Stress Disorder

DSM-5 recognizes the existence of a group of disorders that are, by definition, stress-related. Included here are PTSD and autism spectrum disorder (ASD). ASD has its onset following particularly traumatic (often life-threatening) events, such as violent assault or serious accidents, and is denoted by the presence of prominent dissociative symptoms (e.g., derealization, numbing). When ASD occurs following trauma, it identifies a subset of individuals at several-fold increased risk for the subsequent development of PTSD (and major depression).

Whereas PTSD was not long ago considered to be a disorder of war veterans (15% to 20% of U.S. Vietnam veterans and U.S. soldiers deployed to the more recent Afghanistan and Iraqi conflicts may suffer from this disorder), it is now recognized as a highly prevalent disorder affecting a much larger segment of the population. Among the traumatic stressors that can elicit PTSD are relatively rare events such as natural disasters and frighteningly common events such as criminal victimization. In prior versions of the DSM, it was noted that to qualify for a diagnosis of PTSD, the traumatic event needed to be “beyond the range of normal human experience.” Epidemiologic research has shown that, as much as it is hoped it could be otherwise, horrible things happen to many people and must be considered part of the human experience. Consequently, although the debate continues, it is now generally accepted that any life-threatening (or, perhaps, life-altering) event, however common (e.g., a serious motor vehicle collision), can be considered sufficiently traumatic that it is capable of eliciting PTSD. With this definition in place, recent surveys place the lifetime prevalence of PTSD in the general U.S. population at around 8% to 10%, with a recognition that certain subpopulations (e.g., soldiers, immigrants from war-torn countries, Native Americans living on reservations) may have several-fold higher rates.

The occurrence of PTSD following severe psychological trauma provides the most persuasive evidence in favor of certain kinds of stress-causing psychiatric illnesses. However, it is important to note that the neuroendocrine profile of patients with PTSD is not what one might expect to see following chronic stress, nor is it akin to what is observed in major depression. Whereas the latter two conditions would be expected to be associated with hypercortisolism, many studies of patients with PTSD have instead demonstrated *hypocortisolism*. Although the neurobiologic implications of this finding remain to be elucidated, the message for stress researchers is clear: it is unlikely that a uniform neuroendocrine "stress response" explains the heterogeneity of psychiatric disorders encountered in the wake of psychological stress.

Most severe psychological stressors *do not* result in the development of PTSD (or other forms of psychiatric illness). Even the terror of the attacks on September 11, 2001, resulted in PTSD in only approximately 1 in 10 residents of Manhattan, New York; these data stand as testimony to the resilience of the human psyche. In light of the natural course of timely recovery, it is important for mental health workers to avoid rapidly pathologizing normal reactions to trauma and to debrief cautiously. Certain characteristics of the traumatic stressor or the immediate postexposure response seem to increase the propensity to develop PTSD following exposure. Some risk factors include the magnitude of and proximity to the stressor, the occurrence of physical injury (including even mild traumatic brain injury), and the occurrence of peritraumatic dissociation. Individual differences also contribute to the variance in PTSD expression following trauma exposure; these include female gender, genetic vulnerability, and a history of exposure to early childhood trauma. The following chapter provides a more detailed review of PTSD following critical illness and the postintensive care syndrome (PICS).

There has also been a surge of interest in recent years in the phenomenon of psychological resilience. Whereas serious traumatic stressors almost inevitably result in short-term symptoms and a decline in functioning, some individuals rebound especially quickly from such insults and go on to function extremely well, even in the face of ongoing chronic stress. Determination of individual differences in development and personality, extraindividual factors including social networks and environment, and neurobiologic mechanisms that underlie these observed differences are a subject of intense research scrutiny.

Stress, Personality Traits, and Disorders

The personality trait of neuroticism is directly tied to stress reactivity and the experience of negative, distressing emotions. High neuroticism is a feature of cluster B personality disorders, including borderline personality disorder (BPD). Alterations of stress perception and response have been observed in patients with personality disorders. Exposure to traumatic experiences, particularly early in development, has been associated with subsequent diagnosis of BPD. This association suggests a bidirectional connection between personality and stress.

PHARMACOLOGIC APPROACHES TO STRESS MANAGEMENT

As discussed above, stressors worsen most psychiatric conditions. When major psychiatric conditions like depression or psychosis are present, the most appropriate medications are those for the primary psychiatric diagnosis. However, more typically, the picture is primarily one of anxiety or insomnia, perhaps not of as great a magnitude as that found typically in anxiety disorder, but still very distressing to the patient. In such settings, pharmacologic therapy with anxiolytic medications or short-term hypnotics may be helpful but carries risks. The field is of two minds on this topic and has historically oscillated between extreme viewpoints. Besides the risk for drug dependence, some feel that benzodiazepines may impair the efficacy of psychotherapy by offering a temporary alternative to developing coping skills.

On the other hand, depriving patients of such medication when they are in crisis is unconscionable. Short-term use of low-dose benzodiazepines considerably helps patients struggle with unusual stressors. This intervention in association with supportive psychotherapy is extremely effective in crisis intervention.

COGNITIVE-BEHAVIORAL APPROACHES TO STRESS MANAGEMENT

William James famously suggested that the greatest weapon against stress is one’s ability to choose one thought over another. CBT methods are increasingly used to help individuals better manage their responses to

stressful life events. These treatment methods are based on the notion that cognitive appraisals about stressful events and the coping efforts related to these appraisals play a major role in determining the stress response.

Lazarus et al. have developed stress and coping models that serve as the conceptual foundation for most CBT stress management protocols. These models maintain that two types of cognitive appraisal are especially important in mediating reactions to stress. The first, *primary appraisal*, refers to how a person evaluates the significance or meaning of a given event. When events (e.g., being diagnosed with a chronic illness such as rheumatoid arthritis) are appraised as harmful, threatening, or a loss (e.g., "Because of my rheumatoid arthritis, I will never be able to do anything I really care about"), the individual is more likely to become anxious, depressed, and withdrawn. However, if the same event is viewed as challenging (e.g., "Although my arthritis prevents me from doing some physically demanding activities, there are many other important and meaningful activities that I can do and enjoy"), then more positive outcomes are more likely to occur. *Secondary appraisal* refers to the process of evaluating what can be done about the stressful event and whether or not what can be done will work. Several factors can influence such secondary appraisals, including their learning history, breadth of individuals' repertoire of coping skills, mastery of specific coping skills, and expectation that their skills will be effective.

CBT approaches to stress management have three major aims. The first aim is to help individuals become more aware of their cognitive appraisals of stressful events. The second aim is to educate individuals about how their appraisals of stressful events can influence negative emotional and behavioral responses and help them reconceptualize their abilities to alter these appraisals. The third aim is to teach individuals how to develop and maintain a variety of effective cognitive and behavioral stress management skills.

The Efficacy of CBT in Stress Management

Several controlled studies have documented the efficacy of CBT stress management protocols. Three such controlled studies provide good examples of this type of research.

Individuals who are in the early stages of coping with recovery from breast cancer surgery must cope with treatment-related symptoms and

major disruptions in their work and family life. Investigators conducted a study of newly surgically treated breast cancer patients. Approximately 200 patients were randomly assigned to one of two groups: (1) a comprehensive CBT program focusing on stress management skills, or (2) an educational seminar control condition. Patients in the CBT condition met in groups weekly for 10 weeks and received relaxation, problem-solving, and assertion training. At the end of 3 months, patients in the CBT condition showed significantly greater improvements in intrusive thoughts about cancer, cancer-related anxiety, and emotional distress than patients in the control condition. Recently these patients were recontacted and found to have maintained significantly lower depressive symptoms and better quality of life up to 15 years postintervention.

Human immunodeficiency virus (HIV) is another incurable, high-mortality, highly stigmatized disease that carries a heavy stress burden both from the disease itself and the imperfect treatment options. Several studies have applied similar cognitive-behavioral stress management interventions to HIV-positive patients worldwide. One recent study randomized 71 low-income, racial-minority, HIV-positive, and HPV-positive women to either CBT stress management or a psychoeducation control group. The investigators found that the CBT group demonstrated lower depression scores and stronger immune function postintervention than the control group. Several studies of HIV-positive patients in the United States, Iran, Africa, and elsewhere have similarly demonstrated the effect of CBT stress management to significantly decrease depressive symptoms, increase well-being and sleep quality, and often improve biomarkers such as viral load and rates of cervical intraepithelial neoplasia. The therapy has also been found to alleviate functional dyspepsia symptoms, improve well-being in prostate cancer survivors, and decrease symptom severity and healthcare utilization costs in patients with chronically unexplained medical symptoms.

Stress Management Training

When CBT is used for stress management, training is provided in a wide range of stress management skills. Although space limitations preclude a discussion of all of these skills, it is important to highlight five skills that form the core of almost all CBT stress management programs: Self-observation, cognitive restructuring, relaxation training, time management, and problem-solving.

Table 27.10–1.
A Daily Diary Format for Recording Stress-Related Behaviors

Antecedents (Briefly describe the stressful event)	Stress Rating (Rate how stressful the event was: 0 = not at all, 100 = most stressful event ever experienced)	Behaviors (Indicate how you responded to the event)	Consequences (What was the outcome?)
A minor traffic accident: I was hit from behind at a stop light. Hurt my neck slightly, no damage to the car.	Rating = 70	Thoughts: This kind of thing always happens to me, my boss is really going to be angry at me for missing the morning meeting. Feelings: Frustrated, anxious. Physiologic response: Clenching my teeth, stomach churning. Behaviors: Started shouting at the driver who hit me and then went back to my car to calm myself down and wait for the policeman.	I was able to regain control over my emotions. The policeman came quickly and I was able to make the morning meeting on time.

Self-Observation. One of the most effective ways of helping individuals become more aware of how they respond to problem situations is to have them keep a daily record of their behavior. A daily diary format (Table 27.10–1) is often used with patients who are asked to record how they responded to challenging or stressful events that occurred each day. Entries are made in three columns: antecedents, behaviors, and consequences. In the antecedents column, patients record a specific environmental event that they perceived as stressful. The event might be an interpersonal stressor such as arguing with a spouse, confronting a coworker, or an intrapersonal stressor such as a flare in pain symptoms or a major natural disaster. To assess appraisals of the stressor, evaluators ask patients to rate how stressful they found this event on a 0 to 100 scale (e.g., 0 = not at all stressful, to 100 = the most stressful event ever experienced). Patients are instructed to record their behavioral reactions to the stressful event in the column marked behavior. The term *behavior* is broadly defined so that it encompasses not only overt behavioral responses but also more covert cognitive, affective, and physiologic responses. Thus, in the behavioral response column, individuals might indicate specific coping behaviors they engaged in (e.g., avoidance), cognitive responses to the stressor (e.g., "I am overwhelmed and can't deal with this right now"), negative emotions (e.g., anxiety, depression), and aversive physiologic responses (e.g., increasing sweating, heart rate, or nausea). In the column marked consequences, patients record the outcomes resulting from their behavior in this situation.

Self-observation is effective for several reasons. First, it makes individuals more aware of behaviors they usually fail to notice. Individuals whose deal with social anxiety by avoidance, for example, may avoid potentially stressful situations in a more or less automatic fashion (routinely refuse invitations), or use very subtle forms of avoidance (arriving or leaving a party early). They may arrange their lifestyle (work alone) to have very few chances to confront their fears. By keeping a record of their behavior, individuals often begin to recognize these behavioral patterns. A second important feature of self-observation is that it helps individuals see how their cognitive-behavioral responses are linked to situational antecedents and consequences. Participants who keep daily diaries are often struck by the variations in their reactions across different events. For example, while they may cope effectively with one stressful event (e.g., meeting an important work deadline), they find

themselves unable to deal with another stressful event (e.g., an argument with their teenage son or daughter). Self-observation highlights the role that coping efforts and cognitive appraisals and emotional and physiologic responses play in explaining these very different responses to stressful situations.

With the ubiquity of smartphones, the authors have seen growing interest in daily record-keeping of both behavioral and biologic data collected for individual patients. A wide range of apps have made it easy to document symptoms and situational factors (precipitating events, social context, etc.) in real-time. This approach, called *ecologic momentary assessment*, enables a person to capture stress and coping processes much closer to their occurrence and can increase the accuracy and validity of self-observation. Automatically graphing the timing of anxiety exacerbations, for instance, can aid patients in identifying patterns in order to better understand and change their responses to daily stressors.

Cognitive Restructuring. A hallmark of CBT is its insistence that cognition plays a central role in the stress and coping process. In CBT, cognitive appraisals about stressful events are considered the key factor in determining stress-related responses. Given this emphasis on cognition, it is not surprising that a major thrust of CBT approaches to stress management is helping participants become aware of and change their maladaptive thoughts, beliefs, and expectations.

CBTs have developed protocols for helping distressed individuals restructure dysfunctional or maladaptive thinking patterns. Such cognitive restructuring begins by educating patients about the cognitive model and that underlying cognitions are major determinants of emotional responding. According to the cognitive model, emotional reactions that are excessive or prolonged are often the result of cognitions that are distorted or dysfunctional.

The second step in cognitive restructuring is monitoring and analyzing dysfunctional thoughts. Table 27.10–2 lists several stress-related thoughts that might be identified through daily diary records. As can be seen, each of these thoughts can be linked to a negative emotion. A careful analysis of each thought also reveals an inherent error in logic. Certain types of errors, or cognitive distortions, occur quite frequently, and individuals can, thus, be taught to recognize them.

The third step in cognitive restructuring is to challenge and change cognitive distortions. Participants are often provided with a list of "key questions" (Table 27.10–3) they can apply to their negative thoughts. They are asked to select one or two questions that are useful in identifying the underlying logical problems in their thinking. Finally, participants develop a rational response that represents a more accurate and helpful cognitive response to the situation.

Table 27.10–4 illustrates how one might change various overly negative stress-related thoughts to more adaptive rational responses. If the rational response is to be effective, it must be used frequently, ideally each time the negative thought occurs. To ensure this occurs, therapists give patients home practice assignments in which they are asked to expose themselves to stressful events, monitor their negative thoughts, and respond with a more adaptive thought pattern. They are also asked to keep records of the resulting consequences, both changes in emotions and behaviors.

Table 27.10–2.
Stress-Related Negative Thoughts

Stressor	Cognition	Emotion
Painful medical procedure	I know I won't be able to tolerate the pain.	Fear
Argument with a friend	She will never speak to me again.	Discouragement
Coworker injured on the job	It is my fault. I should have warned him about the danger.	Guilt
Late for a deadline	It's hopeless, I'm always messing things up.	Depression
Spouse criticizes you	He just doesn't get it. He will never understand what I am trying to do.	Anger

Cognitive restructuring is receiving increasing attention among researchers interested in stress management. Some of the most interesting topics receiving recent attention include how cognitive

restructuring alters brain processes related to stress and coping and how cognition changes relate to sudden gains achieved during treatment.

Relaxation Training. Relaxation skills can be very helpful in managing stress. When individuals learn to relax, their overall muscle tension is reduced, as does their overall level of autonomic arousal. Individuals who can relax are also more likely to be able to think more rationally and restructure negative cognitions when faced with stressful events. They are also more likely to rest and sleep better, reducing the fatigue that often accompanies stress. Finally, relaxation skills may help interrupt maladaptive behavior patterns. Progressive relaxation training usually consists of a series of structured exercises involving tensing and relaxing major muscle groups slowly. The exercises are introduced during treatment sessions, and patients are encouraged to practice them daily at home. One of the most important tasks in relaxation training is helping patients learn how to generalize their skills in relaxation from home practice sessions to stressful and demanding daily life events. Several techniques are used to enhance generalization. The first is a method called *differential relaxation*. In differential relaxation, the trainee is instructed to engage in a daily task and only use the necessary muscles for carrying out the task. For example, while writing one's name, there needs to be activity in the hands and arms muscles, but the muscles in the face, lower trunk, legs, and feet can be deeply relaxed.

Differential relaxation is initially practiced in relatively easy situations (e.g., sitting or standing) where the demands are minimal. Over time, however, patients learn how to use differential relaxation in challenging and stressful situations. A second generalization method is the *mini-practice*. This exercise consists of a brief relaxation procedure in which the trainee takes a deep breath and then, while slowly exhaling, focuses on sensations of relaxation flowing downward from the face muscles to those of the neck, shoulders, trunk, and legs. The mini-practice takes approximately 30 seconds and thus can be done repeatedly over a day. Individuals are encouraged to develop innovative reminders to cue themselves to perform frequent mini-practices every day. As individuals increase this frequency, they often report that relaxation becomes more or less an automatic and habitual response.

Table 27.10–3.
Key Questions for Challenging Negative Automatic Thoughts

Is there an alternative explanation?
What is the evidence that this thought is true?
What will be the effect of continuing to think this way?
What is the best outcome, worst outcome, and most realistic outcome?
What is the likelihood that this will happen?

Adapted with permission of Beck JS. *Cognitive Therapy: Basics and Beyond*. Guilford Press; 1995.

Relaxation training is frequently used in managing stress in persons suffering from chronic medical disorders such as cancer, cardiovascular disease, and chronic pain. For some people, relaxation training and its variant of meditation can have powerful effects on physiologic and psychological responses to stressors. The heart rate response to intravenous isoproterenol (Isuprel) is a venerable tool of autonomic physiology with highly predictable results. A serendipitous case observation found that the heart rate response to pharmacologic doses of isoproterenol was blocked in a patient who spontaneously started to meditate during the infusion (Fig. 27.10–7).

Time Management. Time management methods are designed to help individuals restore a sense of balance in their lives. The first step in training in time management skills is designed to enhance awareness of current time use patterns. To accomplish this goal, therapists might ask individuals to record how they spend their time each day, noting the amount of time spent in important categories such as work, family, exercise, or leisure activities.

The second step in time management is designed to help individuals set their priorities. An important distinction can be drawn between urgency and importance in setting priorities. To explore this distinction, it is helpful to envision a table with the dimension of importance and the dimension of urgency along the other axis. Patients are then encouraged to enter into each quadrant of the table examples of activities from their own lives and to reflect on the patterns they observe. Individuals may note that much of their time is spent doing activities in the urgent-not-important quadrant or the not-urgent-not-important quadrant. Alternatively, they may report

spending little or no time engaging in activities in the not-urgent-but-important quadrant. Patients are encouraged to discuss the benefits of increasing the priority they give to such important but less urgent activities such as exercising, resting, relaxing, or doing volunteer work. They are also encouraged to try to match the time spent engaging in such meaningful activities with the priority they place on the activity.

Table 27.10–4.
Negative Thoughts and Rational Responses

Negative Thought	Rational Response
I have no control over this situation.	It's true that I can't change what happened, but I can control how I respond.
I can't return to my old job, I am worthless.	Even though I may not be able to do the same kind of work, there are a number of other jobs that I may be able to do.
It's not fair that I am being treated this way.	Life is not always fair. Sometimes things go my way, other times they don't.
I am a burden on my family.	My family has had to give me more support lately, but I do a lot of things for them as well.
No one really cares about me.	There are people in my life (e.g., spouse or child) that I can turn to for support and love.

FIGURE 27.10–7. The effect of meditation on heart rate response to isoproterenol. The patient (*dotted line*) began spontaneously meditating and her heart rate dropped. The solid line presents the expected heart rate response. The patient was retested and instructed not to meditate (*dashed line*) and her response was then typical. BPM, beat per minute. (Reprinted from Dimsdale JE, Mills PJ. An unanticipated effect of meditation on cardiovascular pharmacology and physiology. *Am J Cardiol*. 2002;90(8):908–909. doi: 10.1016/s0002-9149(02)02726-1.)

Goal setting focuses on specific behavior change targets that fit an individual's long-term priorities. First, the individual is asked to identify a goal to be accomplished in the next week. The goal, for example, might

be to lose 2 lb or to sign up for an exercise program. Second, patients are asked to critically analyze the goal to ensure it is reasonable, specific, and personally meaningful. In the third step of goal setting, individuals are asked to reconfirm a time frame (e.g., 1 week) in which they will meet the goal. This step is important in reducing procrastination, a common obstacle to effective time management. Finally, the individual's efforts in reaching the goal are reviewed. Successful completion of a goal that has been long neglected can be very rewarding.

The evidence base for time management is growing. One meta-analysis of 32 empirical studies of time management found that the increased use of time management behaviors was significantly related to better health, lower levels of stress, and higher job satisfaction.

Problem-Solving. Problem-solving involves several basic steps. The first is problem identification. In this step, an individual tries to identify the key problematic aspects of a stressful event, such as problematic behaviors, thoughts, feelings, and physiologic responses. For example, dealing with the aftermath of a hurricane may be perceived as stressful because it is associated with (1) particular behavioral problems, for example, having to clean up while simultaneously caring for one's children; (2) overly negative thoughts, for example, "We will never recover from this event"; (3) negative feelings, for example, fear, anger, and depression; and (4) physiologic responses, for example, muscle tension, fatigue, and sleep problems. Helping individuals understand the various facets of their problematic responses is often helpful because it suggests what skills might be particularly useful. For example, if the problem is mainly a somatic one (increased tension), relaxation-based strategies may be the most effective.

The second step in problem-solving is generating alternatives. Brainstorming is used to generate a wide range of alternative problem solutions. The rules of brainstorming include: (1) individuals offer as many solutions as they can, even if the solutions do not immediately seem reasonable, (2) no criticism is allowed, and (3) there should be an attempt to mix and match solutions in creative ways.

The third step in problem-solving involves evaluating the alternatives and selecting the best solution. To begin this process, therapists can ask a participant to rate each solution's likelihood of a positive outcome. It is often helpful to discuss some factors that influence how the participant

makes these ratings (e.g., cost, availability of resources, effects of the solution on others). Typically, one solution stands out as the best and most practical.

The final step of problem-solving involves implementing the solution. Participants try to apply the best solution in the problem situation and then review their progress with the therapist.

There is growing recognition that the development of problem-solving skills is crucial to preventing relapse and maintaining the effects of CBT. Participants who learn how to approach a problem situation and formulate and implement effective coping options benefit in several important ways. First, they can often anticipate problems and make plans to avoid them. Second, they cope with setbacks more effectively and can get their coping efforts back on track after a setback to prevent a major relapse. Finally, they are better prepared for termination of therapy because they have learned to engage in a form of “self-therapy” in which they can pinpoint and solve their problems.

Psychological First Aid. Like traditional first-aid, psychological first aid (PFA) is designed to respond to disasters focused on safety and stabilization. It was developed to reduce the incidence of PTSD following trauma and is intended for use by nonmental health professionals and lay responders. See the chapter on Disaster Psychiatry for a more thorough review of PFA.

FUTURE DIRECTIONS

A 51-year-old single woman was seen in psychiatric consultation for help with severe anxiety and occasional panic 8 months after being stabbed by a stranger in an apparent gang initiation assault. She survived without permanent injury but required a chest tube and a short ICU stay at the time and had been afraid to leave her home unaccompanied since the assault. Over the next few months, she began to experience nightmares, insomnia, loss of appetite, and episodes of severe shortness of breath, flushing, and chest pain lasting 15 to 20 minutes about once a week, sometimes leading to emergency department visits. An emergency physician prescribed her low-dose benzodiazepines, which helped her sleep but had begun to create a dependency.

In the consultation clinic, she was jumpy, fretful, and underweight. She reported feeling "stupid" for having been out alone at night. An SSRI was started, and her appetite, hypervigilance, and insomnia improved. She no longer required benzodiazepines. However, her anxiety regarding leaving the house remained, as did her fear of panic attacks and self-blame.

Cognitive-behavioral therapy helped her see this self-blame as a cognitive distortion, and she practiced countering this with affirmations that reassigned the guilt to her attacker. She practiced breathing and muscle relaxation exercises that reduced the fear associated with her panic attacks, and they eventually abated. Her psychiatrist helped her develop a gradual exposure plan to get her out of the house unaccompanied, first briefly in the daytime, then ultimately after dark alone. After 3 months of treatment, she had essentially returned to her full level of functioning.

By way of conclusion, the case study above demonstrates many of the issues discussed in this section—the confluence of adverse life events, physical illness, and emotional distress, and the pharmacologic and psychotherapeutic treatment of stress-related psychopathology.

How would this case be changed 10 years from now? How would it be conceptualized in future taxonomies of psychiatric illness? What sorts of additional information would tomorrow's clinician try to obtain to treat this patient? In other words, how will "stress" be evaluated and treated by psychiatrists in the future? Stressful life events have been a fixture

throughout human history, though the nature of the stressors transforms over time. Crime and violence, for example, are not going to go away. Indeed, with increased population density, climate change, and volatile economies, such transgressions may afflict ever-greater populations. Inequity and racism are increasingly recognized sources of stress that impact disparities in health, including mental health and cognitive outcomes. Psychiatry has an important role in understanding the mechanisms through which determinants of health impact mental life across generations.

Perhaps, in the future, physicians may be better able to forecast individuals' vulnerabilities to such stressors. The extensive epidemiologic literature from military psychiatry and disaster psychiatry are consistent in finding a spectrum of risk among those exposed to major stressors. This finding has led to an emphasis on intervening in those at higher risk. Typically, this has meant focusing on the relatively socially isolated individuals, as social isolation is repeatedly observed as a risk for poorer outcomes after trauma exposure. With increasing research, physicians may also find that interventions are particularly important for individuals with certain life experiences or genetic legacies. With advances in understanding individual vulnerabilities comes the opportunity for early identification and intervention. Future research will no doubt test the efficacy of early treatment with psychopharmacologic, cognitive-behavioral, or combined treatments.

Greater understanding and standardization of the concept of resilience will allow for measurement and rigorous study of factors that predict adaptive outcomes. This will guide efforts to develop systems that foster resilience. Considering resilience as a process involving multiple systems emphasizes the key role of systems and networks beyond the individual (family, community, environment) in weathering challenges. To date, most approaches to managing stress have focused solely on the individual. However, with changes in the way health care is being delivered, there will be a greater need to involve family members, caregivers, and communities in the treatment process. Stress occurs in a social context and, for this reason, involving significant others in the process of both assessment and treatment makes sense. Significant others provide an important role as informants about the patient's status; they also can play an active role in helping patients better understand their adaptation to

stress and encouraging the adoption and continued use of effective stress management interventions.

As medical science advances, new treatments and management approaches are emerging. Psychiatry will continue to play a significant role in coping with both illness and treatment stresses. Psychiatrists will also contribute to further research measuring how stress contributes to the development and trajectory of the disease.

Psychopharmacological interventions will assuredly also be different in the future. The days of prescribing barbiturates to help patients deal with stress are long gone. These dated interventions have disappeared, along with telegraphs and slide rules, to be replaced by more effective and safer agents. As more is learned about the fundamentals of stress, anxiety, and depression, it is only a matter of time before benzodiazepines and SSRIs will be supplanted by pharmacologic agents with different actions and (hopefully) stronger benefits and fewer risks. Moreover, if the promise of personalized medicine is fulfilled, then the ability to match treatments to patients will also improve.

As the current understanding advances and interventions evolve, psychiatrists will continue to provide patients with the tools and therapies required not just to overcome but actually to understand their stress. Looking ahead and to the future, it is important to not forget the insights already recognized at the dawn of stress research. While stress can be a hazard or even a risk factor, it can also be a potent constructive force in patients' lives.

27.11 Psychiatric Morbidity Following Critical Illness

Christian Romanchek, M.D., Dimitry S. Davydow, M.D., M.P.H., F.A.C.L.P., and O. Joseph Bienvenu, M.D., Ph.D.

Mr. Williams was a healthy, busy 35-year-old family man when he developed a cough with fever, diaphoresis, and pleuritic chest pain. At a local emergency department, he was started on oral antibiotics for “walking pneumonia.” However, his wife had to bring him back 2 days later as he had increasing shortness of breath and weakness, and he felt like he was dying. Because of inadequate oxygenation with noninvasive methods (respiratory failure), he was intubated and started on mechanical ventilation. He was diagnosed with acute respiratory distress syndrome (ARDS) and required intensive care for 12 days.

While in intensive care, Mr. Williams did not know where he was and had visual hallucinations of children with animal heads and circular mazes dripping with blood. He was quite agitated and required physical restraints, and his endotracheal tube and Foley catheter were apparently quite uncomfortable. He developed a belief that his penis had been excised and that he would have to pay a large sum to have it reattached. He thought his nurses were variously ignoring and trying to kill him.

After he was extubated and transferred to a general hospital ward, Mr. Williams required physical therapy until he could move around better. However, he remained easily fatigued for months, and his strength returned quite gradually, with substantial effort. He also had trouble getting things done, with his expectations greatly exceeding his abilities. He had trouble with his memory (e.g., where he had put his keys) and difficulty completing sequential tasks (e.g., putting furniture together). The loss of his fast-paced, high-responsibility job had a profound demoralizing effect on him.

Mr. Williams also became very fearful, particularly of infections, as he was told his critical illness stemmed from an infection. He used a mask when cleaning, changed his sheets frequently, and took vitamins and minerals meant to boost his immune system. He feared overdoing it at the gym, and his wife became embarrassed when he frequently spoke of illness to others. When he became ill with a cough or a runny nose, he stayed home or made unnecessary emergency room visits, and he avoided playing with his young son when his son had a cold. He had intrusive memories of wearing an oxygen mask in the emergency department and the sound of the ventilator when he was critically ill. He felt distant from his loved ones, unsupported, and that

no one understood what he had been through. He no longer felt he would have a long life. He felt like a burden, particularly because he could not do much around the house. He wondered if he had done something wrong, why this had happened to him. He was frustrated by his slow recovery and avoided others, not wanting to be bothered. Sometimes he had difficulty falling asleep and would anxiously check his pulse and breathing, especially when concerned he was coming down with something. He was also irritable, especially when people did not show respect or empathy.

With advances in intensive care medicine, many more patients are surviving critical illnesses like severe sepsis and ARDS Unfortunately, many critical illness survivors suffer from post-traumatic stress disorder (PTSD), anxiety, and depressive phenomena, as well as cognitive impairment and physical weakness, and their family members are also often quite distressed. To increase awareness of these common problems, a group of clinical outcomes researchers and other stakeholders coined the term “postintensive care syndrome.” This section will touch on all these problems, as they are often relevant to critical illness/intensive care unit (ICU) survivors and their families, but this section will focus particularly on neuropsychiatric problems.

PSYCHIATRIC MORBIDITY IN CRITICAL ILLNESS SURVIVORS AND THEIR FAMILY MEMBERS

What is Stressful about Critical Illness?

In many ways, critical illness–associated distress is easy to understand. Patients who are critically ill with acute respiratory failure experience pain with endotracheal intubation and suctioning, as well as invasive monitoring and therapeutic interventions such as arterial and central intravenous lines, Foley catheters, and chest tubes. In addition, severe sepsis is associated with systemic inflammation and dysfunction of many organs, including the brain and the adrenal glands (leading to a need for endogenous and exogenous catecholamines to maintain adequate blood pressure). With acute brain dysfunction from infection, organ failure, and sedative medications, patients are often unable to process what they are experiencing (e.g., manipulation of a Foley catheter can be misperceived

or misinterpreted as rape), and frightening hallucinations and delusions are common. All these stresses occur while patients have lost their autonomy and ability to communicate normally. If patients survive, they are often weak and cognitively impaired; thus, their work, social, and family lives are additionally disrupted by these factors. Similarly, family members face a number of stressors, including uncertainty about their loved ones' survival and ultimate functioning, financial difficulties with disrupted jobs and the need to provide informal care, and additional disruptions in work and social lives, including changing roles within the family.

Adult Critical Illness Survivors

Adult critical illness survivors have a substantially higher prevalence of psychiatric morbidity than expected compared to the general population. For example, around 20% of critical illness survivors suffer from clinically significant PTSD symptoms, approximately 30% with clinically significant depressive symptoms, and approximately 35% with clinically significant nonspecific anxiety symptoms. Studies employing clinician interviews suggest lower but still substantial prevalence of PTSD and depression-related diagnoses. Importantly, psychiatric morbidity may explain, at least in part, the frequently low health-related quality of life (HRQOL) in survivors.

Risk factors for psychiatric morbidity in critical illness survivors include prior psychiatric illness, in-ICU benzodiazepine/sedative doses, mechanical ventilation, and post-ICU memories of frightening, often psychotic, in-ICU experiences. In addition, early post-ICU distress strongly predicts later psychiatric morbidity.

Pediatric Critical Illness Survivors

Pediatric critical illness survivors also have higher rates of psychiatric disorders than their general population counterparts. Patient and parent reports indicate that substantial PTSD symptoms occur in 10% to 28% of child and adolescent critical illness survivors, and clinician interview results suggest frank PTSD in 0% to 21%. Patient and parent reports indicate that substantial depressive symptoms occur in 7% to 13% of this patient population, although, as in adults, major depressive disorder appears less common. Also, as in adults, clinically important psychiatric symptoms are associated with worse HRQOL.

As in adult critical illness survivors, a precritical illness history of psychiatric or developmental problems appears to be the most potent predictor of substantial psychiatric symptoms in children after intensive care. Also, in keeping with adult critical illness survivors, early postillness psychiatric symptoms appear to be predictors of later, more persistent PTSD and depressive symptoms. Notably, parental PTSD, anxiety, and/or depressive symptoms after a child's critical illness and the child's post-ICU psychiatric morbidity appear correlated.

Family Members of Critically Ill Patients

As mentioned, critical illness survivors are not alone in facing substantial distress. Family members of critically ill patients also have high prevalence of clinically important psychiatric symptoms, with concomitant poorer functioning and quality of life. Approximately one-third of parents of critically ill children experience substantial acute stress symptoms. Studies using questionnaires suggest that anywhere from 13% to 56% of relatives of critically ill patients have substantial PTSD symptoms, while 8% to 42% have substantial depressive symptoms. Furthermore, 21% to 56% of family members of critically ill patients have substantial nonspecific anxiety symptoms. As noted above, substantial PTSD, depressive, and nonspecific anxiety symptoms tend to co-occur in family members of critically ill patients.

Women with critically ill family members may be at greater risk of developing substantial PTSD and/or depressive symptoms than men. In addition, family members of patients who die or almost die in the ICU, and those family members who have additional stressors beyond their relative's critical illness, appear at greater risk of clinically important psychiatric symptoms. For family members of patients who die in the ICU, discordance between their preferred medical decision-making role and their actual role and being present at the time of the loved one's death may increase risk. Finally, wives of men with substantial functional limitations after a severe illness may be at increased risk of developing substantial distress compared to husbands of women with similar postillness limitations.

COGNITIVE DYSFUNCTION IN CRITICAL ILLNESS SURVIVORS

Prevalence

A growing body of literature suggests that critical illnesses can affect cognitive functioning substantially and persistently. In studies of ARDS survivors, 70% to 100% had evidence of cognitive impairment at hospital discharge, and 25% to 47% had clinically meaningful cognitive impairment at 2-year follow-up. In studies of general ICU survivors, a wider range (10% to 71%) showed evidence of cognitive impairment 1 year after hospital discharge. Notably, the degree of long-term cognitive impairment present in these patients can be comparable to that seen in patients with moderate traumatic brain injury or mild Alzheimer disease.

Affected Cognitive Domains and Neuroimaging Findings

While critical illness survivors can exhibit impairment in all domains of cognitive functioning, the domains most severely affected are attention and concentration, memory, and executive functioning. Neuroimaging studies of critical illness survivors have correlated these phenomena with cerebral atrophy, ventricular enlargement, and hippocampal volume reductions, as well as connectivity disturbances.

Potential Risk Factors

Although older age is a risk factor for persistent cognitive impairment after critical illness, younger and middle-aged adult survivors can also be affected. Preexisting cognitive impairment and depression appear to increase risk.

Several clinical factors appear to be causally related to, or at least markers of risk of, long-term cognitive dysfunction in critical illness survivors. For example, severe sepsis appears causally related, and delirium in the ICU is atleast a marker of risk for persistent cognitive dysfunction. In-ICU hypoxia, hypotension, and glucose dysregulation have all been associated with persistent cognitive impairment, and other clinical, genetic, and treatment factors may be relevant.

PHYSICAL DYSFUNCTION IN CRITICAL ILLNESS SURVIVORS

Neuromuscular weakness after critical illness or intensive care is very common, particularly early in the course of recovery (during the first year).

“ICU-acquired weakness” encompasses critical illness polyneuropathy and myopathy, as well as disuse atrophy. Polyneuropathy can recover particularly slowly (over several years).

Apparent risk factors for critical illness polyneuropathy and myopathy include hyperglycemia, systemic inflammatory response syndrome, sepsis, and multiorgan dysfunction. The causal factor for disuse atrophy is immobility (bed rest).

Importantly, physical functioning (including the ability to perform instrumental activities of daily living) can remain impaired longer than muscle weakness. Some apparent risk factors for reduced physical functioning include ICU administration of systemic corticosteroids, ICU-acquired illnesses, slow resolution of lung injury, depression, and older age.

INTERVENTIONS FOR PSYCHIATRIC DISORDERS IN CRITICAL ILLNESS SURVIVORS

Adult Critical Illness Survivors

Some experts advocate for psychological interventions to begin while patients are still critically ill in the ICU. Indeed, psychologists administering a simplified cognitive behavioral therapy (CBT) intervention in a trauma ICU appeared to substantially reduce the risk of survivors’ long-term emotional distress and need for further psychiatric treatment. Unfortunately, psychologists are not commonly employed in ICUs, and bedside nurses administering a similar intervention did not seem to have a similar salutary effect in a recent large randomized trial.

Another promising intervention to reduce long-term distress in critical illness survivors is ICU diaries. Unlike normal diaries, ICU diaries are written for patients who are critically ill. Clinicians, often intensive care nurses, write in plain language about the patient’s condition throughout the ICU stay, including diagnostic and therapeutic procedures. Family members are also encouraged to write about their observations, thoughts, feelings, and occurrences outside of the hospital. Sometimes the diaries include photographs of the ICU room (± the patient) and of staff. The rationale for ICU diaries is to help patients create a more coherent autobiographical narrative than they may otherwise have due to acute brain dysfunction while critically ill. Patients can process this information

when they are ready and able, at their own pace, sometimes sharing with loved ones. Early studies suggested that ICU diaries are acceptable to patients and families and that they reduce long-term distress. ICU diary programs are becoming fairly common, especially in Europe. Nevertheless, results of recent large clinical trials suggest that ICU diaries may be most useful for patients with substantial emotional distress early in recovery.

Although ICU follow-up clinics are relatively common in parts of Europe, they are not common in North America, and patients face many logistical challenges attending such clinics in any case. Thus, distance interventions employing technology (telephones and computers) deserve consideration and show promise to deliver effective CBT-based interventions. Like ICU diaries, such interventions appear most promising for patients who have substantial distress post-ICU.

Virtual reality interventions also show promise in educating survivors about critical illnesses and intensive care. These interventions will likely help patients comprehend and process their experiences and improve long-term psychiatric outcomes.

Intriguingly, stress doses of hydrocortisone in the ICU also appear to reduce the incidence of post-ICU PTSD phenomena, though glucocorticoids are not prescribed routinely for this purpose.

Children

To date, there has been limited research on interventions to prevent psychiatric morbidity in pediatric critical illness survivors. A randomized controlled trial investigated the efficacy of an emotional regulation and anxiety reduction program for mothers of critically ill children; the children whose mothers received the intervention exhibited fewer behavioral problems following their critical illness. Notably, ICU diaries have also been adapted for use in children.

Families

Results of some studies suggest that ICU diaries prevent long-term emotional distress in relatives. In addition, studies suggest that enhanced communication strategies (e.g., informative brochures, longer care conferences) between critical care health care workers (e.g., physicians and nurses) and family members of dying critically ill patients reduce PTSD, depressive, and general anxiety symptoms in family members. In a

recent study, trained facilitators acting as medical liaisons appear to benefit communication quality and end-of-life care decision-making (with reduced length of stay in patients that would ultimately die), although family members showed no benefits in depression, anxiety, or post-traumatic stress symptoms. Flexible family visitation policies have reduced anxiety and depression scores among family members of critically ill patients without increasing burnout rates among the primary clinical team.

Interventions for Post–Critical Illness Cognitive Dysfunction

There have been few studies of interventions to prevent persistent cognitive dysfunction in critical illness survivors. Preliminary evidence supports a role for in-home cognitive and physical rehabilitation, though larger randomized controlled trials are needed.

Several interventions to reduce or prevent delirium in the critically ill have been evaluated. Dexmedetomidine, a central alpha-2 adrenergic agonist, used for sedation with mechanical ventilation, is less deliriogenic than benzodiazepines. Early physical rehabilitation in the ICU, including during mechanical ventilation, reduces the incidence and duration of delirium. However, it remains unclear whether such delirium reductions will lead to better long-term cognitive outcomes.

Interventions for Post–Critical Illness Physical Dysfunction

The most promising interventions to reduce post-ICU weakness involve minimizing sedation and maximizing physical rehabilitation as early as possible, including while patients are critically ill. Such interventions reduce the need for prolonged mechanical ventilation and ICU stays and, as noted, delirium. Although to the authors' knowledge, the effects of these interventions on long-term neuropsychiatric outcomes are unknown, they seem unlikely to be harmful and likely to be beneficial.

27.12 Psychocutaneous Disorder

Ravenna Khanna, M.D., and Jason P. Caplan, M.D.

EDITOR'S NOTE

Much of this chapter is derived from the exemplary and influential work of Drs. Madhulika A. Gupta and Aditya K. Gupta. Their expertise in the area of psychocutaneous disorders is well known in this country and abroad, especially in Canada, where Dr. M.A. Gupta is a Professor of Psychiatry at the University of Western Ontario and where Dr. A.K. Gupta is a Professor of Medicine at the University of Toronto Medical School. Interested readers are directed to the following source articles for further reading:

Fried RG, Gupta MA, Gupta AK. Depression and skin disease. *Dermatol Clin*. 2005;4:657–664. Gupta MA, Gupta AK. Current concepts in psychodermatology. *Curr Psychiatry Rep*. 2014;16:449–457.

While any organ system is subject to the complex interactions of psyche and soma and their potential to manifest as psychosomatic illness, the skin is unique in that it is the largest organ, the organ most immediately observable to others, and the most immediately accessible to oneself. Thus, the skin may be particularly prone to manifest psychosomatic illness influenced either by disturbances of neurotransmitters, hormones, or cytokines; by psychosocial relationships or disturbances of self; by (conscious or unconscious) self-harm; or by complex interactions of all three.

The field of psychodermatology or psychocutaneous medicine focuses on these interactions between the mind, the brain, and the skin. The interface between psychiatric and dermatologic conditions highlights the common origin of the brain and skin from the embryonic ectoderm. As such, both organ systems are influenced by common hormones and neurotransmitters that impact how they respond to internal and external stimuli. It is important to recognize that interactions between the mind, brain, and skin are multidirectional: psychopathologic factors can play an etiologic role in the development of skin disorders and exacerbate existing skin disorders, while dermatologic conditions may result in psychosocial consequences due to stigmatization and disfigurement. Significant psychiatric and psychosocial comorbidity has been reported in at least 30% of patients with dermatologic illness. Moreover, the vast majority of patients with psychodermatoses do not receive psychiatric care. As such,

psychodermatology as a field encourages an interdisciplinary and humanistic approach to the management of patients with co-occurring dermatologic and psychiatric pathology.

PSYCHOSOCIAL IMPACT OF SKIN DISORDERS

While most individuals with dermatologic illness are able to appropriately adjust to their skin disorder and avoid undue distress, some patients with chronic skin illnesses and appearance-altering conditions experience a significant degree of social, psychological, and physical distress. The patient's experience of psychosocial distress is variable and depends on (1) the characteristics of skin disorder itself, (2) characteristics and demographics of the patient, and (3) cultural attitudes related to skin disease (often expressed as stigma).

In patients with dermatologic disorders, the analogy of "skin failure" (comparable to failure of other organ systems in the body like heart or kidney failure) implies a failure of skin as an organ of physical expression, thus leading to rejection, shame, isolation, and psychosocial impairment. Feelings of stigmatization in patients with psoriasis have been grouped into six dimensions: the *anticipation of rejection* (e.g., "I feel physically and sexually unattractive when my psoriasis is bad"); *sensitivity to opinions of others* (e.g., "Sometimes I feel outcast because of my psoriasis"); *feeling of being flawed* (e.g., "I believe other people think that psoriasis patients are dirty"); *guilt and shame* (e.g., "My psoriasis is a source of deep humiliation and embarrassment for my family and me"); *secretiveness* (e.g., "I try not to share with family members away from me, that I have psoriasis"); and *a more positive attitude which is unaffected by negative reactions of others* (e.g., "If my child has to develop psoriasis, he could develop his potential as though he did not have it"). A previous experience of rejection was considered to be a strong predictor of current beliefs. Some individuals with skin disorders noted that their main difficulties arose not from the disease itself but from others' reactions to their disease.

The desire to be "looked at and admired" may be formulated as a normal narcissistic trait. However, in individuals with skin lesions, to be looked at with surprise, fear, or disdain evokes feelings of painful shame and humiliation. People with normal skin are commonly inclined to turn away physically or psychologically from those suffering from skin

diseases–a reaction that has been suggested to involve “a fleeting identification” with the afflicted person, followed by a negative empathic response. The visible skin lesion symbolizes how defective and vulnerable one can be and when coupled with observed feelings of shame and embarrassment, invokes a momentary flash of empathic identification. The healthy person proceeds to block out and dismiss from their awareness any compassion for the sufferer’s pain and then turns away and distances themselves from the person with skin disease. A similar phenomenon has been described in individuals with psoriasis, who typically report that they would avoid other people with psoriasis if they did not have active disease.

The emotional reaction to a particular skin condition is often affected by the patient’s understanding of its *origin*. A congenitally acquired condition such as a port-wine stain may invoke a different reaction versus an acquired skin disorder such as a sexually transmitted infection, lichen simplex, or prurigo nodularis (PN). The latter two conditions, for example, are induced by scratching, and diagnosis may invoke a sense of guilt and shame. In conditions with a genetic predisposition such as atopic dermatitis (AD) or psoriasis, the patient’s response may include blaming their parents and feelings of frustration or helplessness.

Associated symptoms of itching, burning, or pain may add to distress, insomnia, anxiety, and depression. The location or appearance of skin lesions might affect the patient’s self-image and how they are perceived by others. Lesions directly visible on the face and hands usually cause the greatest concern. Lesions present on the trunk and limbs can result in avoidance of activities that would require exposure, such as the gym, spas, swimming pools, or the beach. Genital lesions can be particularly embarrassing and limit sexual intimacy. Hair loss can diminish self-confidence and affect social poise. Lesions involving the nails and hands may be disabling in occupations involving transactions with others such as banks or retail stores. Congenital conditions like port wine stains or childhood AD can influence a child’s self-image and general emotional development. In adolescents, chronic skin conditions can significantly impact self-esteem and self-image, affecting the maturation of self, sexual identity, and personality. The course of skin illnesses with a chronic relapsing pattern or treatment-related side effects can have a major impact on patients and their families in an enduring fashion.

Age and gender may be important predictive factors when considering the psychiatric sequelae of a chronic dermatologic illness. A young woman suffering from psoriasis may be more psychosocially impacted than a man in the eighth decade of life with a similar condition. Personality traits can similarly influence a patient's reactions and subjective experience of the illness. Narcissistic personality disorder is marked by "an expectation of admiration and attention, sense of entitlement, and excessive concern about how others regard them," and individuals with that diagnosis may be particularly humiliated by a skin disease that impacts their personal appearance. Those diagnosed with a borderline personality disorder may consider skin disease as a specific threat to self-image and autonomy and react with mood instability, severe anxiety, and fear of abandonment when faced with a dermatologic diagnosis. For those with prominent obsessive-compulsive traits, skin disorders may invoke a loss of control over their body and feelings of being unclean or dirty due to skin lesions and topical treatments. The presence of a primary psychiatric disorder can similarly influence the patient's thoughts and beliefs about the skin lesions. For example, depression may increase the sensation of itching in pruritic skin disorders such as AD, psoriasis, and chronic idiopathic urticaria (Fig. 27.12–1).

KOO CLASSIFICATION OF PSYCHOCUTANEOUS DISORDERS

Although there is no single universally accepted classification system of psychocutaneous disorders, the one most widely accepted was devised by John Koo. It includes five different groupings listed in Table 27.12–1, which also includes the corresponding diagnoses and diagnostic codes from the revised fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and the diagnostic codes from the International Classification of Diseases (ICD) 10. *Psychophysiologic disorders* are bona fide skin disorders exacerbated by stress. The term *primary psychiatric disorders* refers to cases without "real" skin disease, but where patients present with significant psychopathology and visible skin lesions are self-induced. The term *secondary psychiatric disorders* refers to cases in which patients develop psychological problems as a result of skin disease and associated disfigurement. Some skin conditions, such as acne and alopecia areata (AA), although not life-threatening, may have a significant

psychosocial impact on a patient's quality of life. The term *cutaneous sensory disorders* refers to cases in which patients have unpleasant sensations on the skin, such as itching, stinging, burning, or crawling, with no proven skin-based etiology, and in which a psychiatric diagnosis may or may not be evident. These are considered to be equivalents of chronic pain syndromes. Subcategories of psychocutaneous disorders are not mutually exclusive. For example, acne can be precipitated by stress (a psychophysiological condition), but acne can also cause social anxiety and depression due to disfigurement (a secondary psychiatric condition).

Koo classification includes a separate category to describe the *use of psychotropic medications* in treating certain skin conditions, which may be more efficacious than traditional dermatologic treatments. For example, many antidepressants, such as doxepin, have shown greater efficacy as antipruritic agents when compared to traditional antihistamines. Psychotropic medications commonly used in the treatment of psychocutaneous disorders are summarized in Table 27.12–2.

FIGURE 27.12–1. Model of psychosocial factors implicated in origin and maintenance of skin-specific affect/distress, and systemic adaptation response. (Adapted and modified from Thompson A. Coping with chronic skin conditions. In: Walker C, Papadopoulos L, eds. *Psychodermatology: The Psychological Impact of Skin Disorders*. Cambridge University Press; 2005:61.)

ESTABLISHED PSYCHODERMATOSES

These diagnoses encompass primary psychiatric disorders and cutaneous disorders, all of which present with both psychopathologic and dermatopathologic features.

Delusional Disorder, Somatic Type: Delusional Parasitosis

Clinical Features. Patients suffering from delusional parasitosis (DP) have the fixed belief that they are infested with parasites. G. Thibiérge first described the condition in the 1890s and called the syndrome *acarophobia*. Other terms used include parasitophobia, entomophobia,

monosymptomatic hypochondriacal psychosis, and Ekbom syndrome. DSM-5 uses the term “delusional disorder (parasitosis),” which presents as a single somatic delusion with no impairment of thought processes. Patients often describe the sensation of bugs crawling on or inside the skin; some report seeing bugs or hearing buzzing sounds; and some “bring the parasites” for further examination (usually pieces of hair, skin, or cloth). This behavior is so characteristic that it has been referred to as “the matchbox sign” since patients will often bring this material to clinical encounters in a small container. Often a patient with DP may report a specific precipitant, such as a history of infection with a contagious organism or an actual infestation. Their attempts for self-treatment include repeated washing, checking, and cleaning; excoriation of skin with needles, knives, or fingernails; discarding household items; and excessive use of insect repellents or insecticides (Fig. 27.12–2). Relatives may share the delusion, and fear of contaminating others is common. Most patients seek dermatologic treatment because their delusion involves skin invasion.

Table 27.12–1.
Classification of Psychocutaneous Disorders

Koo's Classification	DSM-5 Classification (codes listed as DSM-5, ICD-10)
Psychophysiologic disorders	**(1) Psychological factors affecting other medical condition (316, F54**) Atopic dermatitis, psoriasis, alopecia areata, urticaria and angioedema, acne vulgaris
Primary psychiatric disorders	**(2) Delusional disorder, somatic type (297.1, F22)** Delusional parasitosis, delusions of a defect in appearance, delusions of a foul body odor **(3) Obsessive-compulsive and related disorders (OCRD)** Excoriation (skin-picking) disorder (698.4, F42.2), trichotillomania (312.39, F63.3), body dysmorphic disorder (300.7, F45.22) **(4) Unspecified OCRD (body-focused repetitive behavior disorder) (300.3, F42.9)** Onychophagia **(5) Factitious disorder (300.19, F68.10):** Dermatitis artefacta, psychogenic purpura
Secondary psychiatric	(6) Anxiety disorder due to another medical condition (293.84, F06.4) (7) Generalized anxiety disorder (300.02, F41.1) (8) Major depressive disorder (296.3, F33 plus modifiers)
Cutaneous sensory disorders	**(9) Unspecified somatic symptom and related disorder (300.82, F45.9)** Chronic idiopathic pruritus, idiopathic pruritus ani/vulvae/scroti

(10) Somatic Symptom Disorder, with predominant pain (300.82, F45.1)

Idiopathic glossodynia, dysesthetic (essential) vulvodynia

Psychotropic medication for nonpsychiatric indications

Data from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Text Revision, DSM-V-TR, (Copyright © 2022). American Psychiatric Association; Koo J. Psychodermatology: a practical manual for clinicians. *Curr Probl Dermatol*. 1995;7:203–225.

Table 27.12–2.
Psychotropic Medications Used in Treatment of Psychocutaneous Disorders

PRURITUS	**SSRIs and TCAs** (amitriptyline and doxepin): commonly useful in pruritus **Doxepin 5% topical cream**: FDA-approved for short-term management of pruritus in AD **Gabapentin, pregabalin**: effective in prurigo nodularis, neuropathic pain, and fibromyalgia **Aprepitant** (neurokinin receptor [NKR]-1 antagonist): effective in chronic refractory pruritus. NKR-1 is a receptor for substance P, an important itch mediator. **Naltrexone** (opioid receptor antagonist): used in Rx of OCRD
BODY-FOCUSED REPETITIVE BEHAVIORS (under OCRD): SPD, TTM, BDD, dermatitis artefacta	**SSRIs** (fluoxetine, paroxetine, sertraline, citalopram, escitalopram, and fluvoxamine): considered first-line treatment for OCRD **Clomipramine** (TCA): found to be effective in TTM, BDD, OCD; use caution with TCAs (side effects). **Naltrexone** (opioid receptor antagonist): in one study reduced pruritus by 50% in OCRD, body repetitive disorders **N-Acetylcysteine** (NAC): treatment efficacy comparable to CBT in one study for TTM **Olanzapine and aripiprazole**: positive case reports for treatment of SPD and TTM **Mood stabilizers** (lamotrigine, lithium, valproic acid): few positive studies; indicated for Rx of emotional dysregulation/dissociation and comorbid mood disorder

CUTANEOUS DYSESTHESIAS: Glossodynia, vulvodynia, trichodynia/scalp dysesthesia urogenital and rectal pain syndrome	**TCAs** (doxepin, nortriptyline, imipramine, desipramine, and particularly amitriptyline): long h/o use, effective **SSRIs**: considered first-line **Mirtazapine**: useful when anticholinergic side effects of TCAs cannot be tolerated **SNRIs**: have efficacy in pain, neuropathic disorders, and fibromyalgia. **Gabapentin**: useful for neuropathic pain and pruritus, safe, minimal drug interaction, and no abuse potential.
DELUSIONAL PARASITOSIS	**Pimozide**: a potent neuroleptic, most commonly advocated, 60–100% response rate; monitor risk of QT prolongation. **Risperidone, olanzapine, amisulpride**: 75% response rate; preferred over pimozide due to improved side effect profile.

Rx, treatment; AD, atopic dermatitis; SSRIs, selective serotonin reuptake inhibitors; TCA, tricyclic antidepressants; TTM, trichotillomania; SPD, skin picking disorder; OCRD, obsessive-compulsive and related disorders; BDD, body dysmorphic disorder.

Diagnosis. Symptoms of DP can be confused with a specific phobia or obsessive-compulsive disorder (OCD), and the distinction between these conditions has obvious relevance to treatment. The differential diagnosis of DP includes a number of medical, neurologic, and psychiatric disorders, which are listed below in the section on psychogenic pruritus. The effects of certain drugs can mimic DP; cocaine and amphetamines especially may produce a tactile hallucination referred to as “cocaine bugs” or “Magnan sign,” where the affected person believes they have or feel parasites crawling under the skin. Patients with severe alcohol withdrawal may experience visual hallucinations of insects or tactile hallucinations that bugs are crawling over their skin (formication).

FIGURE 27.12–2. Delusions of parasitosis. Lesions are mostly excoriations. Patient picks on skin with nails and needles. (The Barankin Collection. Wolters Kluwer, 2005.)

Pathogenesis. The psychopathology of DP involving specificity of content and fixed belief has been the focus of many empirical studies. The pathogenesis of DP has been considered a multifactorial process in which psychic, cognitive, and social circumstances act as disorder-predisposing, triggering, and maintaining factors, respectively. The psychic factors may add predisposition to a particular delusional theme and involve complex interactions of age, gender, social situation, and other key experiences. Delusions are considered a dynamic process that only persists if disorder-maintaining social factors (isolation, alienation, avoidance behaviors) are operative. Magnetic resonance imaging (MRI) in patients with DP is suggestive of disturbed functioning in brain regions associated with the interpretation of perceptions, involving the putamen and the associated dorsal striato–thalamo–cortical loop (a circuit linked to somatic delusions and tactile misperceptions) along with frontal dysfunction (which is hypothesized to be responsible for disturbed reality testing). The therapeutic efficacy of D2-dopamine antagonists in DP implies a role in dopaminergic dysfunction in these regions. Patients with intoxication from

substances influencing dopamine transmission (e.g., cocaine, amphetamines, etc.) may experience delusional infestation, further validating this hypothesis.

Patients with DP can be further subgrouped as:

1. Patients with *predominantly hypochondriacal traits* are convinced that they have an incurable physical illness. This has been described as a hypochondriacal delusion of parasitosis or simply DP. In some cases, those not suffering from organic psychosis, schizophrenia, or an affective disorder may be considered in the group of monosymptomatic hypochondriacal psychosis.
2. Patients with *paranoid delusions* and without hypochondriacal traits. These individuals tend to fight against parasites that are perceived as impairing their existence. This has been referred to as delusions of infestation. Such patients consult parasitologists, entomologists, and even pest control companies but seldom see dermatologists.
3. Patients with signs of both *hypochondriacal as well as paranoid delusions,* are referred to as hypochondriacal delusions of infestation. Such patients usually present for repeated dermatologic consultation, similar to those in the first group.

Treatment. Patients with DP are reluctant to seek psychiatric treatment. It is important to establish rapport and build a stable relationship based on trust. This is accomplished by listening to patients' stories, showing empathic understanding, asking how the condition affects their lives, and trying to reduce their sense of isolation. It is often counterproductive to inform patients in the first meeting that they are suffering from a delusional disorder. It is best to acknowledge complaints as an experienced reality. Treatment strategies include psychotropic medications as well as psychotherapy. With the implementation of such an integrative approach, improvement in delusional symptomatology can be expected in about two-thirds of patients.

Psychopharmacologic treatment of DP has typically included the use of pimozide, a potent neuroleptic. In one double-blind, crossover-controlled study of treatment of DP with pimozide, 10 of 11 patients improved after 6 weeks of treatment ranging from 1 to 5 mg per day. A follow-up study demonstrated that treatment with pimozide for 5 months resulted in long-term remission in many patients. Full remission of DP has been reported in 50% of those receiving pimozide. Other antipsychotic medications

(risperidone, haloperidol, trifluoperazine, chlorpromazine) have also demonstrated efficacy in uncontrolled trials, and there have been no head-to-head studies to indicate that pimozide is superior to other antipsychotics. Unlike other antipsychotics, however, pimozide is also a potent opiate antagonist and has an antipruritic action which may contribute to the improvement seen in DP patients. As with other neuroleptics, pimozide carries a risk of prolongation of the QT interval, which may limit its use in patients with cardiac dysrhythmia. There are anecdotal case reports of treatment response from selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), and electroconvulsive therapy (ECT). One case report of successful treatment with naloxone and naltrexone lends further weight to a pathophysiologic contribution from the endogenous opiate system.

Morgellons Disease

Morgellons disease (MD) is a pattern of dermatologic symptoms that may present in a manner very similar to DP. The condition was first described many centuries ago but has recently received much attention in the mass media. It has been postulated that patients exposed to information about MD on the internet may develop the strong belief that they too have the condition as a form of shared delusion. As such, many medical practitioners still consider MD a delusional disorder. More recent studies have, however, reported findings to suggest that MD may be a dermopathy associated with tick-borne illness. The diagnosis thus remains controversial.

Clinical Features. Patients with MD experience a crawling or stinging sensation on the skin and often also believe that they are infested with insects. Studies initially suggested that this diagnosis was a purely delusional disorder. More recent investigations, however, have demonstrated an association with spirochetal infection. MD more commonly affects females, with a mean age of 50 to 55 years and a prevalence of 6%. Psychiatric comorbidities (including depression, anxiety, bipolar disorder, ADHD, OCD, and schizophrenia) are noted in 68% to 82% of patients with MD.

Diagnosis. Diagnostic features include ulcerative cutaneous lesions with embedded or protruding microscopic filaments (colored, white, or

black) that resemble textile fibers. Patients experience formication, described as biting, stinging, itching, or crawling sensations on the skin alongside systemic manifestations that mirror those of Lyme disease (LD); these include neuropathy, joint pain, cardiac complications, fatigue, and changes in cognition. A key step to diagnosis is to determine whether the patient presents with characteristics commonly associated with delusions —such as agitation, confusion, and mood or perceptual disturbances. PCR testing and confirmatory DNA sequencing have detected Borrelia DNA in specimens from MD patients, establishing a potential link between LD and MD, though other associated pathogens (such as *Helicobacter pylori*, *Treponema denticola*, and *Bartonella henselae*) have also been implicated in disease pathogenesis. It is plausible that the effects of microbial infection result in prolonged inflammatory processes in the brain, thereby causing neurodegenerative symptoms. While some MD patients exhibit neuropsychiatric symptoms, others do not.

Treatment. There are currently no universally accepted criteria for MD, and the potential physiologic underpinnings of the disease are contested, leaving treatment a challenge for providers. Trials have shown earlier treatment as associated with better outcomes for patients with MD. Intervention should be primarily directed at the underlying tickborne illness if one can be identified. Though there is some evidence suggesting that MD responds to antibiotic treatment, these findings have not been confirmed by controlled trials. Antipsychotic agents have been proposed for patients with neuropsychiatric symptoms. Pimozide, for instance, has been known to show improvement in symptoms such as formication associated with MD. Other studies suggest a combined regimen of antibiotics, antipruritic agents, and antipsychotic medications, though it is unclear which of the three resulted in improvement.

Obsessive-Compulsive and Related Disorders

Trichotillomania (Hair-Pulling Disorder). While François Hallopeau first coined the term trichotillomania (TTM) in 1889, from the Greek for *tricho* (hair), *tillo* (pull), and *mania* (fury), hair-pulling has been described since antiquity. Hippocrates advised physicians to assess hair-pulling as part of a routine mental status examination and described a case of hair-pulling in the apparent context of depression. The phenomenon of a

trichobezoar (gastric hair ball) was first described in the medical literature in the 18th century

CLINICAL FEATURES. Trichotillomania (hair-pulling disorder) is classified in DSM-5 under obsessive-compulsive and related disorders (OCRD). The DSM-5 diagnostic criteria are outlined in Table 27.12–3.

Clinically, patients present with areas of differing hair lengths with blunt or tapered ends or areas of black dots on the surface of the scalp (Fig. 27.12–3). On exam, hair does not pull out easily (negative "pull test"). TTM affects women ten times more commonly than men.

SUBTYPES. Hair-pulling most typically involves the scalp but may also be seen in the eyebrows and eyelashes. Two types of hair-pulling have been delineated. *Focused pulling* describes the use of an intentional act to control unpleasant personal experiences, such as an urge, bodily sensation (e.g., itching or burning), or thought. This behavior is thought to be a compulsion in that the patient resists the act of pulling and feels relieved after pulling. In contrast, *automatic pulling* occurs outside the person's awareness and most often during sedentary activities and has been formulated as more akin to an impulse control disorder. Many patients have a combination of these types of hair-pulling. Lack of awareness of hair-pulling has been postulated to be associated with possible "dissociation and emotional dysregulation" in patients with TTM.

Table 27.12–3.
The DSM-5 Diagnostic Criteria for Trichotillomania (Hair-Pulling Disorder)

A. Recurrent pulling of one's hair resulting in hair loss.
B. Repeated attempts to decrease or stop hair pulling.
C. The hair pulling causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The hair pulling or hair loss is not attributable to another medical condition (e.g., a dermatological condition).
E. The hair pulling is not better explained by the symptoms of another mental disorder (e.g., attempts to improve a perceived defect or flaw in appearance due to body dysmorphic disorder).

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Text Revision, DSM-V-TR, p. 281 (Copyright © 2022). American Psychiatric Association. All Rights Reserved.

PATHOPHYSIOLOGY. Patients with TTM may have comorbid mood, anxiety, and eating disorders. Major depression was the most common mood disorder, and generalized anxiety disorder was the most common anxiety disorder in a study of a large series of patients with TTM. Comorbid cluster B (histrionic 26%, borderline 18%) and cluster C (obsessive-compulsive 27%, avoidant 14%) personality disorders are also commonly seen in patients with TTM. Familial association between TTM and OCD has been found in some studies, and patients with TTM will often report a family history of OCD or other anxiety disorders. OCD is thought to be related to the overactivity of cortico–striatal–thalamic–cortical (CSTC) circuits, which is also hypothesized to play a role in a range of dysfunctional repetitive behaviors, including TTM. One MRI study reported decreased putamen volume (with normal caudate volume) in patients with TTM compared to healthy controls, a finding suggestive of CSTC circuit involvement. A PET study of patients with TTM showed that treatment response to clomipramine was inversely correlated with anterior cingulate and orbitofrontal metabolism. In another study of patients with TTM, high baseline CSF 5-hydroxyindoleacetic acid (5-HIAA) levels predicted a better response to SSRI treatment, consistent with similar studies in OCD.

FIGURE 27.12–3. Picture of patient with Trichotillomania with alopecia of frontal scalp. Areas of different hair lengths with blunt or tapered ends, areas of black dots on the surface of the scalp. The hair does not pull out easily (negative "pull test").

TREATMENT. The primary intervention is often heavily dependent on the age of onset of symptoms. In preschool children, where TTM is more often of the automatic type, parental guidance and increased awareness are most effective. Preadolescents and young adults are often not aware of their hair-pulling and require the establishment of a diagnosis and reassurance that their hair is normal and will regrow when it is left alone. Behavioral modification treatments are recommended if the condition becomes chronic. Adult-onset TTM is usually associated with psychiatric

disorders and requires psychopharmacologic and behavioral interventions. In a double-blind crossover study, clomipramine was found to be more effective than desipramine for the treatment of TTM. More recent open trials of SSRIs (fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram) and venlafaxine for the treatment of TTM suggest overall positive treatment response with both short-term and long-term benefits. Given their superior tolerability compared to TCAs, the SSRIs arguably remain the first-line choice medication treatment for TTM. Various case reports have also documented the potential efficacy of atypical antipsychotics (olanzapine, risperidone, and aripiprazole) in the treatment of TTM either as monotherapy or as augmentation of SSRIs. Mood stabilizers (lithium, oxcarbazepine, topiramate, and lamotrigine) have also been used in TTM patients with mood disorders.

Some studies have examined the effects of naltrexone on hair-pulling. Blocking opioid binding may decrease the positive reinforcement from hair-pulling. An open-label study of 14 children with TTM found naltrexone reduced hair-pulling; another study involving adults reported naltrexone had some improvement in hair-pulling behavior. Another pharmacologic approach to TTM involves the use of the glutamate modulator *N*-acetylcysteine (NAC). In a 12-week double-blind placebo-controlled trial, NAC was used in a dosage of 1,200 to 2,400 mg per day, with 56% of TTM patients showing significant improvement. Other studies using NAC reported treatment outcomes comparable to those seen with behavioral interventions like cognitive-behavioral therapy (CBT).

In terms of psychotherapeutic approaches, CBT which includes “habit reversal training (HRT)” is considered the first-line treatment option. *HRT* has three core elements: first, “awareness training” (self-monitoring), to become aware of urge that precedes pulling; second, “stimulus control,” to reduce the likelihood that pulling behavior begins; and third, “competing response training,” to engage in a behavior, at the earliest sign of pulling, that is physically incompatible with hair-pulling. There is evidence to suggest that combined use of behavioral therapies and medications may be more effective than either treatment alone.

Psychogenic Excoriation: Skin Picking Disorder. The term neurotic excoriation was introduced by Erasmus Wilson in 1875. In 1889, M. L. Brocq used the term *acne excoriée des jeunes filles* to describe the excoriations from self-inflicted lesions in young “neurotic” women with pre-

existing acne. A variety of synonyms have been used to describe skin-picking syndrome, including pathologic skin-picking, neurotic excoriation, dermatillomania, or psychogenic excoriation. DSM-5 uses the term *excoriation (skin picking) disorder* (SPD). The diagnostic criteria for SPD are listed in Table 27.12–4.

Table 27.12–4.
DSM-5 Diagnostic Criteria for Excoriation (Skin-Picking) Disorder

A. Recurrent skin picking resulting in skin lesions.
B. Repeated attempts to decrease or stop skin picking.
C. The skin picking causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The skin picking is not attributable to the physiological effects of a substance (e.g., cocaine) or another medical condition (e.g., scabies).
E. The skin picking is not better explained by symptoms of another mental disorder (e.g., delusions or tactile hallucinations in a psychotic disorder, attempts to improve a perceived defect or flaw in appearance in body dysmorphic disorder, stereotypies in stereotypic movement disorder, or intention to harm oneself in nonsuicidal self-injury).

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Text Revision, DSM-V-TR, p. 284 (Copyright © 2022). American Psychiatric Association. All Rights Reserved.

CLINICAL FEATURES. SPD is a common skin disorder characterized by excessive picking, scratching, digging, rubbing, gouging, or squeezing normal skin or previously diseased skin (typically juvenile acne). Patients experience urges to excoriate their normal-appearing skin or visible pre-existing abnormalities like acne, papules, scabs, scars, or insect bites. The classic lesions of psychogenic excoriation are characterized by clean, linear erosions, scabs, and scars that can be hypopigmented or hyperpigmented. The distribution of excoriations is mostly confined to accessible areas like face, arms (mostly extensor surface), and anterior thigh, with sparing of middle and upper lateral back (resulting in the “butterfly sign” of preserved normal skin in areas the patient is unable to reach). This distribution of skin lesions can give the clinician a valuable

clue, but it is not diagnostic of psychogenic excoriation because any condition that has pruritus as a primary symptom (such as hepatic, uremic, or idiopathic pruritus) can result in a similar distribution of skin lesions. Once the patient begins the process of self-picking, a focal itch sensation may initiate scratching, or the tissue damage caused by scratching may trigger further itching. The itch-scratch cycle may become part of the clinical picture and exacerbate the severity and chronicity of psychogenic excoriation. *Lichen simplex chronicus* is a chronic pruritic lichenoid plaque with skin thickening provoked and maintained by scratching or rubbing. Before arriving at a diagnosis of psychogenic excoriation, other conditions that can cause pruritus or excoriation must be ruled out. In the general population, the lifetime prevalence of SPD in adults is 1.4% or higher. Three-quarters or more of those diagnosed are female. Psychogenic excoriation is reported in 9% of dermatology outpatients presenting with pruritus. Most studies report a mean onset of age between 30 and 45 years, but acne excoriée can begin in adolescence and continue into adulthood.

PSYCHIATRIC COMORBIDITY. Some individuals engage in skin picking that is more focused, that is, with preceding tension and subsequent relief, consistent with obsessive-compulsive symptoms. Some individuals may engage in more automatic picking, occurring without full awareness and without preceding tension. Although the DSM-5 does not specifically classify such patients as dissociative, it has been postulated that patients engaging in skin picking without preceding tension or full awareness are likely to have higher levels of emotional dysregulation and dissociation without necessarily meeting the criteria for a dissociative disorder. Recognition of the dissociative component may thus be of clinical importance, as the standard approaches to treating obsessive-compulsive skin picking (i.e., habit reversal therapy and use of an SSRI) are not sufficient in those with high levels of dissociation.

A lifetime occurrence of other primary psychiatric disorders has been found in 54.5% to 100% of individuals with SPD, with OCD, TTM, generalized anxiety disorder, and major depressive disorder among the most common. Generalized anxiety disorder, panic disorder, social phobia, and posttraumatic disorder are present in 41% to 65% of patients. Mood disorders, including major depressive disorder, dysthymia, and bipolar disorder, are present in 48% to 68% of these patients. OCRD

disorders that commonly co-occur with SPD include body dysmorphic disorder (BDD), compulsive nail-biting, and eating disorders. In one study, 45% of patients with BDD also met diagnostic criteria for SPD. Patients with SPD may have obsessions about contamination and skin abnormalities or may be preoccupied with having smooth skin, flawless complexion, and cleanliness. This obsessiveness and potential resultant compulsions might be severe enough to meet the criteria for OCD. OCRD due to another medical condition refers to “obsessive-compulsive symptoms best explained by the direct pathophysiologic consequence of another medical condition.” Excoriation may occur comorbid with another dermatologic disorder. Whether SPD should be diagnosed in addition depends on the clinical assessment of to what point the skin picking is independent of other disorder.

TREATMENT. There are few controlled data on the pharmacologic treatment of psychogenic excoriation. One randomized controlled trial found that NAC 1,200 to 3,000 mg/day significantly reduced skin-picking symptoms. This suggests that the glutamatergic system may prove a useful target in treating SPD. Most of the available data comes from case studies, open trials, and small double-blind studies, which largely support treatment with SSRIs. Fluoxetine is the most studied SSRI in the treatment of psychogenic excoriation. In one double-blind, 10-week study, at a mean dose of 55 mg per day, fluoxetine was superior to placebo in reducing psychogenic excoriation. Other open trials and case studies report benefit from treatment with other SSRIs, such as sertraline and fluvoxamine, and the TCAs doxepin and clomipramine. SSRIs may be particularly effective in patients with prominent compulsive features, comorbid mood disorders, and anxiety disorders. Naltrexone at a dose of 50 mg per day has shown efficacy in reducing the psychogenic excoriation associated with pruritus. However, many patients with excoriation experienced increased pain with naltrexone treatment-limiting its value. Other case reports suggest neuroleptics such as pimozide, aripiprazole, and olanzapine may be of use. Patients with predominantly impulsive features or co-occurring bipolar disorder may benefit from anticonvulsants such as lamotrigine or divalproex or from atypical neuroleptics such as olanzapine. In one study, lamotrigine was associated with improvements in two-thirds of subjects with pathologic skin picking. A systematic review and meta-analysis of psychiatric treatments for SPD

found a strong effect size for SSRIs, lamotrigine, and behavioral therapy. CBT and HRT have shown benefits in this cohort.

Body Dysmorphic Disorder. Prior to DSM-5, BDD had been categorized as a somatoform disorder but is now grouped under OCRD because of evidence of a relationship of BDD to obsessive-compulsive spectrum disorders.

Table 27.12–5.
DSM-5 Diagnostic Criteria for Body Dysmorphic Disorder

A. Preoccupation with one or more perceived defects or flaws in physical appearance that are not observable or appear only slight to others.
B. At some point during the course of the disorder, the individual has performed "repetitive behaviors (e.g., mirror checking, excessive grooming, skin picking, or reassurance seeking) or mental acts (e.g., comparing his or her appearance with that of others) in response to the appearance concerns." (Gupta and Gupta, 2014, p. 453)
C. The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The appearance preoccupation is not better explained by concerns with body fat or weight in an individual whose symptoms meet diagnostic criteria for an eating disorder.

Specify if:

With muscle dysmorphia: The individual is preoccupied with the idea that his or her body build is too small or insufficiently muscular. This specifier is used even if the individual is preoccupied with other body areas, which is often the case.

Specify if:

Indicate degree of insight regarding body dysmorphic disorder beliefs (e.g., "I look ugly" or "I look deformed").

With good or fair insight: The individual recognizes that the body dysmorphic disorder beliefs are definitely or probably not true or that they may or may not be true.

With poor insight: The individual thinks that the body dysmorphic disorder beliefs are probably true.

With absent insight/delusional beliefs: The individual is completely convinced that the body dysmorphic disorder beliefs are true.

DIAGNOSIS. Table 27.12–5 lists the DSM-5 criteria for BDD. DSM-5-TR, allows for a further specifier indicating the degree of insight regarding

BDD: “with good or fair insight,” “with poor insight,” and “with absent insight/delusional beliefs.”

CLINICAL FEATURES. When BDD involves concern about skin, patients typically present with imagined or slight flaws in one or more body areas. Typically these include the skin, hair, or nose. In the case of the skin, concerns can range from perceived acne or scars, to winkles or other skin lines or a pale complexion. BDD usually manifests during adolescence and has equal sex distribution. Patients with BDD engage in various time-consuming activities to improve the perceived defect, such as camouflaging, mirror checking, comparing with others, questioning, and reassurance seeking. Some patients go through several cosmetic and surgical procedures for their perceived defects. The functional impairment and distress expressed by the patients with BDD include severe depression and low self-esteem, anxiety, social isolation, and work-related problems. BDD is associated with a high rate of suicidal ideation and suicide attempts, especially among adolescents with severe acne. The shame and humiliation associated with BDD play a major role in the underreporting of this disorder.

A largely unexplored phenomenon of disturbed CBI that may represent a specific subtype of BDD is the longstanding practice of skin-bleaching. The desire for fair skin is not uncommon in men and women of Asian and African descent (especially in Fitzpatrick skin types IV-VI) who may be influenced by a society flooded with billboards of predominantly “light-skinned” Bollywood stars and widespread use of skin-lightening creams and cosmetics. Children with darker skin are subject to ridicule—contributing to a disturbed sense of self due to an unrealistic, Eurocentric beauty standard. With the use of skin-lightening practices—from bleaching creams to off-label IV glutathione treatments—this focus on skin tone perpetuates both dangerous skincare practice and mental illness. Beyond the physical consequences associated with unregulated skin-bleaching agents, there is a need to address the cultural, psychiatric, and ethical considerations of skin-lightening practices. As part of a multidisciplinary approach to care, dermatologists should continue to assess CBI as an important component of patient history while screening for potential comorbid psychiatric diagnoses in patients concerned with skin tone. Studies have reported an increased incidence of BDD and

major depressive disorder with seasonal pattern in individuals who engage in frequent tanning practices.

TREATMENT. The prevalence of BDD has been reported as 9% to 15% among dermatology patients and 7% to 8% among cosmetic surgery patients in the United States. Studies suggest that more than 60% of individuals with DSM-defined BDD seek nonpsychiatric medical/surgical treatment, most often resulting in no change in their preoccupation with their perceived flaws. This has important implications in dermatology, as clinical treatment guidelines for dermatologic disorders increasingly emphasize the importance of assessing psychosocial comorbidity, including aspects of CBI (cutaneous body image), in order to achieve optimal treatment outcomes. Convincing patients with BDD to engage in psychiatric treatment can be challenging, and an empathic understanding and establishment of good therapeutic rapport on the part of the clinician are crucial. The efficacy of CBT with a focus on cognitive restructuring has been well-demonstrated. SSRIs are the drug of choice in the treatment of BDD, though studies suggest that individuals with BDD require longer trial durations (mean response time of 6 to 9 weeks) with relatively higher doses of SSRIs. A large study of TCAs has shown a significantly better efficacy for clomipramine when compared to desipramine.

Unspecified OCRDs: Body-Focused Repetitive Behaviors

CLINICAL FEATURES AND EPIDEMIOLOGY. Onychophagia (or chronic nail-biting) is a disorder affecting 20% to 30% of the general population and is common among children, beginning as early as 4 years of age and peaking during the teenage years. Females are more commonly affected than males. A progressive decline in nail-biting after the age of 40 has been described. Patients with onychophagia have clinical features of repetition, resistance, and relief, comparable to hair-pulling and skin picking. Patients with severe and chronic onychophagia can experience significant dental and medical problems, such as hand infections and mandibular deformities. Co-occurring thumb sucking is also frequent. Onychophagia behavior is usually increased during periods of conflict or stress.

DIAGNOSIS. The DSM-5 provides limited diagnostic criteria for unspecified OCRDs, describing instead presentations of symptoms characteristic of

an OCD but not meeting full criteria for a more specific diagnosis. Thus, diagnostic features might be considered to include repetitive behaviors that are refractory to attempts to stop or cut down and produce some degree of functional impairment.

TREATMENT. Behavioral treatments, like habit reversal interventions, have demonstrated the greatest efficacy in treating this disorder. Other trials have seen some success with mild aversive techniques (such as the use of distasteful lacquer) and utilizing a nonremovable reminder (such as a wristband), though significant improvement was only seen when performed in conjunction with self-recording and physician visits.

Factitious Disorders

Dermatitis Artefacta. Dermatitis artefacta (DA) or factitious dermatitis is a disorder in which skin is the target of self-inflicted injury, and the patient uses more elaborate methods than simple excoriation to self-induce skin lesions.

CLINICAL FEATURES. DA can present as an aggravation of dermatosis, with a variety of skin lesions, including blisters, ulcers, erythema, edema, purpura, and sinuses. The morphology of DA lesions is often bizarre and linear, with clear-cut, angulated, or geometric edges. The presence of completely normal, unaffected skin adjacent to horrific-looking lesions is a valuable clue in the diagnosis of factitious dermatitis. Skin damage can be extensive, with full-thickness skin loss and severe scarring requiring plastic surgery (Fig. 27.12–4). The patient's description of the history of the skin lesions is usually vague, lacking detail about their appearance and evolution over time. The natural progression of lesions through different stages of development (as one might expect in a typical dermatosis) is typically absent. DA lesions are usually located in areas easily reached by the dominant hand. Patients with DA are seemingly unmoved by disfiguring and painful lesions and typically deny any role in their causation. This condition has been reported in 3% of dermatology patients with a female-to-male ratio as high as 8 to 1. It can present at any age but occurs most frequently in adolescents and young adults. Those with DA often have a history of other psychosomatic illnesses, have had multiple consultations with physicians, and have trialed multiple "ineffective" treatments. The course of this disorder varies from a brief

episode to a lifelong behavior; one study reported that 30% of factitious dermatitis patients continued to present with lesions over 12 years or more.

PSYCHIATRIC COMORBIDITY. DA has been associated with several psychiatric disorders (besides a primary factitious etiology), with borderline and histrionic disorders being the most commonly reported. Other reported co-occurring conditions include schizoaffective disorder, adjustment disorder, major depressive disorders, PTSD, DP, intellectual disability, pervasive developmental disorders, and use of alcohol, cocaine, or lysergic acid diethylamide (LSD). Patients with factious disorders may have a history of contact with multiple health care services and carry a volume of medical notes. These patients are often aware of their impulsive acts in the context of emotional and relational instability, which may resemble symptoms of obsessive-compulsive spectrum disorders. Factitious dermatitis may have a connection with body image disturbance as a sequela of BDD. A patient with severe BDD focused on the skin may pursue requests for incisive dermatologic treatments or cosmetic surgery and, when denied access to such treatments, may take the initiative to "self-treat," resulting in now "real" pathology.

FIGURE 27.12–4. Picture of a patient with dermatitis artefacta: self-inflicted sharp, rounded lesions on the forearm made with a razor during times of stress and emotional dysregulation.

TREATMENT. There are no controlled trials for the treatment of DA. Patients commonly refuse referral to psychiatry, and direct confrontation may jeopardize the doctor–patient relationship. An effort to develop an empathic therapeutic relationship between the dermatologist and the patient is critical to the management of these patients. Once such a therapeutic relationship is established, some patients may accept appropriate therapeutic approaches and psychiatric referrals.

Psychogenic Purpura

Psychogenic purpura (Gardner–Diamond syndrome), also known as autoerythrocyte sensitization syndrome, is an extremely rare condition typically noted in women with other psychiatric diagnoses.

Clinical Features. Psychogenic purpura is regarded primarily as an autoimmune vasculopathy with sensitization to phosphatidylserine, a component of erythrocyte stroma. Presentation typically involves spontaneous development of painful edematous skin lesions generally following severe stress or emotional trauma. These predominantly occur in the extremities, may be isolated or multiple, and progress to ecchymoses over the next 24 hours. Associated initial symptoms include burning and pain followed by erythema, swelling, and pruritus. Medical work-up, including evaluation of hemostatic and blood coagulation function, is typically normal. The age of onset is variable, and women are affected more frequently.

Pathophysiology. A variety of mechanisms of psychogenic purpura have been proposed, including autoerythrocyte sensitization, conversion reaction, and factitious disorder. The evidence for autoerythrocyte sensitization is very limited. The psychogenic cause of purpura has been supported by some studies because of the association between psychosocial stress and lesion occurrence. Most patients also have multiple other unexplained somatic symptoms and significant psychiatric comorbidity–with generalized anxiety disorder, major depressive disorder, and borderline personality disorder among the most common diagnoses.

Treatment. There is no specific treatment for psychogenic purpura, though symptomatic treatment with antihistamines, corticosteroids, antidepressants, or hormones may be provided for severe general

symptoms. Psychotherapy has shown some benefit in reducing stress-associated lesions.

Unspecified Somatic Symptom and Related Disorder

Pruritus and Chronic Idiopathic Pruritus (also known as Chronic Pruritus of Unknown Origin). Pruritus is a common unpleasant sensation that provokes a desire to scratch. It is a common observation that "itch" can be induced simply by thinking about it. Many patients with chronic pruritus experience scratching as an automatic response to the sensation of itch. Scratching provides immediate relief of discomfort, perhaps even serving to reduce inner tension, and this negative reinforcement leads to conditioned scratching. This culminates in a self-perpetuating cycle of itch-and-scratch, which may prompt a sense of loss of control and feelings of helplessness often accompanied by despondency and guilt.

PATHOPHYSIOLOGY. The epidermis is heavily innervated by axonal nerve endings with nociceptive (pain-sensing) unmyelinated C-fibers (Fig. 27.12–5). The sensation of an itch is mediated by specific nociceptive unmyelinated C-fibers modulated by itch-specific C-receptors. D. Andrew described a separate itch pathway by identifying a "second-order histamine-specific itch neuron" in the dorsal horn of the spinal cord implicated in neuropathic itch syndromes. Signal from the dorsal horn is carried by spinothalamic tract projecting to the thalamus and on to the anterior cingulate cortex, and the insula. The cingulate cortex is an important area in the processing of itch and became significantly activated in patients with AD after administration of histamine. Moreover, the degree of its activation correlated with disease severity and deactivation occurred after scratching in healthy controls. The insula is the seat of *interoceptive representation* and underpins the basis of subjective feelings from all sensory input from the body. Activation of the insular cortex has been reported with skin sensations including pain, itch, touch, temperature, and prickliness. The anterior cortex is known to be involved in the modulation of emotional and cognitive activity (such as reward anticipation). This may provide the neurophysiologic basis for why individuals with difficulties in emotional regulation and interoceptive awareness can engage in body-based repetitive behaviors and thus how emotional factors can affect the perception and processing of itch.

A number of chemicals can provoke or enhance pruritus, including histamine, prostaglandins, proteinases, substance P (SP), neuropeptides (NPs), cytokines, and bile salts. Some of these substances act directly on the free nerve endings, while others act through their action on mast or other cells. Among prostaglandins, PGE-2 does not itself cause itch but lowers the threshold and potentiates the itch provoked by histamine. Endogenous opioids, such as endorphin, met-enkephalin, and leu-enkephalin, can play a role in causing itch by either central or peripheral action. One PET imaging study demonstrated that intracutaneous injection of histamine activated the premotor area and inferior parietal lobule–regions involved in planned movement. One large population study demonstrated a significant correlation between mental stress and itch. Psychological factors such as depression can modulate histamine-induced pruritus by lowering the itch threshold, and the severity of pruritus has also been correlated with the degree of depressive symptoms. Studies further suggest that the presence of marked circulating blood or tissue eosinophilia among patients specifically diagnosed with chronic pruritus of unknown origin should determine treatment choice between immunomodulation or gabapentinoids.

FIGURE 27.12–5. Hypothetical outline of the pathogenesis of atopic dermatitis (AD) correlated with the possible influence of emotional stress (*dotted lines*). SP, substance P; VIP, vasoactive intestinal peptide; CGRP, calcitonin gene-related peptide; Ig, immunoglobulin; H2, type 2 receptors for histamine; PGE, prostaglandin E. (Adapted from Panconesi E, Hautmann G. Psychophysiology of stress in dermatology. The psychobiologic pattern of psychosomatics. *Dermatol Clin.* 1996;14(3):399–421. doi:10.1016/S0733-8635(05)70368-5.)

Chronic idiopathic pruritus has been linked to a wide range of etiologies, including cutaneous, systemic, neurologic, and psychiatric causes. Evaluation of a patient with pruritus should always involve a careful

examination and medical work-up to rule out any condition that may be treatable.

- *Medical conditions associated with pruritus* include chronic lymphocytic leukemia, polycythemia vera, malignant melanoma, syphilis, congestive heart failure, diabetes mellitus, vitamin B_{12} deficiency, pellagra, myxedema, hyperparathyroidism, chronic renal failure, hepatic disease, acquired immunodeficiency virus (AIDS), drug toxicity, and old age.
- *Associated neurologic conditions with pruritus* include dementia, multiple sclerosis, Parkinson disease, Huntington disease, neurofibromatosis, aneurysm, cerebral infarctions, and CNS tumors.
- *Psychogenic pruritus* is often associated with anxiety disorders, OCD, major depression, or psychosis. Chronic idiopathic pruritus, idiopathic pruritus ani (itching of the anal area), pruritus vulvae (itching of the vaginal area), and pruritus scroti (itching of the scrotum) may be the result of a central mechanism. Itch in patients with psychiatric diseases is not uncommon. Idiopathic itch was found to affect 36% to 42% of psychiatric inpatients.

DIAGNOSIS. Several neurologic causes of pruritus may occur in the absence of primary skin lesions and should be considered in the evaluation of potential psychogenic pruritus. Psychogenic pruritus is characterized by: (1) temporal association with psychiatric symptoms; (2) absence of awakening from sleep or insomnia due to pruritus; and (3) paroxysmal nature with sudden onset and resolution of increased severity and intervening symptom-free periods. Both psychogenic and organic pruritus may coexist, resulting in a mixed clinical presentation.

TREATMENT. Doxepin has been used effectively in chronic idiopathic pruritus. Amitriptyline may work well in itching associated with pain. Case reports have indicated some efficacy for the SSRIs and mirtazapine in the treatment of psychogenic pruritus. Gabapentin has been shown to be effective for PN, neuropathic itch, and uremic pruritus. Aprepitant, a neurokinin receptor (NKR)-1 (a receptor for SP—an important itch mediator) antagonist that has been used as an antiemetic, has been reported to be effective for chronic refractory pruritus. CBT and HBT can prevent the long-term complications of itching (such as lichen simplex chronicus) by interrupting the itch-scratch cycle. Some reports document

the successful use of naltrexone as an antipruritic agent and demonstrated success with intranasal butorphanol (an opioid receptor agonist-antagonist) as a rescue therapy for chronic intractable itch.

Somatic Symptom Disorder, with Predominant Pain

Glossodynia. Patients with *glossodynia* present with chronic pain or burning affecting the tongue (or other areas inside the oral cavity). Other associated sensory changes may include paresthesia, changes in taste and smell, and mouth dryness. Glossodynia typically affects women, is most frequently reported in the sixth decade of life, and is observed in over 5% of patients seen by dentists. The condition is usually idiopathic, but glossodynia may be caused by vitamin B deficiencies, diabetes mellitus, candida glossitis, hormonal changes around menopause, salivary disturbances, and problems related to dentures or dental fillings. While higher rates of anxiety and depression are reported in patients with glossodynia, any causal relationship remains undefined. The duration of glossodynia is variable and may last for years.

Vulvodynia. The term vulvodynia is defined as “chronic vulvar discomfort with abnormal sensations” in the absence of skin disease or infection. A prevalence of 15% among patients of gynecologic outpatient practices has been reported. Most women with this disorder are between 20 and 50 years of age and have had pain for several years by the time they present for treatment. Women with vulvodynia are usually sensitive to touch or light pressure in the vestibule of the vagina, have pelvic floor musculature with altered contractile characteristics, and may also have heightened pain sensitivity in their arms or legs. There is growing consensus that vulvodynia is a chronic pain disorder. Vulvodynia patients experience sexual dysfunction as a result of their primary symptoms. The associated symptoms of allodynia (pain elicited by a nonpainful stimulus) and *hyperdynia* (when a stimulus causes greater pain than expected) suggest a neuropathic cause. The term *dysesthetic vulvodynia* is used to describe increased pain perception in the vulvar area without a known cause and may be of central or nerve root origin. This condition often occurs in perimenopausal or postmenopausal women, and they have fewer symptoms of dyspareunia and less point tenderness on examination than the “classic” vulvodynia cohort.

DIAGNOSIS. While somatization appears to be an important factor in cutaneous sensory syndrome patients and higher rates of anxiety and depression are found in this population, cutaneous sensory disorders are not specified in DSM-5. A comprehensive medical, neurologic, and psychiatric work-up should be performed to exclude any organic pathology.

TREATMENT. Once the diagnosis is made, the physician should acknowledge and validate the patient's experiences and symptoms. Pharmacologic interventions target the sensations of pain both peripherally and centrally. TCAs (amitriptyline, desipramine), SSRIs, gabapentin, and pregabalin have been effective in therapeutic trials. There are several case reports and uncontrolled trials suggesting the efficacy of the SNRIs venlafaxine and duloxetine. Augmentation with antipsychotics may be used in refractory cases. Controlled studies of CBT and biofeedback training to reduce pelvic floor spasms have indicated that these treatments are effective in symptom reduction.

PRIMARY DERMATOLOGIC DISORDERS ASSOCIATED WITH PSYCHIATRIC SYMPTOMS

The following diagnoses encompass primary dermatologic conditions with secondary psychiatric disorders.

Alopecia Areata

AA is a common disease involving localized loss of hair in round or oval areas, without visible inflammation of the skin (Fig. 27.12–6).

FIGURE 27.12–6. Alopecia areata of scalp. Sharp outline, without scaling, erythema, atrophy, or exclamation point hair. (From Fleisher GR, Ludwig S, Baskin MN. *Atlas of Pediatric Emergency Medicine*. Lippincott Williams & Wilkins; 2004.)

Clinical Features. Breakage of the hair shaft results in characteristic "exclamation-mark" hairs. Any hair-bearing surface may be affected, but AA most frequently occurs on the scalp (70% to 90%), eyebrows (4%), eyelashes, and beard (28% in males). About 1% of the U.S. population has at least one episode of AA by age 50, with 60% of cases presenting before 20 years of age. AA accounts for 2% of new dermatology outpatient visits in the United States. Incidence is equal across the sexes. AA is a partial loss of hair; alopecia totalis is a total loss of scalp hair, and alopecia universalis is a total loss of hair on the scalp and body. The course of AA is variable; 30% of cases end in complete recovery while 20% to 30% never recover. Poor prognosis is associated with prepubertal

onset, atopy, rapid evolution of hair loss, nail dystrophy, and extensive hair loss.

Pathophysiology. The causes of AA remain unknown. Some evidence suggests that AA is a T-cell–mediated autoimmune condition that is most likely to occur in genetically predisposed individuals. There are associations between AA and autoimmune disorders such as Hashimoto thyroiditis (prevalence varies from 8% to 11.8%). The autoantibody response is heterogeneous and targets multiple structures of the anagen phase hair follicle. Whether these antibodies play a direct role in the pathogenesis or are epiphenomena is not yet known. There has been some investigation of how stress might precipitate AA. Acute stress leads to the release of corticotropin-releasing hormone (CRH) and activation of overexpressed type 2-β CRH receptors around the hair follicles, resulting in intense local inflammation. M. Toyoda and colleagues postulated a role for NPs in the pathogenesis of AA. SP is released by dermal nerve fibers around hair follicles, and their study revealed that SP and its degrading enzyme neural endopeptidase (NEP) were strongly expressed in affected hair follicles in the acute progressive as well as chronic stable phase of the disorder. It is possible that different pathogenic mechanisms may be involved in different subtypes of AA, leading to a variable prognosis.

Psychiatric Comorbidity. In a study of 294 patients with AA, the prevalence of major depression was 8.8%. Another study of 31 patients with AA found a 39% prevalence of major depression and a 79% lifetime prevalence for any psychiatric disorder. A study of 32 patients with AA reported a 66% prevalence of psychiatric disorders, including generalized anxiety disorder, adjustment disorder, and major depressive episodes. Patients with highly stress-reactive AA report more depressive symptoms than patients who deny an association of stress with their AA.

Treatment. The standard treatment of AA involves topical and intralesional steroid injections as well as systemic glucocorticoids. There are few studies involving psychiatric approaches to AA. In one randomized, double-blind, placebo-controlled trial, patients given imipramine at a dose of 75 mg per day had significantly more hair regrowth than those in the placebo arm. AA patients with comorbid major depression or anxiety disorders showed more improvement in AA symptoms when they were treated with SSRIs. Use of relaxation

techniques, stress management, and psychotherapy has been recommended for AA, but there are no data from controlled studies to support their efficacy.

Prurigo Nodularis

PN is a chronic, pruritic skin disease marked by numerous hyperkeratotic nodules symmetrically distributed across the trunk and extensor surfaces of the extremities. The severity can range from presentations of a few to more than one hundred nodules that develop in the setting of chronic, refractory pruritus.

Clinical Features. Though nodules can erupt across any region of the body, patients present to the clinic with “the butterfly sign” with sparing of skin on the upper back. Most PN lesions are anywhere from several millimeters to 2 cm in diameter and the result of a cycle of chronic itch followed by repeated scratching. PN most commonly affects adults in middle age and is more frequently diagnosed in females. It is a relatively rare condition with a prevalence of 72 per 100,000 and is 3.4 times more likely to present in Black as compared to White patients. It is common with concomitant AD and has been associated with both HIV and hepatitis C infection. Of note, PN can be the presenting symptom of hematologic malignancies, in which case improvement or the resolution of lesions is seen after cancer treatment.

Pathophysiology. Though the exact pathogenesis of PN remains unknown, studies have demonstrated that immune cells and altered neural circuitry are both involved in the pruritus associated with PN. Perivascular infiltrates in the dermis of PN lesions are marked by an increase in T lymphocytes, mast cells, and eosinophilic granulocytes. Levels of both IL-31 and IL-4 are increased in PN skin lesions. Several NPs, specifically calcitonin gene-related peptide (CGRP) and SP, have been implicated in disease pathogenesis. CGRP causes neurogenic inflammation and dysregulated expression of mu and kappa opioid receptors, likely contributing to the pruritus associated with PN.

Psychiatric Comorbidity. PN is commonly associated with increased rates of depression and anxiety. Increased rates of eating disorders, self-harm, attention-deficit/hyperactivity disorder (ADHD), and schizophrenia

have also been described in patients with PN. A national inpatient sample database study found longer inpatient stays and increased rates of psychiatric hospitalization in this patient population.

Treatment. Treatment of PN centers on breaking the itch-scratch cycle. Intralesional injections of triamcinolone acetonide (10 mg/mL) have been shown to improve PN lesions. High-potency topical corticosteroids can reduce pruritus and flatten nodules, while topical anesthetics such as 1% pramoxine lidocaine spray can provide modest itch relief. Medicated occlusive dressings also act as a barrier to excoriation. Other nonsteroid topical agents, including calcineurin inhibitors and topical capsaicin (0.025% to 0.3%), have demonstrated efficacy in the relief of itching and healing of nodules. Phototherapy, gabapentanoids, and systemic immunosuppressants (such as methotrexate and cyclosporine) also have reported benefits in the treatment of PN. Paroxetine, fluvoxamine, and duloxetine may also be successful in reducing pruritus associated with PN.

Vitiligo

Vitiligo is an acquired, autoimmune skin condition characterized by chronic depigmentation of the skin and mucosa. It is a disfiguring pigmentary disorder with a profound impact on quality of life due to social stigmatization. Misconceptions persist in some cultures that vitiligo is contagious and a sign of leprosy or sexually transmitted infection.

Clinical Features. Vitiligo has a global prevalence of 0.2% to 1.8%. Half of all cases have a childhood onset, but vitiligo may present throughout the lifespan. Females with vitiligo tend to have their first presentation earlier in life than their male counterparts. The condition is characterized by the development of well-circumscribed white macules and patches commonly seen on the face and acral regions. Vitiligo is typically otherwise asymptomatic, but lesions may itch and have a propensity to sunburn. Vitiligo is typically more noticeable in darker skin, and lesions commonly develop in areas of friction (Koebner phenomenon). Examination with a Wood lamp can be helpful in diagnosis.

Pathophysiology. Vitiligo results from the autoimmune destruction of melanocytes. Though the exact pathogenesis remains unknown, it is

thought that disease development may be associated with increased expression of interferon-gamma and tumor necrosis factor (TNF) alpha and decreased expression of tumor growth factor (TGF) beta. Antibodies against anti-inflammatory enzymes (like tyrosine hydroxylase) may also play a role. Increased levels of homocysteine (associated with increased inflammation) may predispose patients to the disease.

Psychiatric Comorbidity. Approximately 75% of vitiligo patients are reported to have a co-occurring psychiatric disorder, most frequently depression. One large-scale cohort study found that patients with vitiligo had a 2.9-fold increased risk for psychiatric disorders, with increased rates of OCD, anxiety, MDD, bipolar disorder, and schizophrenia. Acral (facial) vitiligo has the greatest association with psychiatric morbidity (87%), followed by generalized vitiligo (68%) and mucosal vitiligo (63%).

Treatment. Standard treatment for vitiligo consists of topical corticosteroids, calcineurin inhibitors, and phototherapy. Given the limited efficacy of these measures, treatment should focus on optimizing patient quality of life. CBT, peer support groups, and interventions targeting co-occurring psychiatric disorders can play a substantial role in the management of individuals with vitiligo.

PSYCHOPHYSIOLOGIC DISORDERS

These diagnoses describe skin diseases precipitated or exacerbated by psychological stress.

Acne

Clinical Features. Acne is an inflammation of the pilosebaceous glands mainly involving the face and trunk that most frequently occurs in adolescence and manifests as comedones (comedonal acne), papulopustules (papulopustular acne), or nodules and cysts (nodulocystic acne and acne conglobata) (Fig. 27.12–7). Possible complications such as pitted, depressed, or hypertrophic scars may result from all types, especially in nodulocystic and conglobata acne. It is a very common skin disorder among young people and usually begins at 10 to 17 years of age in females and 14 to 19 years in males. The course is usually self-limiting, and most individuals improve over a period of months to years. Acne may

persist into the third or fourth decade of life, especially in women. Genetic predisposition is multifactorial, and most patients with cystic acne have a family history of severe acne. Severe acne may be associated with XYY syndrome.

Pathophysiology. Acne results from changes in the keratinization pattern of sebaceous glands followed by dense keratin blocking the secretion of sebum. The keratin plugs are called *comedos,* and they cause collection of sebum within pilosebaceous units prompting complex interactions of androgens and bacteria (*Propionibacterium acne*) within the plugged sebaceous glands. Androgens stimulate the sebaceous glands to produce more sebum. Bacteria containing lipase breaks down lipids into fatty acids and produce proinflammatory mediators like IL-1 and TNF-α, which combine to cause a sterile inflammatory response. Ultimately, the distended follicle wall breaks, releasing the contents (sebum, lipids, fatty acids, keratin, and bacteria) into the dermis, invoking an inflammatory foreign body response resulting in the formation of pustules, nodules, and scarring. Patients with acne vulgaris frequently experience a stress-induced exacerbation of their acne lesions. This association is postulated to involve stress-induced activation of the hypothalamic–pituitary–adrenal (HPA) axis followed by increased secretion of glucocorticoids and androgens, exacerbating the inflammatory response within the pilosebaceous unit. Increased levels of anxiety in patients with cystic acne have been associated with higher blood catecholamine levels which then decrease with acne treatment.

FIGURE 27.12–7. Acne vulgaris, nodulocystic type, with nodules, cysts, and pustules. (The Barankin Collection. Wolters Kluwer, 2005.)

Psychiatric Comorbidity. Disfigurement from acne can lead to depression, social phobia, anger, and low self-esteem. One study reported a 5.6% prevalence of suicidal ideation in adolescents and young adults with noncystic facial acne. In a large study of 4,376 patients with dermatologic disorders, 53% of those with acne reported a close chronologic association between emotional stress and exacerbation of their acne lesions (with an average latency of 2 days). In a study of 317 students aged 14 to 16 years, those with significant (i.e., more than 12) lesions had higher levels of emotional and behavioral difficulties than those with minimal acne. In adolescence, acne can significantly interfere with social interactions, sports, academic performance, and dating behavior. There is a highly significant positive association between acne and poor self-image. In one study, patients' ratings of their acne were consistently more severe than ratings provided by a clinician, and the patients rated their treatment outcomes significantly less favorably than their treating dermatologist. Even mild-to-moderate acne has been associated with depression, suicidal ideation, and completed suicide. Often, the presence of a primary psychiatric disorder such as OCD, delusional disorder, or eating disorder can add to the severity and

chronicity of acne, as demonstrated in cases of acne *excoriée*, where the urge to persistently pick acne lesions results in severe disfigurement from scarring.

Treatment. Since younger patients with acne vulgaris have a higher risk of developing depression and suicidal ideation, it is important to educate and monitor each patient carefully. Treatment options for depression, anxiety, and social phobia in patients with acne include CBT, relaxation training, self-hypnosis, and pharmacotherapy if indicated. One study reported a greater degree of improvement in acne when the use of cognitive imagery and biofeedback relaxation was added to typical medical treatment, and discontinuation of such interventions led to a relapse in acne severity. There are case reports of improvement of acne after treatment of depression with paroxetine.

There has been extensive attention to the antiacne agent isotretinoin and its association with depression, suicidal ideation, and suicide attempts. An additional warning has been added to the psychiatric section of the package insert of the drug regarding aggressive or violent behaviors. A large epidemiologic study, however, failed to demonstrate a higher prevalence of depression and suicide in patients treated for acne with isotretinoin versus those treated with antibiotics. Design limitations of this and other studies preclude the establishment of firm conclusions about a possible causal relationship between isotretinoin and psychiatric pathology. A careful history will reveal whether or not an exacerbation of depressive symptoms is temporally related to initiating isotretinoin treatment. The acne patients with symptoms of depression should routinely be assessed for suicide risk regardless of the treatment employed.

Atopic Dermatitis/Eczema

Clinical Features. AD is a chronic inflammatory disease of the skin, characterized by pruritus, mild to severe erythema, scaling, excoriation, and lichenification of the skin (Fig. 27.12–8). AD typically begins in infancy or young childhood, presenting as erythematous and pruritic maculopapular eruptions. Subsequent rubbing and scratching leads to lichenification and further itching and scratching cycle (itch–scratch cycle). The pruriginous lichenoid papules and lichenification in flexor areas and hands become more prominent in adolescence and adulthood. Individuals

with AD may have a personal or family history of atopic disease (including allergic rhinitis, allergic conjunctivitis, bronchial asthma, or seasonal allergies). It is estimated that 1% to 3% of adults and 5% to 20% of children have AD. AD manifests in the first year of life in about 60% of cases and 30% in the subsequent 1 year. The clinical course of AD improves by puberty, and initial presentation is rare after puberty. Both sexes are affected, but boys are somewhat more afflicted during the infantile phase. The hygiene hypothesis proposes that a Western lifestyle with early exposure to psychosocial stress and reduced microbial exposure (from near-sterile food preparations and large-scale immunizations) affects the differentiation of T cells toward an atopic profile of predominant TH2 cells. A combination of early-onset severe dermatitis, comorbid asthma, or allergic rhinitis is often associated with disease chronicity.

FIGURE 27.12–8. Atopic dermatitis. Infantile-confluent erythema, microvesiculation, scaling, and crusting on face. (Reprinted with permission from Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders*. 2nd ed. Lippincott Williams & Wilkins; 2003.)

Pathophysiology. AD's pathophysiology involves multiple factors, including genetic, environmental, and psychosocial factors, which interact with underlying psychoneuroimmunologic mechanisms.

A genetic predisposition is implicated in the development of AD, and about two-thirds of patients have a positive family history of AD. The concordance rate for monozygotic twins (0.75) is higher than dizygotic (0.25) twins. Inheritance is considered to be polygenic and multifactorial. The inheritable traits of AD are thought to involve HPA axis abnormalities and an imbalance of the immunoregulatory T-lymphocyte system, leading to defective cell-mediated immunity and increased IgE production.

The psychosocial sequelae of AD have been described as including perceived maternal rejection and emotional separation from the mother from lack of early cutaneous stimulation, altered psychodynamics of the mother–child relationship, temperamental changes in AD infants, problems with self-esteem and relationships in childhood, and development of conflicted personality styles.

Psychiatric Comorbidity. Individuals with AD have been found to have increased rates of anxiety and depression. Scheich and colleagues reported that AD patients have higher traits of excitability and inadequate stress coping mechanisms, with these traits being particularly prominent in those with serum IgE levels greater than 100 IU/mL. M. Hashiro and M. Okumura examined immunologic markers and found that NK-cell activity and IL-4 levels are lower in AD patients with depression or anxiety, and IFN-γ levels are higher in AD patients than in controls. Decreased NK-cell activity is more strongly correlated with higher levels of anxiety. The severity of pruritus was directly correlated with the severity of depressive symptoms in AD patients, which is consistent with findings that depression and anxiety can magnify the itch perception and enhance scratching behavior. Higher anxiety levels in AD patients are correlated with ease of conditioning to develop an itch-scratch response. The emotional state of children with AD varies closely with the severity of the dermatitis. Adult patients with AD have been reported to have chronic anxiety disorders and a tendency to internalize anger.

Treatment. The role of psychiatric treatment in patients with AD includes reduction of itching and scratching and treatment of associated anxiety and depressive symptoms. Behavioral modalities focus on interrupting the itch–scratch cycle (HRT). Controlled trials found that topical 5% doxepin cream was effective in reducing pruritus because of its potent antihistaminic action. Trimipramine, which also features histamine antagonism, has been shown to improve sleep quality and reduce nighttime scratching in AD patients.

One meta-analysis examined various psychotherapeutic approaches (including CBT, relaxation training, meditation, and stress management) with respect to skin condition and subjective well-being. These treatments were significantly more effective than standard somatic treatments used alone and were effective in reducing anxiety, depression, and neuroticism. Combinations of psychotherapeutic interventions resulted in a reduction of

the itch–scratch cycle, less use of local and systemic steroids, and longer periods of remission.

Psoriasis

The writer John Updike, who had psoriasis, poignantly wrote: “I am silvery, scaly. Puddles of flakes form wherever I rest my flesh. Lusty, though we are loathsome to love. Keen-sighted, though we hate to look upon ourselves. The name of the disease, spiritually speaking, is Humiliation.”

Clinical Features. Psoriasis is a chronic, relapsing skin disease presenting with erythematous, scaling papules and indurated plaques, arising preferentially on the elbows, knees, and scalp (Fig. 27.12–9). The clinical presentation takes various forms, sometimes causing nail dystrophies and arthritis. It affects 1.5% to 2% of the population in Western countries, with 3 to 5 million people with psoriasis in the United States. Psoriasis is hereditary, with an age of onset mostly in the early 20s. Childhood-onset predicts a severe and chronic course and is usually associated with a positive family history. Common trigger factors include physical trauma (Koebner phenomenon: rubbing and scratching stimulate the psoriatic proliferative process), acute bacterial or viral infections, and drugs like lithium, antimalarials, interferon, oral alcohol, β-adrenergic blockers, and the withdrawal of corticosteroids. Psychological stress is another reported trigger of exacerbations of psoriasis, with one large study reporting that 33% of patients noticed new lesions at times of distress. Another investigation of 536 patients found that 42% of them reported worrying was associated with exacerbation of their lesions, with the majority of those specifically noting the disease-related stress from cosmetic disfigurement and social stigma as more impactful than stressful major life events.

FIGURE 27.12–9. Psoriasis vulgaris, chronic stable type. Multiple large scaling plaques on the legs. (Reprinted with permission from Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders*. 2nd ed. Lippincott Williams & Wilkins; 2003.)

Pathophysiology. Psoriasis plaques are produced largely by the activity of hypertrophic keratinocytes (multiplying approximately 28 times faster than normal skin) and inflammatory changes in the dermis. Histologic markers include capillary dilatation, sterile microabscesses, parakeratosis, and hyperproliferation of cutaneous nerves. The *neurogenic inflammation* hypothesis of psoriasis describes central roles for NPs like SP and nerve growth factor (NGF). SP and other NPs are released from the unmyelinated terminals of sensory fibers in the skin and generate local neurogenic inflammation in genetically predisposed individuals. Both lesional and symptomless psoriatic skin have been found to have increased numbers of neural filaments containing NPs like SP, vasoactive intestinal peptide (VIP), and CGRP. The specific effects of NPs on target cells in psoriasis are listed in Table 27.12–6.

Increased levels of SP both centrally and peripherally have been associated with increased levels of stress. Descending autonomic pathways via the dorsal root ganglia in the spinal cord can stimulate the further release of cutaneous NPs through SP-containing neurons. There is evidence for higher NGF levels in response to stress, which plays a central role in regulating skin innervation and upregulating NPs. Several studies indicate that increased expression of NGF in keratinocytes may be an early event in the pathogenesis of psoriasis. NGF stimulates T-lymphocyte proliferation and mast cell degranulation and induces expression of a potent chemokine RANTES, which has chemotactic effects on resting $CD4^+$ memory T cells and memory T cells.

There has been significant attention to the role of T lymphocytes in the pathogenesis of psoriasis, but the role of autoimmune inflammation in the pathogenesis of psoriasis remains controversial. The T-cell paradigm alone does not explain some of the important clinical features of psoriasis, including the Koebner phenomenon, the symmetrical distribution of lesions, and increased nerve density and NP expression in psoriatic lesions.

Table 27.12–6.
Neuropeptides and Their Effects on the Various Skin Cells

Target Cells	Neuropeptides		
	SP	CGRP	VIP
Endothelial	Proliferation, ↑ permeability	Proliferation, IL-8 secretion	Proliferation
Keratinocyte	Stimulates IL-1, IL-8, comitogen with CGRP, LTB4	Proliferation in association with SP	Mitogenic proliferation
Lymphocyte	Stimulates proliferation and synthesis of IL-2, ↑ IgA and IgM, B-cell differentiation	Chemotactic T-cell proliferation	Inhibits NK-cell activity
Macrophage	Stimulates IL-1, IL-6 secretion	Impairs antigen presentation	—
Mast cell	Proliferation, histamine and TNF-α release	Degranulation: histamine release	Histamine release
Monocyte	↑ Chemotaxis, phagocytosis, arachidonic acid synthesis	—	Enhanced migration
Neutrophil	Stimulates chemotaxis, phagocytosis	Enhances chemotaxis	—

↑, increase; SP, substance P; VIP, vasoactive intestinal peptide; CGRP, calcitonin gene-related peptide; Ig, immunoglobulin; IL, interleukin; NK, natural killer; TNF-α, tumor necrosis factor α.

Psychiatric Comorbidity. Patients with psoriasis have been reported to have higher prevalences of generalized anxiety disorder, major depressive disorder, and personality disorders. Suicidal ideation was

reported in 7.2% of severely affected psoriasis inpatients versus 2.5% among less severely affected outpatients. Psoriasis-related stress has been associated with greater psychiatric comorbidity. Social deprivation and the experience of stigmatization were found to be correlated with higher depression scores. Adult psoriasis patients who experienced touch deprivation in social interactions had higher depression scores compared to those who did not perceive touch deprivation. The severity of pruritus is also associated with higher depression scores and a greater risk for suicide, with amelioration of pruritus associated with a decrease in depression scores. Early-onset psoriasis has been associated with greater difficulties with the expression of anger, a trait that may result in increased vulnerability to stress and depression.

Treatment. The therapeutic modalities with evidence for significant clinical improvement in patients with psoriasis include arousal reduction techniques like hypnosis, mindfulness meditation, and guided imagery training. CBT may be of specific value in addressing illness perceptions, including beliefs about the control and curability of illness. Data from controlled trials investigating the effects of psychopharmacologic interventions in psoriasis are quite limited. TNF-α antagonists are safe and effective in improving both the physical severity of psoriasis and quality of life. Depression is also associated with increased levels of TNF-α, and it is speculated that it may have a role in the fatigue and sleep disturbances seen in depression. The TNF-α antagonist adalimumab has been shown to improve depressive symptoms and fatigue in patients with psoriasis. Reduction in anxiety and depression scores has also been reported with the use of ustekinumab (an anti-IL-12/23 agent used to treat psoriasis). Psychotropic medications should be used with some caution in patients with psoriasis due to several conflicting case reports of induction or exacerbation of psoriasis with the use of fluoxetine and bupropion. Lithium is well-associated with precipitation or aggravation of psoriasis and should be avoided.

Telogen Effluvium

Clinical Features. Telogen effluvium (TE) is a scalp disorder characterized by the excessive shedding of hair in response to a variety of triggers, including drugs, trauma, and emotional or physiologic stress. The time between trigger exposure and hair loss is typically 8 to 12 weeks,

differentiating this diagnosis from anagen effluvium, which describes the more immediate hair loss seen in response to some drugs, including cancer chemotherapeutic agents. It is also one of the most common causes of alopecia with trichodynia, a painful sensation of the scalp without underlying cutaneous disease. Diagnostic tests include the “hair wash test” (where after a period of abstaining from hair washing, the hair is washed and any shed hairs are trapped and assessed for quantity and length), trichograms (hair is plucked and microscopically examined), phototrichograms (hair in a 2 cm^2 area is clipped to a length of 1 mm and serial weekly photographs are used to monitor growth) and scalp biopsy.

Pathophysiology. Hair shedding in TE can be attributed to a variety of potential changes in the hair follicle growth cycle. In some instances, hair follicles leave the anagen phase prematurely, resulting in increased shedding 2 to 3 months later. In other cases, the anagen stage becomes delayed, resulting in heavier than normal telogen shedding. Drugs such as oral contraceptive pills, retinoids, β-blockers, ACE inhibitors, heparin, anticonvulsants, and antidepressants have all been associated with TE—usually 12 weeks after starting the regimen. A variety of stressors have been linked to TE, including psychological stress, surgery, childbirth, and jet lag. Severe deficiencies of zinc or vitamin D decreased iron stores, and calorie restriction have also been reported to trigger TE.

Psychiatric Comorbidity. One study found that 76.5% of patients with TE had symptoms of psychiatric illness. Trichodynia is commonly associated with TE and is also associated with depression, anxiety disorders, dysthymic disorder, and OCD. Disturbances in sleep have also been linked to TE.

Treatment. Effective treatment of TE hinges on the identification and elimination of the trigger. Minoxidil and finasteride are commonly used but have minimal efficacy. Topical corticosteroids can be effective in decreasing trichodynia associated with TE, and systemic corticosteroids can be employed in cases of TE associated with underlying systemic disorders. If a measurable nutritional deficiency is detected, it should be corrected with supplementation, a balanced diet, and stabilization of body weight. Clinicians may recommend meditation, yoga, or mindfulness exercises to address psychological stress, but there are not yet controlled

data to support therapeutic efficacy vis-à-vis hair loss. TE is ultimately self-limiting and will not result in complete baldness.

Urticaria and Angioedema

Clinical Features. Urticaria is composed of wheals (hives) which are characterized by transient, well-circumscribed edematous papules and plaques that are usually pruritic and involve the superficial (papillary) dermis. Angioedema describes a large, deep, ill-defined edematous area involving the dermis and subcutaneous tissue. Thus, urticaria and angioedema are the same edematous process involving different levels of the cutaneous vascular plexus. Fifteen to 23% of the population may have a lifetime occurrence of this condition, with a chronic course in about 25% of the cases. *Acute urticaria* has a sudden onset with frequent recurrence within 30 days. It usually presents with large wheals, often associated with angioedema. Acute urticaria is IgE-dependent and associated with common triggers such as alimentary parasites, infection, and intolerance to some drugs or food. Urticaria reactions are mediated by vasoactive mediators in the skin, such as histamine from mast cells and basophils. *Chronic urticaria* has a recurring pattern over more than 30 days and presents with both small and large wheals. These wheals are *rarely* IgE-dependent but are often due to anti-FcεR and/or anti-IgE autoantibodies, suggesting autoimmune pathogenesis. Since an etiology is unknown in 80% of cases, the condition is considered idiopathic. Chronic urticaria predominantly affects adults and is twice as common in women as in men. About 40% of patients with chronic urticaria persisting for more than 6 months will continue to have urticaria for 10 years or longer with a serious compromise of quality of life.

Pathophysiology. Urticaria and angioedema can be subcategorized on the basis of etiology, including *immunologic* (IgE-mediated, complement-mediated, autoimmune, immune contact type), *physical* (friction-induced “dermographism,” cold urticaria, solar, cholinergic, pressure angioedema, vibratory angioedema), *idiopathic*, and *hereditary angioedema*. Of particular interest is adrenergic urticaria, presenting as typical “halo-hives” (papules surrounded by a white halo), which develop in response to acute emotional stress and are usually associated with increased plasma levels of epinephrine and norepinephrine. Adrenergic urticaria improves after

treatment with β-blockers such as propranolol and can be induced by intradermal injection of norepinephrine.

Psychiatric Comorbidity. The role of psychological factors in chronic idiopathic urticaria is unclear. One study reported higher prevalences of depression and anxiety in women with chronic urticaria. Historically, angioedema has also been referred to as “angioneurotic edema” because of the frequent clinical observation that stressful events preceded its onset. The physiologic basis for stress-induced urticaria and angioedema is likely to involve secretion of NPs, such as VIP and SP, resulting in vasodilatation and urticarial wheal formation.

Treatment. In urticaria with a known trigger, treatment includes the prevention of future attacks by avoiding exposure to that agent. Controlled trials have indicated that antidepressants like doxepin (10 mg three times a day) are more effective than diphenhydramine (25 mg three times a day) in managing chronic angioedema. There are anecdotal reports of improvement in urticaria symptoms with the use of SSRIs in patients with urticaria and co-occurring panic disorder. One controlled study found that hypnosis and relaxation reduced the subjective sense of pruritus in cases of urticaria but did not affect the number of wheals.

SLEEP, CIRCADIAN RHYTHMS, AND SKIN

Sleep is vital to the growth and renewal of multiple physiologic systems. From a dermatologic perspective, chronic poor sleep quality is associated with increased signs of intrinsic skin aging, diminished skin barrier function, and lower satisfaction with appearance. Slow-wave sleep stimulates the release of growth hormone and promotes normal tissue repair.

The human sleep–wake cycle is tightly coupled to the circadian course of *core body temperature*. Heat loss in the evening, via distal skin regions, is intimately associated with sleepiness and ease of sleep initiation. The preoptic anterior hypothalamus (POAH) region of the brain is the main integrator of sleep and thermoregulation. If thermoregulatory function is impaired as a result of a skin disorder and heat is not dissipated normally, sleep onset may be prolonged, resulting in a decline in restorative sleep and subsequent risk of poor health outcomes.

The stratum corneum is the outermost layer of the epidermis. It undergoes circadian changes in its permeability, with higher permeability in the evening. Aquaporin-3 is protein found in the collecting duct cells of the epidermis, allowing water to exit cells. It is regulated by molecular clocks, and more active in the evening, resulting in increased pruritus at night.

In addition to Aquaporin-3, several other factors may contribute to nocturnal pruritus, including peripherial vasodilation at night with an consequential increase in skin temperature. Corticosteroids also have a circadian pattern and release of these is decreased at night; the result is a decreased anti-inflammatory response and associated pruritus. Prostaglandin D2 and E2 are elevated at night, and may also exacerbate pruritus. Many other substances, such as cytokines, NGF, and endogenous opioids, all which have circadian patterns, may also influence pruritus.

DERMATOLOGIC SIDE EFFECTS OF PSYCHOTROPIC MEDICATIONS

Dermatologic side effects of psychotropic medications are fairly common though the majority of them are benign and easily treatable. Most drug reactions are hypersensitivity reactions with an underlying immunologic mechanism; however, some reactions are attributed to cumulative dose, drug overdose, and drug–drug reactions. Dermatologic side effects of psychotropic medications are summarized in Table 27.12–7.

When categorizing dermatologic side effects, it is valuable to consider potential mechanisms responsible for the cutaneous pathology. Most common are Type A drug reactions (e.g., phototoxic reactions, anticholinergic effects, or extrapyramidal effects), which are due to the pharmacologic or toxic effects of the drug. They are well-defined adverse reactions that can be predicted to occur in a segment of the population exposed to the drug and are frequently dose-dependent. Type B drug reactions, on the other hand, are far less common and less predictable. Those experiencing them may have an innate predisposition for the reaction due to their genetic or metabolic makeup. Type B reactions are immunologically mediated (usually type I or IV hypersensitivities) and are thus largely unpredictable and not dose-dependent.

Risk factors associated with cutaneous drug reactions include female sex, HLA subtype, African American ethnicity, winter season, increased age, active substance abuse, and a high-loading dose on initiation of the drug. The amount and the rate of administration may also influence the likelihood of an adverse cutaneous reaction. Up to 95% of cutaneous drug reactions present with erythematous macules and papules (an exanthematous eruption) within 10 days of starting treatment. Steven–Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and drug-induced hypersensitivity syndrome (DIHS) are relatively rare reactions to psychotropics but are true dermatologic emergencies that require immediate recognition to allow for timely discontinuation of the offending agent. Other less important but noteworthy reactions include photosensitivity, pigmentation reactions, acneiform eruptions, lichenoid reactions, alopecia, erythema multiforme, and cutaneous pseudolymphoma.

Table 27.12–7.
Dermatologic Adverse Effects of Psychotropic Medications

Drugs	Skin Adverse Effects
MOOD STABILIZERS	
Lithium	Hair loss, acne, nail pigmentation, exacerbation of psoriasis
Valproic acid	Hair loss, hair color change, lupus, scleroderma, skin vasculitis
Lamotrigine	Stevens–Johnson syndrome, toxic epidermal necrolysis, angioedema
Carbamazepine	Pruritic rash, hair loss, Steven–Johnson syndrome, hypersensitivity reaction
ANTIDEPRESSANTS	
SSRIs	Allergic reaction (hives, urticaria), excessive sweating, pruritus; hair loss reported with fluoxetine
Bupropion	Erythroderma, erythema multiforme (rare)
Venlafaxine	Erythroderma, erythema nodosum
Duloxetine	Erythema multiforme
Mirtazapine	Erythroderma
TCAs	Photosensitivity, erythroderma
Vortioxetine	Pruritus
Vilazodone	Drug rash
ANTIPSYCHOTICS	Drug hypersensitivity
Haloperidol	Skin pigmentation (blue-gray discoloration)
Phenothiazine	Erythema multiforme, Steven—Johnson syndrome, drug hypersensitivity
Clozapine	Erythema multiforme, erythroderma
Risperidone	Drug rash with eosinophilia
Olanzapine	Erythroderma
Ziprasidone	Drug rash (rare)
Aripiprazole	Drug rash, pruritus, angioedema (rare)
Lurasidone	Drug rash
Paliperidone	
ANXIOLYTICS	
Alprazolam	Photosensitivity

Steven–Johnson Syndrome (SJS) and Toxic Epidermal Necrolysis (TEN)

Diagnosis and Clinical Features. Diagnosis is based on clinical assessment in conjunction with histopathologic findings of subepidermal blisters. Both conditions manifest with an “influenza-like” prodromal phase marked by malaise fevers with subsequent painful mucosal and cutaneous lesions. The two conditions are classified according to the degree of skin detachment: SJS involves <10% skin involvement, whereas TEN encompasses >30% skin involvement. SJS/TEN overlap refers to anywhere from 10% to 30% skin detachment. All forms of the disease are characterized by blisters (either partially or completely detached) with Nikolsky positive, detachable areas. Nasopharyngeal, esophageal, and genital mucosal lesions or strictures may occur, along with pulmonary, ocular, renal, and hepatic manifestations. Sepsis, however, is the leading cause of morbidity and fatality in the acute phase of the disease. A majority of cases of SJS/TEN due to psychotropic exposure can be attributed to the use of carbamazepine (67.8%) though the reaction has also been associated with exposure to lamotrigine oxcarbazepine and phenobarbital.

Treatment. The acute management of SJS/TEN requires a multidisciplinary approach with immediate withdrawal of causative agent and prompt referral to a medical center for supportive treatment with systemic corticosteroids, immunoglobulins, and cyclosporine A. Cyclophosphamide and thalidomide have previously been used in the treatment of SJS/TEN but are no longer recommended due to high mortality rates and little efficacy as a treatment.

Most Common Associated Cutaneous Adverse Events

Mood Stabilizers. Mood stabilizers are the class of psychotropics most likely to produce cutaneous adverse events, and neuroleptics are the least common. Of the mood stabilizers, carbamazepine and lamotrigine are associated with the highest rates of cutaneous drug reactions. There is evidence that concurrent use of valproic acid considerably raises the risk of a cutaneous drug reaction with lamotrigine administration. The overall incidence of cutaneous effects with lithium is low. The most frequent

cutaneous reactions reported with lithium use are psoriasis, acneiform eruptions, folliculitis, alopecia, and exanthems.

Antidepressants. Of the antidepressants, TCAs have the highest reported incidence of cutaneous reactions, though these reactions often resolve with discontinuation of the offending agent. Of all the SSRIs, fluoxetine has been noted to have the highest association with purpura and ecchymosis, whereas alopecia has been reported with the use of all the SSRIs. Although there is conflicting data regarding hyperhidrosis with the use of SSRIs, it seems to be a relatively common issue that negatively impacts patient adherence to treatment with this drug class. The most common cutaneous effect of the SNRIs is hyperhidrosis which is thought to be induced by the inhibition of norepinephrine uptake resulting in the stimulation of peripheral adrenergic receptors.

Neuroleptics. The most common cutaneous side effects associated with the neuroleptics are pigmentation changes and photosensitivity, with chlorpromazine being the agent most frequently associated with either of these reactions. Discontinuation of the drug and avoidance of sunlight are essential in the treatment of this cutaneous reaction. Loxapine may be used as an alternative to phenothiazines to avoid skin pigmentation.

Treatment

Simple discontinuation of the offending drug often resolves cutaneous adverse effects, but this decision should be made with careful attention to the risk/benefit calculus. In cases of lithium and carbamazepine, lowering the dose can result in a resolution of the skin condition. Specifically for carbamazepine, lower loading doses on initiation and a slow increase in dosage can help avoid cutaneous eruptions altogether. Mild cases of hyperhidrosis can be managed with topical aluminum chloride hexahydrate. For the treatment of cutaneous drug reactions, antihistamines are used approximately 50% of the time, topical steroids 39% of the time, and oral steroids 37% of the time. If fever, arthralgia, palpable purpura, cutaneous sloughing, or mucus membrane erosions are noted, the drug should immediately be discontinued and an emergent dermatology consultation obtained. Patients who manifest with lesions over a large surface area should be hospitalized as these lesions may

result in dehydration or infection, similar to that seen in patients with burns.

Prevention may soon become the focus of drug-induced cutaneous eruptions. There are compelling data that show a strong association between certain HLA subtypes and drug-induced cutaneous hypersensitivities. The FDA recommends genetic testing before initiating carbamazepine therapy and warns against using the drug in those with Asian ancestry or those known to have the HLA-B 1502 genotype on the product label. The label for carbamazepine also includes a warning regarding the risk of SJS/TEN in those positive for HLA-A 3101. Labeling for oxcarbazepine carries a similar warning regarding HLA-B 1502.

FUTURE DIRECTIONS

Psychocutaneous disorders span the interface between dermatology and psychiatry, encompassing a wide range of conditions with mixed etiologies with a significant impact on quality of life. Despite this, psychodermatoses remain largely understudied, with few large-scale trials to assess effective treatment. There is also a need for a better understanding of the impact of skin disorders on development in childhood and adolescence, self-image (CBI), early relationships, psychosocial functioning, and the roles of stigma and stress in the exacerbation of skin disorders. A growing understanding of psychoneuroimmunology is underscoring the role of emotional stress in the pathogenesis of some skin disorders and elucidating potential mechanisms that may mediate the bidirectional influences of stress and skin and provide targets for clinical interventions that may dampen or eliminate stress-induced exacerbation of dermatologic illness.

27.13 Organ Transplantation

Andrea Frances Dimartini, M.D., Mary Schwab Seligman, M.D., M.A.R., Ph.D., Catherine Chang Crone, M.D., and Gerald Scott Winder, M.D., M.Sc.

Although solid organ and other tissue transplants had been attempted since the early 1900s, it was not until 1954 that the first successful organ transplant was accomplished by Joseph Murray using an identical twin brother as a kidney donor. Despite this surgical breakthrough, routine transplantation of organs would not be possible until the challenge of adequate suppression of the immune system was resolved. In the early 1960s, the development of chemical immunosuppression allowed the first deceased donor kidney, liver, lung, and pancreas transplants to be performed, followed by the first heart transplant in the late 1960s. Two decades later, the discovery and development of cyclosporine, a much more powerful and specific immunosuppressant drug, provided selective immunoregulation of T cells without excessive toxicity. Cyclosporine's approval by the FDA in 1983 for use in solid organ transplantation led to a dramatic increase in the numbers of transplants performed, decreases in recipient morbidity, and increases in posttransplant survival rates. This drug and others that followed changed organ transplantation from an experimental procedure to the standard of care for many types of advanced organ disease.

In 1984, the U.S. Congress enacted the National Organ Transplant Act (NOTA), establishing a regionalized system of equitable organ distribution, and the U.S. Department of Health and Human Services contracted with the United Network of Organ Sharing (UNOS) to administer the nation's Organ Procurement and Transplantation Network (OPTN). A central feature of NOTA was a prohibition on the buying or selling of human organs for transplantation, heralding some of the controversies to come in this complex field. In addition to the OPTN's primary goals of increasing the efficiency of organ sharing and the supply of donated organs, UNOS collects extensive data on all solid organ transplants in the United States

(e.g., waitlist counts, survival rates), serves as an educational resource, and guides policymaking through the OPTN. OPTN-mandated data collected from transplant programs, maintained by the Scientific Registry of Transplant Recipients (SRTR), are available for public access on the SRTR website (http://srtr.transplant.hrsa.gov). Although transplantation has become a life-sustaining procedure for those with advanced organ disease, the stresses inherent in the process—including the severe medical illness of the candidate, lack of available organs, and the uncertainty of surviving transplantation, risk of surgery, and the challenges of postoperative recovery—place enormous demands on transplant candidates, recipients, and their caregivers. In addition, the organ shortage—as well as extensive health care resources and the degree of personal responsibility required of transplant patients for successful outcomes—has created an environment where transplant programs attempt to select candidates deemed to have the best chance of optimal posttransplant outcomes. Due to these issues, psychosomatic medicine specialists and other mental health professionals are frequently involved in the evaluation, selection, treatment, and long-term care of transplant candidates and recipients. Knowledge of the organ-specific disease process is important, but one should be additionally familiar with transplant-specific issues in order to care for these complex and unique patients. This section will review the essential elements of adult solid organ transplantation, including the epidemiology of transplantation, the common types of organ disease leading to transplantation, and the course and prognosis for the transplant patient. Within the course and prognosis sections, the emphasis will be on the assessment of candidates and the specific phases of the transplantation process, as these areas must be understood in order for the mental health professional to provide appropriate patient care. In addition to the more common psychological factors and psychiatric disorders affecting the process and outcomes of organ transplantation, this section will also review issues particular to transplantation, including bridge-to-transplant technology, living organ donation, treatment issues specific to transplantation, and immunosuppressive medication neuropsychiatric side effects.

ORGAN TRANSPLANTATION

Definition and Comparative Nosology

Organ transplantation includes most of the solid organs either singly or in combination: kidney, pancreas, kidney–pancreas, liver, heart, lung, heart–lung, intestine, and multivisceral (e.g., multiple abdominal organs or heart–liver). A new area of organ transplantation recognized by the U.S. Department of Health and Human Services in 2014 is vascular composite allograft (VCA) transplantation. VCAs are a heterogeneous category of "organs" that include the face, limb, long bones, and soft tissues. Because they are rare in the United States, the remainder of this section will focus on other types of organ transplantation.

Transplantation can be performed with deceased donor organs, using either complete or partial organs (i.e., split liver, single lung, partial intestine, or pancreatic islet cells), or can otherwise involve a living donor who provides either a complete organ (i.e., single kidney) or partial organ (i.e., portions of the liver and intestine). For the past 10 years, living donors have accounted for 18% to 20% of all transplants performed. Even a heart can be donated through a domino procedure in which a recipient who requires a heart–lung transplant but has a sufficiently healthy heart can donate their heart to another. Although rarely performed in the United States, domino hearts have been predominantly from patients with cystic fibrosis or pulmonary hypertension. Whole-organ xenotransplantation has been unsuccessfully attempted in the past using pig and baboon organs. Currently, only pig islet cells are being investigated for transplantation in patients with pancreatic disease. However, xenogeneic rejection due to immune incompatibility and concerns over the risk for cross-species infections remain significant challenges.

Epidemiology

The greatest obstacle to receiving a transplant is the shortage of donated organs. The number of wait-listed individuals greatly exceeds the availability of donated organs. However, there has been some increase in organ availability as well. In 2003, the Department of Health and Human Services created the Organ Donation Breakthrough Collaborative designed to replicate and promote best practices by national organ procurement organizations for deceased donor consent that would increase access to available organs. The efforts of the collaborative are credited with an estimated 4,000 additional annual transplants per year. Unfortunately, the increasing number of deaths from the opioid crisis has also been credited with recent increases in organ donation. In addition,

due to the ability to manage donor-derived infections, organ utilization has increased to include the use of less-than-perfect organs (i.e., those coming from a high-risk profile or Hepatitis C virus [HCV]-infected donors). A transplant candidate has to opt-in to accept such an organ. Over 50% of transplant candidates are willing to consider such organs. The limited organ availability has also increasingly led to the consideration and use of living organ donors. In kidney donation, to deal with incompatible living donor–recipient pairs, paired donation exchanges and, later in 2005, domino chains (beginning with a nondirected donor who initiates a sequence of kidney transplants) using computer algorithms to match successive donor–recipient pairs were initiated to efficiently maximize the available living donor pool. While performed for nearly a decade in Asia, where the living liver donor experience is widespread, paired exchange liver donor transplants were not done in North America until 2019. However, while these efforts have increased the numbers of donor organs, the numbers of wait-listed patients continue to steadily rise while the number of transplants performed each year is fairly stable (Fig. 27.13–1). Although the average amount of time on the waitlist depends on the type of organ required, the severity of illness, and the blood type of the candidate, for all major organ types, over 40% of U.S. wait-listed candidates waited 2 years or more for an organ. Unfortunately, 10% to 18% are removed (die or are too ill for the transplant) while on the waitlist.

Following transplantation, recipients of living kidney and living liver grafts show the highest long-term survival rates 10 years posttransplantation (79% and 74%, respectively) (Fig. 27.13–2). Recipients of deceased donor kidneys, deceased donor livers, and heart recipients have somewhat lower 10-year survival (62%, 63%, and 64%, respectively), and lung and intestine recipients have the poorest 10-year survival (33% and 45%, respectively). Even so, these data are from transplants performed over 10 years ago, and with advances in technology, immunosuppression, and medical care, the survival rates continue to improve. Graft survival rates are generally lower than patient survival rates, indicating that many transplant recipients eventually require retransplantation. For example, non–high-risk kidneys are expected to function between 9 to 12 years. In addition, many immunosuppressive medications are nephrotoxic, and liver, heart, lung, and intestine transplant recipients may eventually develop renal failure requiring kidney transplantation.

FIGURE 27.13–1. Waiting list statistics in the United States: 2002 to 2018. (Organ Procurement and Transplantation Network [OPTN] and Scientific Registry of Transplant Recipients [SRTR]. OPTN/SRTR 2021 Annual Data Report. 2023. Accessed June 2, 2023. http://srtr.transplant.hrsa.gov/annual_reports/Default.aspx.)

Etiology

The diseases that typically result in solid organ transplantation are listed in Table 27.13–1 by organ type and frequency. Advanced organ disease can occur acutely as in fulminant hepatic failure (e.g., acetaminophen overdose, acute viral hepatitis) or can be a chronic, progressive disease process (e.g., primary sclerosing cholangitis, chronic obstructive pulmonary disease). The disease could involve the organ parenchyma (e.g., diabetic nephritis), the vascular flow to the organ (e.g., Budd–Chiari syndrome), or transplantation could be required due to cancer in the organ (e.g., hepatocellular or renal cell carcinoma) or traumatic injury (e.g., blunt force trauma, inhalation/burns injury). In liver transplantation, recent shifts in the epidemiology of liver diseases, from an increase in the prevalence of nonalcoholic fatty liver disease (often from morbid obesity) and curative treatments for HCV (often incurred through injected drug use), are changing the referral diseases and reasons for pretransplant psychiatric consultation.

Course and Prognosis

Transplantation can be envisioned as a continuum demarcated by specific phases. The development of advanced organ disease heralds the beginning of the process. From evaluation at the transplant program to waiting on the national list, then early and longer-term recovery and adaptation to life as an organ recipient, each phase is associated with different stressors and requires different skills and resources from patients, caregivers, and mental health clinicians caring for them (Fig. 27.13–3). Mental health professionals are perhaps most frequently called on to aid in the evaluation of the prospective transplant candidate. Because these evaluations require a focus on transplant-specific areas somewhat different from a typical psychiatric consultation, they are addressed in detail below.

Clinical Evaluation for Transplantation. Due to the limited availability of donor organs, the considerable medical, social, and financial resources necessary for successful transplantation, the degree of personal responsibility of recipients, and the needed involvement of their family and other caregivers, careful assessment of transplant candidates and their caregivers is required. Pretransplant evaluations typically involve two components: a medical and a psychosocial assessment. During the medical assessment, patients are evaluated to determine whether there is a clear physiologic indication for transplantation based on OPTN criteria and to rule out significant medical comorbidities that pose additional risks or diminish the possibility of successful transplantation. For example, concurrent diabetes mellitus, morbid obesity, or a history of malignancy are conditions that can considerably raise the risk for posttransplant morbidity and mortality. Whether these conditions or others make a patient ineligible for transplantation will partly depend on the severity of the comorbid diseases but also on the transplant team's level of experience, ability, and comfort in working with high-risk patients.

FIGURE 27.13–2. Transplant patient survival by organ type. (Organ Procurement and Transplantation Network [OPTN] and Scientific Registry of Transplant Recipients [SRTR]. OPTN/SRTR 2021 Annual Data Report. 2023. Accessed June 2, 2023. http://srtr.transplant.hrsa.gov/annual_reports/Default.aspx)

Table 27.13–1.
Diseases Resulting in Listing for Transplantation in the United States as of December 2019

Organ Type	Percentage	Organ Type	Percentage
Kidney, *n* = 101,337		**Liver, *n* = 12,555**	
Diabetes mellitus type I and II	38%	Alcoholic	31%
Hypertensive nephrosclerosis and malignant hypertension	21%	Hepatitis C	14%
Chronic glomerulonephritis	14%	Cholestatic disease	9%
Cystic kidney disease	9%	Acute liver failure	1%
Other	18%	Other[a]	35%
Heart, *n* = 3,385		**Lung, *n* = 1,423**	
Cardiomyopathy	59%	Obstructive lung disease (e.g., COPD/emphysema)	38%
Coronary artery disease	29%	Restrictive lung disease	44%
Congenital	6%	Pulmonary vascular disease	11%
Valvular disease	1%	Cystic fibrosis and immunodeficiency disorders	7%
Other	5%		
Intestine, *n* = 226		**Pancreas or Kidney Pancreas, *n* = 2,372**	
Other short gut syndrome	27%	Diabetes mellitus	
Congenital short gut syndrome	21%	Type I	76%
Necrotizing	10%	Type II	16%

enterocolitis			
Pseudo-obstruction	7%	Other	8%
Enteropathies	3%		
Other	32%		

[a]Other category presumed mostly nonalcoholic fatty liver disease according to 2021 OPTN annual report.

Organ Procurement and Transplantation Network (OPTN) and Scientific Registry of Transplant Recipients (SRTR). OPTN/SRTR 2021 Annual Data Report. 2023. Accessed June 2, 2023. http://srtr.transplant.hrsa.gov/annual_reports/Default.aspx.

FIGURE 27.13–3. Organ transplant timeline: Critical events, time periods, and health and psychosocial issues. **Tx**, transplant; **QOL**, quality of life. (Adapted from Dew MA, Manzetti J, Goycoolea JR, et al. Psychosocial aspects of transplantation. Table 27.13–2.
Goals of the Pretransplant Psychosocial Evaluation

1. Foster a working relationship between patients and transplant team
2. Educate and prepare patients for transplantation
3. Reinforce the informed consent process for patients
4. Evaluate patients' coping strengths and weaknesses/vulnerabilities
5. Assess treatment adherence and ability to make lifestyle/behavior changes
6. Diagnose and recommend treatment options for active psychiatric disorders
7. Assess amount, stability, and availability of social support system
8. Develop individualized treatment plans for patients including requirements for listing
9. Provide input to team regarding transplant candidacy

RELATIVE IMPORTANCE OF PSYCHOSOCIAL CRITERIA. Although there is general consensus about the medical assessment and the criteria used for transplant candidacy, there are considerable differences among teams regarding the purpose of psychosocial evaluations, who performs these evaluations, the content of the evaluation, and the use of the psychosocial information obtained. This may be because transplant teams have differing opinions about the relevance and significance of psychosocial criteria. In addition, there are no national psychosocial criteria for candidate listing in the United States; although there are published consensus guidelines on the basic components of the psychosocial evaluation (see Tables 27.13–2 and 27.13–3 for the goals and content of the psychosocial evaluation). As a result, each transplant program must decide on the pertinent psychosocial criteria and the relevance of these criteria for individual patients, often with input from mental health professionals. In general, heart transplant teams are more likely to view psychosocial issues as potential contraindications, while kidney programs tend to be the most lenient. This difference may be partly due to the complexities of a heart transplant with poorer survival than in a kidney transplant combined with the greater availability of kidneys for transplantation and favorable cost benefits of kidney transplantation compared to dialysis. Differences in approaches toward substance use and addictive disorders and whether a specified period of abstinence is

required prior to evaluation or listing vary substantially, and not all substances are considered equally across different types of organ transplant programs.

Table 27.13–3.
Components of a Comprehensive Pretransplant Psychosocial Evaluation

Current medical history and knowledge of current illness	Course of advanced organ disease (acute vs. chronic), prior hospitalizations, treatments, complications, level of functioning/disability, quality of life, current symptoms, understanding of illness and limits of currently received treatments
Attitude toward transplantation	Circumstances leading to referral for transplantation, understanding of reasons for referral, receptiveness to transplant, prior experience or knowledge about transplantation, concerns/fears/reservations, expectations about transplantation
Knowledge about transplantation	Knowledge about risks and benefits of treatment options, given patients severity of illness; understanding the reasons that transplantation is being considered; e.g., patient's initial education about the pre- to posttransplant process, additional research/reading of their own on transplant, understanding of the risks and benefits involved with transplant, understanding of the long-term commitment to ongoing medical follow-up, immunosuppressants, monitoring, and lifestyle/behavioral changes required
Treatment adherence	Past and current medical adherence; knowledge about current treatment regimen and willingness to adherence to the posttransplant regimen; e.g., self-monitoring (e.g., checking blood sugar, blood pressure), diagnostic testing, other

	treatment interventions (e.g., operations, supplemental oxygen, pulmonary rehabilitation), diet, fluid restrictions, exercise, abstinence from alcohol/drugs/tobacco
Coping with illness	Response to illness and coping skills and strategies used to manage the illness and its daily impact; expression of acceptance or denial about prognosis and treatment options; e.g., utilization of active vs. passive coping skills for dealing with his or her illness (e.g., self-education, adjusts activity level vs. avoidance, heavy reliance on spouse, etc.), expressions of distress or feeling overwhelmed with his or her illness, methods for managing these feelings
Past medical history	Prior illnesses, hospitalizations, operations, experiences with health care system
Psychiatric history	Past and current history of mood disorders, anxiety disorders, or other disorders symptom severity, course of symptoms, chronicity of symptoms, receipt and response to past or ongoing treatment and willingness to undertake additional treatment hospitalizations, treatment adherence, thoughts of suicide or self-injury or prior suicide attempts
Substance use/abuse	Drugs/alcohol/tobacco frequency of use, amount, duration, diagnosable disorder, level of impairment to health/work/relationships, legal issues, knowledge of and insight into their addiction, commitment and

	ability to remain abstinent including prior attempts to reduce usage or prior periods of abstinence, prior and number of attempts at formal rehabilitation/counseling, attendance at 12-step meetings, sponsors, willingness to get therapy when needed, supports for abstinence, family history of substance abuse
Current medications	Knowledge of current medications including dose and frequency, understanding the purpose of each medication
Family history	Current and past history of medical, psychiatric, and substance abuse disorders
Social history	Developmental history, childhood experiences, educational background, literacy and health literacy, history of trauma, significant relationships, occupation/work experience, current living arrangements, financial status, dependents, concurrent life stressors (e.g., family dysfunction), cultural background including religious/faith practices, legal issues
Support system	Availability, stability, willingness and extent of support available to help care for patient before and after transplantation, including family members, friends, neighbors, religious organizations, and coworkers, understanding of these individuals about illness and treatment options and their role in assisting patient

Mental status examination and capacity	Level of consciousness, appearance, behavior, speech, presence of psychomotor agitation or retardation, mood, affect, thought process/content, insight into organ disease/transplant, judgment, attention, concentration, memory, and executive functioning, capacity to comprehend information and engage in decision making

UNIQUE ROLE OF THE PSYCHOSOCIAL EVALUATOR. Due to these differences, the mental health professional must be knowledgeable about their team's approach to psychosocial issues and may need to educate the team on the prognosis and treatment of psychiatric disorders. Thus, mental health professionals have dual functions in the transplant evaluation process, serving the needs of both the transplant team and the transplant patient. Balancing these two roles may be complicated, but the mental health professional can both advocate for the patient and communicate and interpret the transplant team's requirements back to the patient. Information gathered during the psychosocial evaluation is essential to the transplant team's complete understanding of the patient. The communication back to the patient provides education on specific transplant-related expectations, the team's requirements for listing the patient as a transplant candidate, and the importance of these requirements to the success of transplantation. Assisting with an appropriate referral for recommended psychiatric or psychological treatment can be provided along with ongoing monitoring of the patient's progress in this treatment arena. In these ways, the mental health professional can facilitate the development of a long-term collaborative relationship between the patient and the transplant team.

SCREENING AND CONTENT OF THE PSYCHOSOCIAL EVALUATION. At most centers, psychosocial evaluations are performed by clinical social workers. Typically, this evaluation serves as a screening evaluation, with a

more comprehensive psychiatric assessment requested for patients identified as having prior or current psychiatric histories or psychosocial issues requiring additional attention. This two-stage approach can be an efficient use of resources because the sheer number of candidates may preclude a comprehensive psychiatric evaluation of all patients, and additionally, with thorough screening, an evaluation may not be indicated.

A comprehensive pretransplant psychosocial evaluation contains all the areas of a typical comprehensive psychiatric assessment, with the addition of transplant-specific areas (e.g., coping with illness, adherence, and other health or illness behaviors) (Tables 27.13–2 and 27.13–3). Standardized transplant-specific assessment tools (i.e., Psychosocial Assessment of Candidates for Transplantation, Transplant Evaluation Rating Scale, Stanford Integrated Psychosocial Assessment for Transplantation, and Structured Interview for Renal Transplantation) can be used alongside the clinical interview to ensure that relevant topics are covered. These instruments should be completed by a trained clinician and provide a useful organization of information pertinent to transplantation. Non–transplant-specific instruments assessing psychiatric symptoms or cognitive status are sometimes used in the evaluation. Collateral information from family members, partners, medical and pharmacy records, toxicology screening, attendance at clinic appointments, and current or past health care providers to determine adherence and treatment engagement is often essential to substantiate or clarify information obtained from patient interviews. If a candidate has undergone a prior transplant evaluation, this information should be reviewed. Expanded medical record review is being facilitated by the increasing use of electronic medical records connecting both intra- and intermedical system data.

SPECIAL AREAS OF TRANSPLANT ASSESSMENT

Social Supports. Assessment of the presence of an adequate, stable, and available support system to help the patient through transplantation is another area requiring careful evaluation. Patients often require assistance with activities of daily living, medications, dressing changes, and transportation both before and after transplantation. Particularly while awaiting a transplant, some patients may be too ill to physically care for themselves. Others may develop cognitive impairments that require

constant monitoring for safety. Caregivers often feel the need to present themselves to the transplant team as being a capable and concerned support system for the patient. However, the best evidence of adequate support is consistent behavior demonstrating this ability. Thus, the patient's caregivers should be present during the evaluation process so that their knowledge, ability (cognitive and physical), and willingness to take on these responsibilities can be assessed.

Treatment Adherence. Nonadherence to the posttransplant regimen and immunosuppressive medications, in particular, has been associated with poor clinical outcomes, contributing substantially to late acute rejection and graft loss. For these reasons, transplant teams are highly invested in a patient's ability to adhere to the long-term medical, behavioral, and lifestyle requirements necessary to optimize outcomes and survival. Following transplantation, patients must take daily medications; monitor critical parameters such as vital signs, blood sugar, and pulmonary functions; come to clinic appointments; undergo diagnostic tests; follow dietary restrictions; participate in physical rehabilitation or exercise programs; and adhere to restrictions on the use of illicit drugs, tobacco, and often alcohol as well. Lifelong adherence to immunosuppressants is necessary, as is adherence to other medications such as antihypertensives, lipid-lowering drugs, hypoglycemic agents, antibiotics, and antifungals. Despite this, immunosuppressant nonadherence alone is well recognized as a common cause of late-onset acute rejection, antibody-mediated rejection, graft dysfunction, and ultimately, transplant loss. Furthermore, a comprehensive meta-analysis of adherence studies across all organ types identified a rate of 23 cases of immunosuppressant nonadherence per 100 transplant recipients per year. Rates of nonadherence to other posttransplant requirements vary, with higher rates for home self-care behaviors (e.g., diet, exercise, home monitoring of vital signs) and lower rates of nonadherence in the areas of attending clinic appointments and use of restricted or banned substances.

Identification of the reasons and risk factors for nonadherence is one goal of the pretransplant evaluation. Pretransplant factors such as a history of nonadherence, being an adolescent or young adult, substance misuse, poor perception of health, and poor social supports appear to be most commonly associated with posttransplant nonadherence. In addition to commonly assumed behavioral reasons for poor adherence (e.g., poor

organizational skills, failure to accept personal responsibility for one's health, etc.), other social issues such as type of insurance coverage or transportation availability or even ambivalence about treatment should be considered. These factors and their impact on current adherence should be assessed during the psychosocial evaluation. Patient education on the importance of adherence and plans for pretransplant monitoring may be required. In addition, a posttransplant plan for monitoring and education should be considered because patient adherence often worsens with time since transplantation.

Substance Use. Substance use and substance use disorder is an area of special concern for transplant teams, especially in liver and heart transplantation, where the use of drugs or alcohol often leads to the need for transplantation. Inquiries about substance use or substance use disorder should be made with all patients, regardless of the primary cause of their advanced organ disease, and transplant programs may perform toxicology screening on all candidates at evaluation. Substance use disorder may not be assessed by other transplant team members for patients whose organ failure was not directly linked to alcohol or drugs, and the mental health professional may be relied on to address this area (see Table 27.13–3 for areas of substance use assessment). In the United States, cannabinoid use has increased with the passing of medical cannabis prescribing laws and legalization in many states. While smoked and edible cannabis has known health risks, there is no consensus in the transplant community regarding medical or recreational cannabis. There are also no guidelines for the use of electronic cigarettes containing tetrahydrocannabinol though their use has been linked to lung injuries and subsequent transplant. The issue of other medicinal or recreational cannabinoid use, like cannabidiol, is even more unclear. Many transplant programs exclude patients who are actively using recreational cannabis. In addition to drugs and alcohol, the cessation of tobacco use (both smoked and smokeless) has been a requirement for heart and lung transplant listing and is increasingly seen as a contraindication to listing for abdominal transplantation as well (see tobacco section below). There is no consensus on the use of nicotine-containing electronic cigarettes. Some programs may not allow listing while a patient is using nicotine replacement therapy for smoking cessation, so the specific allowances of the transplant team must be known. Transplant programs attempt to

select patients deemed unlikely to relapse posttransplant due to concerns that substance use will diminish patient or graft survival (e.g., patients and transplanted organs at risk from direct toxicity of the substance, increased risk of infection due to risky behaviors, or increased morbidities) or that substance use relapse would lead patients to become nonadherent (see substance use outcomes below).

Informed Consent in Terminally Ill Transplant Candidates. The importance of informed consent for organ transplantation cannot be overemphasized, given the need for patient commitment to long-term responsibilities along with the potentially serious risks and complications that can arise in both the early and late term following transplantation. Psychosocial evaluations help to address how well patients understand their illness, prognosis, treatment options, and the transplant process itself, thereby facilitating the informed consent process. However, evaluating patients' understanding of their options may be problematic under the circumstances in which transplant patients are evaluated. Often, patients with advanced organ disease referred for transplant evaluation are facing life-or-death decisions, with transplantation being the only means to extend their survival. For other patients, alternative treatments such as hemodialysis have become too difficult to tolerate, or their quality of life has become unacceptable. Whether their circumstances are truly desperate or only perceived to be so, patients may have limited ability to fully appreciate, comprehend, and consider all aspects of transplantation. Their illness may have resulted in acute or chronic cognitive impairments that also reduce their ability to comprehend and make informed decisions (see additional discussion of impairments below). Given these factors, a careful psychosocial assessment with attention to informed consent should be performed, balanced with realistic expectations about a patient's behavior under such emotionally difficult conditions. The evaluation can identify areas in which the provision of additional information on risks versus benefits of transplantation is required before an informed decision can truly be made by the patient.

Emergency Evaluations. Requests for emergency psychosocial transplant evaluations may occur for patients with fulminant liver failure or acute ischemic or idiopathic cardiomyopathy who have not been previously evaluated by the transplant team. These patients may be stuporous, on mechanical ventilation, or be in a primary or drug-induced

coma. Under these circumstances, the majority, if not all the pretransplant evaluation information gathered will depend on thorough interviews with family, friends, and health care providers and attempts to obtain previous medical and psychiatric records. The informed consent process remains a concern, but the focus will be on the ability of the family or surrogate decision maker to understand the patient's medical condition and the transplant process and maintain respect for the patient's wishes. Establishing whether a stable support system exists for these patients is especially important as neither patient nor family may have had the opportunity to prepare themselves for transplant or the posttransplant regimen.

Patients with fulminant hepatic failure due to acetaminophen-induced liver injury require special evaluation for psychopathology. Determining whether the ingestion was a mistake made by a patient attempting to treat pain or cold symptoms or an intentional act of suicide will lead to different recommendations and care plans. As with any suicide attempt, the nature of the attempt (e.g., impulsive vs. planned), current stressors, presence of active psychiatric illness, and other risk factors for subsequent suicide attempts or gestures need to be assessed. Whether specific patient characteristics could interfere with the patient's ability to develop a long-term collaborative relationship with the transplant team and consistently follow medical directives must be considered.

Living Donors. As noted earlier, organ transplantation increasingly often relies on living donation, particularly in kidney transplantation. Donor safety is of utmost concern, given the altruistic nature of living donation and the fact that donors have no medical need for surgery. As donation has expanded beyond biologically or emotionally close relatives of transplant patients to donors with little if any pre-existing relationship to the recipient, the medical and psychosocial evaluation of prospective donors has become more extensive. Currently, the evaluation process at U.S. centers is specified by OPTN policy, which includes requirements for the donor psychosocial evaluation and components that must be reviewed (see https://optn.transplant.hrsa.gov/media/1200/optn_policies.pdf). The evaluation is as detailed and exhaustive in prospective donors as in prospective transplant candidates (Table 27.13–4). Mental health professionals must assess the psychiatric history of prospective donors and determine their current level of functioning and their cognitive

capacity to make an informed decision about donating. Consensus opinions and both OPTN and Centers for Medicare and Medicaid Services policies also require that all potential living donors be provided with an independent living donor advocate (ILDA) who is not responsible for the transplant candidate's care or the decision to list the candidate for a transplant. The ILDA also evaluates the donor, assists them in gaining additional education about possible donation, and advocates on their behalf.

Table 27.13–4.
Areas of Assessment for Living Donor Evaluation

- Relationship between donor and recipient
- Reasons for donation
- Donor's knowledge about the surgery including:
  - Donation and transplantation procedures
  - Risks to self
  - Risks to recipient
  - Expectations about donation/recovery
- Motivations including:
  - Urgency of the medical condition of recipient
  - Lack of other donors
  - Guilt
  - Psychological expectations (e.g., desire to be hero, special, etc.)
  - Expectations about postdonation relationship with recipient
  - Ambivalence
  - Evidence of coercion/inducement
  - Attitudes of significant others and family toward the donation
  - Availability of support
  - Financial resources and donor's understanding of financial implications of donation
  - Work- and/or school-related issues (if applicable)
  - Timing of the donation relative to work, school, or other important life events
- Donor's psychological health and history, including the following:
  - Psychiatric disorders
  - Personality disorders
  - Cognitive capacity
  - Coping resources/style
  - Pain syndromes
  - Prior psychological trauma/abuse
  - Substance use
  - Presence of any behaviors that may increase risk for disease transmission to the organ recipient

Need for any educational or therapeutic interventions before a decision can be made regarding suitability to donate.

Adapted with permission from Levenson JL. *The American Psychiatric Publishing Textbook of Psychosomatic Medicine*. American Psychiatric Publishing; 2005. All Rights Reserved and from OPTN Policy 14 (http://optn.transplant.hrsa.gov/governance/policies/).

Under most circumstances, current active psychiatric or substance use disorders are contraindications to donation. However, exceptions may arise under certain circumstances, such as a parent donating to a critically ill child. Therefore, psychiatric management of prospective donors and follow-up to continue psychiatric treatment after donation may be required.

Outcomes following living donation are given special considerations later in this section.

A 30-year-old woman seeks to be evaluated as a living–related kidney donor for her older brother, who has advanced renal failure secondary to diabetes mellitus. She states that she first learned about her brother's need for transplantation 6 months ago when she was contacted by their mother. Before this, she had been estranged from the family for several years due to their disapproval of her lifestyle, which included drug abuse and unstable relationships with various men. She reports that she has tried to re-establish ties with her family before, but they have not been receptive to her efforts even when she has tried to show them she is leading a more stable lifestyle. When asked about her motives for wanting to donate to a brother with whom she has had no contact for years, she emphasizes that no one is pressuring her to donate. However, she admits feeling that her brother has been more responsible than she has been and a "model son" when it came to helping their parents through difficult financial times. She expresses hope that donating a kidney will help her family to see that she is now acting like a responsible adult and family member. In this case, the evaluator should be concerned over her motives for desiring to donate. Issues to explore would include her expectations of her relationship with her family and especially her brother following donation, feelings of guilt, and a desire to restore her status in the family.

COMMUNICATION REGARDING TRANSPLANT CANDIDATE AND LIVING DONOR EVALUATION RESULTS. Communication about patient suitability for

transplantation or living donation and recommendations to the team should be plainly stated with minimal psychiatric jargon, providing straightforward guidance. However, caution must be taken regarding comments on a patient's suitability for transplant, partly because there is a lack of consensus on what psychosocial issues would make a patient unacceptable for transplant and because third-party payors may review the psychosocial assessment as part of their process to determine whether to financially approve a patient for transplant coverage. In some cases, health insurers may use information from the psychosocial evaluation to set forth more restrictive psychosocial requirements for the patient to fulfill before they agree to cover transplantation costs. Fortunately, most transplant teams do not reject candidates outright but allow an opportunity for psychosocial issues to be addressed or resolved, followed by a re-evaluation for candidacy. Areas of preparation that are of particular importance to transplantation are addressed below.

Preparation for Transplantation. In addition to addressing the transplant team's concerns about psychiatric or psychosocial issues and aiding in candidate eligibility determinations, the pretransplant psychosocial evaluation can be used to develop an individualized treatment plan to educate and prepare candidates for transplantation and optimize posttransplant outcomes (Table 27.13–2). For example, the concerns, fears, or even ambivalence about the surgery that patients express during the evaluation can be useful to allow the evaluator to target appropriate interventions. Optimally, candidates should be referred for any psychotherapeutic interventions early in their illness before medical or cognitive deterioration (e.g., encephalopathy) that will limit their ability to participate in or benefit from such treatment.

A 54-year-old woman with familial cardiomyopathy is referred for cardiac transplantation. Despite agreeing with her cardiologist about his referral, she fails to contact the transplant center until he reminds her during a follow-up appointment. When she begins her evaluation, she cancels some of the appointments and tests she is asked to complete. The transplant coordinator asks about these cancellations and the patient states they were due to scheduling difficulties at her job. When seen by the team's social worker, she admits to being hesitant about transplant due to her cousin's experience several years prior. Her cousin developed recurrent episodes of rejection and died 5 years after her transplant. The patient is afraid the same fate awaits her and only agreed to an evaluation upon her family's insistence. Once her fears are uncovered, the transplant team assures her that she would not be pressured to be listed for transplant. The coordinator meets with the patient and her family to better educate them about transplantation. During this meeting, the patient is able to gather information about her specific situation, the risks of surgery, and life as a transplant recipient. The patient also meets with the team's psychiatrist for several sessions to address her fears in greater depth and to reinforce her coping skills. Her anxiety lessens over time, and she eventually decides she wants to pursue transplantation.

BEHAVIORAL AND CONTINGENCY CONTRACTING. For patients with significant psychosocial risk factors such as substance abuse, treatment nonadherence, or other psychiatric disorders requiring ongoing treatment, transplant teams may decide to use behavioral contracts to stipulate requirements for listing or monitoring during the waiting period for transplantation. These contracts can positively encourage behavioral change, minimize miscommunication, foster collaboration between patient and team, and reinforce the need for patients to take active responsibility for their health care. Although not a legal document, behavioral contracts clearly define what is expected of patients, how their adherence to the contract will be assessed, and what consequences they will face if they cooperate with or fail to cooperate with listed expectations. Successful adherence to these requirements would result in listing for transplantation; nonadherence would lead to removal from the waiting list. For example, patients with psychiatric disorders may be required to receive ongoing

outpatient psychiatric care and be periodically reassessed by the team to determine whether the psychiatric disorder is under adequate control. Patients with a history of treatment nonadherence may be asked to demonstrate adherence to various aspects of their care (e.g., medications, appointments, tests, dialysis, dietary, or fluid restrictions) for a period of time prior to listing and continue to be monitored during the waiting period leading up to transplantation.

A 58-year-old man is referred for cardiac transplantation due to a long history of ischemic cardiomyopathy. He suffered his first myocardial infarction in his mid-30s but was able to return to an active lifestyle after several months. He followed up with a cardiologist for a few years but eventually stopped as he was feeling well, had stopped smoking, and was exercising regularly and watching his diet. Despite his efforts, he suffered a second infarction in his early 40s and a third at age 50. Since his last infarction, he has developed steadily worsening symptoms of congestive heart failure. He has followed up with a cardiologist regularly and is on medications, but he argues with his physician whenever a new medication is added, or a dose increase is advised. He has occasionally tapered the doses of some of his medicines to see if he could get by with less. He complains that each medication adds new side effects and he hates being a “walking pharmacy.” He is very interested in transplantation as he feels his quality of life is poor, but he knows he will have to be on a large number of medications posttransplant. In preparation for transplant listing, he is required to demonstrate consistent medication compliance and begin psychotherapy. In counseling, he is able to identify previously unresolved issues about his vulnerability, lack of control over his condition, and anger toward health care providers as they remind him of his debility. He is able to address these issues and develops a realistic approach to his health and health care.

SUBSTANCE USE—DISORDERED PATIENT. Requirements for the length of sobriety and addiction rehabilitation vary greatly from program to program and among different organ types even within a transplant program. Although stable abstinence is measured in years, not months, many liver transplant programs—for example—focus on the length of abstinence as

the main criterion, with 6 months of abstinence being a benchmark for listing. Except for short abstinence, no single risk factor strongly predicts future use, although poor social support, family history of addiction, polysubstance use, and failed rehabilitation have been associated with increased risk. Addiction counseling before and after transplant remains the best treatment option for providing education about the illness and strategies for monitoring and avoiding relapse, lifestyle, and behavioral changes, as well as for identifying appropriate supports to maintain abstinence. For those with short abstinence (less than 1 year) and no prior therapy, addiction counseling is highly recommended as a prerequisite to transplant listing. Patients with some period of abstinence but no addiction rehabilitation may not perceive a need for addiction treatment. Many have stopped actively using substances due to being ill but have not incorporated the skills or strategies to stay sober and prepare for continued abstinence posttransplant. Motivational interviewing may be needed to assist those reluctant to engage in treatment. However, for some, outright mandating of addiction treatment as a requirement for transplant listing may be needed. The intensity of addiction treatment may need to be tailored or adjusted over time to the medical debility of the patient. An example is acute alcohol-related hepatitis, in which patients with very short abstinence (if any) experience a rapidly deteriorating course and programs must quickly consider whether to transplant such patients and how to address their addiction after transplant. Mental health professionals should be prepared to evaluate and provide treatment recommendations for such short-abstinence patients, keeping in mind that limited time and potential encephalopathy and/or physical debility could impede engagement in treatment and shorten the time frame to make listing decisions. As mentioned above, some centers use behavioral contracts stipulating the frequency and duration of addiction counseling. Others require ongoing, random toxicology screening to demonstrate that substances are not being used. Even after wait-listing, ongoing periodic clinical and toxicologic reassessment and monitoring are recommended because of the continued risk for relapse.

Transplant programs may also require patients on methadone maintenance therapy (MMT) to discontinue methadone either as a prerequisite for transplant listing or in the immediate postoperative period. However, the process of transplantation is very stressful for patients and is not an optimal time to attempt the additional challenge of a methadone

taper. Although progressive medical illness may necessitate a decrease in the methadone dose, requiring a patient to discontinue MMT specifically for transplant listing could be considered unethical because a premature taper off methadone may precipitate a relapse, which would then prohibit the patient from transplantation. Patients who are taking buprenorphine may require supervised dose reductions preceding transplant to enable adequate perioperative pain management.

REASSESSMENT OF WAIT-LISTED CANDIDATES. Periodic psychosocial follow-up with wait-listed candidates, either in the hospital or outpatient setting, is desirable because the candidate's status may change with respect to affective symptoms, stress, coping, cognitive functioning, adherence, substance use, social support, and financial issues. In some cases (i.e., resumption of substance use), reassessment may lead a candidate to be removed from the transplant list. More often, however, ongoing pretransplant reassessment not only provides continuity of care but can also improve the team's understanding of the candidate, help identify problems that need to be resolved pretransplant, foster a collaborative relationship with the team, and enhance adherence. Some candidates may not return until the point of transplantation, and ongoing reassessment at the transplant program may not be geographically or financially feasible for the candidate and family. Appropriate psychiatric services should be identified for those at a distance from the transplant program if issues arise, and information on the treatment or resolution of the problem should be forwarded to the transplant team. Psychiatric clinicians and other physicians in the community, who may be providing services to transplant patients but are not familiar with transplantation, may benefit from a discussion with the psychosocial evaluator regarding the transplant team requirements for treatment goals or from the receipt of available written educational materials on transplantation.

Patient Adaptation through the Transplant Time Course

EVALUATION AND WAITING PERIOD. Patients face significant adaptive challenges as they proceed through the pre- to posttransplant course. Successful completion of the transplant evaluation and the individualized requirements to be accepted for listing on the national organ transplant candidate list are only the first hurdles. Many patients and their families perceive the waiting period to be even more psychologically stressful. This

is especially the case if patients are newly adapting to their diagnosis of terminal advanced organ disease and considering for the first time the transplant surgery and future life as a transplant recipient. The patients' level of adjustment at the point of transplant evaluation may depend on how sick they are, how long they have lived with their illness (acute vs. chronic), and how long they have been anticipating (either positively or negatively) the issue of eventually requiring organ replacement. With chronic illness, there can be progressive debility, loss of vitality and physical and social functioning, changes in or loss of family or social roles, loss of independence, and financial hardships. Adapting to these changes can elicit anxiety, depression, avoidance, and denial and may require working through the grief of these losses. Unless candidates have a living donor and can therefore choose the timing of their surgery, they must endure the uncertainty of the wait time, the extent of their medical deterioration, and loss of functioning before the transplant surgery occurs. In addition, wait-listed candidates may develop medical contraindications to transplantation (i.e., infection, serious stroke, progressive organ dysfunction), and both patient and family should be made aware that their eligibility might change for many reasons over time. These inherent stresses in the transplant process will tax the character style, coping, and social support resources of patients and caregivers, and these stresses can increase over time. Psychological counseling for patients and families can aid in successfully negotiating these transitions and prepare them for either transplantation or death.

PERIOPERATIVE PERIOD. For patients fortunate enough to survive the waiting period and undergo transplantation, the immediate perioperative period is a time of recovery and adjustment to new challenges. In some cases, recovery will be rapid and uncomplicated, while in others, it may be prolonged and marked with multiple complications. Except for renal transplantation, patients begin their postoperative recovery in the intensive care unit. Common postoperative complications such as bleeding, infections, rejection episodes, immunosuppressive medication side effects, and perfusion injury to the donor organ delay recovery may be perceived as setbacks by the recipient and can lead to growing discouragement and frustration. Assisting patients through this period typically involves a combination of adequate pain control, education, reassurance, and careful monitoring for early psychiatric and

psychological complications. Delirium is common during this period (see cognitive disorders and neuropsychiatric side effects of immunosuppressant sections below). Without complications, a typical posttransplant length of hospital stay can be as short as 3 to 4 days for kidney recipients, 7 to 10 days for liver and heart recipients, and approximately 2 weeks for lung recipients.

EARLY POSTTRANSPLANT ADAPTATION. The immediate postdischarge phase places tremendous burdens on recipients and their families and caregivers now responsible for following complex medical regimens posttransplantation. In addition to new combinations of multiple medications, patients and caregivers must attend clinic appointments and get laboratory tests frequently, sometimes several times a week for at least the first several months after hospital discharge. Complications that arise may necessitate additional procedures and tests at the hospital or emergency room. At home, patients and caregivers must monitor vital signs, follow specific diets, and adhere to restrictions on physical activity (e.g., lifting weight, driving) and on the use of alcohol, drugs, and tobacco. As recovery progresses, the regimen may become simpler, and clinic visits and laboratory tests less frequent, and some restrictions may be removed. Eventually, recipients are encouraged to return to physical activity and even employment if indicated.

TRANSPLANT-RELATED ILLNESS BEHAVIOR. Maladaptive illness behavior can interfere with successful psychological adaptation to the demands of transplantation. Experience working with adult transplant recipients suggests two major types of such illness behavior. First, for patients with a long history of living with chronic disease, transplantation may represent a transition from one state of illness to another, with the transplant process being a familiar part of life as a patient. However, some chronically ill patients may psychologically adapt to the sick role, developing coping strategies that perpetuate their dependency on being ill. These patients can have difficulty adjusting to or transitioning into a healthier state of being. They may feel that the transplant team is expecting too fast a recovery or pressuring them to get better. They may develop unexplained somatic complaints, such as chronic pain, or become nonadherent with posttransplant care recommendations. They may experience concern, anxiety, or fear over being seen by the transplant team less frequently as

their postoperative course improves. The second pattern of maladaptive behavior can be observed in patients who become acutely ill and undergo emergency transplantation (e.g., due to fulminant hepatic failure or acute drug toxicity). For these individuals, with only the briefest period of pretransplant infirmity, the transplant can be an unwelcomed event. Awareness of their organ failure, their life-and-death circumstances, and their need for a donor organ may not occur until the perioperative period. These patients may feel a heightened sense of vulnerability and may have difficulty accepting or be in denial over their medical situation. They may attempt to return to normal functioning as quickly as possible posttransplant, recovering faster than the transplant team expects, yet possibly suffering later from pushing themselves too fast (i.e., returning to work before they are physically ready). They may resent having received a transplant with all the inherent restrictions, lifestyle changes, and regimens, and they may act out their anger or denial in episodes of nonadherence.

LONG-TERM OUTCOMES. Long-term physical functioning depends in part on recipients' initial state of health, postoperative complications, other medical comorbidities, the degree of adherence to medical directives, and their motivation to stay fit. Most transplant recipients experience a multiyear period following the first anniversary of the transplant in which they achieve maximal functioning of the transplanted organ, with a relatively low level and severity of complications and infrequent episodes of acute organ rejection. Their relatively good health during this period appears to contribute to improved emotional well-being. With time, however, other problems with the organ will develop (e.g., chronic graft rejection), and patients will develop long-term immunosuppressive medication complications, including renal insufficiency or failure, diabetes, hypertension, and cancers. In fact, 10% to 20% of nonrenal transplant recipients will experience renal insufficiency or failure in the 5 years following transplantation. In addition, some patients will have a recurrence of or ongoing organ damage from their primary disease that can eventually destroy their transplant. Overall, transplantation extends life and improves health and quality of life compared to pretransplant functioning, but for most transplant recipients, their health and quality of life remain somewhat lower than that of a normal healthy person (see

Figs. 27.13–2 and 27.13–3 on survival and long-term health issues posttransplant).

PSYCHIATRIC DISORDERS AFFECTING ORGAN TRANSPLANTATION

Similar to other populations with chronic physical illnesses, organ transplant candidates and recipients are at elevated risk for elevated psychiatric symptom levels and diagnosable psychiatric disorders. Mood- and anxiety-related disorders are the most common psychiatric illnesses observed both pre- and posttransplant, although acute cognitive impairment and delirium are often seen shortly pretransplant and perioperatively due to metabolic perturbations and the effects of surgery. Some residual cognitive impairments may remain in the long-term posttransplant, although whether transplant recipients are at increased risk for dementias is unknown. In subpopulations of transplant recipients with histories of substance use disorders (e.g., patients with alcohol-related liver disease [ALD]), the risk for relapse remains a concern both pre- and posttransplant. Psychosis in transplant populations, although rare, is a significant concern because of its potential impact on health and well-being if not carefully managed. There is mounting evidence that, if not well managed, each of these classes of psychiatric disorders can affect patient health outcomes after organ transplantation.

Mood Disorders

Up to 20% of kidney recipients, 30% of liver recipients, and 63% of heart recipients experience mood and anxiety disorders during the first several years after transplant. The most common mood disorders observed in transplant populations are major depressive disorder, dysthymia, and adjustment disorders. Elevated levels of subclinical depressive symptomatology have also been noted in most studies. The risk for depression appears to be greatest during the first year posttransplant. Indeed, rates of mood disorders have been observed to be higher during the first year posttransplant than during either the waiting period for transplant or during patients' lifetimes before they became transplant candidates. The heightened risk during the first year after the transplant has been linked to stressors associated with physical recovery and rehabilitation; adaptation to immunosuppressive medications and a new

medical regimen; and psychosocial and role changes as the transplant recipient transitions from critical illness to a less illness-focused lifestyle. After the first year, the likelihood of additional episodes of mood disorders appears to decline for a period of several years. Although there is little empirical evidence on the prevalence of mood or other disorders beyond about 5 years posttransplant, anecdotal accounts suggest that the prevalence of these psychiatric disorders, depression, in particular, may begin to rise in the face of the late-term transplant-related health changes noted earlier.

A growing number of studies Indicate that the presence of either diagnosable mood disorders or elevated depressive symptomatology increases the risk of poor health outcomes in transplant candidates and recipients. In a recent meta-analysis of the transplant literature, Dew et al. demonstrated that depression, either pre- or posttransplant, has a strong negative impact on posttransplant survival, increasing the relative risk of mortality by 65%. Risk does not appear to differ by type of transplant. Although morbidities are infrequently studied, depression also appears to increase the risk of death-censored graft loss in kidney recipients. To date, however, no studies have examined the mechanism by which depression may lead to poor posttransplant health outcomes, although it is speculated that depression might result in poor health behaviors (e.g., nonadherence) and/or pathophysiologic abnormalities (e.g., neurovegetative symptoms or immune mechanisms) that could contribute to morbidities and mortality. Regardless of the mechanism, the potential for depression to at least predict morbidity and mortality, combined with the fact that depression contributes to poor quality of life and functional disability in both patient and nonpatient community populations, suggests the importance of timely treatment of this condition in transplant recipients. Screening for depression, especially in the early posttransplant phase, merits consideration.

Anxiety Disorders

Anxiety disorders appear to be less prevalent than mood disorders both before and after transplantation. They have been observed in up to one-third of transplant recipients, although there have been too few studies to specify prevalence rates of each type of anxiety disorder. Some anxiety disorders (e.g., panic disorder) appear to be more common in patients with advanced lung disease than patients with other types of advanced

organ diseases, and these disorders may be more common after transplantation in these patients as well. As with mood disorders, the prevalence of anxiety disorders appears to decline beyond the first year posttransplant, although stressors associated with the development of medical complications in the very late years posttransplant may precipitate new episodes of anxiety disorders.

Anxiety disorders may have the capacity to predict health outcomes in transplant recipients, although research remains sparse, and the findings are mixed. Moreover, other studies have found little impact of anxiety disorders such as generalized anxiety disorder or panic disorder. However, the potential quality-of-life benefits of treating such conditions emphasize the importance of monitoring transplant recipients for the development of anxiety.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) has received increasing attention in transplant recipients and may account for a significant proportion of all cases of anxiety disorder, especially during the first year posttransplant. Factors contributing to PTSD include actual events surrounding the transplant experience (e.g., critical medical events during the waiting period, the surgery itself, and the perioperative recovery period), as well as patients' experiences of hallucinated events and delusions during delirium.

One study found that PTSD experienced during the first year after heart transplantation predicted mortality during the subsequent 2-year follow-up period. However, persistent non-PTSD anxiety symptoms were unrelated to either mortality or morbidities in the cohort. The mechanism by which PTSD predicted mortality is not clear, and whether treatment would improve transplant recipients' health outcomes is unknown.

Psychotic Disorders and Mania

Psychosis, including conditions such as schizophrenia, schizoaffective disorder, mania, and psychotic depression, is rare in any population, including transplant recipients. Moreover, unlike the depressive and anxiety-related disorders discussed above, which occur in transplant recipients both with and without earlier lifetime histories of such disorders, psychosis emerging beyond the postoperative recovery period (and which can therefore not be ascribed exclusively to acute metabolic perturbations

associated with surgery and marked medication changes) appears to occur almost exclusively in individuals with pretransplant histories of such illness. In fact, individuals with a history of psychosis are at high risk for posttransplant recurrences. A survey found that 37% of such patients experienced manic or psychotic episodes in the first several years posttransplant. Nevertheless, these patients can do well posttransplant if good social supports, adherence to medical and psychiatric directives, ongoing mental health treatment, and good control of psychotic symptoms are established prior to transplant. Under these circumstances, these patients do not have rates of nonadherence that differ from other transplant recipients. The potential for good management posttransplant, plus the very negative effects if psychoses are not well managed, make them important conditions to consider during the pretransplant assessment. Despite common beliefs, it is not clear that a prior psychiatric history makes a patient more susceptible to the potential of immunosuppressive medications, especially steroids, to produce or exacerbate psychotic symptoms or mania (i.e., “steroid psychosis”). The appropriate use of antipsychotic medication is usually adequate to prevent or manage these symptoms if they emerge, and care must be taken that these medications are not inadvertently discontinued in the early posttransplant phase.

Alcohol and Other Substance Use Disorders

Mental health professionals are most likely to be called on to evaluate patients for these disorders in the context of liver transplantation. ALD and HCV (most often incurred due to injected drug use) are two common indications for liver transplantation in the United States (Table 27.13–1). Alcohol use disorders, predominantly in liver transplant patients, have thus received the most attention with respect to candidacy issues, policy, and pre- and posttransplant outcomes. Although the use of other substances by the liver as well as other solid organ transplant patients is equally important, other substance use appears less prevalent and has received much less consideration.

There is no direct concordance between the alcohol amount consumed, an alcohol use disorder diagnosis, and either the development of ALD or alcohol-related cardiomyopathy. Evidence from the natural history of alcohol-related cardiomyopathy and ALD suggests that the risk for these diseases increases in a dose-dependent fashion with 10 years or more of

daily consumption. Even modest exposure cumulatively over time can cause cirrhosis. For example, the daily consumption of two to four drinks increases the risk of cirrhosis two- to threefold for men and women compared to abstinent persons. Due to the focus of their interview, a mental health professional may be more likely than other clinicians to gather information on the quantity, frequency, and duration of alcohol use that can aid in establishing the ALD diagnosis. Importantly, the mental health assessor should establish the severity of the alcohol and other substance use disorders, length of abstinence, efforts at treatment, and whether treatment is needed to prepare for transplantation.

The rates of problematic alcohol and other substance use are relatively low posttransplant, perhaps due to rigorous selection criteria. Over the long term following liver transplant for ALD (including projections out to 10 years posttransplant), although 30% to 50% may drink (including those who have had only a single drink), some who drink will begin or return to addiction counseling, and only a smaller percentage, 10% to 20%, will continue to drink in a pattern potentially harmful to their health or graft functioning. However, since even a single drink can lead to a heavier or hazardous pattern of alcohol use, the identification of any use is a reason for concern and an opportunity to provide education and referral for addiction counseling. At both U.S. and European programs, posttransplant alcohol consumption that results in premature death or graft failure is uncommon, and long-term survival of patients with alcoholic liver disease is equal to those transplanted for other causes, even among those who drink most heavily. Nevertheless, among the heaviest drinkers, alcohol can contribute to medication nonadherence, which in combination with alcohol-related liver damage can lead to loss of graft function and death. Other nonalcohol substance use is uncommon. In a meta-analysis of studies reporting posttransplant substance use, the relapse to illicit drugs for transplant recipients with a pretransplant history of such drug use was 3.7 cases per 100 patients per year (PPY). The rate was significantly lower in liver transplant recipients (1.9 cases per 100 PPY) compared to other organ types (6.1 cases per 100 PPY). These favorable results suggest that the most important task for transplant teams is to continue ongoing monitoring for substance use posttransplant, not to condone or dismiss any use, and to provide resources for psychiatric assessment, intervention, and treatment as soon as any substance use is discovered.

Characteristics that predict relapse to use in the general population also appear to predict posttransplant relapse to use, including the severity of the substance use disorder, family history of addiction, failed rehabilitations, multiple substances of abuse, poor social support for abstinence, and short pretransplant length of abstinence. However, these risk factors have been largely studied in relation to alcohol relapse; risk factors for other substance use have been mostly unexplored.

A few studies have addressed outcomes in MMT transplant recipients. These studies show little evidence that MMT participants have problems with posttransplant relapse or nonadherence. Although postoperative pain management may be more complicated for these patients in the immediate posttransplant period, methadone can be used as their primary analgesic. Close coordination with and transition back to their outpatient MMT program is essential when the patient is medically and physically capable. In one study of MMT, liver recipients mostly were eventually returned to their original methadone dose, with only a few requiring a modest dose increase. There is very little literature regarding the use of buprenorphine in transplant patients.

Nicotine Dependence: Smoked and Smokeless Tobacco

There is substantial evidence of the contribution of tobacco use to posttransplant vascular complications, health problems, cancers, graft loss, and death. Transplant patients may be at higher risk of tobacco-induced cancers due to the effects of immunosuppression. For example, in one study, compared to nonimmunosuppressed individuals, ALD transplant recipients had a 4-fold increased risk for lung cancer and a 25-fold increased risk for oropharyngeal cancer, risks presumed due to tobacco use. As noted earlier, all types of solid organ transplant programs are increasingly likely to suggest or require candidates to be tobacco free for transplant listing. Nevertheless, significant rates of tobacco use resumption occur after transplantation. Tobacco use posttransplant is particularly common in patients transplanted after histories of alcohol or illicit drug use, with a rate of 10 cases per 100 PPY, compared to the rate of 3 cases per 100 PPY in the general transplant population. Thus, posttransplant clinicians should be vigilant in monitoring for tobacco use and counseling for cessation. Little is known about the effects of electronic cigarette use or any differences in risk compared to tobacco use.

Cognitive Disorders

Cognitive dysfunction is prevalent in patients with end-stage disease and transplant recipients alike. Assessing cognitive function in transplant candidates is essential to identifying deficits that could compromise patients' ability to follow medical directives and capacity to comprehend and participate in decision making before surgery. Caregivers may need to assist the patient with following medical directives or even with basic activities of daily living if deficits are severe. Pretransplant cognitive impairments can occur due to their advanced organ disease. For example, in heart failure patients, low cardiac output and hypoperfusion or reduced cerebral blood flow, impaired cerebrovascular reactivity, ischemia in the absence of cerebrovascular events, and even medications such as inotropic agents can contribute to cognitive impairments. Patients with older, pulsatile ventricular assist devices (VADs) pretransplant may have microemboli to the brain, leading to temporary or permanent cognitive impairment (see VAD section below). Newer nonpulsatile VADs are half as likely to associate with neurologic and psychiatric dysfunction. Cognitive impairment is also relatively common in lung transplant candidates due to ineffective pulmonary gas exchange. Both elevated arterial partial pressure of carbon dioxide (P_{CO_2}) and decreased partial pressure of oxygen (P_{O_2}) contribute to these deficits. Oxygen therapy may improve cognitive functioning in certain candidates, but whether hypercapnia or hypoxemia will lead to permanent brain damage is unclear.

Prior to transplantation, it is critical to differentiate between the fluctuating course of delirium that is potentially reversible posttransplantation and more persistent cognitive deficits that may represent pre-existing dementia or a static cognitive impairment. Serial cognitive examinations are crucial to properly evaluate the impact of chronic and end-stage disease as well as the impact of the transplant itself. If possible, therapies to reverse or alleviate the metabolic or physiologic effects of organ disease should be implemented and re-examination performed. Existing impairments can persist or worsen posttransplant. Even if reversible, posttransplant symptoms of cognitive impairment may take months to years to resolve, are associated with poor quality of life, and are unlikely to match healthy individuals. Older age and lower education are risk factors for ongoing poor cognitive performance.

Although organ dysfunction–related cognitive impairment may be reversed by transplantation, postoperative delirium or neuropsychiatric side effects of corticosteroids and immunosuppressants may worsen cognitive symptoms (see the section on neuropsychiatric side effects of immunosuppressants below). Delirium is the most common cognitive disorder associated with transplantation, can be caused by multiple factors (Table 27.13–5), and arises as part of pretransplant medical conditions or postoperative recovery. Patients with pre-existing delirium (e.g., hepatic or uremic encephalopathies, discussed in more detail below) often have persisting symptoms postoperatively, with added vulnerability to other deliriogenic risks. Patients with other pretransplant central nervous system (CNS) insults may similarly be more vulnerable to delirium postoperatively. In a prospective study of cognitive impairment in lung transplant patients, 57% showed neurocognitive impairment at transplant hospitalization discharge, while only 45% were impaired prior to transplant. Although delirium-associated impairment tended to improve at 3-month follow-up, 80% of those with pretransplant impairment remained impaired at follow-up with older age, and lower education associated with poorer neurocognitive performance. In a cohort of liver transplant patients, cognitive impairment characteristic of hepatic encephalopathy (HE) largely resolved after transplant. However, new-onset cognitive impairments emerged by 1-year posttransplant in 70% of recipients and were not related to a history of encephalopathy, primary liver disease, immunosuppression regimen, or prior alcohol use. Overall, transplant recipients' cognition may be expected to improve the following transplant. However, cognitive functioning is unlikely to ever fully recover or return to the preillness baseline.

Table 27.13–5.
Perioperative Causes of Delirium

Anesthesia and the stress of surgery	Inhalational and intravenous anesthetics, sedative, analgesic and paralytic agents, intraoperative events, inflammation
Hypoxia	Anemia, hypotension, pulmonary emboli, pulmonary insufficiency, ARDS
Infection	Aspiration pneumonia, peritonitis, pneumonia, sepsis, stasis/decubitus ulcer, wound infections, urosepsis
Neurologic events	Abscess, cerebrovascular accident, central pontine myelinolysis, intracerebral hemorrhage, meningitis, posterior leukoencephalopathy syndrome, seizures
Metabolic imbalance	Acidosis, alkalosis, hypo- and hypercalcemia, hyponatremia, hypo- and hyperglycemia, hypo- and hyperkalemia, hypo- and hypermagnesemia
Nutritional deficiency	Protein-calorie, vitamin (B_{12}, folate, niacin, thiamine)
Medications	
Immunosuppressants	Cyclosporine, mycophenolate mofetil, steroids, tacrolimus
Antibiotics	Aminoglycosides, cephalosporins, fluoroquinolones, sulfonamides
Antifungals	Itraconazole, voriconazole
Antivirals	Acyclovir, famciclovir, ganciclovir, valaciclovir
Cardiovascular	ACE inhibitors, β-blockers, calcium channel blockers, clonidine
Gastrointestinal	Metoclopramide, proton pump inhibitors, ranitidine

Narcotics	Morphine sulfate, dihydromorphinone, etc.
Respiratory	Albuterol, montelukast, pentamidine
Sedatives	Benzodiazepines, diphenhydramine, zaleplon, zolpidem
Drug withdrawal	Narcotic or benzodiazepine withdrawal

ARDS, acute respiratory distress syndrome; *ACE*, angiotensin-converting enzyme.

Hepatic Encephalopathy in Liver Disease. HE is classified by the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) as a delirium due to another medical condition. HE is commonly encountered in patients with significant liver disease and manifests in a constellation of signs and symptoms that can include alteration of consciousness (including stupor or coma), cognitive impairment, confusion or disorientation, affective or emotional dysregulation, psychosis, behavioral disturbances, bioregulatory disturbances, and disturbances of the motor system represented by asterixis, tremor, increased tendon reflexes, increased muscle tone, ataxic gait, bradykinesia, slurred speech, or incoordination. HE identification is important, given its effects on patient quality and quantity of life. Minimal HE predicts overt HE, and fulminant HE is associated with intracranial hypertension, cerebral edema, seizures, and death pretransplant. Persistent HE is rare and is observed predominantly in patients with extensive portacaval collateral circulation or after surgical or transjugular portosystemic stent shunting procedures.

HE reflects a continuum of symptoms, with subclinical or minimal HE lying at the milder end of the spectrum. Even minimal HE is clinically important, however, as it affects up to 60% of cirrhotic patients, impairs patient safety (such as the ability to drive a motor vehicle), job functioning, and quality of life, and is associated with persistent cognitive deficits after liver transplantation. The earliest signs of HE include sleep disturbances and subtle behavioral changes, which may not be obvious on clinical examination and should be elicited from patients and caregivers. Minimal HE is primarily associated with abnormalities in attention, memory, and response inhibition and also may not be readily discernable on typical clinical examination. Additional neuropsychological tests assessing psychomotor speed, praxis, concentration, and attention, such as Trail-

Making Tests A and B, Digit Symbol, and Block Design Tests, are useful in identifying minimal HE but are not commonly employed due to time and expertise limitations. A smartphone application utilizing the Stroop cognitive screening test has been validated against a standard neurocognitive battery to screen for HE and may represent a more feasible way to detect and track HE. Although an electroencephalogram (EEG) may also show common abnormalities, such as generalized slowing of dominant rhythm, cognitive testing is more efficient and perhaps more sensitive to minimal HE.

Although HE has a multifactorial pathogenesis, a predominant treatment strategy is to reduce the production of ammonia from protein in the intestinal tract and reduce its absorption through the utilization of daily medications. In addition, a variety of other compounds and metabolites are implicated in HE (e.g., mercaptans, false neurotransmitters, aromatic—phenylalanine, tyrosine, and tryptophan—and branched-chain amino acids, manganese, endogenous benzodiazepines, and increased concentrations of CNS γ-Aminobutyric acid (GABA)) alongside processes such as edema, inflammation, and increased permeability of the blood–brain barrier. HE can be precipitated by gastrointestinal hemorrhage, uremia, use of some psychoactive medications or diuretics, significant protein intake, dehydration, or electrolyte imbalance, and these problems should be detected and corrected first. Medications that can contribute to symptoms of HE or slow intestinal motility (anticholinergic drugs, tranquilizers, narcotics, and sedatives) should generally be avoided.

Uremic Encephalopathy in Renal Disease. Chronic renal failure frequently causes multiple pathophysiologic changes involving catabolic, metabolic, and endocrinologic processes that contribute to uremic encephalopathy (UE). In uremia, the accumulation of organic substances that act as neurotoxins (e.g., urea, uric acid, guanidine compounds, hippuric acid, various amino acids, indoleacetate, and others) are believed to be related to the encephalopathy, but no single metabolite has been identified as the sole cause. Other pathophysiologic changes also implicated in UE include hormonal elevations, electrolyte imbalances (e.g., acidosis, hyponatremia, hyperkalemia, hypocalcemia, hypermagnesemia), anemia, malnutrition, and CNS factors (increased calcium and decreased GABA and glycine activity). Reduced levels of thiamine, a water-soluble vitamin, have been noted in hemodialysis

patients, and cases of Wernicke encephalopathy have been mistaken for UE.

UE symptoms typically fluctuate and can begin insidiously, with patients reporting mild symptoms of irritability, insomnia, or cognitive, attentional, and memory impairments. Patients may complain of physical symptoms of slurred speech, muscle twitches, or restless legs. Symptoms can progress slowly or rapidly to confusion, lethargy, seizures, overt delirium, psychosis, catatonia, and stupor or coma. An EEG can aid in diagnosis (typically showing a generalized slowing of the dominant rhythm) and detect seizures, including nonconvulsive status epilepticus, which can occur in uremia and could be mistaken for UE.

UE has also been associated with a cliniconeuroradiologic syndrome termed posterior reversible (leuko) encephalopathy syndrome (PRES) (see the section on PRES in the neurotoxicity of immunosuppressive medications below). Characteristic radiographic findings on CT or MRI are seen in the posterior cortical and subcortical white matter.

Removal of uremic toxins by hemodialysis, correction of electrolyte imbalances and anemia, and treatment of malnutrition can diminish UE symptoms and improve cognition. Seizures may be treated with anticonvulsants. Drugs that are sedating or require the elimination of the parent compound or active metabolite by renal clearance should be avoided or dosages appropriately adjusted for the degree of impaired renal functioning. As even patients well into their 70s are being considered for kidney transplantation, the risk of permanent cognitive deficits or dementia from chronic dialysis and comorbidities needs to be considered pretransplant. Kidney transplantation is the definitive treatment for UE, but one cross-sectional study of kidney transplant recipients who averaged 3.4 years posttransplant found that 58% met the criteria for cognitive impairment.

SPECIAL ISSUES IN TRANSPLANTATION

Life-Sustaining Technologies and Their Effects

Dialysis. Most renal transplant candidates are on maintenance dialysis prior to transplantation, although almost 20% receive kidney transplants as their first advanced renal disease therapy—the majority being living donor recipients. Without a living donor, a U.S. adult kidney candidate can

expect a median wait time of 3 to 5 years. Thus, survival on dialysis until transplant remains an important issue. According to the U.S. Renal Data System statistics, dialysis survival after 1 year is 81% and only 45% after 5 years, but these rates are dependent on age, primary disease, and medical debility. Although there is no specific age limit for renal transplantation, advanced age in combination with medical comorbidity makes transplantation less of an option. Cardiovascular diseases are common reasons why patients are ineligible for transplantation and are also common causes of death on dialysis.

In addition to medical criteria, candidates should demonstrate good adherence to dialysis and follow-up with their nephrologist. Pretransplant adherence to dialysis is a useful indicator of posttransplant adherence. Patients must not only comply with dialysis sessions but with dietary and fluid restrictions as well. Attendance at dialysis and missed or shortened sessions should be evaluated. If nonadherence is identified, the reasons should be explored and addressed. Comorbid depression can affect adherence to dialysis and, if treated, can improve adherence. UE can impair functioning and quality of life during the wait period (see the section on UE above). Following transplantation, recipients often report good overall quality of life, with distinct improvements in physical, mental, and social functioning compared to pretransplantation.

VADs in Heart Transplantation. Progress in the development of VADs from extracorporeal devices to implantable devices has dramatically improved both the physical and psychological health of patients with advanced heart failure. These devices are now used both to “bridge” patients to transplantation and as long-term (“destination”) therapy for patients ineligible for transplant. The newest VADs now include implantable left ventricular or biventricular versions that have improved mobility, ease of wearability, and quality of life. Portable pneumatic drivers are compact and lightweight and can be worn on a shoulder strap or towed on a luggage-type carrier. Patients must be able to comply with postoperative care of the device and driveline site, as well as anticoagulation or other medical regimens. Following hospital discharge after implantation, patients are encouraged to be physically active (including walking, driving, dancing, and even work). Most patients can achieve New York Heart Association functional status I or II on a VAD. In addition, while supported on a VAD, patients can achieve significant gains

in physical and physiologic rehabilitation and rebuild muscle mass, potentially stabilizing their cardiac condition. With the patient in a less urgent status, the transplant team can wait for an optimal donor organ. These benefits notwithstanding, the logistics of arranging for a VAD patient to live outside of the hospital require that patients and their family caregivers be extensively trained, with suitable home arrangements (e.g., availability of a reliable source of electricity). VAD program team members must be available at all times to advise patients, families, and any local emergency paramedical personnel near the patient's home if there is a sudden medical crisis. Despite these requirements, patients' ability to reside at home comes with many personal advantages for patients, including reduced financial burden, compared to prolonged hospitalization.

VADs can lead to major improvements in quality of life. They allow not only for improved mobility and function for most activities of daily living but also improvements in mental health and cognitive functioning. Adjusting to the VAD can be psychologically difficult for some patients, and incorporating the machinery into their bodies can evoke feelings of a damaged body image and sense of self, intense vulnerability, and fear of a VAD malfunction or infection. Psychotherapy to address these issues for both patients and caregivers may ease the transitions onto a VAD and help them prepare for eventual transplant. VAD recipients are also at risk for neurologic events (e.g., thromboembolism), although continued improvements in VAD design and management have reduced the risk for these events. Nevertheless, when they occur, they can lead to major cognitive impairments that may be irreversible. Thus, prevention and timely intervention for such events is critical for preserving patients' cognitive status and ability to function during VAD support and, potentially, after transplantation.

Living Organ Donor Outcomes

Living liver donation is much more surgically complex, invasive, and potentially riskier for the donor than kidney donation. In fact, since laparoscopic donor nephrectomy is most common for kidney donation, donors experience relatively limited postoperative pain, brief hospital stays (as little as 2 to 3 days), quicker recovery times than with open surgical procedures, and favorable cosmetic results. Although mortality rates are well less than 1% for both kidney and liver donors, at least one-

third of liver donors have perioperative complications, with serious complications occurring in 6% to 14% of donors. Kidney donors typically require 4 to 6 weeks of recovery before returning to work. Liver donors require 8 to 12 weeks of recovery or longer, especially if the job involves heavy lifting.

Donor quality of life and emotional well-being do not appear, on average, to be adversely affected by organ donation. In fact, there is literature dating back to the mid-1960s showing that donors can accrue significant personal benefits from the donation in terms of feelings of self-esteem and self-worth. Extremely low percentages of donors regret having donated or state that they would not donate if they had it to do over again. For the majority of donors, there is little evidence that mental health, physical health, or quality of life are worsened by donation. However, adverse outcomes remain a possibility and have been observed in donors. The development of mood and anxiety disorders has been noted, and several case studies have documented completed or attempted suicide (although the extent to which the suicides were attributable to donation has usually been unclear). A growing literature shows that, on average, kidney donors' and liver donors' health-related quality of life is high and exceeds that of the general population even many years after donation. Nevertheless, up to 20% of donors may show quality of life impairments in one or more areas, including mental health and emotional well-being. A history of psychiatric difficulties increases donors' risk of experiencing mental health problems postdonation.

Treatment Issues Specific to Transplantation

Psychotherapeutic Treatment Modalities. For the pretransplant period, several randomized controlled studies have examined a variety of cognitive behavioral and education-based therapeutic interventions to address issues specific to this phase, including uncertainty of wait time or ability to survive to transplant, a decline in health and increasing dependence on others, losses of roles and functioning, and decrements in quality of life. Some studies have included caregivers as well. Results have been mixed but mostly demonstrate improvements in quality of life and reduction in psychological distress among candidates in the active treatment arms.

Following transplantation, individual psychotherapy appears beneficial in addressing three recurring psychological themes: (1) fear of organ

rejection, (2) feelings of paradoxical loss posttransplant despite successful transplantation, and (3) psychological integration of the organ. Group therapy and other innovative strategies have also been employed to deal with specific issues of transplantation and to also address logistics and staffing resources. Group therapy is a frequently and successfully used technique for organ transplantation patients and family members. Educational groups are often used to provide information to transplant candidates about the transplant process, systems issues, and the responsibilities of transplant recipients and caregivers. Depending on the available resources and number of patients near to the program location, support groups may also be comprised of pre- or posttransplant patients, patients' family caregivers, and organ-specific or cross-organ type participants. Group therapy participants report decreases in negative affect, increases in positive affect and happiness, less illness intrusiveness, improved quality of life, and decreased need for contact from their transplant coordinators both in the clinic and by telephone for social support. Additional support can be found through the Transplant Recipient International Organization (www.trioweb.org), a nonprofit international organization that provides support, education, and advocacy for transplant recipients worldwide. The member chapters usually have regular meetings of transplant recipients, and they provide group support for transplant candidates, recipients, and their families.

Some transplant programs have formal and informal peer mentoring programs whereby an already transplanted recipient augments patient care by the staff. Mentors can provide information and support from a peer perspective. Mindfulness-based stress reduction and other non–transplant-specific therapeutic approaches have demonstrated benefits to patients' psychological adjustment and quality of life. Dew and colleagues developed an internet-based intervention to deal with the logistical problem of recipients living at a distance from the transplant program. The multicomponent intervention included stress and medical regimen management workshops on the website, monitored discussion groups, access to electronic communication with the transplant team, and information on transplant-related health issues. Compared to patients without access to the website, heart recipients who used the internet intervention had significant decreases in depressive and anxiety symptoms, their quality of life in the social functioning domain significantly improved, and their caregivers had decreases in anxiety and hostility

symptoms. In addition, the subgroup using the website's medical regimen workshop showed significantly better adherence to multiple elements of the medical regimen.

Interventions for Adherence to the Posttransplant Regimen. As discussed earlier, lifelong adherence to the posttransplant regimen can be difficult. Many factors contribute to posttransplant nonadherence, including medication side effects, behavior problems (e.g., poor planning, poor health responsibility), and social issues (e.g., insurance coverage, copays, transportation). Eliciting patient-specific barriers will guide the selection or development of the best approach for intervention. Patient involvement in the selection of adherence intervention and allowing them, with support, to make decisions about their care is important to success. Trials designed to minimize posttransplant nonadherence show no single intervention to be superior, and a combination of interventions might be the best approach. Re-education about the regimen and its rationale can be helpful and educational interventions delivered by pharmacists have been effective. Problem-solving, cognitive behavioral therapy or other behavioral therapies may be useful. Patients traumatized by the transplant experience may have associated adherence issues that could be targeted with psychotherapy. Identification and treatment of depression and/or substance use may improve adherence.

Interventions have included a variety of approaches: case management/coaching and educational interventions, multicomponent interventions, patient-tailored interventions with a multidisciplinary approach and with the widespread use of technology, cognitive educational interventions making use of the internet, and electronic feedback (including real-time feedback). Electronic health (eHealth) interventions, including apps and other mobile health strategies, hold promise for improving patient self-monitoring and adherence to posttransplant care, ideally increasing patients' involvement in their care. Consensus is growing that short-term, time-limited interventions are inadequate; either intervention must be ongoing (e.g., via eHealth) or periodic booster or maintenance sessions may be required to maintain optimal adherence.

Psychopharmacologic Therapy. Pharmacotherapy is complicated during the pretransplant period due to the presence of advanced organ disease. Pharmacokinetic alterations caused by changes in perfusion,

fluid status, protein binding, hepatic drug metabolism, and excretion are common in advanced organ disease and require careful selection of medications and dosage. In addition, pretransplant patients are more susceptible to adverse side effects (e.g., encephalopathy, arrhythmia) and potential drug–drug interactions, as it is not uncommon for them to be on a number of medications prior to transplantation. Some psychotropic agents should be avoided in advanced organ disease, particularly when advanced cirrhosis is present. In general, pharmacotherapy in pretransplant patients calls for using lower starting dosages and slower titration of drugs until they reach clinical effectiveness.

Following transplantation, pharmacokinetic alterations caused by advanced organ disease usually resolve, but considerations about potential drug–drug interactions arise. In particular, many of the immunosuppressive agents (tacrolimus [Prograf], cyclosporine [Neoral and others], sirolimus [Rapamune], mycophenolate mofetil [Cellcept, Myfortic]) are primarily metabolized by cytochrome (CYP) 450 3A4; thus, psychotropic medications that strongly inhibit CYP 450 3A4 may pose a risk. Such psychotropic drugs include, in decreasing order of inhibition: fluvoxamine, nefazodone > fluoxetine > sertraline, tricyclic antidepressants, paroxetine > venlafaxine. Although fluoxetine and tricyclic antidepressants have been used to treat depressed transplant recipients without significant changes in immunosuppressant levels, nefazodone has resulted in toxic immunosuppressant levels with serious complications. Although this suggests that the amount of CYP 450 3A4 inhibition may not create clinically meaningful drug interactions for all patients, these drugs should be used cautiously and with frequent monitoring of immunosuppressant levels. Most immunosuppressants have significant metabolic side effects (e.g., weight gain, hyperlipidemia, glucose intolerance), which must be considered with choosing psychotropics to prescribe. Table 27.13–6 summarizes primary considerations about psychotropic agents pre- and posttransplantation.

Due to its narrow therapeutic window, the use of lithium before and early after transplantation can be complicated due to fluctuations in fluid status (e.g., edema, dehydration) and renal function causing unstable lithium levels and potential toxicity. In addition, lithium can cause renal tubular damage that might be problematic when combined with the nephrotoxic effects of immunosuppressant medications. If lithium is necessary, monitoring of lithium levels, fluid status, electrolytes, renal

functioning, and creatinine clearance should be closely followed and lithium discontinued if renal insufficiency develops.

The use of antipsychotic medications may be necessary posttransplant to manage delirium, marked immunosuppressant-induced mood changes, or a pre-existing psychotic disorder. Symptomatic treatment of agitation, hallucinations, or paranoia usually calls for the use of atypical antipsychotic agents or traditional neuroleptics (e.g., haloperidol). Due to the risk of QT prolongation associated with these medications, along with the likely presence of other medications (e.g., tacrolimus) or conditions that have also been linked to torsades de pointes, electrocardiogram (ECG) monitoring is recommended.

Benzodiazepines are effective for anxiolysis before and after transplant, but care is needed when selecting these agents. Oversedation increased cognitive impairment, and reactivation of a past substance use disorder are potential risks. Pretransplant, impaired hepatic oxidation can delay clearance of benzodiazepines and increase the risk for adverse side effects. Use of agents that only require conjugation (i.e., lorazepam, oxazepam, temazepam) would be preferable. Buspirone can also be beneficial for anxiety and may also have respiratory stimulating properties, especially beneficial for patients with lung disease or those attempting to wean from a ventilator.

Medications that may reduce cravings and potentially diminish the risk for relapse to alcohol (e.g., acamprosate, ondansetron, naltrexone) or opioids (naltrexone) have not been studied in transplant patients. Naltrexone has a small risk of hepatotoxicity (contained in a black box warning) and is not recommended for patients with active liver disease, hepatitis, or liver failure, making it less suitable for liver transplant patients. At doses higher than recommended (more than 300 mg per day), naltrexone can be a direct hepatotoxin. Disulfiram blocks the oxidation of alcohol at the acetaldehyde stage and can create severe nausea, vomiting, and hemodynamic instability. It requires hepatic metabolism for conversion into an active drug. In addition, a metabolite of disulfiram is an inhibitor of CYP 450 3A4, and posttransplant may interfere with immunosuppressant metabolism.

For tobacco users, in addition to smoking cessation counseling and nicotine replacement therapies (gum, patches, lozenges, and inhaled), the use of medications (bupropion or varenicline) may aid in cessation. Bupropion should not be used in those with a history of a seizure disorder

or electrolyte disturbances that could contribute to a seizure. Varenicline is excreted by the kidneys, and dose adjustment is required for patients with moderate to severe renal impairment. Both medications can increase the likelihood of success and should be continued for 6 to 8 weeks after tobacco cessation to prevent relapse.

Neurotoxicity of Immunosuppressant Medications

While transplant teams tend to focus on the neurotoxic effects of corticosteroids (e.g., delirium, agitation, insomnia, depression), the impact of these agents on transplant recipients is often transient and occurs early posttransplant when higher doses are utilized. Of greater significance are calcineurin inhibitors (CNIs), which continue to serve as a mainstay of immunosuppressive medication regimens in solid organ transplantation. Tacrolimus and cyclosporine have similar neurotoxic side-effect profiles, with as many as 40% to 60% of transplant recipients experiencing mild neurologic symptoms such as tremulousness, headache, restlessness, agitation, insomnia, vivid dreams, paresthesias, and mood changes. Moderate-to-severe neurotoxic side effects (e.g., delirium, seizures, cortical blindness, catatonia, coma) occur less often but can reach 20% to 30% in the early postoperative period. Neurotoxicity is likely more common with tacrolimus but can occur with either agent even at therapeutic drug levels. Liver transplant patients appear to be more susceptible to these neurotoxic side effects than heart and lung transplant recipients.

Table 27.13–6.
Pharmacotherapy Considerations in Transplant Patients

Medication	Specific Considerations for Transplant Patients
Antidepressants	
SSRIs	
Citalopram	Lack of drug–drug interactions, possible QT prolongation
Escitalopram	Preferred, lack of drug–drug interactions
Fluoxetine	Reduce dosage or lengthen dosing interval in HI; risk of interaction with immunosuppressants
Fluvoxamine	Consider lower initial dose and slow titration in HI; risk of interaction with immunosuppressants
Paroxetine	Reduce initial dose and slow titration in moderate-to-severe RI and HI. Anticholinergic side effects
Sertraline	May consider lower or less frequent dosing in HI
SNRIs	
Venlafaxine	Reduce total daily dose in moderate-to-severe RI/hemodialysis/HI; risk of elevated blood pressure
Desvenlafaxine	Dose should not exceed 50 mg/day in moderate RI; no more than 50 mg every other day in severe RI
Duloxetine	Avoid use in HI and in severe RI.
Vortioxetine	Not recommended in severe HI/cirrhosis
Others	
Bupropion	Limit dose to 150 mg of XL formulation every other day in severe HI; 100 mg/day of SR formulation; reduce initial dose in RI
TCAs	Cardiovascular side effects are undesirable in cardiac patients. Anticholinergic side effects
MAOIs	Significant risk of drug–drug interactions make this undesirable in transplant patients
Mirtazapine	Clearance reduced in moderate-to-severe RI/HI.

	Consider lower initial dose and slower titration, sedative, and weight gain side effects
Vilazodone	No dose adjustment necessary in RI/HI, Not recommended in severe RI
Nefazodone	Avoid use due to risk of drug–drug interaction with immunosuppressants
Brexanolone	Avoid use in ESRD (eGFR <15 mL/min/1.73 m^2, no dose adjustment necessary in mild–severe RI)
Esketamine	Not recommended in severe HI, monitor longer for adverse reactions and moderate HI
Anxiolytics	
Benzodiazepines	Lorazepam, oxazepam, temazepam do not require hepatic oxidation. Safer choices in presence of HI; risk of respiratory depression
Buspirone	Not recommended in severe RI or HI
	All pose risk of QT prolongation; atypical agents also increase risk of metabolic syndrome
Antipsychotics	
Atypical	
Aripiprazole	No dose adjustment needed in RI/HI
Asenapine	Use contraindicated in severe HI
Clozapine	Risk of seizures, agranulocytosis, orthostatic hypotension complicate use in transplant
Lurasidone	Moderate HI and moderate-to-severe RI: starting dose 20 mg/day, total dose not to exceed 80 mg/day; severe HI: total dose not to exceed 40 mg/day
Iloperidone	Use not recommended in severe HI
Olanzapine	Poses greater risk of metabolic syndrome.
Paliperidone	Clearance reduced in RI; for moderate-to-severe RI: starting dose 1.5 mg/day, total dose maximum 3 mg/day

Risperidone	Severe RI: start dose at 0.5 mg bid. Slow titration is recommended
Quetiapine	No dosage adjustment needed in RI/HI
Ziprasidone	No dosage adjustment needed in RI/HI; greater risk of QT prolongation
Brexiprazole	For moderate–severe RI/HI, maximum dose 2 mg/day for major depression, 3 mg/day for schizophrenia
Cariprazine	Not recommended in severe RI/HI
Lumateperone	Not recommended in moderate–severe HI
Typical	
e.g., haloperidol	No dosage adjustment needed in RI/HI
Mood Stabilizers/Anticonvulsants	
Lithium	Moderate RI: use 50–75% of usual dosage hemodialysis-supplemental dose of 300 mg once after each dialysis session May be difficult to use due to shifting fluid status, unstable levels, risk of toxicity; cyclosporine reduces Li clearance
Carbamazepine (CBZ)	CYP 3A4 inducer effects of CBZ lower levels of immunosuppressants, risk of organ rejection
Oxcarbazepine	Avoid extended-release formulation in severe HI; severe RI: reduce initial dose to 300 mg/day, titrate slowly, CYP 3A4 inducer drops immunosuppressant levels
Lamotrigine	Severe HI with ascites: reduce initial, escalation, and maintenance dose by 50%; without ascites: reduce by 25%
Topiramate	Moderate-to-severe RI: reduce dose by 50%; cognitive side effects may be problematic for transplant patients
Valproic acid	Avoid use in HI if possible due to reduced clearance; reduced serum albumin can raise

	free VPA levels
Gabapentin	Moderate RI: 600 mg/day; severe RI: 150–300 mg/day; hemodialysis: may require both maintenance and supplemental dose after dialysis session
Psychostimulants	
Atomoxetine	Moderate HI: reduce initial and total dose by 50%; severe HI: reduce initial and total dose by 75%
Methylphenidate	No dosage adjustment needed in RI/HI; use in cardiac patients limited by cardiovascular side effects
Amphetamine	No dosage adjustment needed in RI/HI; use in cardiac patients limited by cardiovascular side effects
Modafinil	Severe HI: reduce dose by 50%.
Armodafinil	Severe HI: reduce dose due to reduced clearance; severe RI: lack of dosing info prevents safe use
Anticraving Medications	
Buprenorphine	Moderate-to-severe HI: use with caution and at lower dose; may have longer exposure and activity
Naltrexone	Use in severe RI/HI has not been studied—thus, safety is unknown
Methadone	RI/HI: lower initial dose and slow titration advised; can prolong QT interval; use with caution in cardiac patients
Varenicline	Severe RI: initial dose of 0.5 mg/day, may increase to 0.5 mg bid; risk of neuropsychiatric side effects
Acamprosate	Moderate RI: initial dose of 333 mg tid; severe RI: use is contraindicated
Disulfiram	Can cause dangerous hemodynamic instability in medically vulnerable patients if they drink, HI: use with caution; may cause hepatotoxicity even

	without alcohol use; a metabolite is a 3A4 inhibitor so could raise immunosuppressant levels

HI, hepatic insufficiency; *RI*, renal insufficiency; *moderate RI*, creatinine clearance 30–50 mL/min; *severe RI*, creatinine clearance <30 mL/min; *moderate HI*, Childs–Pugh class B; *severe HI*, Childs–Pugh class C.

The actual mechanism of CNI neurotoxicity is unclear but possibly multifactorial. Investigations into the etiology of more serious neurotoxic side effects suggest associations with biochemical and electrolyte derangements, including higher plasma levels, intravenous administration, hypocholesterolemia, and hypomagnesemia. However, these features are not present in every case. Neurotoxicity of CNIs may involve drug-induced vascular changes or direct action at the CNS neuronal level. Studies have revealed that CNIs increase sympathetic outflow and nerve activity, alter mitochondrial function, may be selectively toxic to white matter, and are capable of disrupting the integrity of the blood–brain barrier. In some cases, correcting the metabolic disturbance or reducing the CNI drug level will lead to the resolution of neurotoxic side effects, though severe symptoms may require discontinuation of the CNI.

While CNIs are highly effective immunosuppressants, their toxic side effects, particularly nephrotoxicity, have led to the search for alternate immunosuppressant agents that might serve as substitutes or allow reductions in CNI dosage. Within the past several years, a number of newer medications have been developed, including mycophenolate mofetil, sirolimus, everolimus, belatacept, as well as monoclonal antibodies such as basiliximab and daclizumab. Monoclonal antibodies are used for the treatment of acute rejection and as induction therapy during the first days or weeks after transplantation, but not for maintenance therapy. These offer reduced nephrotoxicity and also generally demonstrate less neurotoxic side effects (Table 27.13–7). However, there are infrequent complications that can arise with either CNIs or some of the newer immunosuppressants—namely, PRES or, rarely, progressive multifocal leukoencephalopathy (PML). PRES usually arises in the first month posttransplantation, though it can arise years later, and presents with a range of symptoms including seizure, headache, visual changes, confusion, ataxia, and other neurologic symptoms depending on the location of the lesion. Diagnosis via MRI usually reveals

T_2-weighted and fluid-attenuated inversion recovery (FLAIR) MRI images showing hyperintense lesions typically in the subcortical and cortical regions of the bilateral parieto-occipital lobes, but lesions can occur in other areas and in the brainstem. Discontinuation of CNI or sirolimus usually leads to the resolution of clinical and radiologic abnormalities. PML is a rare and severe demyelinating disease caused by the reactivation of the JC virus that can develop in immunocompromised patient populations.

Table 27.13–7.
Neurotoxicity of Immunosuppressant Medications

Medication	Side Effect(s)
Calcineurin inhibitors	Headache, tremor, paresthesia, visual disturbances, insomnia, delirium, seizures, apraxia, parkinsonism, cortical blindness, anxiety, mood changes, cognitive impairment, agitation, PRES, PML
Corticosteroids	Euphoria, depression, anxiety, agitation, insomnia, delirium, irritability, hallucinations, psychosis, cognitive impairment
Sirolimus	Headache, dizziness, tremor, depression, insomnia, PRES, PML
Everolimus	Tremor, somnolence, dizziness, paresthesia, hypoesthesia, fatigue, weakness, headache
Mycophenolate mofetil	Headache, insomnia, anxiety, dizziness, weakness, fatigue, PRES, PML
Belatacept	Headache, Guillain–Barré syndrome, PML
Azathioprine	PML
Monoclonal antibodies	
Basiliximab	Headache, tremor, insomnia, anxiety, depression, fatigue
Daclizumab	Insomnia, fatigue
Rituximab	Anxiety, depression, delirium, hallucinations
Alemtuzumab	Headache, dizziness, light-headedness, weakness, fatigue

PRES, posterior reversible encephalopathy syndrome; *PML*, progressive multifocal leukoencephalopathy.

27.14 Psychiatric Care of the Burned Patient

Martha C. Gamboa, M.D., Ejine Okoroafor, M.D., F.A.P.A., Reena Baharani, M.D., Yvette Smolin, M.D., M.Ed., and Michael Blumenfield, M.D.

Burn injuries represent a major global public health burden and constitute the fourth most common type of trauma worldwide, following traffic accidents, falls, and interpersonal violence. Across the globe, fire, heat, and hot substances incidents resulted in nearly 9 million injuries and more than 120,000 deaths worldwide in 2017. The mortality and morbidity related to fire, heat, and hot substances–related injuries generally decreased between 1990 and 2017 across income groups. However, approximately 96% of fatal fire-related burns continue to occur in low- and middle-income countries.

In 2019, in the United States, local fire departments responded to an estimated 1.3 million fires. These fires caused roughly 3,700 civilian fire-related deaths and 16,600 reported civilian fire injuries.

Major medical and surgical advances have greatly increased the burned patient's survival. The 2017 National Burn Repository (NBR) reviewed the combined data set of more than 212,820 acute burn admissions between 2008 and 2017, data provided by 101 hospitals from 37 states and the District of Columbia. The two most common etiologies were fire or flame burns and scalds, accounting for 76% of cases reported. Scald injuries were most prevalent in children under age 5, while fire/flame injuries dominated the remaining age categories. More than 67% of the reported total burn sizes were less than 10% of total body surface area (TBSA). These cases had a mortality rate of 0.6%. The mortality rate for all cases was 3.1% and 5.6% for fire or flame injuries. The mortality rate declined from less

than 4% to less than 3% for both men and women. The length of hospitalization was slightly greater than 1 day per percentage TBSA burned. The length of hospitalization for women declined from 9.4 days to 7.3 days, and for men, it declined from 9.5 to 8.5 days.

Increased survival rates translate to a larger number of burn patients that require physical, psychological, and social rehabilitation. Burn patients often suffer severe pain, major psychological distress, and very complicated psychosocial disruption to their lives. Psychiatrists and other mental health professionals working in the medical and surgical settings have a major role to play in the care of these patients.

RISK AND ASSOCIATED FACTORS FOR DEVELOPING BURN INJURIES

Burns result from the destruction of one or more cell layers of the skin or other organ tissues in contact with hot liquids (scalds), solids (contact burns), or flames (flame burns). Injuries due to ultraviolet radiation, radioactivity, electricity, or chemicals, as well as respiratory damage resulting from smoke inhalation, are also considered to be burns.

According to the World Health Organization (WHO), some of the major risk factors for sustaining burn injuries around the world are alcohol and smoking, particularly in combination. Contributory factors include local cultural practices, such as floor-level stoves, bedside fires, loose flammable attires, and fire walking; socioeconomic status (for both developed and developing countries); overcrowded living conditions; lack of proper safety measures; and insufficient parental supervision. There is notably an increased risk of burn injuries in vulnerable populations, including children, women, and the older adults.

Table 27.14–1.
Factors that Contribute to the Risks of Childhood Burn Injury

Physical Environment

- Structural materials of residence (substandard housing)
- Heating mechanisms (space heaters), objects, or flame (candles, stoves, bathtub)
- Presence of smoke/carbon monoxide detectors/alarms, fire extinguishers (half of all home fire deaths occurred in homes without alarm)
- Awareness of fire safety precautions and services, including adequate means of egress
- Rural areas
- Fall and winter months

Family, Cultural, and Social Structure

- Level of supervision of children
- Overcrowding
- Low-income status
- Traditional practices (e.g., open flame ovens)

Developmental/Gender (Chronologic, Emotional, and Intellectual Stage)

- Incredibly young children, especially under 4 years old
- Boys, greater than girls (boys are with more risk-taking behaviors) and use of flammable materials
- Increased levels of risk-taking behavior and exploration
- Epilepsy
- Learning disabilities and mental retardation

Psychological/Behavioral Disturbances of Child or Caregiver

- Alcohol/substance abuse and smoking
- Childhood/adult depression
- Violence/abuse
- Oppositional defiant disorder, attention deficit hyperactivity disorder, bipolar disorder

The 2017 NBR reported that in the United States, the two most common etiologies for burn injuries across all age groups are flame burns and scalds, accounting for almost 8 out of 10 reported burn cases. Scalds are more prevalent in the younger population, especially among those younger than 5 years of age, while fire/flame burns prevail in the remaining age categories. The vast majority of burns seen at burn centers were considered accidental, with only 13% of these related to work and only 3% specified as nonaccidental. The home continues to be the most common place of burn injury occurrence (73%). According to the 2017 NBR, males predominate in almost all age categories in comparison to females, except in individuals older than 80. Children between 1 and 15 years of age accounted for 23.5%. Patients between the ages of 20 and 59 years old represented 55% of the burn cases. Patients older than 60 represented 15% of the burn cases.

Table 27.14–2.
Typical Signs of Physical Abuse in Burned Children

Bilateral burns to feet, buttock, or back by dipping in hot water bath
Unburned lower extremity flexion creases, as child reflexively tries to avoid pain
Cigarette-sized round lesions
Posterior deep burns, with sharp margins from sustained or forced contact with hot object (child prevented from withdrawing)
Illogical, inconsistent explanations of the burn event provided by caregiver
Failure to thrive
Physical numbness to pain
Depression, unresponsiveness, intense fear reaction
Multiple injuries at different stages of healing, including fractures

The risk of burns in children usually results from the interplay between environmental, developmental, behavioral, and familial factors. Some of the environmental risk factors include lack of

supervision, proximity to burning substances, clothing made of flammable materials, congested housing, low socioeconomic status, and poor social support. Behavioral factors include risk-taking tendencies, fire setting, as well as abuse of alcohol or illicit drugs. Familial factors including parental illiteracy, parental psychopathology, and parental stress or neglect also contribute to burn injuries in children. Child neglect or abuse causes about 6% to 20% of pediatric burns, with scalds as the prevalent etiologic factor.

The average rate of burn injuries decreases from age 5 until adolescence. However, after age 15, the incidence rate of burn injuries begins to increase again, presumably because of greater exposure to hazards, experimentation, and risk taking, as well as employment. Psychiatric diagnoses usually associated with increased risk of burn injuries include childhood depression, learning disorders, intellectual disabilities, substance use disorders, oppositional defiant disorder, conduct disorder, attention deficit hyperactivity disorder, and bipolar disorder.

The risk factors for burn injuries in adults include chronic mental illness, neurocognitive disorders, alcohol and substance use disorders, character disorders, history of suicide attempts, as well as a history of abuse or homicide. Factors like prior physical or sexual abuse, substance use disorders, affective disorders, psychotic disorders, and personality disorders significantly contribute to the risk of self-inflicted burns. Conduct disorder, personality disorders, bipolar disorder, major depression, schizophrenia, factitious disorder, and substance use disorders are some of the psychiatric diagnoses associated with increased risk for self-inflicted burns. Female gender, Black ethnicity, unemployed, single, and homeless status, and Medicaid funding are common characteristics found in the majority of patients with assault-related burn injuries.

Some medical and neuropsychiatric conditions interfere with intact sensory, motor, or cognitive functions, and in turn, decrease the patient’s ability to properly recognize and respond to situations that can represent a risk for burn injury. In the setting of insufficient or inappropriate caregiver supervision, early-onset neurologic impairments including cerebral palsy, spina bifida, attention deficit

hyperactivity disorder, intellectual developmental disorder, and autism increase the risk of sustaining scalds, flame burns, and contact burns during activities related to cooking, eating, and bathing. The lack of temperature control settings in the shower for this group of patients is an additional risk factor.

In addition, natural disasters can create special circumstances that increase the risks of burns. A retrospective study reviewing the burn patient records at Staten Island University Hospital Burn Center following Super Storm Hurricane Sandy estimated that the widespread power outages and losses of hot water and heat that followed the storm led to a majority of scald injuries because of the damage to hot water pipes and hot water heaters and the use of portable heating sources to cook food and boil water.

A 62-year-old widower with a history of diabetes mellitus for 20 years, complicated by peripheral neuropathy and no psychiatric history, suffered 18% scald burns to her lower extremities while taking a hot shower. She only felt mild discomfort on her feet and hours later noticed erythema and blister formation. She then decided to go to urgent care and was referred to the burn unit. During a psychiatric assessment, she reported being distracted thinking about the upcoming death anniversary of her late husband and forgetting to call her heating company for her water heater tune-up, which was overdue. Upon further questioning, she endorsed mild depressive symptoms, including low mood, decreased energy, decreased appetite, and decreased concentration, as well as anticipatory anxiety related to dressing changes. She was started on sertraline and individual supportive psychotherapy. Prior to discharge to the physical rehabilitation unit, she reported improved mood and appetite. She was referred to a private psychiatry group that took her insurance.

ALCOHOL, SUBSTANCE ABUSE, AND BURN INJURY

The association between burn injuries and alcohol is widely studied and accepted. It has both a direct and an indirect causal effect. Approximately 50% of burn patient fatalities have a history of alcohol use. Alcohol use is also known to increase the morbidity and mortality of hospitalized burn-injured patients. This is due in part to delay in treatment prior to coming to the hospital, increased ventilatory days and respiratory infections, sepsis, blood loss, and a decreased immunologic response. Older individuals are at greater risk of dying after their burns. Burn patients admitted with either alcohol intoxication or a history of alcohol use tend to have an increased percentage of TBSA burned, higher rate of inhalation injury and mortality as well as longer length of hospital stay and, consequently, increased medical costs in comparison to burn patients who are nonalcoholic users. Alcohol exposure is frequently associated with deaths from cigarette-ignited fires. An association exists between alcohol and/or substance use with suicide by burning and other intentional burn injuries, including assault and self-mutilation. Those who have used both drugs and alcohol are 10 times more likely to die from their burn injuries compared to those who have not used either.

It is sometimes difficult to distinguish the specific drug or if alcohol is involved in a particular burn injury. Illicit drug use is associated with a greater proportion of patients with flame burn and a larger average burn size (except for marijuana in most cases). In addition, these patients have longer hospital and intensive care unit (ICU) stays and rates of intubation but not a higher risk of mortality. In some studies, self-inflicted injuries were more likely to be seen if the patient had used drugs. Illegal drug manufacturing and the use of peculiar drug paraphernalia pose added and somewhat novel risks for various types of thermal injury. For example, freebasing cocaine may cause burns to the face and hands. Smoking crack has led to accidental inhalation of crack pipe “brillo” screens resulting in burns to the trachea, mouth, and esophagus. Methamphetamine laboratory explosions have been shown to inflict blast injury, and smoking in bed while intoxicated can cause flame burn and inhalation injury. Ignited alcoholic drinks are vastly becoming a popular fad, whereby

mixed high-proof alcohol drinks are ignited before serving and pose significant risks for facial, chest, esophageal, and other burn injuries.

Receiving an agitated patient to a burn unit who is most likely delirious, in pain, and unable to provide a history makes it difficult to provide accurate, comprehensive care. An astute clinician rules out alcohol or other substance intoxication. Blood alcohol level and urine toxicology screens should be standard tests in the evaluation of burn patients to provide them with optimal care. Timely intervention and initiation of treatment for withdrawal symptoms undoubtedly help to save lives, time, and money. Uncontrolled withdrawal poses significant problems for both patient and staff and utilizes a staggering degree of hospital resources as patients may require any combination of services, including one-to-one observation due to multiple periods of agitation or attempts to leave against medical advice, frequent (sometimes hourly) assessment of vital signs, frequent administration of intravenous (IV) medications and close observation for effects of the central nervous system (CNS) depression secondary to benzodiazepine treatments, and intubation if withdrawal progresses to alcohol withdrawal delirium and is accompanied by seizures. Fluctuating fluid levels, multiple pain medications, anoxic injury, and CNS anesthetics greatly complicate the use of any standard alcohol withdrawal protocol. These patients must be assessed frequently for withdrawal and their treatment adjusted as needed. This treatment may be required for days to weeks, depending on the severity and duration of the withdrawal, which is affected by the age of the patient, the number of drinking years, the level of sustained drinking, the existence and severity of comorbidities, and a history of withdrawal symptoms. Drug or alcohol abuse or dependence can profoundly impact all phases of burn recovery, including the rehabilitation phase. Chronic alcohol use can (1) depress the immune function, leaving compromised patients less able to battle infection, (2) cause malnutrition, when adequate nutrition is one of the most important factors in healing from burn injury and graft surgery, and (3) damage multiple organs such as liver, heart, and brain.

This patient was a male in his 50s, an unemployed musician who lived alone, never married nor with kids. He had relationships though none lasted for more than a few years. He never smoked cigarettes, snorted cocaine and heroin, never IV, and drank alcohol. His alcohol use was a few times a week but had increased during the covid pandemic. He worked from home, had lost his gigs due to the pandemic, and saw very few people. He did have some friends but saw them less and less, especially since he spent all of his time alone these days.

As his life options became fewer and fewer, he thought on more than one occasion as to whether life was worth living. Though he had these thoughts for years, they seemed to come more frequently, especially when he was drinking alcohol. His past psychiatric history was significant for dysthymia, sometimes burgeoning into major depression, though he was never really in therapy and tried an antidepressant two times but stopped both times impulsively.

On the night of the admission, he was feeling particularly low due to his poor financial picture. He drank a six pack of beer followed by a pint of gin, finishing off the night by snorting the remaining heroin he had in his apartment. One of the last things he remembered was heating soup on the stove since he had forgotten to eat all day. In taking the soup off the stove, his shirt caught on fire. Neighbors heard his yells and smelled smoke and called the ambulance.

When arriving at the hospital, it was determined he had 35% TBSA around his face, hands, and chest. Ambulance workers reported that they had seen empty alcohol bottles in his apartment, and he was started on a withdrawal protocol of benzodiazepines. When he was able to be psychiatrically evaluated, he said this had not been a suicidal attempt but admitted to having passive suicidal thoughts. The patient did not think he had a significant substance abuse problem but acknowledged that he had been depressed for some time and consented to a trial of an antidepressant. He was unable to have

visitors in the burn unit due to covid precautions but allowed his brother to be called for collateral information. He reiterated some of what the patient had told the team. It was decided that after discharge, he should go to a physical rehabilitation program. From there, he was going to move in with his brother for a while and attend an outpatient clinic to deal with his depression, still refusing help for his substance abuse.

DELIRIUM

Delirium is a highly prevalent neuropsychiatric syndrome among hospitalized burn patients. It is generally caused by the dysregulation of the baseline neuronal activity secondary to systemic disturbances, leading to alteration in the level of attention, awareness, and other areas of cognitive functioning. The onset of delirium is acute, usually developing over a short period of a few hours to a few days, and tends to fluctuate in severity. There are three major types, including the most frequent hyperactive delirium characterized by psychomotor agitation and restlessness.

The hypoactive delirium is less frequent, challenging to diagnose, and presents with decreased psychomotor activity and level of arousal. The third type is mixed, which combines hypoactive and hyperactive features.

The most identified causes of delirium in burn patients are cerebral anoxia, skin infections, fluid or electrolyte imbalance, and withdrawal from opiates and benzodiazepines. Some burn patients with an underlying psychiatric diagnosis can intermittently have the manifestation of delirium erroneously mistaken for a flare-up of their or other mental illness. If unidentified or left untreated, delirium leads to poorer patient outcomes, prolonged hospital stays, increased medical costs, and higher mortality.

The evaluation and diagnosis of delirium in burn patients, as in any patient, include full bedside assessment and measurement of vital signs, including pulse oximetry, ECG, and chest radiography. Comprehensive medical history, including the history of current

illness, past psychiatric, medical, surgical, and substance abuse histories, are required. Collateral input is required in most cases because of the confused state of these patients. The confusion assessment method (CAM) remains one of the commonly used assessments for screening. Appropriate laboratory tests, including complete blood count, comprehensive metabolic profile, ammonia and uric acid levels, Vitamin B12, thyroid-stimulating hormone, urinalysis, and drug levels, are assessed. Prolactin and troponin levels are checked if clinically indicated. Radiologic and other investigations, including CT scan, MRI, EEG, cerebrospinal fluid examination, Doppler ultrasound scans, arterial blood gas, and lung perfusion scans, are intermittently indicated to ascertain pertinent underlying medical causes.

Treatment of Delirium in the Burn Patient

While the identification and correction of underlying medical issues remain paramount in the treatment of delirium, ensuring patient safety is also a priority. A delirious patient can present as confused, agitated, or disinhibited. They are also at risk of falls, wandering, hurting themselves or others, pulling out of venous accesses, dressings, other tubing, or equipment. Safety measures, including placement of side rails on the beds or soft restraints, suffice for some patients. Others will require constant one-to-one observation for their safety.

The treatment of delirium in burn patients does not differ greatly from the treatment of delirium in patients with other medical conditions. However, the evidence for definite pharmacologic treatment remains scarce, and guidelines are controversial. For hyperactive delirium associated with agitation, antipsychotics are usually the first line. QT interval corrected for heart rate (QTc) must be checked prior to their initiation and to reduce risks of torsade de pointes and ventricular tachycardia. If the delirium and agitation are perceived to derive from benzodiazepine and alcohol withdrawal, then benzodiazepine constitutes the main treatment than antipsychotic. Other factors affecting treatment choice include

underlying cardiac, hepatic, renal, and endocrine illness, dystonic reactions, neuroleptic malignant syndrome, and seizures, among others. The use of IV haloperidol is not approved by the FDA but does not restrict the use in burn units and other critical care settings. It is administered frequently under close cardiac monitoring for effective and rapid control of hyperactive delirium in patients without oral access. The starting doses of IV haloperidol in burn adults and older children are 0.5 to 2 mg. Incremental and frequent doses may be necessary while the patient is closely observed on a cardiac-monitored intensive burn unit bed. Benzodiazepines are recommended if anxiety or extreme agitation dominates the clinical picture or in alcohol withdrawal delirium, but caution is necessary since the addition of benzodiazepines can increase the risk of delirium and should be tapered off quickly.

In children, it is especially important to differentiate insomnia, agitation without delirium, and anxiety from delirium as the former two are effectively treated with benzodiazepines. Some studies had found an association in the use of IV haloperidol in the treatment of acute pediatric burn patients with dystonia, hypotension, hyperpyrexia, and respiratory and renal failure, leading to death in one child. Despite these observations, haloperidol remains frequently used parenterally to control agitation in older burn children for 2 to 3 days with rapid relief. It is essential that such treatment be very carefully monitored. Second-generation antipsychotics (SGA) are more frequently used in the treatment of agitated delirium in adolescents and adults with oral access.

The alpha-2 agonist dexmedetomidine is very useful in the treatment of delirium by shortening its duration, the duration of mechanical ventilation, and the length of stay in the ICU. Another alpha-2 agonist clonidine may also be used. Relief of delirium can be achieved within minutes or hours, but it can persist for days or weeks, especially if the etiology is not correctly identified and addressed.

Alongside psychopharmacology, multiple-component nonpharmacologic interventions are implemented in the prevention and treatment of delirium. These include facilitating and promoting

orientation to the environment, for example, allowing the patient who wears glasses and hearing aids to have them available and encouraging them to wear them, placing a visible calendar in the patient's room, and giving the patient straightforward statements regarding the procedures that will be done and the things that are expected from them. Maintaining consistency in the room setting and nursing staff who care for the patient may be helpful measures to help orient the delirious patient to an unusual and possibly perceived threatening environment. Early mobilization, adequate hydration and nutrition, adequate pain management, and maintenance of sleep–wake cycles are some of the other nonpharmacologic interventions used.

PAIN MANAGEMENT

A patient in significant pain has little tolerance for a meaningful conversation; therefore, it is not possible to properly assess the psychological issues such as the reaction to the injury, depression, guilt, body image, or cognitive deficits in such a state. Any effort to talk to the patient without addressing pain status will likely be experienced as insensitive and irrelevant. The proper treatment of burn injuries usually requires debridement, daily wound care, skin grafting, and retraction release surgeries, followed sometimes by weeks or months of physical therapy. These treatments can be extremely painful. Patients have different thresholds for pain, different coping abilities, and different physiologic responses to treatment. For these reasons, it is important to create a multimodal individualized pain control plan for each burn patient as well as to inquire about the adequacy of pain control during each contact with the patient and address it accordingly as is recommended by the International Society for Burn Injury Practice Guidelines.

Background pain refers to the underlying pain from the initial injury. It is ongoing and present even in the absence of activity or procedures. Management of this type of pain is generally accomplished through the use of long-acting analgesic agents.

Breakthrough pain is more intense, episodic, and associated with activities of daily living and other minor activities that require movement or manipulation of injured areas. It is usually managed with short-acting agents.

Procedural pain is associated with invasive procedures and ongoing daily burn care, such as wound cleansing, dressing changes, and physical and occupational therapy. A structured approach to pain management should aim to control all three types of pain. Acute pain disrupts normal physiologic functions and increases stress.

Poor pain control causes sleep disturbances and increased anxiety, which further exacerbate pain. It has been shown that uncontrolled pain has physiologic effects that impede wound healing. In addition to the pain that arises from the burned tissues and donor sites, burned patients may experience additional pain from wound infections, concomitant injuries suffered at the time of the burn, pre-existing conditions, or abdominal pathology related to sepsis or due to heterotopic calcifications.

Psychological addiction is infrequently caused in the context of burn care, but some patients treated with high opiate doses for the long term can develop physiologic dependence, and acute tolerance has been documented in children during the initial phases of intensive care. There is no evidence that opioid addiction occurs more often in burn patients compared to other patients requiring opiates for acute pain. Patients with active substance use disorders who are victims of burn injuries require higher doses of opiates than their counterparts to achieve adequate analgesia. Frequent assessment of the patient's pain and general condition by experienced burn unit staff and the collaboration of the pain service consultants help to elucidate the appropriate time for changes in the medications' dosages and forms of administration in an effort to effectively control the pain and at the same time avoid unnecessary exposure to high opiate dosing. Despite the goal of adequate pain control, patients are frequently undermedicated for pain. This can lead to a full range of psychiatric symptoms, which include anxiety, depression, and post-traumatic stress disorder (PTSD).

Although quantifying pain can be difficult, a burn injury must be considered the most painful trauma that a person can sustain. The assessment of pain should be conducted at different phases of care (at rest, during physical therapy sessions, prior, during, and after procedures, whenever feasible) and documented in a standardized manner. Methods to measuring pain include subjective reports, as determined by rating scales, questionnaires, and more objective measures such as physiologic parameters. The visual analog scale, the numerical pain scale, and the Wong-Baker FACES Pain Rating Scale appear among the most used. The Initial Pain Assessment Tool and the Brief Pain Inventory are two useful questionnaires that provide options for the initial evaluation of acute or chronic pain by a comprehensive set of questions on the nature and effects of pain. It has been accepted that on a 0 to 10 scale (where 10 equals the maximal pain), the pain is well controlled if it is patient self-rated between 3 to 5 or less at rest and between 5 to 7 or less during procedures. An unmarked 100-mm scale can also be used, where the score is determined by measuring the distance between the two poles of “no pain” and “the most pain you can imagine.” This visual analog scale translates the subjective experience of pain to a specific number from 1 to 100. An electronic device can also be used to do this. Documenting the pain in a standard manner will allow the team to communicate in a consistent language and to address the pain needs more reliably.

Objective indicators of pain such as sweating, increased pulse, elevated blood pressure, agitation, and increased respiratory frequency could be due to other causes such as hypoxia, hypoglycemia, and alcohol withdrawal, to name a few examples. The Critical Care Pain Observation Tool (CPOT) can be used when a patient is not able to interact or communicate their individual assessment of pain.

Pharmacology of Pain Management

Opioid administration is the foundation of effective burn pain management. The choice of the opioid agent should be based on

physiology, pharmacology, and physician experience. Opioids should be tailored to each patient's needs and continuously adjusted throughout their care. Attempts should be made to use the lowest opiate dosing needed to achieve the desired level of pain control. Whenever appropriate, patient-controlled analgesia (PCA) should be utilized. PCA prevents delays in medication administration by nursing staff, leads to more consistent pain relief, and decreases the patient's level of anxiety by providing a sense of control.

Opiates and benzodiazepines are often given together for the management of pain and pain-associated anxiety control in burn patients. It is often observed that burn patients require exceptional doses of opiates and benzodiazepines to relieve pain and anxiety, compared to the standards in nonburned patients, to compensate for their hypermetabolic state. The preferred routes of opiate administration are IV and oral, taking into account that a normal intestinal function is needed to ensure the effectiveness of the oral route. Very close monitoring for respiratory depression is of paramount importance in patients receiving such medications.

Fentanyl (Actiq), a synthetic opioid around 100 times more potent than morphine, is available in injectable, transmucosal, and sustained transdermal presentations. The oral transmucosal form appears promising in addressing anxiety and pain in burned children.

Methadone (Dolophine) is a long-acting opioid with properties similar to morphine. Its *N*-methyl-D-aspartate (NMDA) antagonist properties are postulated to moderate opioid-induced tolerance, hyperalgesia, and neuropathic pain.

Buprenorphine has been increasingly prescribed over the last 10 years in response to the opioid epidemic as a maintenance treatment for opioid dependence. It is available in a sublingual form as Subutex and, to deter misuse, it is also available in a formulation with naloxone as Suboxone. Buprenorphine is a partial mu-agonist with a strong affinity to the mu-opioid receptor.

As a result, it only partially activates the mu-receptor and also makes it more difficult for mu-agonists to fully activate the receptor causing attenuation of other opioids' analgesic effects. In patients on

buprenorphine therapy for opioid use disorder, the management of acute pain from burn injuries can become challenging. Recommended approaches include consideration of several factors, including the maintenance dose, the severity of the injury, the expected severity of the pain associated with the procedures the patient will need to endure, and the estimated time of analgesic requirements. If the maintenance buprenorphine dose is low, this can be continued while starting other opioids. Patients maintained on buprenorphine will require much higher doses of a full opioid agonist to obtain analgesia. Patients maintained at higher doses may benefit more from decreasing the buprenorphine dose while starting full mu-agonists. Stopping buprenorphine in order to manage intense pain with other opioids is acceptable as well. However, it poses the issue of opioid withdrawal symptoms during the reinduction of the partial agonist.

Meperidine hydrochloride (Demerol) is not used due to its short half-life and because normeperidine, its major metabolite, can cause agitation, hallucinations, and seizures and may accumulate to dangerous levels with repeated dosing.

Anesthetic agents such as ketamine (Ketalar), propofol (Diprivan), and nitrous oxide are being used more often to facilitate the performance of burn care. Low-dose ketamine can be used as an adjunct to opioid therapy in patients who could benefit from reduced opioid consumption, particularly in the postoperative period. It is important to keep in mind that propofol is a sedative that lacks analgesic properties.

Dexmedetomidine (Precedex) is an alpha-2 adrenergic receptor agonist that can be used as a first-line sedative in the intubated burn patient. Dexmedetomidine and clonidine are recommended as pain management adjuncts in the setting of signs of withdrawal or prominent anxiety symptoms.

Acetaminophen can be used in burn patients while monitoring the maximal daily dose. Nonsteroidal anti-inflammatory drugs (NSAIDs) can be considered in burn patients taking into account individual comorbidities, particularly renal function. Agents for the treatment of neuropathic pain, such as gabapentin (Neurontin) or pregabalin

(Lyrica), can be used as an adjunct to opioids in patients with neuropathic pain or who are refractory to standard therapy.

Antidepressants such as TCAs and SNRIs block the uptake of serotonin and norepinephrine, increasing the activity of descending inhibitory pathways. The effect on pain typically antecedes the effect on anxiety and depression and requires lower doses than those needed for effect in mood.

Psychotherapeutic Strategies for Pain

Providing the burned patient with education regarding the analgesic strategy and its ongoing re-evaluation typically provides reassurance and strengthens the therapeutic alliance. Psychological approaches to pain management can increase the patient's sense of control over the painful burn care procedures. Any psychotherapeutic approach that successfully addresses the patient's anxiety, depression, guilt, acute stress syndrome, or other psychological issues stands a good chance of reducing the patient's pain experience. Some randomized prospective small-sample studies using adjunctive psychological techniques in the burned patient utilizing pain and anxiety self-report, as well as observer, rated measures have been conducted.

Ideally, burned patients should be offered a nonpharmacologic pain control technique. Cognitive-behavioral therapy, hypnosis, and virtual reality have the strongest evidence.

In order to use cognitive interventions for the adjunctive treatment of pain, it is important for the clinician to recognize the patient's coping skills. Patients who cope with avoidance will be most likely to benefit from distraction during short procedures and deep relaxation and distraction imagery during longer procedures. Patients who focus on the procedure may benefit from reappraisal techniques. They should be encouraged to differentiate sensory from affective components of pain and evaluate its meaning. They usually benefit from being told that pain sensation is a positive sign of wound healing. Distraction therapy using pleasant videos along with administration of analgesics during burn dressing changes has demonstrated significantly reduced pain and anxiety. There is also

some supporting evidence that the use of virtual reality provides analgesia with minimal side effects and little impact on the physical hospital environment. Virtual reality takes distraction one step further by using a visual stimulus instead of the power of suggestion. Visual stimulus is provided through a headset that covers the eyes. An auditory stimulus can be provided through associated earphones. A controlled study using virtual reality showed a reduction in pain, nausea, and anxiety during physical therapy. The management of burn pain is multidisciplinary and dynamic as the burn wound pain is essentially multifaceted. Several psychological approaches have been proven effective as adjuvants of the pharmacologic treatment, but larger studies are still needed. Pain management needs to be individualized to each patient's needs and continuously monitored for optimum control.

Hypnosis and Pain

Hypnosis can help to control pain during burn wound debridement and is a viable adjunct treatment for burn pain. Hypnosis can be used in the short term. It has been reported that in less severe burns, hypnosis may help prevent the postburn inflammatory response and reduce burn severity. Hypnosis is also helpful as an adjuvant in the treatment of pain and pain-related anxiety. During burn dressing changes, anxiety appears to be better controlled by hypnosis than by stress-reducing strategies. Hypnosis is particularly valuable when there are medical contraindications to adequate narcotic control of pain.

Relaxation Techniques

It is widely accepted that relaxation enhances the effectiveness of analgesics by reducing muscle tension and increasing blood flow. Breathing exercises, guided imagery, and deep muscle relaxation are all examples of practical bedside interventions to alleviate tension and enhance the patient's sense of control and well-being.

BURN INJURY AND PSYCHOPATHOLOGY

Through the stages of acute treatment to rehabilitation and reintegration, burn patients contend with multiple stressors, including severe pain, disfiguring scars, loss of functionality, and other distress. Some of these factors lead to enduring psychosocial and psychological difficulties. Greater psychosocial distress during acute hospitalization for burn injury has been shown to result in a more difficult rehabilitation and recovery. As recent major medical and surgical advances have greatly increased the survival rates of burn patients, there has also been increasing interest in their psychiatric and functional sequelae.

Depression and PTSD, prevalent in 13% to 23% and 13% to 45% of cases, respectively, have been the most common areas of research in burn patients. In the case of depression, risk factors have been found to include premorbid depression and female gender in combination with facial disfigurement. For PTSD, premorbid depression also as well as type and severity of baseline symptoms, anxiety related to pain, and visibility of burn injury are all contributing factors. It is also noted that the emergence of acute stress disorder (ASD) and/or PTSD symptoms in the first few weeks of hospitalization can be a predictor of the subsequent development of chronic PTSD. However, PTSD symptoms can singularly occur months after a burn injury has occurred in a significant minority of patients who had never exhibited symptoms of ASD or PTSD during acute hospitalization. Both neuroticism and avoidant coping styles are important personality dimensions linked to the development of PTSD as well.

Great levels of acute pain have been associated with negative long-term psychological effects such as ASD, depression, suicidal ideation, and PTSD for as long as 2 years after the initial burn injury. Subjective reports of feelings of “alienation and anxiety” experienced during hospitalization are also linked with distress for up to 2 years in burn patients.

Burn patients can experience difficulties in sexual life and social interactions. Even burn patients who never develop chronic psychological sequelae following burn injury will frequently experience, especially early in recovery, episodic expressions of

stress, depression, dysthymia, acute stress disorder or PTSD, other anxiety disorders, or psychosis. The quality of life of burn patients initially seems to be lower in comparison to the general population; however, over a period of many years, quality of life normalizes or becomes rather good.

The treatment of psychopathologies associated with burn injuries does not differ greatly from the treatment of the general population with similar ailments. The psychiatrist on initial assessment must screen for underlying risk factors including premorbid psychiatric disorders, personality characteristics, peri- and post-traumatic factors, as well as proneness to shame, body image problems, and self-esteem issues in case of patients with disfigurement. Psychotherapy (cognitive, behavioral) and pharmacologic treatments (SSRI, SNRI, etc.) are valuable in the treatment of depression. Exposure therapy and eye movement reprocessing and desensitization have been successful in the treatment of PTSD as well as available pharmacologic treatments. Additional measures including social skills training, community interventions, sexual health promotion, and counseling have all been found helpful in enhancing the quality of life of these patients.

PSYCHOTHERAPEUTIC INTERVENTIONS

There has been a wide variety of psychotherapeutic modalities used in treating patients who have suffered a burn injury. They include cognitive behavioral, supportive, brief and short-term psychodynamic, and exposure therapies, debriefing, eye movement desensitization, and psychoeducational interventions, all of which have reportedly been used with varying levels of success. Authors reviewing general trauma treatment were rather unimpressed by any of the myriad modalities, including medication therapy. However, exposure therapy garnered substantial research results as a relatively effective treatment for ameliorating some PTSD symptoms. Pain control, as previously discussed, may be one of the most crucial treatment modalities for adults and children because, if effective, it may reduce the potential for developing post-traumatic

symptoms. The choice of therapeutic intervention is often dependent on the stage of recovery from burn injury.

Acute Phase

During the acute phase, the burned patient faces multiple immediate stressors, including fear of death, acute pain, being in an acute care environment such as the emergency room and ICU (burn unit), and concerns for other victims of the same burn event. The patient may experience delirium manifested by fluctuations in the level of consciousness, confusion, agitation, and disorientation. The delirium could be related to the acute physiologic effects of the burn itself, alcohol withdrawal, metabolic complications, infection, medication, or substances of abuse. At this stage, psychological interventions focus on immediate concerns such as pain control, anxiety, management of delirium, and sleep. The priority at this stage is survival; therefore, in-depth psychological interventions are not indicated at this point.

The initial psychiatric assessment offers patients an opportunity to recount the burn event if they are psychologically prepared to do so. As patients reveal their understanding of their injuries, the consulting psychiatrist, in concert with the treating surgical team, orients patients and families to burn unit protocols and prepares them for the journey that lies ahead. A crucial part of providing psychiatric care to a burned patient is building a therapeutic alliance with their family or support system. If the patient is unable to provide information, the initial history can be provided by collaterals, which can serve as an opportunity to facilitate the family's understanding of the injury and its treatment course. The presence of distressed family members may enhance the patient's anxiety. Efforts to moderate caregiver stress may also serve to lower a patient's anxiety and stress reaction.

Chemical neurologic embedding of traumatic memories is thought to involve sympathetic nervous system release of norepinephrine. Adequate treatment of acute pain and anxiety symptoms after burn injury may prevent some psychological sequelae by moderating the serum levels of norepinephrine and possibly other neurotransmitters

and endogenous hormones associated with the stress response. Historically, treatments in the acute phase have also involved pharmacologic methods such as oral and IV administration of opiates and benzodiazepines for pain and anxiety, selective serotonin reuptake inhibitors (SSRIs), tricyclic, and monoamine oxidase inhibitor antidepressants, beta-blockers, and D-cycloserine in conjunction with exposure therapy. The antihypertensive prazosin (an alpha-adrenergic blocker) is being used to treat traumatic nightmares related to various types of trauma, including combat events. It is reported to improve sleep onset and, if taken during the day, has been reported to reduce irritability and other hyperarousal symptoms in some. In one literature review, prazosin doses varied between 1 and 16 mg, though higher doses have been needed to achieve remission of nightmares and have been used with positive effects. Researchers continue to examine the role of neuroactive steroids in the development and treatment of PTSD and the biochemical or genetic individual differences that may underlie variable responses to pharmacotherapy. Benzodiazepines have not been found effective in treating symptoms of PTSD, although they are widely prescribed for anxiety and agitation. Some evidence is cited in a recent literature review to support the use of pharmacologic intervention in reducing the risk for adults of developing PTSD after trauma, specifically hydrocortisone administered immediately after trauma exposure. In the same review, researchers found no supporting data for propranolol, escitalopram, temazepam, or gabapentin in the prevention of PTSD. Critical stress debriefing used in the early treatment of traumatic stress has been shown to have neutral or harmful effects.

A 55-year-old male patient with no visible wounds sustained an electrical injury from contact with an underground power line. A psychiatric consult was ordered on day 1 of this patient's hospitalization for repeated signs and symptoms of anxiety and panic, including increased blood pressures, diaphoresis, subjective report of nightmares, and awakening in a cold sweat, "feeling in a daze." The patient associated the onset of symptoms with the sounds of the arrival and departure of the hospital medical transport helicopter. He had been transported to the hospital by helicopter after suffering electrocution. The patient was relocated within the burn unit, and lorazepam was ordered to be given as needed for anxiety. Interestingly, once the source of his reaction was identified, he reported a reduction in anxiety while awake, even without medication. By subjective report, benzodiazepines helped this patient achieve restful sleep with a decrease in startled nighttime awakenings and nightmares.

A 34-year-old man came to the burn unit following a chemical burn on his hands and legs that occurred at work. He complained bitterly about his care and the various policies of the burn unit to the embarrassment of his wife. The staff frequently defended the care that he received and argued on behalf of the doctors. Negative feelings about the patient were discussed at psychosocial rounds with the mental health team. This patient believed that the statements that he was making were true, and he would increase his attacks if the caregivers attempted to argue with him. The approach with this patient was to acknowledge his beliefs but not to offer an opinion about them. Occasionally, asking the patient for his patience with difficult situations steered him away from being defensive and put him in a more cooperative mode. As soon as possible, he was taught to do his own dressing changes and allowed to take showers to help him feel more in control and reduce his reliance on staff members, whom he did not trust. The family was counseled in an effort to help them understand that the patient's complaints may have stemmed from his fear and sense of helplessness, more so than with the quality of care.

Intermediate Phase

Once acute medical issues have been stabilized, increasing the likelihood of survival, the patient enters the intermediate phase. The focus of treatment shifts toward restorative care. Most of the burn wounds have been grafted and are in various stages of healing, and ventilator support, sedation, and severe infections become less prevalent. However, patients continue to undergo painful procedures. They become more aware of the physical and functional impact of their injuries and, at the same time, are more psychologically ready to participate in a psychiatric diagnostic assessment. Anxiety and depression-related symptoms often begin to appear in this phase. Sleep disturbances can be related to anxiety, depression, pain, and the noises and routines of the intensive care setting. Symptoms and

behaviors related to premorbid psychopathologies such as personality disorders and substance abuse may surface in this stage. A dysfunctional pattern of coping of the individual can have an adverse impact on outcomes, including increased length of hospital stay and more serious psychopathologies after the injury. During the intermediate phase, the grieving process is more evident. Burn patients may have lost family members, friends, pets, their home, or personal property, as well as aspects of their former life: work, appearance, and physical abilities.

Optimum pain control facilitates the patient's ability to participate in treatment protocols and allows for the development of a sense of hope for recovery. As discussed above, psychological interventions are helpful adjuvants to appropriate psychopharmacologic treatment in the management of pain and anxiety. Cognitive-behavioral therapy and hypnosis have proven to be effective in treating procedural pain. Virtual reality utilizing special computerized programs is used as a distraction technique during painful procedures. A recent pilot study using a manualized cognitive-behavioral treatment protocol developed specifically for treating PTSD and psychosocial sequelae following burn injury resulted in improvements in PTSD and depressive symptoms, self-image, and aspects of reintegration.

Brief supportive psychotherapy to treat depression and anxiety in combination with appropriate psychopharmacologic interventions is also helpful in this phase in managing depression and anxiety. Informing patients that nightmares are common and usually subside over time can help reduce stress and anxiety, increasing patients' understanding of the psychological healing process. Other forms of psychotherapy utilize cognitively oriented psychoeducation. Large burn centers may offer a variety of rehabilitation support groups for adults, children, adolescents, and parents, using various modalities, including expressive and cognitive-behavioral therapies. The focus of interventions during the intermediate phase is the assessment of emotional and cognitive adaptation to the injury, treatment and surgical procedures, and readying patients for transfer to rehabilitation care or discharge home and return to school or work. The importance of psychoeducation and preparation for future care

and other postdischarge issues must be highlighted. Knowledge of and engagement in the planning of upcoming surgeries, for example, gives patients a sense of control as they anticipate and prepare for the experience. Supportive treatments and normalizing the emergence of psychiatric symptoms related to the trauma can be very helpful during this and all phases. Appropriate mental health care referrals should be made at discharge for surveillance and treatment of current or evolving psychological concerns.

Recovery Phase

The recovery phase usually begins at the time of discharge from the hospital, when the patient begins to reintegrate into society and is marked by the promise of survival. Patients with severe burns may still require long-term outpatient physical rehabilitation, including painful procedures such as dressing changes and surgeries. Ongoing sufficient nutritional intake is still imperative for healing skin and grafts. During the recovery stage, patients have significantly more control over their treatment than while acutely hospitalized. The timing and extent of plastic and reconstructive surgeries are collaborative decisions made by the patient and surgeon. The duration of this phase depends on the extent of impairment and the need for corrective surgeries. A patient may require multiple surgeries over a span of several years to release scars and improve function or restore appearance. Forty-six percent of patients presenting for these reconstructive surgeries were found to suffer from mild to moderate depression. Body image dissatisfaction was predictive of increased depression scores.

Psychological challenges in this stage include regaining a sense of competence while adjusting to the practical limitations of the injury. Psychological considerations during this phase include body image changes, self-esteem issues, adjustment to functional impairments, and depressive and anxiety disorders, particularly PTSD and phobias. Ongoing issues of grief, guilt, and premorbid psychiatric conditions continue to require psychotherapeutic support.

Social stressors in this stage include vocational rehabilitation, readjustment to work, family strains, and lack of social support, among others. Appropriate interventions of this phase involve psychiatric outpatient follow-up, social skills training, support groups, peer counseling, vocational counseling, and substance abuse relapse prevention.

Functional and cosmetic outcomes following burn injury have dramatically improved over the past few decades. Evolving techniques of cell culturing have resulted in improved skin grafts, and advances in plastic and reconstructive surgery have reduced permanent disfigurement. With the advent of specialized burn and trauma units, climbing survival rates of even massively burned individuals has placed significant emphasis on the recovery phase.

Factors Influencing Recovery. Patients influence the rate of progress during rehabilitation by their degree of participation and cooperation. If they are or become unmotivated, anxious, or depressed, outcomes will be less than optimal. One study related larger burns and more psychological distress (during acute hospitalization) to more physical impairment and a slower recovery. In addition, a greater subjective psychological burden was associated with slower psychosocial recovery and more postburn psychological impairment. Patient participation in recovery and rehabilitation programs can be maximized by adequate attention to pain and anxiety control. Treatment plans are more successful if premorbid physical, developmental, and psychiatric status are assessed in order to set realistic goals for recovery.

Three important factors affecting burn recovery are pain, brain injury, and overall psychological adjustment. Uncontrolled pain has been linked to increased anxiety and can limit motivation, affecting optimal recovery. Brain injury potentially limits full participation in rehabilitation efforts and can involve periods of impaired impulse control and agitated delirium. Psychological distress also affects motivation and participation. In this regard, whenever appropriate, there should be some effort to explore the question that nearly all patients ask themselves: “Why did this happen to me?” Burn injuries,

like many traumatic experiences, can be a turning point for some people, demanding major internal and external shifts in priorities, self-image, relationships, and life goals. Useful psychological information can be obtained by asking the patient, “Do you have any thoughts or fantasies about why this might have happened?” The answer to the question may present a starting point in the therapeutic process.

Although many burn victims sustain only small physical scars, due either to limited injury or to the skills of plastic and reconstructive surgeons, some studies have found that the size of the burn is not directly related to the degree of periburn emotional trauma or later development of psychopathology. For example, small burns have been shown to result in disproportionately severe psychological trauma, especially if the injury involved hands (decreasing functional capacity), face (altering self-image and increased visibility of scarring or disfigurement), or perineum (complicates elimination and sexual activity/identity).

A 20-year-old Hispanic female with prior history of PTSD and substance abuse suffered 65% total body flame burns primarily involving her upper body, including face and hands. Drug dealers had set the house on fire as she slept inside. Acute hospitalization lasted for approximately 1 year, and she required a chemically induced coma for over a month while fragile skin grafts healed, and plastic and reconstructive surgeons attempted to repair her ears and nose. Several years after discharge, she continued to undergo reconstructive and release surgeries to remove keloid scars. During this recovery phase, the plastic surgery department, physical therapy office, mental health clinic, and Alcoholics Anonymous (AA) became alternate homes for her, where acceptance, hope, and structure were provided. At a point in her recovery, she gave meaning to this traumatic experience by using it in a constructive way. She began speaking to groups of adolescents about the realities and dangers of substance abuse. This case exemplifies much of what has been discussed in this section, including the relationship of burns to substance abuse and premorbid psychiatric disorders, advancements in trauma and surgical treatments and survival of massive burn injury, the importance of psychiatric involvement at all phases of burn injury, psychological adjustment to new body image, and finding meaning in a life-altering traumatic event.

THERAPEUTIC APPROACH TO GRIEF, REGRESSION, AND ANGER IN THE BURN PATIENT

Grief

Grief work is necessary as any patient who suffered a burn has sustained some kind of loss: appearance, function, role, independence, sense of safety in the world, possessions, or even

loved ones. In facilitating grief work, it is useful to have in mind certain principles:

1. *Acknowledging the loss:* It is useful to prompt the patient to look at the losses by bringing up the topic that family and others often avoid. Most patients are willing to talk about their losses, and providing the patient with an opportunity to do so may promote an outpouring of emotions that the listener should be prepared to hear.
2. *Allow the patient to be with pain:* The pain of the loss is not eliminated with words. It is preferable to avoid rationalizations about “the good that will come of the loss,” which often makes the caregiver feel better but not the patient. More helpful interventions are focused on providing the patient with space and time to convey the full power of their emotions and to feel heard by an empathic listener. After the patient has amply expressed their feelings, it is useful to provide reassurance about the gradual subsiding of the emotional pain with time.
3. *Affirm the individual’s experience as real and part of normal grief:* Somatization, preoccupation with the lost object, guilt, hostility, and changes in normal patterns of conduct are anticipated components of a normal grief reaction.
4. *Provide assurance by exploring past coping patterns:* Burned patients may perceive their loss as unbearable and may be helped to use their coping skills by being encouraged to think of how they dealt with other losses in the past, if any. This process requires careful probing as the cumulative pain of prior losses not fully experienced may be rekindled.
5. *Monitoring danger signals:* Persistent thoughts of self-harm, neurovegetative symptoms of depression, failure to make progression in the grieving process, and exacerbation of previous mental illness should prompt pertinent interventions. These include increasing the level of monitoring, adjusting psychotherapeutic and psychopharmacologic approaches, and, if necessary, admitting the patient to an inpatient psychiatric treatment.

Regression

A common behavior noted among burn patients is regression. The patient, feeling overwhelmed by the physical and psychological distress, may attempt to return to the comfort of earlier stages in life. Staff and family members may have negative reactions to this phenomenon. In managing regression, it is useful to:

1. Recognize the regressed behavior as a coping mechanism.
2. Examine the caregivers' responses and provide them with necessary feedback.
3. Determine if the regressed behavior interferes with the immediate patient care goals and decide the proper intervention accordingly. Behavioral modification techniques with rewards for achieved goals are effective in some patients.
4. Develop a consistent plan to handle regressed behavior. Such a plan needs to be clearly explained to the patient and their family, allowing frequent communication.

Anger

When anger begins surfacing during interactions with medical or mental health staff, it is useful to acknowledge this expressed emotion with a supportive approach instead of attempting to talk the patient out of any feelings they have. It is useful to pay attention to the interactions with family members, who usually feel uncomfortable with expressed negative emotions, and try to redirect the patient to avoid talking about them. Some family members may express their own anger, fueling the patient's emotions.

Although nursing staff can handle and provide opportunities for the patient's expression and abreaction of angry feelings, it is sometimes advisable that a psychotherapist talks with the patient about their feelings and meets with the patient regularly, even for a short period. On the surface, patients' anger is directed outward toward causes of the accident, missing work, being in pain, being hospitalized, and perceived inconsiderate treatment by hospital staff. Patients often avoid expressing anger toward the hospital staff as they depend on

them. The ultimate object of the anger may be “self.” Patients blame themselves for being in the situation in which they were burned whether or not there is validity to this idea. This is not easy to accept, and the patient may displace their anger toward themselves or toward family members. They may push away their family and even their health care team by utilizing acting out behavior, projection, and projective identification. A differential diagnosis in terms of potential causes of mood changes or mood disorders needs to be considered and pharmacologic interventions implemented when needed. Patients are really angry at themselves for either their role in the burn injury (real or imaginary), their lack of ability to avoid the situation, losses they “caused,” for not recovering fast enough, for needing pain medication, for not tolerating the hospitalization, and so forth. As these feelings are unconscious and unacceptable to the patient, they are displaced onto external objects, sometimes in excess.

In this setting, the most successful interpretation is that allowing patients to realize that they are really angry at themselves while blaming others. However, it is very important to be aware that taking away the defense against inwardly directed hostility can elicit profound depression and even suicidal ideation. Precautionary measures need to be in place. Supportive techniques may be used here to express respect for the patient and for their acknowledgment of true feelings. Another technique is that of an inexact interpretation that can be used to diffuse the displacement of anger toward staff. Using objects directly or indirectly related to the burn injury such as “the malfunctioning furnace,” “the drunk driver,” and so forth, rather than focusing on the patient’s guilt and self-blame, is more likely to be accepted by the patient.

Expressive and abreactive techniques, time-limited psychotherapy, and psychodynamic life narrative treatment approaches may be successfully applied in the treatment of burn patients to allow verbalization of emotions, examination of separation, and acceptance of the meaning of the injury in the context of the patient’s life trajectory.

PLASTIC SURGERY AND FACE GRAFTS

The overall incidence of burn injuries has declined during the recent decades in the United States, but the proportion of survivors of large burn injuries has increased, carrying with it more severe aesthetic and functional sequelae. Facial and body disfigurement as a result of burns are known causes of profound shame, stigmatization, and isolation. Deep burns frequently result in loss of function and damage of cosmetically important body areas. Many of these burn victims suffer long-term morbidity as a result of functional impairment and severe facial defects.

Deep burns can involve not only the skin but also adjacent tendons, cartilage, and bone structures, contributing to complex deformities. The defects that result from burn injuries include hypertrophic scars, contractures, disorders of pigment, and loss of anatomic parts. Burn reconstructive surgery attempts to help the burn survivor to recover, as much as possible, normal appearance and functioning. There is still a need to identify and develop novel strategies to treat burn deformities in order to obtain improved outcomes. Early closure of the wounds translates to less severe scarring, lower mortality from infection, lower mortality from other complications, decreased stress, decreased hypermetabolic response, and decreased bacterial load.

Burn patients require multiple procedures arranged over months or years to address the deformities. Empathy from staff with the experience of being burned can assist the patient in adapting to a new appearance. Burns may profoundly affect body image, self-esteem, and interpersonal relations, as well as ego functioning. Skin allografts transplanted between genetically nonidentical individuals of the same species mostly come from cadaveric sources but can also come from close family members. Close relative intermingled skin allografts along with autografts have been satisfactorily used in a small number of child and adult burn victims. Among other advantages, this technique allows the active participation of family members in the treatment of the burn victim, creating other interesting dynamics and ethical issues. Synthetic acellular skin

substitutes have been used in the treatment of burns, which have the advantage of being readily available for immediate coverage of the wound.

Face Reconstructive Surgery

The human face is a functional, dynamic, and esthetic organ with critical roles in individual development since birth. There is evidence supporting that newborns have an innate ability to recognize individual human faces shortly after birth. The face is ingrained in the concept of one's identity and comprises a very individualized set of tools that allows the human being to effectively communicate and relate to others. In a patient with facial disfigurement, effective communication is impaired due to self-perception but also as a result of verbal and nonverbal responses of the nondisfigured. In addition, the face includes basic bodily functions, such as breathing and eating. The optimal result of facial soft tissue reconstruction should achieve aesthetic balance and symmetry, distinct facial planes, skin texture appropriate for camouflage, and facial animation, as well as functionality. The deformity caused by massive facial burns is an indication for the consideration of facial allograft transplantation. Partial face transplantation became a reality in recent years, with the first two partial facial transplants performed in France (2005) and China (2006). The first total facial transplant took place in Spain (2010). To date, approximately 40 face transplants have been completed across the world.

The goal of facial transplantation is to enhance aesthetic, functional, and psychological quality of life instead of improving survival. Facial transplantation requires the presence of a multidisciplinary team composed of plastic and transplant surgeons, psychiatrists, psychologists, ethicists, social workers, radiologists, infectious diseases specialists, and nephrologists. From the pretransplant phase to long-term post-transplant support, psychiatry has a very important role as a part of the facial transplant multidisciplinary team. The goals of the pretransplant psychiatric evaluation include the selection of motivated patients, discussing

options besides face transplant, including risks and benefits of transplantation, educating the patient about the expected success rate and rescue procedures, immunosuppression, and diagnosing substance use and psychiatric disorders requiring treatment. During the evaluation, the psychiatrist explores the patient's motivations and expectations regarding transplant, their psychological strengths, coping style, self-esteem, body image, and identity issues, the functionality of the support network, and in detail assesses the capacity to consent for the surgery. Following the surgery, the psychiatrist provides ongoing care, which includes psychopharmacologic and psychotherapeutic intervention as the patient goes through the process of integrating the donated face into their self-schema.

Ethical Considerations of Face Transplantation. Despite the significant advances in technology and surgical technique, facial transplants remain controversial due to multiple ethical concerns surrounding the procedure. These include the rationale behind the exposure of individuals to the sequelae of lifelong high-dose multidrug immunosuppression, the development of waiting lists for non–vital organ transplantation, the risk of potential immunologic rejection of the facial graft with its potentially devastating consequences, the consent of the donor's family, the cost to society of such highly technical procedure and the potential damage caused to other organs of the donor during the face harvesting period. Results, however, show that from a clinical, technical, and immunologic standpoint, facial transplantation has achieved functional, aesthetic, and social rehabilitation in severely facial disfigured patients. Early involvement of a hospital bioethics committee is advocated to ensure compliance with ethical standards in this procedure that requires research in order to establish the risk of experimental interventions.

FAMILY SUPPORT

Family members and loved ones of critically injured burn patients face great strain in all phases of treatment. Worst still if they witnessed the accident and ensuing painful medical treatments. The health and mental well-being of family members are frequently impacted as well. In the course of acute or initial phase treatment of the burned patient, it is important to regularly provide their family with updates on the patient's condition and evolving treatment plans as information becomes available. Family members may be anxious and distressed while observing the patient undergo treatment which fosters the same response in the patient. It is important to help family members understand this effect and help them to convey a sense of calmness and hope to the patient. If possible, burn unit staff should describe to patients' loved ones any changes in the patient's appearance resulting from burn injury or treatment. This will help them prepare and process the information related to the extent of the burn injury and the impact of the injury on the patient's functioning in the future. Patients with an extensive burn injury can display disconcerting behaviors related to states of pain or delirium, and they may be agitated, anxious, or confused during family visits. In response, loved ones may make unrealistic demands on burn unit staff. The restrained patient often elicits great concern from family members. Taking the time to listen to their concerns and to describe the reasons for restraints (or 1:1 supervision), the expected course of treatment and recovery, as well as the likely etiologies of the patient's current states may help to ease their distress.

Once the family understands the nature of the injury and its treatment and begins to feel supported and reassured that staff is doing all they can, the family can often help calm the patient. Denial, and other defensive mechanisms, can be employed by patients and loved ones in the setting of acute and critical injury and should be respected as a method of psychological protection and a phase of healing. It should also be noted that the long-term consequences and disability after burns place a considerable strain on burn survivors and their families.

The presence of mental health staff can be helpful to family members in all phases of recovery. Psychiatric consultants should be

present and available and introduced to patients and family members as part of the treatment team. This approach may help to destigmatize mental health involvement in the burn unit.

SELF-INFLICTED BURNS

Self-inflicted burns are rare and horrific forms of burn injuries. In the United States, these types of burns account for 1% of burns. In developing countries, they account for 25% to 30% of burn unit admissions. In the United States and other developed countries, these individuals usually have an increased TBSA percentage resulting from flame and inhalation injuries. They have a past psychiatric history, worse physical and psychological outcomes, and are more likely to be men. Additional risk factors are alcohol and substance abuse, stress, impulsivity, previous suicide attempts, low economic status/being homeless, single marital status, and chronic medical issues.

The prevalence of self-inflicted burns increases in some developing countries and within certain cultures, though the incidence can vary within continents, countries, and cultures. In developing countries, the incidence of self-inflicted burns is 10 times greater than in high-income countries. These burns are usually perpetrated by women who are uneducated, unemployed, and from rural areas. The women are often victims of domestic violence or financial stress, living in a male-dominated society. Other contributing factors are financial hardship, history of suicide attempts, marital/family conflicts, and feelings of guilt and shame.

Self-immolation is the act of setting oneself on fire with a flammable liquid in pursuit of a cause or statement. This dramatic action can be seen throughout history. Though this can be seen in Greco-Roman mythology, there is a deeper history associated with religion in Asian cultures such as Buddhism and Hinduism. More recently, self-immolation has been a sign of protesting political movements and wars such as the Vietnam War and Arab Spring. The mode of self-immolation has changed over the years from funeral pyres to gasoline.

Compared to survivors of unintentional burns, those with self-inflicted burns suffer more severe injuries with higher rates of morbidity and mortality and require longer periods of acute hospitalization. Injuries usually affect the upper body, including the face, chest, arms, hands, and ventral thighs. Self-inflicted patients are younger, unmarried, male, unemployed, burned by fire/flame, and substance abusers. They also have minimal social support, low socioeconomic status, poor coping skills, and previous self-harm experiences. In a prospective study looking into long-term physical and mental health morbidity and mortality of self-inflicted versus non–self-inflicted burn injuries, a surprising finding was that the patients with self-inflicted burns had increased all-cause mortality during the 24-month period after injury. The severity of these burns may be due to the deliberate use of liquid accelerants on clothing, which keeps the skin in contact with the fire. In addition, the person who intends to die by fire is less likely to extinguish the flame, compared with victims who suffer burns by assault or accident.

There is a paucity of written/described literature on nonsuicidal burn patients, those who burn themselves without the clear intent to kill themselves. In this population, the majority of which are women, injuries are due to scalding, chemical, or contact means of burning. The distribution of burns is the forearms and lower extremities. The TBSA percentage is less than suicidal-inflicted burn patients, and their psychiatric history is more likely due to personality disorders.

Patients who attempt suicide, especially by such unequivocal and aggressive acts, can evoke extreme emotional responses from others, including from medical providers and loved ones, the individuals responsible for the direct care and support of the patient. Some caregivers may even feel it is the right of the patient to die, given the extremes to which they have gone. These emotional responses, among others such as anger and anxiety, may affect the care and survival of the patient. Treatment of the psychiatric and emotional needs of the patient, family, and, at times, staff, is imperative.

The process of discharging patients with a recent suicide attempt and severe burns challenges all hospital services involved in

arranging placement and aftercare. Inpatient psychiatric units vary in their ability to absorb severely burned patients, given the complex nature of the injury and the need for medical and surgical follow-up care. The creativity and adaptability of the burn unit staff, including psychiatry, may make the difference between a timely discharge and the patient needlessly remaining on the burn unit for months. Inpatient psychiatric units are often reluctant to manage the medical follow-up care of severely burned patients. Rehabilitation facilities are reluctant to admit patients with complex psychiatric needs and a recent suicide attempt. Some suggest that the best approach would be to establish secure psychiatric units within rehabilitation centers.

Self-inflicted burn injury continues to present a complex medical and psychiatric challenge to all involved and requires a coordinated and multidisciplinary approach. Recent studies acknowledge the paucity of quality research data related to self-inflicted burns and suicide attempts by self-immolation. Larger, controlled, prospective studies are needed to further elucidate factors that might lead to prevention and treatment modalities. There is evidence that, with appropriate treatment, patients with self-inflicted burns can go on to live productive lives.

CHILDREN AND BURN INJURY

Burns are a major source of morbidity and mortality in children. Almost one-quarter (24%) of all burn injuries occur in children under the age of 15. According to WHO, globally, more than 95,000 minors die of burns each year or approximately 262 children per day. Table 27.14–1 lists some of the risk factors for burns in children. They are usually an interplay of all or some of the listed factors.

The 2019 NBR reported that in the United States, the two most common etiologies for burn injuries across all age groups are flame burns at 41% and scalds second at 31%. Scalds are more prevalent in the younger population, especially among those younger than 5 years of age, while fire/flame burns prevail in the remaining age categories. Most burn injuries are accidental and are the fifth leading cause of injury deaths for children from ages 1 to 4 in the United

States, and third for those aged 5 to 9. However, child abuse or neglect also causes about 6% to 20% of pediatric burns, with scalds as the prevalent etiologic factor. Child abuse or neglect must be ruled out by pre-evaluation and treatment of the burned child. The nature of the burn wounds is intermittently indicative of abuse, as listed in Table 27.14–2. Other indicative factors of abuse include large tap water burns, delay in seeking care as well as if the history and description do not appear to match the injury pattern. Parent–patient interaction might also raise suspicion of abuse or maltreatment.

Underreporting of abuse is common. Another adult, besides the perpetrator of the abuse, often presents the child for treatment. Child victims of abuse are reluctant to present for treatment for fear of legal, physical, or emotional repercussions. Children generally want to remain with their primary caregivers at all costs. It is critical to recognize the signs of abusive burn injuries because they are shown to have increased mortality, require longer hospitalizations, and are often more severe than accidental burns. The average rate of burn injuries decreases from age 4 until adolescence, and after age 15, the incidence rate of burns increases again, presumably due to greater exposure to hazards, experimentation, risk-taking behaviors, and employment. The two major determinants of survival in children are burn size and the presence of inhalation Injury.

Psychological Sequelae of Burn Injury in Children

Psychological distresses are frequent and debilitating complications of the postburn injury. Recent research into the prevalence of post-trauma reactions in pediatric patients after sustaining a burn injury identified that 35% were diagnosed with at least one psychological disorder. Sociodemographic factors and clinical characteristics of the burn injury are some of the major factors influencing psychological symptoms. Among the sociodemographic factors, high living expenses, low income, and female sex appear to be good predictors of psychological symptoms after burn injury. Some studies claim that compared to sociodemographic variables, clinical characteristics

such as the degree of the burn and duration of the burn have a greater effect on the development of psychiatric disorders for burn patients. Greater levels of acute pain have been found in studies to be associated with negative long-term psychological effects, including ASD, depression, suicidal ideation, and PTSD for as long as 2 years after the initial burn injury. For children, particularly, inadequate pain control and lengthy periods of hospitalization, coupled with long periods of separation from primary caregivers, can exacerbate the developing, often fragile, psychological and ego stability of children. The psychological development of burned children can be affected by a decrease in their ability to form adaptive behaviors. Adaptability is a necessary emotional tool for adjusting to life's challenges at any age and can ultimately influence maturation, which may, in turn, affect behavior.

Common assumptions exist about the negative effects of disfiguring burns on a child's general attitudes. One study evaluating attitudes of adolescents burned as children contradicted these beliefs and found them to have positive attitudes about their appearance and about how others viewed them, as well as good quality-of-life assessments.

Acute Stress and PTSD Symptoms in Children

The burn injury threatens the child's health and bodily integrity, which results in psychological trauma in the child. Furthermore, burn injury may result in permanent scarring, limited functionality, and intensive and long-standing physical treatments, all of which may place the affected children at the risk of psychiatric disorders. A significant number of burned children present with ASD during hospitalization and typically occur within the first month of injury. It is the core feature of a child's reaction to a traumatic event. The risk factors for ASD include burn size, high pain level, increased pulse rate of the child or the parent, and poor body image of the child. PTSD is another common ailment seen in burned children and can occur even in toddlers aged 1 to 2 years. They occur after a month and up to 2 years or more after the actual injury. The development of PTSD

is frequently predicted by ASD. PTSD is associated with long-lasting neurobiologic abnormalities, such as reduced hippocampal size due to autonomic arousal and acquisition of conditioned fear with chronic re-experiencing of traumatic events. Two biologically separate routes have been proposed in the development. One involves separation anxiety as it relates to increased pain levels, and the other connects the expression of dissociation with burn size. The importance of these recent findings lies in the possibility of preventing the development of PTSD by detecting and treating early signs and symptoms of acute stress.

Medical and Psychiatric Treatment of Burned Children

Recent reports indicate up to 50% decline in the numbers of burn-related deaths and hospital admissions in the United States. This is attributed to more effective preventative measures and advances in therapeutic strategies, leading to a decrease in the number and severity of burns and improved clinical outcomes. Great advances in the spheres of resuscitation, wound coverage, support of the hypermetabolic response to injury, infection control, treatment of inhalation injury, as well as recognition and treatment of the psychological sequela in the burn patient accounts for the improvements in clinical outcomes.

Pain management in the burned child remains an arduous task, despite the aforementioned improvements, specialized pain management departments, an arsenal of pain medications, and alternative methods of treatment, including hypnosis and guided imagery. Too often, the pain remains difficult to treat or is undertreated. Adequate pain control is critical in the management of the burned children, especially as unresolved pain causes negative short- and long-term psychological outcomes. It may also trigger anticipatory anxiety for future medical procedures. Increased pain and anxiety are found to decrease wound re-epithelialization, which can also lead to long-term consequences for growth and mobility. Increased pain can also influence the possibility of patients and families displaying signs of PTSD.

The combination of the constant presence of caregivers on burn and trauma units, child life specialists, and administration of medications, such as benzodiazepines, SSRIs, and tricyclic antidepressants, have significantly improved the treatment of anxiety and other psychological sequelae of burn injury.

The parental level of coping with the stress of caring for a burned child influences the child's recovery. Treatment of the caregiver may be essential for optimum recovery of the child. In addition, educating parents about the psychological effects of burn injury on their child will help them to be more attuned to the child's needs and stages of healing. A holistic and family-centered approach consisting of both pharmacologic and nonpharmacologic techniques helps provide optimal care for the burned child.

Lisa, an 11-year-old girl, suffered a 70% TBSA burn. Following a protracted, critical hospital course and treatment in the acute inpatient setting for over a year, she was finally transferred to a specialized long-term rehabilitation center. Toward the later parts of her acute inpatient stay and prior to transfer, Lisa was gradually coming into her own again besides developing meaningful friendship ties with the staff. She had also started exhibiting typical adolescent behaviors of boredom, rebellion, and stubbornness while re-establishing connections with a few of her old friends via the internet. She, however, remained reluctant to confront her new appearance. A few months later, at the rehab center, coupled with continued progress in other spheres and building up trust in new staff at the rehab center, she was finally comfortable enough to request a full-length mirror. Huge shock and devastation were evident at her first glimpse of the full extent of her scarring and disfigurement. However, her family and staff were immensely supportive and reassuring. She eventually came to terms with her new appearance and started entertaining visits from friends.

Developmental Considerations

The prevalence of premorbid dysfunction in burned children is high and estimated at over 50%. Pre-existing developmental issues, including learning difficulties, emotional and behavioral disturbances, and developmental delay, are significant risk factors for a burn injury in children. The complexities of burn treatment and often lengthy recovery times can adversely affect the physical and emotional development of the burn child. Preburn physical, intellectual, and emotional levels will help determine realistic rehabilitation goals as much as will the extent and impact of the burn injury. The burden of postburn injury morbidity, including long-lasting physical and psychological effects, may, unfortunately, be experienced by children in the remainder of their lifetime. A child's level of resilience is likely due to some combination of preinjury emotional stability, level of support, family construction, socioeconomic status, temperament or genetics, and certain aspects of after-burn care and rehabilitation.

Health care providers involved in a child's or adolescent's transition to rehabilitation must take premorbid and postinjury developmental status into consideration when assessing the goals of the child, family, and caregivers during discharge planning. The survival of the burn patient, children in tow, had greatly improved over the years, even in those with large total body burns. Decreasing caregiver stress can have a direct correlation with the well-being of the patient, as shown in several studies focused on the effect of stress levels in parents of injured or ill children.

STAFF SUPPORT

Hospital burn unit staff are repeatedly exposed to severely traumatized bodies and minds. Patients and their families depend on the staff for support, clinical updates on the patient's condition, and glimmers of hope that "everything will be okay." When patient outcomes are positive, these responsibilities can provide staff with great satisfaction and the sense that they have been able to adequately minister to the patient. As in any critical care unit, morbidity and mortality rates can be high. Factors that contribute to burn unit staff burnout and increased levels of staff stress include (1)

high acuity, and the labile nature, of burn-injured patients' physiologic and psychological states; (2) understaffing of the unit or lack of organizational support and guidelines to reduce work stress; (3) physical isolation of the burn unit from other areas of the hospital and avoidance by other services; (4) "secondary traumatization" via repeated visual exposure to the disfigurement and severely burned body parts of patients and by repeated descriptions in rounds of the actual burn event; (5) reactions and demands of traumatized patients and their families; (6) pressure to make life and death ethical decisions; (7) managing patients' ongoing pain; (8) lengthy hospital stays; and (9) substance abuse issues.

The pandemic has increased psychological distress, contributing to stress/burnout factors for providers on burn units. The risk of viral transmission to staff and patients has been of the greatest concern. In the current (as of this writing) world of SARS-CoV-2, concerns of social distancing, PPE procurement and use, testing, quarantining, and unit staffing have taken over ordinary routines. The daily race is to take all of this into account and learn as you go to keep ahead of the virus and prevent deaths. Keeping up with new protocols is important and helpful to feel in command of all the information and yet stressful at the same time since keeping up with the new information is time-consuming and not always clear.

Many burn units are tucked away in relatively remote areas of the hospital. The isolation of the physical plant may mirror and enhance the psychological isolation felt by the staff when handling critically ill or multiple acute patients. Caring for a burned patient may require repeated visual impressions of maimed, grafted, or amputated body parts or of the patient wrapped in gauze with only eyes and mouth exposed. Many burned patients are protected from infection by isolation precautions and live behind a glass window. One must gown and glove with each visit. This is exponentially intensified due to the covid precautions hospital staff are now taking. The patient may have suffered or required amputation(s), causing disfigurement and altering their life in many ways. The heavy weight of these burdens can create feelings of helplessness and despair in staff and loved ones as well as the patient. To avoid these painful emotions,

staff and family may struggle with urges to avoid the patient at any stage of treatment or recovery. In addition, consultants may try to avoid coming to the burn unit, another factor that contributes to feelings of isolation among burn unit staff.

Studies have shown an increase in mistakes made by caregivers with increased levels of stress. Acute and chronic stress in the workplace leads to staff with lowered morale, impaired performance, increases in turnover, and absenteeism. At a particularly high risk of increased stress is the burn unit staff in charge of critical decision making, as they attempt to balance the needs of the patient and the unit and implement national guidelines and local standards of care with the resources available to the unit, hospital, and community. Training and supervision of ICU nursing staff have been shown to reduce absenteeism and turnover and improve patient care. There is a need to psychologically support health care workers. There are programs created for health care to educate, bolster support, and promote resilience through in-person as well as internet programs.

There are great challenges in taking care of burn patients. Adding substance abuse, psychiatric issues, and the stress of working in difficult conditions to the clinical picture increases those challenges, all of which can contribute to a myriad of feelings that can get played out and contribute to negative countertransference and staff burnout. The psychiatric consultant can play an integral role in reducing staff stress by making daily rounds on the burn unit, making recommendations for the treatment of patients' psychological, neurologic, pain, as well as safety issues. Liaison work with families and staff conveys a sense of connection, support, and understanding. The psychiatric consultant can explore these feelings that the staff may be experiencing, which can assist them in working with patients and their families.

END OF LIFE AND ETHICS

Consultation liaison psychiatrists are regularly called upon to help evaluate multiple ethical queries arising from the management of burn patients. Patients with massive burns are now more likely to

survive than in the past. These patients can fall into protracted shock or unresponsiveness, rendering them incapable of making their own medical decisions. Thus, burn injuries can bring up a myriad of complex ethical challenges, including capacity for medical decision making, the appointment of a health care proxy, continuation of treatment, do not resuscitate or intubate orders, medical futility, quality of life concerns, and initiation of comfort measures as opposed to standard treatment.

While dealing with such complex issues, the principles of autonomy, beneficence, nonmaleficence, and justice must be considered. While there is no simple algorithm to help solve the ethical challenges that present in the management of the severely burned patient, there are frameworks that may help clinicians work through these ethical dilemmas.

One such approach, known as the “Four Quadrant Approach,” described by Jonsen, Siegler, and Winslade, uses the above principles to analyze ethical problems in the context of four areas: medical indications, patient preferences, quality of life, and contextual features (i.e., social, economic, legal and administrative).

- *Medical indications:* In the first quadrant, the medical facts of the case are described. Diagnosis, prognosis, proposed treatment, and expected outcomes fall under this quadrant. In the context of burn care, this may include the type and severity of the burn injury, planned interventions, and the expected course and outcome for the patient. This stage is important to highlight the purpose and goals of the planned interventions, risks, and benefits of the proposed interventions. Having the facts, an accurate diagnosis, prognosis, and severity of the burn can help guide any ethical dilemmas that may arise surrounding goals of care and how management decisions might benefit or harm the patient. While this may occur in any clinical discussion, it becomes especially important when ethical questions arise.
- *Patient preferences:* Patient’s exercise of autonomy is usually central to the resolution of ethical dilemmas often posed in their care. If the patient has decision-making capacity, their

preferences should be respected and guide medical care. If the patient cannot participate in decision making, the patient's wishes or best interests should be carried out by a health care proxy or a surrogate decision maker.

Determining decision-making capacity in an acute burn patient poses unique challenges. Patients usually have a lucid period at the start of initial resuscitation in which patients demonstrate an ability to participate in their medical decision making. However, obtaining informed consent during this time period can be controversial because patients may be cognitively and emotionally incapable of making life-changing decisions so soon after the injury. Family members may also find themselves highly distressed and may not be able to process all the information given to them. Patients and families should be educated about their medical choices with guidance and support from the medical team.

Ideally, patients should be asked the type of care that they would wish or do not wish to receive at the start of the initial resuscitation, a period in which they are usually lucid.

- *Quality of life:* Burn injuries can negatively affect a patient's quality of life. Patients with severe burns may lose functionality, have significant scarring, and deal with life-altering impairments. These may lead to employment and financial issues, isolation, and poorer social supports. While treatment generally focuses on preserving and restoring quality of life, clinicians should aim to determine whether therapeutic interventions are likely to positively or negatively affect the quality of life.

An often-arising intricate ethical query is withholding or withdrawal of care in severely burned patients. Even in cases when this is the patient's wish or when the staff feels death is inevitable, making this decision can still cause high anxiety in both staff and family members. A "consensus conference" can be used to help the burn team discern the judgment of the group. All involved staff members discuss and resolve their differences of opinion and unify their position prior to presenting to the patient or their family. This group

decision helps remove the burden of responsibility on individual staff members as well as on family members, who may otherwise bear the burden of making a decision that may ultimately end with the patient's death.

Pain control and management are of paramount importance in all burn patients as this might be an underlying element behind a burn patient's refusal of further treatment, dressing changes, and other related procedures, as well as in terminally ill burn patients where adequate comfort and sensible care should be ensured. A consulting psychiatrist must evaluate for pain control and advocate for optimal pain control in these patients. Comforting words may be of help even in seemingly unresponsive patients. All involved staff should also help patients and their families with anticipatory grief and with concrete plans in order to help alleviate their distress.

- *Contextual features:* Family dynamics, financial resources and socioeconomic issues, religious/cultural identity, and personal bias of anyone involved in the care of the patient should also be considered.

In conclusion, the consulting psychiatrist must evaluate the medical indications for treatment, including risks, benefits, and potential burdens; the patient preferences based on patient's autonomy; quality of life issues; and contextual features, including socioeconomic, family, and legal issues. Patients' surrogates may aid in decision making and must be adequately informed regarding the extent of the burn injury, treatment options, likely outcomes, and prognosis. The hospital's bioethics committee is sometimes involved in the resolution of very complex ethical situations.

Several years ago, at a conference, one of the authors (MB) was on a panel discussing ethical issues in the burn patient. Another guest panelist was a nonphysician professional who had suffered a major burn injury that had severely scarred his face and body, causing blindness. He subsequently went on to graduate school, got married, had children, and reported that he enjoys his family very much. However, his point to the panel is that during his acute hospitalization, he asked numerous times that his treatment be stopped and that he be allowed to die because he found the treatment intolerable. He believed that it was wrong that his wishes were not respected, and he was advocating that this should be done in the future with other patients in this situation. He was asked by this author whether he had adequate pain control during his treatment and replied definitely not. He agreed that he might feel different if there had been better pain relief of his severe pain.

27.15 Management of Chronic Pain

J. Gregory Hobelmann, M.D., M.P.H., and Michael R. Clark, M.D., M.P.H., M.B.A.

DEFINITION AND COMPARATIVE NOSOLOGY

Pain is a complex experience integrating cognitive, behavioral, and affective factors serving as a warning of impending or actual injury. The International Association for the Study of Pain defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage." This definition recognizes that pain may be experienced in the absence of tissue damage and is, therefore, a subjective experience. As such, the patient's report of pain should be considered valid in the absence of evidence to the contrary.

There are many terms used to describe different types of painful experiences (Table 27.15–1). Pain can be either acute or chronic. Acute pain is typically the result of actual tissue damage secondary to injury, surgery, or the exacerbation of chronic disease. It has survival value in that it promotes behaviors that minimize repeat injury. If pain persists on a daily basis for a month beyond what would be considered necessary to heal the underlying injury, it is generally considered chronic. Chronic pain seems to serve no purpose and is much more complex and difficult to manage than acute pain. The development of chronic pain is multifactorial and involves physical, cognitive, and emotional processes but is not fully understood. The intensity of pain can be classified as mild, moderate, or severe and is usually measured on a 10-point numerical rating scale.

Pain is further classified as either nociceptive or neuropathic (Table 27.15–2). Nociceptive pain results from injury or disease and can be divided into somatic or visceral pain. Somatic pain is usually well-localized and results from injury or disease of the skin, muscle, bone, or related structures. Examples of somatic pain conditions are arthritis, fibromyalgia, and myofascial pain. Visceral pain arises from internal organ dysfunction as the result of inflammation, ischemia, or organ distention and is usually poorly localized and difficult to characterize. Examples of visceral pain conditions are endometriosis, appendicitis, and interstitial cystitis. The quality of

nociceptive pain is often described as throbbing, aching, or pressure-like pain.

Table 27.15–1.
Types of Painful Experiences

Allodynia	A painful response to a normally non-noxious stimulus
Deafferentation pain	Pain resulting from loss of sensory input into the central nervous system
Dysesthesia	An abnormal pain that can be spontaneous or evoked
Hyperalgesia	An exaggerated painful response to a normally noxious stimulus
Hyperesthesia	Increased sensitivity to stimulation that excludes the special senses
Hyperpathia	An exaggerated painful response evoked by a noxious or non-noxious stimulus
Hypoesthesia	Diminished sensitivity to stimulation that excludes the special senses
Nociception	Detection of tissue damage by transducers in skin and deeper structures and the central propagation of this information via A delta and C fibers in the peripheral nerves
Paresthesia	An abnormal nonpainful sensation that is either spontaneous or evoked
Sensitization	Lowered threshold and prolonged/enhanced response to stimulation

Neuropathic pain is pain arising from a lesion or disease of the somatosensory system and is often accompanied by maladaptive

changes in the nervous system. The distinction is made between peripheral, as in peripheral neuropathy and postherpetic neuralgia (PHN), or central, as in multiple sclerosis and central poststroke pain. The quality of neuropathic pain is usually described as shooting, stabbing, or electric-like pain. Conditions such as headache and cancer pain can involve both nociceptive and neuropathic pain. Over time, all types of chronic pain produce more difficult-to-reverse changes in the functioning of the CNS as well as the structure of its components termed central sensitization.

EPIDEMIOLOGY

Pain is the number one reason that patients present to their physician, and the societal burden of pain is considerable. It is the most important current and future cause of morbidity and disability globally and is a feature in a wide range of medical conditions. In 2008, about 100 million adults in the United States reported a chronic pain condition. Chronic back pain is the most common condition, followed by severe headaches, arthralgias, and neck pain. Patients with chronic pain utilize about twice as many health care resources as the general population. People with moderate to severe pain lose 8 days of work every 6 months on average. The total health care costs secondary to pain ranged from $560 billion to $635 billion in 2010, eclipsing the cost of heart disease, diabetes, or cancer.

Many factors have been linked to the development of chronic pain. According to the available literature, the effect of age is inconsistent, with some studies reporting an increase in the prevalence of chronic pain with age and others reporting a decrease. Most studies report that women present with more severe, frequent, and longer-lasting pain than men. There appears to be an inverse relationship between socioeconomic status and the prevalence of chronic pain, with a higher prevalence in patients with lower income, lower levels of education, and who are unemployed. Several factors, including smoking, alcohol use, lack of physical activity, and poor nutrition, are associated with the development of chronic pain. The burden of

chronic pain is worse in developing countries and appears to be increasing over time, despite improvements in medical care. The most reliable factors for the development of chronic pain are a history of a previous episode of pain and a more severe intensity of acute pain.

Table 27.15–2.
Neuropathic and Nociceptive Pain Conditions

NEUROPATHIC	
Peripheral	**Central**
Peripheral neuropathy	Spinal cord injury
Postherpetic neuralgia	Central poststroke pain
Trigeminal neuralgia	Parkinson disease
Chronic postsurgical pain	Multiple sclerosis
Phantom limb pain	Seizure disorder
Complex regional pain syndrome	
Radiculopathy	
Nerve entrapment	
NOCICEPTIVE	
Somatic	**Visceral**
Arthritis	Irritable bowel syndrome
Myofascial pain	Endometriosis
Fibromyalgia	Interstitial cystitis
Connective tissue disorders	Ulcers
Surgical/trauma-related pain	Appendicitis
Burn pain	Cholecystitis

ETIOLOGY AND PATHOPHYSIOLOGY

The neurobiology of pain is complex and involves peripheral, dorsal horn, ascending tract, and descending inhibition mechanisms. Pain results from the activation of peripheral receptors, or nociceptors, by a stimulus. Ongoing stimulation causes changes in peripheral nerves, spinal cord structures, and supraspinal structures, which can result in the development of chronic pain. Our understanding of potential mechanisms that result in chronic pain remains relatively unclear but involves dimensions such as stress, age, genetics, environment, emotional response to injury, and immune responsivity, among others.

Peripheral mechanisms begin with primary afferent nociceptors responding to a mechanical, chemical, or thermal stimulus. Myelinated A-delta fibers transmit mechanothermal information with a sharp, prickling quality. Unmyelinated C-fibers are polymodal and transmit pain with a burning, aching quality. Usually, stimulation activates only high-threshold nociceptors. In conditions of nerve injury or inflammation, peptides such as substance P and neurokinin A are released, causing neurogenic inflammation. This results in nerve fibers becoming excitable, vascular structures dilating with extravasation of plasma proteins, and inflammatory cells releasing a variety of chemical mediators. These chemicals can alter the response of the high-threshold nociceptors by reducing the response threshold called peripheral sensitization. In peripheral sensitization, there is a zone of allodynia around the site of injury in which low-intensity stimulation can produce pain.

The primary afferent nociceptors terminate in the dorsal horn of the spinal cord. The dorsal horn is the site of action of many neurotransmitters and neuromodulators that act at several receptors, including *n*-methyl-D-aspartate (NMDA), kainite, glutamate, opioid, and GABA, among others. The second-order neurons can be classified into nociceptive- specific/high-threshold or wide dynamic range neurons. Allodynia occurs when wide dynamic range neurons become sensitized and fire at an increased frequency. Central sensitization is a state of increased sensitivity to central pain signaling neurons and also occurs in the dorsal horn. It refers to

several modifications resulting from prolonged activation of nociceptive afferent fibers. These modifications include windup (progressive increase in neuronal activity during stimulation), facilitation (magnification and prolongation of the neuronal response), action potential threshold reduction, receptive field expansion, oncogenic induction, and long-term potentiation (strengthening of the synaptic transmission after stimulation). NMDA receptor activation by glutamate is thought to be an important mechanism for the production of central sensitization.

Second-order neurons project to supraspinal structures in the ascending tracts of the spinal cord. These ascending tracts are located in the contralateral anterolateral spinal cord (spinothalamic, spinoreticular, spinomesencephalic) and latent ipsilateral pathways. The ventroposterior nuclei of the thalamus represent temporal and spatial aspects of pain, while the medial nuclei are involved in the affective-motivational features of pain. Other subcortical structures, such as the basal ganglia, hypothalamus, amygdala, and cerebellum, are thought to function in the transmission of nociception and perception of pain. The role of cortical structures in pain perception is not well understood, but it is postulated that the parietal lobes and somatosensory cortex contribute to the sensory-discriminative component while the cingulate cortex is involved with the affect component.

Pain can be decreased by descending inhibition. This is a complex mechanism involving many structures and neurotransmitters throughout the central nervous system. Treatment modalities involving electrical stimulation attempt to activate descending inhibition to reduce the activation of nociceptive mechanisms.

DIAGNOSIS AND CLINICAL FEATURES

Pain is a subjective experience and is difficult to assess, especially in people with cognitive limitations or other chronic degenerative diseases. Complaints of pain should always be taken seriously. There are no diagnostic tests that can ascertain the existence of pain or measure the severity of pain. The evaluation of pain should

always be individualized and begins with a thorough history and physical examination. A comprehensive history should include the quality and location of the pain, associated signs and symptoms, exacerbating and alleviating factors, temporal aspects, interference with daily functioning, and responses to prior treatments. Acute pain is usually the result of an inciting insult such as trauma or surgery, but the etiology of chronic pain is usually more insidious, and often the etiology of chronic pain cannot be determined. As a result, chronic pain conditions result in more psychological sequelae than acute pain conditions.

The severity of pain can be assessed using a variety of rating scales, including verbal, numerical scales from 0 to 10 and the visual analog scale (VAS). The VAS consists of a 10-cm line with “no pain” on the left and “worst possible pain” on the right. For consistency, the same scale should be used over time in individual patients. For patients that have difficulty using these scales, such as young children or cognitively limited patients, substitutes such as the facial expression scale have been validated. In addition to severity, other important aspects of pain should be assessed, including functional capacity, psychological and emotional function, satisfaction ratings, and adverse treatment effects. Distinguishing between neuropathic and nociceptive pain is also important as treatment approaches to each vary considerably.

A psychological history must be included in the evaluation as well. A focused exam should include prior psychiatric diagnoses, work history, legal history, substance abuse history, and prior or current suicidality. Up to two-thirds of chronic pain patients have comorbid psychopathology. Depression is the most common comorbidity, followed by anxiety disorders, somatoform disorders, and substance use disorders (SUDs). It is important to elicit these disorders and treat them concurrently, as they have been associated with poorer treatment prognoses. In addition, people seeking care for chronic pain may also be more likely to have personality vulnerabilities which can act as a barrier to effective treatment.

Physical examination of the patient should include all body systems because pain is often a manifestation of systemic disease.

However, a focal neurologic and musculoskeletal examination may be appropriate in patients with limited complaints. It is important to evaluate for sensory changes, motor changes, passive and active range of motion, and postural and gait abnormalities. The examination findings are rarely pathognomonic but rather serve to select patients for further imaging studies or invasive diagnostic procedures to focus on a specific etiology.

Pathology and Imaging Studies

Various imagining techniques have become commonly utilized in the search for the cause of chronic pain. However, they have several drawbacks and are limited in their utility. The correlation between MRI findings and the severity of pain is poor. Greater than 50% of asymptomatic patients will have abnormalities on lumbar, thoracic, or cervical films, and early imaging for back pain does not appear to improve outcomes or affect decision-making. MRIs are indicated in patients with serious or progressive neurologic deficits, bowel or bladder dysfunction, suspected metastatic disease, or infection.

For nonspinal conditions, MRI is best for inflammation and soft tissue disease, and CT scanning is better for detecting bone disease and bleeding. Plain films can be useful to detect gross bone abnormalities and joint degeneration. Ultrasound is infrequently used but has the advantages of being inexpensive and does not expose patients to radiation. In most instances, imaging serves to alert the practitioner to seek further invasive diagnostic procedures.

Electromyography and nerve conduction studies (NCS) can be helpful in detecting lesions of large nerves. They do not detect impairment of smaller nerves, however, and are associated with significant false-negative and false-positive rates. For peripheral neuropathies, skin biopsies are sensitive tests that demonstrate decreased density of epidermal nerve fibers.

Recent studies have shown that the brains of people with chronic pain are different from those of people without pain complaints. There are morphologic alterations such as decreases in the gray matter in the areas involved in the perception of pain. This appears

to be a result of the pain and can be reversed with successful treatment. Functional MR-based brain imaging methods are developing rapidly and will likely be utilized more in the diagnosis and treatment of pain in the future.

DIFFERENTIAL DIAGNOSIS

Acute pain is usually the result of an injury or trauma and determining the underlying cause is straightforward. Chronic pain, however, often has no identifiable etiology, and management must be focused on the suppression of symptoms. The more common chronic pain syndromes (Table 27.15–3) are discussed in the next section.

Low Back Pain

Low back pain (LBP) is one of the most common physical complaints and the most expensive condition when health care costs and loss of productivity are considered. Approximately 25% of adults in the United States have experienced at least 24 hours of LBP in the last three months, and lifetime prevalence ranges from 65% to 80%. Psychological factors such as depressed mood and somatization are highly correlated with LBP and predict the transition from acute to chronic pain. The most powerful predictor of chronicity is poor functional status 1 month after seeking treatment. Both economic and social rewards have been associated with higher levels of disability and depression in patients with chronic LBP.

The presence of a depressive disorder increases the risk of developing chronic LBP and musculoskeletal pain in general. Depression has been associated with a nearly fourfold increase in the likelihood of seeking treatment for new-onset LBP. On the other hand, chronic disabling LBP can result in significant psychopathology that affects outcome and treatment response.

Chronic LBP is a condition that exemplifies the complexity of chronic pain treatment. Patients with chronic LBP present with symptoms representing numerous diagnoses that require multimodal

treatment approaches. Treatments can often reduce symptoms, but there is conflicting evidence about their ability to improve functional status and return patients to work. Almost all treatment modalities, including conservative interventions, have produced inconsistent results. A thorough evaluation and individualized treatment plan for each patient presenting with LBP are essential.

Table 27.15–3.
Common Chronic Pain Conditions

HEADACHE

- Migraine
- Tension-type headache
- Cluster headache
- Headache associated with trauma
- Chronic daily headache
- Cervicogenic headache
- Postdural puncture headache

OROFACIAL PAIN

- Trigeminal neuralgia
- Geniculate neuralgia (Ramsay Hunt Syndrome)
- Glossopharyngeal neuralgia
- Superior laryngeal neuralgia
- Tolosa–Hunt syndrome

LOW BACK PAIN

- Spondylosis
- Spondylolisthesis
- Spondylolysis
- Disc herniation
- Foraminal stenosis
- Facet arthropathy
- Spinal stenosis
- Fracture
- Musculoligamentous
- Discogenic pain
- Congenital disease

BUTTOCK PAIN

- Sacroiliac dysfunction
- Piriformis syndrome

PERIPHERAL NEUROPATHIES

- Painful peripheral neuropathies (e.g., diabetes)
- Focal entrapment neuropathies
- Postsurgical syndromes
- Traumatic brachial plexus avulsion
- Ischemic cerebrovascular injury

- Syringomyelia
- Arachnoiditis
- Complex regional pain syndrome
- Meningoradiculopathies
- Epidural spinal cord compression
- Herpes zoster and postherpetic neuralgia

PELVIC PAIN

- Endometriosis
- Infection
- Uterine pain
- Pelvic congestion
- Pelvic adhesions
- Ovarian remnant syndrome
- Cancer pain

CENTRAL PAIN STATES

- Spinal cord injury pain
- Poststroke pain
- Parkinson disease
- Multiple sclerosis

FIBROMYALGIA

MYOFASCIAL PAIN SYNDROME

PHANTOM PAIN

SICKLE CELL ANEMIA

Peripheral Neuropathic Pain

Peripheral neuropathy caused by a lesion or disease of the somatosensory nervous system is common and can have a major impact on quality of life. It often causes pain, numbness, and weakness and usually occurs in the hands and feet but can occur in other areas of the body. There are numerous etiologies of peripheral neuropathy, including diabetes mellitus and excessive alcohol consumption. Approximately 25% of patients with diabetes will experience painful diabetic neuropathy, and a longer duration of disease and poor glycemic control increases the risk. The pain from peripheral neuropathy is often described as burning and lancinating

and can be constant or episodic as well as spontaneous or evoked. The pain is primarily the result of axonal degeneration, segmental demyelination, sites of ectopic impulse generation, and activation of immune cells and can occur anywhere along the peripheral nerve up to the dorsal root ganglion. Voltage-dependent sodium channels contribute to hyperexcitability, and central sensitization amplifies and sustains pain by a variety of mechanisms. Pharmacologic treatment can help to reduce symptoms, but a reversal of the pathology is rarely attainable.

Postherpetic Neuralgia

PHN is responsible for about 15% of referrals to pain clinics. It is defined as pain that persists or recurs at the site of shingles at least 3 months after the onset of an acute varicella-zoster rash. PHN occurs in about 10% of patients with acute herpes zoster and in over 50% of patients over the age of 65. Risk factors for the development of PHN include advanced age, cancer, diabetes mellitus, immunosuppression, longer duration of prodromal symptoms, greater pain and severity of the rash, sensory impairment, and psychological stress. Although it generally improves over time, 25% of patients with PHN continue to complain of pain for longer than 1 year.

Degeneration and destruction of motor and sensory fibers of the dorsal root ganglion characterize acute herpes zoster. In PHN, further neurologic damage, including inflammation of the spinal cord, myelin disruption, axonal damage, and a decrease in the number of nerve endings in the affected area, have been demonstrated. Studies have suggested the role of both peripheral and central sensitization in PHN. Early detection and treatment of herpes zoster with antiviral medication and analgesics may have the potential for the prevention of PHN. In addition, a live attenuated virus vaccination for the prevention of herpes zoster is now available and has reduced the burden of illness in adults older than 60 years.

Migraine and Chronic Daily Headache

The lifetime prevalence of migraine is 18% in women and 6% in men. The peak incidence occurs between the third and sixth decades of life. Common migraine is unilateral and pulsatile and may be accompanied by nausea, vomiting, photophobia, and phonophobia. Prodromal symptoms, such as scintillating scotomata, are typically present in the classic form of migraine. Complicated migraine includes focal neurologic symptoms such as cranial nerve palsies or other neurologic deficits and is often described by the deficit, such as hemiplegic or basilar migraine. The definitive pathogenesis has not been described, but identification of new migraine-associated genes, the visualization of involved brain regions, a greater appreciation of the potential role of cervical nerves, and the recognition of the role of neuropeptides are among the advances that have led to novel targets for treatment. Management of migraine starts with the identification and control of comorbidities and risk factors that predispose individuals to migraines. Beta-blockers, flunarizine, valproate, topiramate, and CBT appear to be the best prophylactic agents, and several studies have demonstrated the efficacy of nonsteroidal anti-inflammatory medications and triptans in the treatment of acute attacks.

The most common reason for lost productivity in the US workforce is headaches, and about 5% of the population suffers from chronic daily headaches. Patients with chronic daily headaches are more likely to have psychiatric comorbidities such as depression and anxiety and report functional disability. They also tend to overuse analgesic medications leading to rebound headaches. Patients with chronic daily headaches are a difficult group to treat, and studies suggest that treatment with medications and CBT together is better than either treatment alone.

Central Poststroke Pain and Spinal Cord Injury

Lesions of the central nervous system, such as stroke or spinal cord injury (SCI), are commonly associated with pain. Symptoms of central pain are generally poorly localized and vary over time. Patients may experience allodynia, hyperalgesia, muscle and

visceral pain, and lancinating pain. The pain can be described as burning, aching, lacerating, or pricking but tends to vary widely among patients. The pain may not occur until 1 month or longer after the initial insult. There are likely many processes involved in the generation of the pain, and excitatory amino acids have been implicated in the generation of central sensitization after a stroke or SCI.

Central poststroke pain and SCI pain can be severe and disabling but are commonly underreported and often overshadowed by neurologic complications such as weakness, spasticity, and aphasia. It is associated with clinically diverse features, which has limited the ability to consolidate a definition and clinical characteristics. Studies indicate that treatment with analgesics, adjuvant medications, and in some cases, electrical stimulation can significantly reduce pain in these conditions. The studies have been small, however, and more research is needed to determine which treatments are most efficacious.

Fibromyalgia

Fibromyalgia is characterized by widespread musculoskeletal pain in all four extremities as well as the trunk, exaggerated tenderness, and stiffness. It is also commonly associated with fatigue, sleep disturbances, and other cognitive and somatic symptoms. It is diagnosed in 2% to 8% of the population, but this may be an overestimation as criteria for the condition have been debated. Musculoskeletal pain is the most prominent feature of fibromyalgia, but it should be suspected in any patient who has multifocal pain that is not explained by a definable etiology. Because pain is amplified and can occur anywhere in the body, sensory hyperresponsiveness, chronic headaches, somatic pain, and visceral pain are quite common. Studies suggest that muscle relaxants, membrane stabilizers, selective serotonin/norepinephrine reuptake inhibitors, and tramadol are effective in reducing pain associated with fibromyalgia.

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS) was formally called reflex sympathetic dystrophy (RSD) and causalgia. It is described as an array of painful conditions characterized by continued pain that is precipitated by trauma or immobilization that is usually associated with allodynia or hyperalgesia. The pain is regional but is not limited to a specific dermatome or peripheral nerve, and there is no confirmatory test or definitive treatment. In acute stages, inflammatory symptoms prevail. In chronic stages, symptoms can include hyperalgesia, sensory loss, motor changes, sudomotor dysfunction, edema, blood flow abnormalities, perception disturbances, and complications of disuse and physical deactivation. These changes are due to central neuroplasticity and likely involve neurogenic inflammation and neuropeptides such as calcitonin gene-related peptide, cytokines, nerve growth factor, and substance P. Sympathetically maintained pain is often present and may result from the coupling of the sympathetic and sensory neurons. Patients with sympathetically maintained pain can receive temporary relief from sympathetic blockade. Mood, anxiety, and substance abuse disorders are fairly common in patients with CRPS. These disorders are generally considered a consequence rather than a cause of the condition.

Pharmacotherapy for CRPS has limited efficacy, but there is evidence supporting the use of anti-inflammatory drugs, gabapentin, pregabalin, carbamazepine, tricyclic antidepressants, and opioids. Physical therapy, graded motor imagery, and graded pain exposure can help to overcome central reorganization. If psychiatric comorbidity is present, the patient should be referred for specialized treatment. Invasive treatment, such as electrical stimulation and surgical sympathectomy, should only be offered after psychosomatic assessment and careful patient selection. The prognosis for recovery from CRPS is now thought to be better than was historically assumed if treatments facilitate the rehabilitation of the affected limb with activated movement and use.

Phantom Limb Pain

Phantom limb pain is a type of neuropathic pain that originates in the distal territory of an amputated limb. It can also occur after the surgical removal of other body parts, such as the breast, rectum, penis, eye, or tongue. It occurs in 50% to 80% of amputees and is generally described as stabbing, throbbing, aching, burning, or cramping. While studied extensively and easy to diagnose, phantom pain can be challenging to treat. Pharmacologic treatments and neural blockade seem to have limited efficacy, but morphine, calcitonin, and mexiletine have been shown to reduce pain lasting more than 6 months, suggesting a role for the usual pharmacologic treatments of neuropathic pain and central sensitization. The limited success with pharmacologic treatments has spawned interest in psychological interventions, such as CBT and biofeedback, for the treatment of phantom limb pain. The limited available evidence demonstrating the effectiveness of these treatments has shown various degrees of success.

Orofacial Pain

Orofacial pain is defined as pain occurring on more than 15 days per month that lasts for more than 4 hours daily and has persisted for greater than three months. There are a variety of conditions that are categorized as orofacial pain, and we will review a few of the more common syndromes.

Trigeminal neuralgia, or tic douloureux, is a chronic pain condition with severe, paroxysmal, recurrent, lancinating pain in the distribution of the facial nerve (cranial nerve V). It is usually unilateral and involves the mandibular or maxillary branch of the nerve. Episodes of pain are often spontaneous but can be evoked by nonpainful stimuli or environmental conditions. Motor and sensory deficits are not typically present. Uncontrolled pain with frequent or severe attacks increases the risk of developing anxiety, depression, insomnia, weight loss, and social withdrawal.

In most cases of trigeminal neuralgia, there is evidence of trigeminal nerve root compression and demyelination by blood

vessels, mass lesions, or other diseases such as multiple sclerosis or herpes zoster. Compression and demyelination cause hyperactivity of the trigeminal nucleus. Carbamazepine is the first-line treatment, and there is evidence to support the use of oxcarbazepine and lamotrigine. If pharmacologic approaches fail, there are several invasive procedures such as microvascular decompression, percutaneous gangliolysis, and stereotactic radiosurgery that can be considered.

Temporomandibular disorder (TMD) refers to conditions that involve pain from the temporomandibular joint, muscles of mastication, or other orofacial musculoskeletal structures. Most commonly, pain arises from the muscles of mastication and is precipitated by the movement of the jaw when chewing or talking. The pain is generally sharp, sudden, intense, and localized to the preauricular area, and joint sounds such as “popping” or “clicking” are common. Other symptoms include feelings of muscle fatigue, weakness, tightness, and changes in bite or ability to open or close the jaw. TMD is often associated with psychological stress, which is responsive to behavioral treatments. Treatment of patients with TMD should initially be based on the use of conservative and evidence-based therapeutic modalities, with more invasive interventions, such as surgery, being reserved for refractory pain.

Burning mouth syndrome (BMS) is an array of conditions characterized by pain in the oral and pharyngeal cavities that are often associated with dryness and taste alterations. Middle-aged and postmenopausal women are most frequently affected. Although most cases are idiopathic, BMS can be associated with other conditions such as bruxism, poorly fitting dentures, oral candidiasis, hypothyroidism, diabetes mellitus, and neoplasm. Psychiatric comorbidities are fairly common and include anxiety, depression, traumatic life events, and somatization. Treatment begins with identifying potential underlying etiologies such as anxiety and depression, nutritional deficiencies (iron, folate, and B-vitamins), maladaptive oral habits, and iatrogenic causes. Symptomatic treatments include tricyclic antidepressants, anticonvulsants, soft

desensitizing oral appliances, vitamins, hormonal supplements, and habit awareness counseling.

There are a number of less common orofacial pain conditions. These include cluster headache, short-lasting, unilateral, neuralgiaform pain with conjunctival injection and tearing (SUNCT), Tolosa–Hunt syndrome, and atypical facial pain.

COURSE AND PROGNOSIS

Pain is a complex perceptual experience that is not only affected by the activation of nociceptors but also emotions, cognition, expectations, and social and cultural context. In acute pain, the course and prognosis are fairly predictable with the resolution of pain when the initial insult has resolved. In chronic pain, however, the course and prognosis vary widely and are difficult to predict. Certainly, psychiatric comorbidities and their treatments influence the course and prognosis greatly. Below are some of the psychiatric comorbidities that are frequently associated with chronic pain conditions.

Somatic Symptom Disorder

When a somatic cause for the pain cannot be identified, practitioners often begin to look for psychological causes. Pain caused by emotional factors was first introduced in the DSM-II under psychophysiological disorders and has gone through several modifications in subsequent editions. The authors of the DSM-5 created a new category name, somatic symptom and related disorders, and its prototype is the somatic symptom disorder (SSD). The criteria for SSD have been modified substantially from its predecessor, somatoform pain disorder (SPD). The most radical change is the abolition of the distinction between medically explained and medically unexplained somatic complaints. This will likely increase the number of patients with SSD considerably compared to SPD.

The main feature of SSD is a patient's concern with physical symptoms for which no biologic cause can be found. A psychiatric evaluation is essential in the work-up to exclude or identify comorbid psychiatric disease. Failure to recognize SSD may lead to diagnostic or therapeutic procedures that could result in iatrogenic complications. It may also result in an increased financial burden on the healthcare system. In general, patients with SSD have a poorer prognosis with continuing use of medical services. Proven treatments include cognitive behavioral therapy, mindfulness therapy, and antidepressants. A stepped care approach with close cooperation of a primary care provider, a somatic specialist, and a mental health care professional is recommended.

Substance Use Disorder

The prevalence of severe SUD in patients with a chronic pain condition is estimated to be 7% to 20%. Although a relatively large proportion of patients with SUD report chronic pain, a much smaller but significant proportion of patients with chronic pain report SUD. The essential criteria to note for SUD in patients with chronic pain are continued use of a substance despite negative consequences, loss of control of substance use, and excessive preoccupation with using the substance. Americans account for only 5% of the world's population but consume 80% of the global opioid supply.

Aberrant medication-taking behaviors are often assumed to be abuse or addiction. However, chronic, persistent pain can lead to an increased focus on taking opioid analgesics. Understandably, patients fear the reemergence of pain or withdrawal if they run out of medication and often take measures to assure that they have an adequate supply. About 20% of patients on long-term opioid therapy for pain may have what has been termed "complex persistent dependence (CPD)," which is qualitatively more severe than simple physical dependence. A hallmark of CPD is that patients are unwilling or unable to taper opioids despite functional or medical deterioration, and classic opioid use disorder-like behaviors often emerge with a reduction of the opioid dose. There are several

patterns of misuse of or nonadherence to prescribed medications that can occur when patients are concerned about medication. In general, patients take more medication than prescribed. This occurs when patients are concerned about withdrawal, tolerance, addiction, scrutiny of medication by others, or a greater perceived need for medication. Having these concerns is a risk factor for developing a SUD. Patients are at greatest increased risk for SUDs during the first 5 years of chronic pain treatment, and the risk is higher if they have a history of substance abuse or psychiatric comorbidity.

Aberrant medication-taking behaviors are present in about 50% of chronic pain patients who are prescribed opioid analgesics. However, studies suggest that only about 10% of patients with aberrant medication-taking behaviors do so as the result of a SUD.

Patients with a history of SUD are at increased risk for relapse when prescribed opioid analgesics for pain, but the process is not well understood and is likely multifactorial. The cycle of pain followed by relief after taking medication is reinforcing and certainly plays a role. In patients who develop a new SUD, the prescribed medication is commonly involved. Risk prediction tools such as the opioid risk tool (ORT), screener and opioid assessment for patients with pain (SOAPP), and current opioid misuse measure (COMM) are available to offer guidance, but they are self-assessment tools that have limitations.

Conversely, patients with SUDs are at increased risk of having a chronic pain condition. This can lead to stigmatization and undertreatment of their pain. This is potentially a difficult population to treat because opioid-dependent patients with chronic pain have relatively high rates of SUDs. Most chronic pain patients who enter a treatment facility for a SUD reported that they received a prescription for opioids from a clinician. They also frequently reported obtaining opioids illegally and altering the route of administration, which suggests that they had progressed to a severe SUD.

Frequent follow-up care is necessary for patients with chronic pain who are prescribed opioids. Prior to the initiation of opioids, the risks and benefits of the medication should be discussed with the patient, and the clinician should have the patient sign an opioid consent

form. Close monitoring with intermittent, random toxicology testing should also be performed. Integrating care for chronic pain with innovative stepped-care models of substance abuse could improve outcomes by tailoring the treatments and their intensity to the needs of the individual. However, there is a lack of high-quality evidence on the prevalence, risk factors, and optimal treatment approaches related to concurrent chronic pain and substance misuse. There is an urgent need for high-quality research to guide evidence-based medicine and health policy considering the escalating epidemic of harms related to opioid misuse.

Depression and Affective Illness

There is an intimate and bidirectional relationship between pain and depression. Patients with major depression often have physical symptoms, and about 60% of depressed patients complain of pain. It has been estimated that patients with depression have about a fourfold increase in the prevalence of chronic pain conditions. Baseline symptoms of depression have been found to predict future pain and disability better than initial ratings of the pain itself.

There are higher rates of lifetime major depression in patients with chronic physical complaints. Of patients that present to pain clinics, up to 50% meet the criteria for major depressive disorder. In patients with chronic LBP, the rate of depression is greater than three times the rate in the general population. In patients with chronic pain, depression is associated with greater severity and persistence of pain, greater interference from pain, more pain behaviors observed by others, and early retirement from working. These patients are also more likely to use medication, including analgesics and sedative-hypnotics, daily. Studies indicate that comorbid pain and depression almost double the health care costs of managing the conditions.

Patients with chronic pain syndromes such as migraine, chronic abdominal pain, and orthopedic pain conditions also report greater suicidality. Rates of suicidal ideation, suicidal attempts, and suicide completions are two to three times greater in these patients. Risk factors for suicide in this population include depressive symptoms,

anger problems, harmful habits, childhood adversities, family history of suicide, and occupational disability. There tends to be a decrease in self-efficacy in chronic pain patients that contributes to feelings of hopelessness. Depression is the most consistent and strongest predictor of suicide in patients with chronic pain, although other psychosocial variables likely play a role.

Comorbid pain can result in depression that is more resistant to treatment. Depression should not be viewed simply as an expected outcome in patients with pain and should be treated aggressively. Successful treatment of depressive symptoms often results in the reduction of pain and improvement in functional status and quality of life. This effect is independent of the direct treatment of pain and can likely be explained by the fact that the neurobiology of pain and depression overlap.

Anxiety Disorders, Fear, and Anger

Anxiety symptoms are present in almost half of patients with chronic pain conditions. Up to 30% of these patients meet the criteria for an anxiety disorder such as generalized anxiety disorder, panic disorder, agoraphobia, and post-traumatic stress disorder (PTSD). PTSD is increasingly recognized as a comorbid condition in patients with medical illnesses, especially chronic pain. It is associated with greater levels of pain, emotional distress, interference in function, and disability. On the other hand, anxiety is associated with high levels of somatic preoccupation and physical symptoms. Pain complaints are present in up to two-thirds of patients with panic disorder, and pain intensity is greater in patients with symptoms of anxiety. Pain is associated with higher levels of anxiety and more frequent panic symptoms.

Fear of pain, movement, and reinjury can result in the avoidance of activities that can promote the transition to and maintenance of chronic pain. Restriction of activities can result in physiologic changes, such as weight gain and muscle atrophy, and functional deterioration. This process is reinforced by feelings of low self-efficacy, catastrophic interpretations, and expectations of failure in

rehabilitation. The fear-avoidance model of pain incorporates components such as fear of and attention to pain, catastrophizing, escape or avoidance behavior, disability, disuse, and vulnerability to help explain the transition from acute to chronic pain. Fear-avoidance beliefs have been shown to be one of the most significant predictors of failure to return to work. They can reinforce disability through operant conditioning if the avoidance provides short-term benefits, such as relieving anxiety or unwanted responsibilities. Decreasing work-specific fears can be more important than addressing the general fears of activity when trying to improve the physical capability to work.

Catastrophic thinking can be described as the amplification of threatening information. It involves elements of cognitive rumination, symptom amplification, expectations of pessimism, and feelings of helplessness. Catastrophizing interferes with the patient's ability to remain involved in productive activities and intensifies the experience of pain, emotional distress, and perceived disability. Cognitive distortions such as catastrophizing and fear-avoidance beliefs predict poor coping and adjustment to chronic pain better than objective factors such as disease status and physical impairment. Catastrophizing is also a predictor of suicidality, independent of pain severity and depressive symptoms.

TREATMENT

The primary aims in the treatment of pain are elucidating a cause, alleviating suffering, and restoring function. Biologic, psychological, and social factors all play a role in the perception of pain, and each should be addressed. Pain reduction, functional improvement, minimizing psychological comorbidities, and improving social interactions are all important goals. The traditional biomedically oriented treatment with a focus on pharmacotherapy and passive interventions has not proven to be an effective treatment strategy for patients with chronic, disabling pain. A strong consensus exists that an interdisciplinary rehabilitation approach to the treatment of pain is beneficial.

Pharmacologic Treatment

There are numerous medications used to treat chronic pain. These medications target the mechanisms of peripheral and central nervous system sensitization such as sodium and calcium channel upregulation, descending modulation, loss of inhibitory interneurons, spinal hyperexcitability, and aberrant sympathetic-somatic nervous system interactions. Antidepressants, anticonvulsants, and antipyretic analgesics are the best-studied medications and are recommended as first-line agents. Opioids are also well studied and frequently used in the treatment of pain but are not without significant drawbacks, and long-term effectiveness has not been demonstrated in rigorous research. There is no simple medication algorithm that provides a straightforward approach to the complexities encountered in the treatment of chronic pain.

Antipyretic Analgesics

Aspirin, acetaminophen, and nonsteroidal anti-inflammatory drugs (NSAIDs) are the backbone of pharmacologic management of acute pain. Aspirin is the most widely used analgesic in the world. These drugs inhibit cyclooxygenase, which is the rate-limiting enzyme in the production of prostaglandins. Prostaglandins regulate inflammation and sensitize nociceptors. Acetaminophen works primarily in the central nervous system, lacks anti-inflammatory effects, and is a weaker analgesic than NSAIDs. NSAIDs work both centrally and peripherally, making them effective orally and topically. Antipyretic analgesics are more effective in the treatment of nociceptive pain than they are for neuropathic pain. They are appropriate treatments for mild to moderate pain, but they have a ceiling effect and usually cannot be used as standalone agents in the treatment of severe chronic pain. They work synergistically with opioids and have proven opioid-sparing effects.

Antipyretic analgesics, in particular NSAIDs, have significant side effects, including bleeding, gastrointestinal ulceration, renal toxicity, and increased risk of cardiovascular events. The use of cyclooxygenase-2 selective inhibitors, such as celecoxib, and acid-

reducing agents, such as proton pump inhibitory, may reduce the risk of gastrointestinal complications, but nothing can attenuate the renal and cardiovascular risks. As such, they should be prescribed at the lowest effective dose for the shortest duration possible. When appropriate, topical NSAIDs can be used and have comparable efficacy for regional pain conditions.

Opioid Analgesics

Opioid analgesics interact with opioid receptors in both the peripheral and central nervous systems to reduce the sensory and affective components of pain. They are the cornerstone of treatment for cancer pain, but controversy surrounds their long-term use for chronic nonmalignant pain. Several reviews have indicated that they provide prolonged relief and improvement in function in a few individuals, and their superiority over other analgesics is inconclusive.

There are several available guidelines for the use of opioids in chronic nonmalignant pain, and careful attention to balancing the beneficial effects with undesirable adverse effects is necessary. Rational use requires an understanding of the clinical pharmacology of opioids, including potency, duration of action, bioavailability, pharmacokinetics, and pharmacodynamics. The side effects of opioids are numerous and include sedation, nausea, constipation, respiratory depression, pruritus, urinary retention, and endocrine dysfunction. Important steps in the managing of chronic pain patients on opioid therapy are a thorough evaluation, detailed documentation, a function-based treatment plan with an exit strategy for discontinuing opioids, patient education, informed consent, frequent follow-up, and close monitoring. Patients who are appropriate for opioid analgesia include those with moderate-to-severe pain lasting for more than 3 months that adversely affect function or quality of life. Prior to starting opioid therapy, factors such as the patient's particular pain condition, response to therapy, and potential for aberrant drug-related behaviors should be considered. Treatment

outcomes, such as degree of analgesia, activities of daily living, and adverse events, should be routinely assessed.

Long-term opioid use is associated with tolerance and dependence. Cross-tolerance among opioids is incomplete and alternating opioids may result in up to a 50% reduction in equianalgesic dose, so opioid rotation is a strategy that may be employed when tolerance is suspected. Reported addiction rates in chronic pain patients who are prescribed opioids vary widely and range from 5% to 50%. A synthesis of evidence suggests that about 50% of patients will exhibit aberrant drug-related behaviors, 20% will abuse the medications, and 10% will develop an opioid use disorder.

Clinically available opioids include naturally occurring compounds, such as morphine and codeine; synthetic opioids, such as fentanyl, methadone, and tramadol; and semisynthetic derivatives, such as oxycodone, hydrocodone, hydromorphone, and oxymorphone (Table 27.15–4). Morphine has poor oral bioavailability due to its hydrophilicity and delayed central nervous system absorption, and the onset of action. This delay prolongs the analgesic effects of morphine, which decreases the potential for accumulation and toxicity with repeated dosing. Oxycodone is a popular analgesic used to treat chronic pain patients. It has higher bioavailability, faster onset of action, and more predictable plasma levels compared to morphine. These qualities may increase the risk of abuse and addiction. It has similar analgesic efficacy to morphine but causes less histamine release and fewer hallucinations. Hydrocodone is similar to oxycodone with regards to its rapid oral absorption and onset of action but is a less potent analgesic. It is metabolized to hydromorphone, which has properties similar to those of morphine but has lower rates of side effects. Fentanyl is highly hydrophilic with an affinity for neuronal tissues. It is frequently used intravenously in the treatment of acute surgical pain but can also be delivered via transdermal and transmucosal routes for the treatment of chronic pain.

Table 27.15–4.
Clinically Available Opioids Used in Chronic Pain Conditions

Drug	Equianalgesic Dose	Duration of Action
Pure Agonists		
Morphine	30 mg	3–6 hours[a]
Oxycodone	20 mg	3–6 hours[a]
Hydrocodone	30–60 mg	3–6 hours[a]
Hydromorphone	3–6 mg	3–6 hours[a]
Oxymorphone	10 mg	3–6 hours[a]
Fentanyl	12.5 mcg/h (TD)	72 hours (TD)
	800–1,000 mcg (TM)	1.5–3 hours (TM)
Codeine	200 mg	3–6 hours[a]
Methadone	2–20 mg	6–12 hours for pain
Agonist/Antagonists, Partial Agonists		
Buprenorphine	0.3 mg (SL)	6–8 hours (SL)
	5–70 mcg/h (TD)	7 days (TD)
Butorphanol	1 mg (IN)	3–4 hours
Pentazocine	90 mg	8 hours
Weak, Dual-Action Agonists		
Tramadol	150–300 mg	4–6 hours[a]
Tapentadol	75–110 mg	4–6 hours[a]

[a]Long-acting formulations available.
TD, transdermal; TM, transmucosal; SL, sublingual.

Methadone for use in the treatment of chronic pain warrants special consideration because of its stigma, low cost, high bioavailability, rapid onset of action, long half-life, multiple receptor

affinities (NMDA), lack of neurotoxic metabolites, and incomplete cross-tolerance with other opioids. It has a significantly greater risk of overdose because of the longer time needed for adaptation and its long and variable half-life (15 to 120 hours). Methadone is also associated with QTc prolongation and torsades de pointes at high doses (>100 mg per day), as well as increased rates of all-cause mortality at all doses. Although once-daily dosing is adequate to prevent withdrawal symptoms due to its extensive tissue distribution, its analgesic effects only last about 6 hours due to biphasic elimination. Repeated dosing can increase the analgesic period to 8 to 12 hours because it accumulates in tissues, but this same phenomenon can also increase the risk of delayed respiratory depression, overdose, and death.

Tramadol and tapentadol are a newer class of analgesic drugs with weaker analgesic effects and a dual mechanism of action. They are weak opioid agonists that also inhibit the reuptake of serotonin and norepinephrine. Adverse interactions can occur when administered with coumadin, selective serotonin reuptake inhibitors, and serotonin-norepinephrine reuptake inhibitors, and they are associated with tolerance, dependence, and abuse.

Butorphanol, nalbuphine, and pentazocine are opioid agonist-antagonist drugs. Buprenorphine is a partial agonist at the mu-receptor and antagonist at the other opioid receptors. These drugs should be used with caution in patients taking pure agonist drugs because they can precipitate withdrawal. Buprenorphine (in combination with naloxone) is available orally for the treatment of opioid use disorder and as a transdermal patch for the treatment of chronic pain.

Antidepressants

The analgesic effects of antidepressants are thought to be independent of their antidepressant effects and are mediated primarily by the reuptake inhibition of serotonin and norepinephrine. Increased levels of these neurotransmitters, particularly norepinephrine, enhance the activation of the descending inhibitory

neurons in the dorsal horn of the spinal cord. They may also produce antinociceptive effects through a variety of other mechanisms as well including modulation of monoamines, interaction with opioid systems, inhibition of ion channel activity, and NMDA, histamine, and cholinergic receptors. This suggests that all antidepressants would be effective in the treatment of chronic pain, but the analgesic properties of these medications remain underappreciated.

Tricyclic Antidepressants

Studies have confirmed that TCAs are the most effective agents for the treatment of neuropathic pain. They are also effective in the treatment of headache syndromes, central pain syndromes, PHN and other painful neuropathies, and postmastectomy pain syndrome. They have not been shown to be effective in treating SCI pain, phantom limb pain, or painful HIV neuropathy. All TCAs have equal analgesic effects, but the secondary amines, such as nortriptyline, are better tolerated than the tertiary amines, such as amitriptyline. TCAs may produce analgesia at lower doses than needed for the treatment of depression, but treatment should be guided by titration to efficacy. Advantages of TCAs include cost-effectiveness and that optimal titration can be monitored with serum levels to ensure adequate trials and the avoidance of toxicity.

Serotonin-Norepinephrine Reuptake Inhibitors

SNRIs include duloxetine, venlafaxine, desvenlafaxine, and milnacipran, and they inhibit the presynaptic reuptake of serotonin, norepinephrine, and, to a lesser extent, dopamine. They are associated with fewer side effects than TCAs and can be titrated quicker, but titration cannot be monitored by serum levels. Duloxetine more potently blocks serotonin and norepinephrine than venlafaxine. It has been shown to be effective in the treatment of fibromyalgia and painful diabetic neuropathy. Venlafaxine has been shown to reduce neuropathic pain breast cancer treatment, decrease hyperalgesia and allodynia in neuropathic pain and atypical facial pain, and prevent migraines. Milnacipran reduces hyperalgesia

mediated by monoamine and opioid systems and is effective in the treatment of fibromyalgia.

Selective Serotonin Reuptake Inhibitors

The efficacy of selective serotonin reuptake inhibitors in the treatment of chronic pain conditions has been inconsistent in clinical trials. For some conditions, such as migraine, SSRIs do not appear to be more efficacious than placebo. For other conditions, such as fibromyalgia, abdominal pain associated with irritable bowel syndrome, and painful diabetic neuropathy, there is evidence that their use can reduce pain, independent of changes in affective disorders. Because of these inconsistencies, SSRIs are not recommended as first-line agents. Instead, they should be used as alternatives to TCAs or SNRIs when they are ineffective or not well tolerated.

Novel Antidepressants

The neurobiology of pain suggests that all antidepressants would be effective for the treatment of pain, but there is little evidence to support the use of novel antidepressants such as mirtazapine, bupropion, trazodone, vortioxetine, and vilazodone. Mirtazapine has been shown to decrease the duration and intensity of chronic tension-type headaches, and bupropion has been effective in the treatment of neuropathic pain by decreasing pain intensity and interference with pain with quality of life. Several reports have suggested that trazodone is effective for treating chronic pain, but side effects can hinder titration to effective doses. Vortioxetine and vilazodone are fairly new antidepressants that selectively inhibit serotonin reuptake and also have action at 5-HT3 and HT1A receptors. They have been shown to be effective antidepressants, but their efficacy in treating pain has not yet been established.

Anticonvulsants (Antiepileptics)

Anticonvulsants reduce pain by inhibiting excessive neuronal activity. They block voltage-gated sodium channels, modulate calcium

channels, inhibit excitatory amino acid neurotransmitters, and enhance amino acid-mediated inhibitory neurotransmitters. Although top-tier evidence is lacking, studies have demonstrated efficacy for the treatment of diabetic neuropathy, trigeminal neuralgia, PHN, and migraine recurrence.

First-generation anticonvulsants have been used in the treatment of pain since the 1940s, when phenytoin was first reported to be successful in the treatment of trigeminal neuralgia. Carbamazepine is the most widely studied anticonvulsant in the treatment of neuropathic pain and is still the first-line treatment for trigeminal neuralgia. Valproic acid is commonly used in the prophylaxis of migraine but has also been shown to be effective for other neuropathic pain conditions as well.

Second-generation anticonvulsants include gabapentin, pregabalin, lamotrigine and topiramate. Gabapentin and pregabalin decrease the influx of calcium, modulate the release of substance P and glutamate and activate the descending inhibitory of nociception. They are effective in the treatment of painful diabetic neuropathy, PHN, fibromyalgia, phantom limb pain, and SCI-associated pain. Using flexible titration schedules has been associated with fewer discontinuations, higher final doses, and slightly better pain relief compared to fixed schedules. Lamotrigine is effective in treating HIV-related neuropathy and central poststroke pain but has been disappointing in treating other neuropathic pain conditions. Topiramate has been effective in migraine prophylaxis, chronic LBP, lumbar radiculopathy, and painful diabetic neuropathy. It has the advantages of minimal hepatic metabolism, few drug interactions, and a long half-life; it also has the unusual side effect of weight loss.

Oxcarbazepine is a carbamazepine derivative with an improved safety profile that is considered a next-generation anticonvulsant. Studies have demonstrated its efficacy in painful diabetic neuropathy and refractory PHN. Other next-generation anticonvulsants include tiagabine, vigabatrin, retigabine, levetiracetam, and zonisamide. They have a wide spectrum of pharmacologic actions and antinociceptive effects in animals, but studies in humans are sparse. They are also associated with significant cognitive impairment and

are not recommended as first-line treatments for chronic pain conditions. Combinations of anticonvulsants with complementary mechanisms of action should always be considered as they may increase effectiveness and decrease adverse effects of high-dose monotherapy.

Other Adjunctive Drugs

Antipsychotics have been used in diabetic neuropathy, PHN, headache, facial pain, musculoskeletal pain, and pain associated with AIDS and cancer, and there is increasing evidence to support their effectiveness. Compared to typical antipsychotics, atypical antipsychotics offer a broader therapeutic spectrum, have lower rates of extrapyramidal side effects, and have greater potential for augmentation in the treatment of depression. However, they are associated with metabolic disruptions, including weight gain, new-onset diabetes, hyperlipidemias, and cardiac arrhythmias, which offset their benefits.

Oral and topical local anesthetics have long been used in the treatment of pain. Topical lidocaine is approved for the treatment of PHN but has been shown to be ineffective in the treatment of HIV neuropathic pain. It does not produce significant serum levels. Oral mexiletine is effective in the treatment of diabetic neuropathy, peripheral nerve injury, and alcoholic neuropathy. There are mixed reports for its use in phantom limb pain, and it appears to be ineffective in treating cancer-related pain. The analgesic effects of mexiletine did not correlate with serum levels.

Calcium channel blockers have also been used in the treatment of chronic pain syndromes. Verapamil is the most commonly prescribed of the calcium channel blockers and is effective in the treatment of migraine and cluster headaches. Ziconotide is a neuron-specific calcium channel blocker that is derived from the toxin of the cone snail, Conus magus. It has been approved for intrathecal use in the treatment of refractory cancer or AIDS pain and has potent analgesic effects that can be synergistic with morphine. However, it produces

common side effects, including dizziness, nausea, confusion, and headache, that often make it difficult to tolerate.

Several potential targets have been identified for the development of new analgesic medications, including nerve growth factor (NGF), 1.7-selective voltage-gated sodium channels, N-type voltage-gated calcium channels, and angiotensin II (Ang II) AT_2 receptors. In addition, tumor necrosis factor alpha (TNF-alpha) has been implicated to play a pivotal role at both the peripheral and central levels of pain sensitization, and anti-TNF-alpha therapy has potential use for the treatment of neuropathic pain. Despite being counterintuitive, the use of low-dose naltrexone, an opioid antagonist, has been demonstrated to reduce symptom severity in a variety of conditions such as fibromyalgia, Crohn disease, multiple sclerosis, and CRPS, but its superiority to placebo has yet to be verified.

Benzodiazepines are commonly prescribed for chronic pain patients to treat insomnia, anxiety, and spasticity, but practitioners must use them with caution in this population. Their use in treating target symptoms is not supported in the literature. In fact, benzodiazepine use has been associated with decreased activity levels, higher rates of health care visits, depression, increased domestic instability, and more disability days. In combination with opioids, their use can be counterproductive and potentially dangerous. In studies of opioid-related mortality, concomitant benzodiazepine use was frequently implicated.

Psychological Treatments

Cognitive-Behavioral Models. Many psychological treatments have been used in the treatment of pain and its associated distress and disability. Wilbert Fordyce pioneered the psychological treatment for chronic pain using an operant conditioning behavioral model. The behavioral approach focuses on understanding pain occurring in a social context. The behavior of chronic pain patients is not only reinforced by others but also reinforces the behavior of others, including physicians. Pain behaviors, such as grimacing, guarding,

and taking pain medications, are indicators of perceived pain severity and functional disability. It has been shown that these pain behaviors alone are predictors of whether or not opioid analgesics were prescribed to patients. The behavioral model assumes that pain and disability will persist if these behaviors persist. In CBT, healthy behaviors are targeted for reinforcement to replace extinguished pain behaviors.

The cognitive-behavioral model of chronic pain is based on the theory that individual beliefs, attitudes, and expectations affect emotional and behavioral reactions to life experiences. Pain and the resulting pain behaviors are influenced by biologic, psychological, and socio-environmental variables. Patients will experience more negative affective responses, increased pain, and decreased functioning if the patient believes that pain is inevitable and uncontrollable. This cycle of disability can be interrupted by CBT approaches, including relaxation, biofeedback, guided imagery, meditation, motivational interviewing, external reinforcement, cognitive restructuring, and the development of coping strategies. Patients are taught to be active participants in the management of their pain by using these methods to minimize distressing thoughts and feelings. The goal of CBT is to increase activity, independence, and resourcefulness regardless of the particular technique used. CBT has been proven to be effective in reducing pain severity, pain behaviors, distress, and depression and improving coping mechanisms. These benefits can persist for longer than 6 months after the completion of treatment.

A heterogeneous group of behavioral treatments has been termed “third-wave psychotherapies.” These include acceptance and commitment treatment, behavioral activation, cognitive-behavioral analysis system psychotherapy, dialectical behavioral therapy, mindfulness-based cognitive therapy, and metacognitive therapy. These therapies incorporate a variety of psychological and social theories that emphasize the context and function of psychological phenomena rather than just form. The goal is to create strategies for creating change in context and experience to develop broad, flexible, and effective repertoires to improve quality of life. These therapies

have added to the spectrum of empirically supported treatments for mental disorders and could certainly be useful in the treatment of pain disorders.

Beliefs

Beliefs can be conceptualized as the thoughts that patients have about their personal pain problems. Psychosocial dysfunction has been correlated with believing emotions are related to pain, receiving overly solicitous responses from others, and attributing dysfunction to pain. Patients have also endorsed the belief that pain signifies injury and that, therefore, activity should be avoided. A change in perceived control over pain has been shown to be a predictor of the beneficial effects of CBT in the treatment of chronic pain.

Self-efficacy, outcome expectations, and locus of control are cognitive variables derived from the social learning theory. Self-efficacy is a belief about one's ability to perform a specific behavior, and outcome expectation is a belief about the consequences of performing the behavior. Patients are more likely to engage in coping efforts that they believe are within their capabilities and will result in a positive outcome. Patients who score higher on self-efficacy measures or have an internal locus of control have reported lower levels of pain, higher pain thresholds, increased exercise performance, and more positive coping efforts.

Acceptance of pain is associated with multiple domains of the experience of pain, including lower pain intensity, less pain-related anxiety, and avoidance, less depression, less disability (physical and psychological), more daily uptime, and better work status. It predicts a patient's adjustment to the illness and is independent of catastrophizing, coping skills, and pain-related beliefs and cognitions.

Coping

Coping has been defined as an individual's cognitive and behavioral efforts to solve personal or interpersonal problems that are appraised as taxing or exceeding the person's resources. Coping

strategies support the cognitive-behavioral model of chronic pain, whether they are active, passive, adaptive, or maladaptive. However, patients who remain passive or continue to use maladaptive coping strategies such as catastrophizing, ignoring or reinterpreting pain sensations, or diverting attention from pain have a higher disability.

The effectiveness of particular coping strategies is dependent on many aspects of the patient's experience with pain. For example, reinterpreting pain as not being a sign of ongoing injury had been found to be useful in reducing experimentally induced pain. However, focusing on pain and disability for greater amounts of time, as is needed in CBT to help patients reinterpret pain sensations, can be detrimental. It can divert patients from engaging in social activities and healthy behaviors. When patients perceive an increase in the effectiveness of a new coping skill, pain and disability can be decreased, and their use of maladaptive coping strategies can be reduced.

Physical Therapy and Exercise

As pain persists, activity is often reduced, resulting in deconditioning of the individual. The deconditioning and worsening of pain, in turn, results in less activity. As such, resuming normal activity should be an immediate goal. Delaying the resumption of normal activity may lead to greater disability. Physical exercise has been established as a safe and effective way to help manage chronic, debilitating pain. Treatment with physical therapy aims to reduce disability and suffering by reducing pain and increasing tolerance to movement. Physical therapy, aqua therapy, and exercise to improve range of motion and strength can improve function, pain, and quality of life in patients with chronic pain. Yoga, aerobic training, and supervised strength training have also been shown to reduce pain. Mood and levels of anxiety may also improve. The importance of physical therapy and exercise must be stressed as an essential component of a pain recovery program.

Placebo Response

Placebo effects are complex phenomena that are similar to those of active treatments and can be biologically measured. The literature supporting the placebo response has been criticized as flawed and overrated. Clinically, it is difficult to distinguish improvements from treatment and placebo responses. In the past, placebo interventions were a part of the paternalistic practitioner's treatment armamentarium. Currently, however, controversy exists over the evidence of clinically important effects that justify the use of placebo treatments. A positive placebo response does not prove that the patient's pain is psychogenic or that the patient would not benefit from active treatment, and the use of a placebo to determine if the patient's pain is "real" is dishonest and counterproductive. Such an intervention can result in the loss of trust in the practitioner and render future treatments less effective.

Multidisciplinary Rehabilitation

Chronic pain patients have greater reductions in physical, psychological, and social well-being and lower-rated quality of life than those with any other medical condition. The goal of treating chronic pain is to ease suffering and end disability that prevents people from returning to productive activities. Evidence suggests that early failures in single-modality treatment for chronic pain can have devastating consequences for future treatment effects. Furthermore, analysis of multidisciplinary programs that use comprehensive assessments, step-care treatments, and rehabilitation goals result in significant reductions in pain along with functional and quality-of-life improvements. Evidence-based practice guidelines emphasize interdisciplinary rehabilitation, integrated treatment, and patient selection criteria. Furthermore, interdisciplinary pain rehabilitation programs (IPRPs) are efficacious in returning patients to work and ultimately can reduce the economic burden of chronic pain.

Invasive Treatments

Nerve Blocks. In the treatment of chronic pain, injections can be performed for diagnostic and/or therapeutic purposes. Injections with

local anesthetics may work by enhancing blood flow, releasing entrapped nerves, and interrupting the processes involved in central sensitization. Adding corticosteroids to local anesthetics may provide the added benefits of blocking the inflammatory cascade and inhibiting the synthesis of prostaglandins which can sensitize nociceptors.

Although nerve blocks are rarely curative, they may provide pain relief for a time and facilitate rehabilitative therapy. Peripheral nerve blocks that can provide relief in properly selected patients include trigger point injections for myofascial pain, intra-articular injections for osteoarthritis, and direct nerve blocks for entrapment syndromes. Spinal injections include epidural steroid injections for radicular pain and facet injections, sometimes with radiofrequency denervation, for facet joint pain. Other neuroablative procedures using alcohol or glycerol, such as celiac plexus neurolysis for pancreatic cancer and hypogastric plexus neurolysis for pelvic pain, can provide pain relief for several months. However, they can be associated with severe rebound pain and should be avoided in patients with nonmalignant pain conditions.

Electrical Stimulation

Spinal cord stimulation (SCS) is a reversible treatment that uses low-voltage electrical pulses to manage chronic, intractable pain conditions. The procedure includes the implantation of a pulse generator, extension cable, and leads, which are placed in the dorsal spinal column near the nerve root that is thought to be associated with the pain. An electrical current induces paresthesia or a tingling sensation that is meant to mask the pain. SCS was developed based on the gate-control theory, which postulates that activation of peripheral sensory A-fibers can attenuate pain signaling by C-fibers. SCS is typically used in pain conditions that have been refractory to other treatments, including failed back surgery syndrome and CRPS.

Surgery

Surgical interventions should be reserved for chronic pain patients who have failed to respond to more conservative measures. It can be challenging to decide when operative procedures are appropriate because of the difficulty involved in establishing a causative relationship between the targeted pathologic process and pain. In many individuals, the targeted disease may not be the primary cause of pain. Rarely does removing a painful body part result in long-term pain relief. Furthermore, the sequelae of the surgery itself can result in worsening pain, such as when scar tissue or adhesions develop. Careful patient selection is a necessity in deciding who should receive surgery for relief of a chronic pain condition.

CONCLUSION

Chronic pain is a significant public health problem and negatively impacts those who are affected by it. The traditional view that pain is either caused by tissue pathology (nociception) or psychological states (suffering) is too simplistic and outdated. It is now widely recognized that the relationship between pain and nociception is complex and must be understood in terms of the situation of the whole individual. There are high rates of psychiatric comorbidity in patients with chronic pain, and a psychiatric evaluation should be part of any comprehensive pain evaluation. Psychiatric diagnosis and treatment can add an essential and often neglected component to the conceptualization and treatment of chronic pain disorders. Care for patients with chronic pain should occur in a medical treatment setting, as this is the most effective way to reassure patients that the somatic elements of their pain are not neglected, and it allows effective integration of somatic and psychological treatments. A shift from traditional, single-provider care to a multispecialty, integrative approach results in improved outcomes and reduced economic burden.

Additional Conditions That May Be a Focus of Clinical Attention

28.1 Malingering

Frank John Ninivaggi, M.D.

The condition termed *malingering* was formally introduced into psychiatry in 1980 in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III). Psychiatrists deal with health and examine disorders to discern whether they are real, imagined, or created. DSM-5 (2013) denotes *malingering* as the intentional production of false or grossly exaggerated physical or psychological symptoms motivated by external incentives and states aspects of it may represent adaptive behavior. The symptoms of malingering are under voluntary control. This behavior reflects intentionally contrived statements and actions with both conscious and nonconscious components, all of which intend to mislead the evaluator, usually in medical and legal contexts.

Emphasis is given to the conscious awareness the malingerer has of the malingering presentation as a behavioral strategy. Malingering is the production of, for example, false or exaggerated symptoms using a deliberately invented presentation. The malingered presentation is fluid, can change over time, and shift across changing contexts, circumstances, and situational demands. Malingering, as a form of illness behavior, suggests dysfunction but not real psychopathology. This section discusses the psychiatric condition and clinical indicators suggestive of malingering, primarily as they present in the psychiatric assessment. Neuropsychological investigations are often used as one part of comprehensive evaluations. Legal considerations and determinations are not part of the psychiatrist's role. Empirically reliable evaluations include multimodal elements: clinical interviews over time, mental health histories, legal and criminal

histories, objective psychological testing, family, occupational and medical, and other relevant collateral information. Informant reliability presumes that information is genuine, accurate, and not biased. An evaluation *team* is best to gather the elements mentioned above.

Misconceptions regarding malingering abound. Some consider it rare; some think it is common. Some equate all medical deception with malingering and correlate this feigning with a wholesale antisocial personality disorder. However, studies show antisocial personality disorder is not more likely to malinger or be more successful than the general population. Mild exaggeration of symptoms and efforts at "impression management" or reasonable attempts to put oneself in a good light does not constitute malingering. When malingering is present, it is thought to be a static response with a stable base rate; this is not true. Some think of it as a diagnosis with clear-cut criteria; instead, it is a condition with broad parameters. Malingering does not preclude genuine disorders, such as post-traumatic stress disorder (PTSD), depression, traumatic brain injury (TBI), and others discussed later. While DSM-5 gives malingering criteria, some have suggested these require further precision to ensure greater validity.

The 2001 edition of the *New Oxford American Dictionary* denotes a *malingerer* as one who exaggerates or feigns illness to escape duty or work. It dates the origin of the term in English to the very early 19th century, describing it as "back-formation from *malingere*, apparently from French *malingre*, perhaps formed as *mal-* 'wrongly, improperly' + *haingre* 'weak,' probably of Germanic origin." The term *malingerer* is said to have first appeared in 1785 in a French dictionary. It denoted a soldier who feigns sickness or induces or protracts an illness to avoid his duty. This 200-year history suggests only relatively recent attention to an individual problem with critical social implications. Malingering is socially problematic behavior.

The relative newness of this DSM entity has brought with it a plethora of conceptual difficulties. In the last 25 years, the psychiatric, psychological, and sociologic literature on this topic has increased. Contributions from these varied sources have been replete with various terms attempting to capture core meanings and attendant nuances. The following definitions will hone the concept and establish a tentative yet uniform lexicon for this section.

1. *Response style* denotes how an individual who is being evaluated communicates self-disclosures (e.g., in revealing or deceiving ways). Replies include personal goals, desired consequences, and their predicted utility in a specific instance and a particular context with a situational demand. Response styles include all linguistic and paralinguistic communications.
2. *Dissimulation* is the broadest term encompassing all forms of deception, often regarding psychological symptomatology. *Dissimulate* denotes deliberate misrepresentations, concealing, hiding, distorting, or disguising perceived truth under cover of deliberate, voluntarily controlled pretense. The dissimulated

appearance is fake, not genuine, counterfeit, and a sham. In the vernacular, this concept resembles a *hoax*, a falsehood intended to deceive or produce a facade of deliberate trickery. If intended to gain an external advantage, it suggests malingering, primarily if symptoms are used.

3. *Dissimulation* concepts encompass three principal subcategories:
   a. Malingering and factitious disorder
   b. “Defensiveness”
   c. Markedly inconsistent, evasive responses

Dissimulation in psychiatry correlates with malingering, *faking good*, *faking bad*, and factitious disorder.

Malingering is medical deception, asserting one has significantly distressing symptomatology in its actual absence. However, malingering spans a spectrum from complete misrepresentation to partial shifts in emphasis that skew the presentation to favor the patient’s receiving some desired external goal. Its range of shaded meanings points to a core denotation of *deliberate illness misrepresentation to obtain an external reward that is unmerited*. In this sense, the *gross* exaggeration of feigned symptoms for external gain in ordinary circumstances is typically not merely a plea for help; it suggests malingering. Nuanced terminology about such situations includes feigning, fabricating, disguising, deceiving, lying, misleading, masquerading, tricking, and faking. The terms “ruse,” “subterfuge,” and “wile” also capture the intention to deceive.

Factitious disorder is the presentation of physical or psychological symptoms (sometimes “signs”) that are self-induced, thus deceptively created with the inferred goal of achieving the sick role to receive medical help. Malingering and factitious disorder are a deliberate misrepresentation of symptoms. They differ because the malingerer seeks an actual external reward, whereas the patient with factitious disorder appears to look for sympathy and care, short of genuine material gains.

Some researchers restrict the denotation of *feigning* to mean deliberate fabrication or gross exaggeration of symptoms *with no assumption about its goals*. In feigning, the underlying motivation is not or cannot be determined. This use is a precise denotation used when psychological tests cannot validate and assess an individual’s motivations—intended purposes or reasons for actions—a key feature of malingering. Psychological tests can establish feigning. Often, feigning means, simply, intentional deception, and this is the way it is used in this section unless qualified. However, the malingerer may be considered deliberately to take on an impostor’s role, one whose *conscious motivation* seeks to achieve an intentionally misleading and deceptive appearance to get an external reward. In this section, the word “motivation” is used as found in the malingering literature. In other nontechnical contexts, motivation is used to mean reasons or the drive behind one’s actions in general; this has a positive connotation. By contrast, the

word “motive” connotes ulterior and suspicious reasons behind specific actions; this use has a negative sense in those everyday frameworks.

The term *defensiveness* has been used in the malingering literature, at times, loosely. Typically, it denotes the masking (e.g., deliberate denial or gross minimization) of symptoms, difficulties, or impairments, in the malingering studies. It would be better not to use this term or to qualify it unambiguously. For example, defensiveness could signify *consciously intended denial or minimization (e.g., faking good) or gross distortion (e.g., faking bad) of symptomatology*. The malingering literature emphasizes “defensiveness” when medical patients minimize or deny their real symptoms, that is, *faking good*. Using *faking bad* in medical contexts suggests malingering since some external incentive or gain is presumed. These clarifications distinguish it from the concept “defensiveness” in psychiatry, which means ego defense mechanisms elicited to modulate and contain the anxiety caused by unrefined impulsive drives and emotions seeking to overwhelm and impair the ego’s functioning. Such defensiveness is nonconsciously motivated, whose outcome is minimization and modulation of unbearable anxiety.

“Defensiveness” as *faking good* is a dissimulation by the omission of negative material, difficulties, or impairments. It denotes consciously minimizing or denying present and perceived symptoms having negative consequences, hence their intentional suppression. It is deceptive impression management. *Faking good* is a guarded attempt actively to portray oneself in a better light than is actually the case. For example, pedophiles seeking to avoid criminal culpability might use *faking good* strategies, referred to as a “dance of denial,” to minimize incriminating behaviors when being examined. In child custody cases, a parent may also intentionally *fake good* to minimize perceived negative behaviors that might jeopardize that parent’s chances of gaining or maintaining custody. Deception and desired external goal point to malingering. Faking good, like faking bad, is an intentionally motivated form of response bias: actively reporting material thought to be the “right” answer to achieve a goal. *Faking good* is deliberately emphasizing good or positive aspects of oneself, that is, positive impression management that is deceptive. This response style spans the spectrum from being prosocial (positive impression management; here, not malingering) in getting the desired job to antisocial (deceptive impression management; here, suggests malingering) to deny criminal or illegitimate behaviors. Impression management in the workplace shows in various ways: disclosure, concealment, or hinting at any material that may bias.

Malingering has also been termed *faking bad*, which denotes consciously creating false, untrue, yet apparently distressing symptoms. *Faking bad* is creating a bad impression, including intentionally over-reporting, embellishing, amplifying, or elaborating present symptoms, but not as problematic as the individual tries to convey in such grossly exaggerated fashion. Symptom

education through Internet-derived information is commonplace today. When a clear external goal is sought, malingering needs consideration.

The term *simulation* has been used as a synonym for malingering but will not be used in this way here. *Simulation* more precisely denotes a consciously contrived pretended situation, an imitation, or a representation (not a deceptive misrepresentation) of one process or situation using a different approach or condition in an illustrative and instructive context. The simulated appearance is usually a “make-believe” condition used for illustration or learning. For example, simulation or analog research protocols examining dissimulation or contexts in which faking is studied using a quasi-experimental design. Participants randomly assigned to an experimental group (e.g., participants asked to dissimulate and deceive) or to a control group (e.g., participants asked to be honest) are the groupings.

In the last decade, the condition of malingering within the field of psychiatry has been a focus of concern in assessments such as medico-legal contexts, for example, insurance claims, disability requests, physical injury litigation, harassment suits, post-trauma cases, neurocognitive dysfunction, chronic pain, and criminal culpability situations. The malingerer seeks *unmerited recompense*. Not only attorneys and courts but also hospital inpatient services request such assessments and consultations. The forensic evaluator (e.g., psychiatrist, psychologist, or attorney)—especially in criminal contexts—acts primarily as a factfinder, discovering facts based on credible evidence, often on a short-term basis. This consultant role differs from the therapeutic relationship that the longer-term treater establishes in a clinically oriented helping situation. More traditional, forensically related general psychiatry assessments were in the realms of suicide, professional boundary violations, informed consent, capacity, and competency, medical errors, civil commitment, confidentiality, domestic violence, and abuse and neglect.

The psychiatrist’s primary goal in evaluations is first to establish the real presence of actual disorders and then discern whether and in which areas genuine symptoms are present and whether the condition of malingering might exist. Malingering is the presence of consciously produced symptoms that are not genuine and motivated by external incentives. Psychodynamic awareness can address the role of *projective identification* (e.g., implicit bias) because input from patients, legal systems, and the psychiatric community may unwittingly and implicitly act in the coauthoring of symptoms influencing the psychiatrist’s decision-making processes striving for objectivity. Making sense of a presentation with strong emotional components requires a working knowledge of emotional intelligence. An intelligent understanding of emotions and complex feelings deepens psychiatric perspectives and interpretive options. The wide array of individual differences in response styles may have crucial emotional determinants needing deliberation in assessments. One strength distinguishing the psychiatric

evaluation of complex, often ambiguous, information is an explicit recognition of unconscious psychodynamics, individual differences, and subtle unique distinctions. Considerations of the presence of what malingering connotes, especially inconsistencies and discrepancies, in any patient's presentation (e.g., self-reports, complex response styles, direct observation, and especially from collateral data) will guide the astute clinician in proper assessments. Included in treatment planning is the rational prescription of medications.

DEFINITION AND COMPARATIVE NOSOLOGY

DSM-5 describes the condition of *malingering* as follows:

> The essential feature of malingering is the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives such as avoiding military duty, avoiding work, obtaining financial compensation, evading criminal prosecution, or obtaining drugs. Under some circumstances, malingering may represent adaptive behavior—for example, feigning illness while a captive of the enemy during wartime. Malingering should be strongly suspected if any combination of the following is noted:
>
> 1. Medicolegal context of presentation (e.g., the individual is referred by an attorney to the clinician for examination, or the individual self-refers while litigation or criminal charges are pending).
> 2. Marked discrepancy between the individual's claimed stress or disability and the objective findings and observations.
> 3. Lack of cooperation during the diagnostic evaluation and in complying with the prescribed treatment regimen.
> 4. The presence of antisocial personality disorder.
>
> (Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Text Revision, DSM-V-TR, p. 835 [Copyright © 2022]. American Psychiatric Association. All Rights Reserved.)

Malingering differs from factitious disorder in that the motivation for the symptom production in malingering is an external incentive, whereas in factitious disorder external incentives are absent. Malingering is differentiated from functional neurological symptom disorder (conversion disorder) and other somatic symptom-related mental disorders by the intentional production of symptoms and by the obvious external incentives associated with it. Definite evidence of feigning (such as clear evidence that loss of function is present during the examination but not at home) would suggest a diagnosis of factitious disorder if the individual's apparent aim is to assume the sick role, or malingering if it is to obtain an incentive, such as money.

Thus, the malingerer through misrepresentation seeks two aims: (1) to gain a desired external, material advantages such as financial, another material benefit, probation, better sentencing or accommodations in the justice system, or illicit

substances; and (2) to avoid something undesired, for example, fulfilling an obligation, a jail sentence, and military or other service obligations.

Malingering is coded in DSM-5 as Z76.5 as a condition (not a mental disorder) that may be a focus of clinical attention. DSM-5 differs from DSM-IV-TR because it adds under #1 above: “or the individual self-refers while litigation or criminal charges are pending.” This addition emphasizes the prevalence of suspected malingering in this population. DSM-5 also includes a new discussion of malingering, factitious disorder, and somatic symptom-related disorders and their distinctions. Thus, in factitious disorder, the voluntariness of pursuing the sick role as a psychological conclusion is emphasized in contrast to malingering. The voluntariness of symptom production in the quest for financial or other external goals yielding a behavioral conclusion is malingering.

The 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) lists malingering in Chapter XXI of this text as code Z76.5, page 244. It codes the following:

- Malingering (conscious simulation)
- Person feigning illness (with obvious motivation)

The ICD-10 chapter containing malingering states these categories are provided for occasions when circumstances other than a disease, injury, or external cause classifiable to categories A00–Y89 (more clear-cut medical and psychiatric disorders) are recorded as “diagnoses” or “problems.” This situation can arise when a person who may or may not be sick encounters the health services for some specific purpose or when some circumstance or problem influences the person’s health status but is not in itself a current illness or injury.

International Classification of Diseases for Mortality and Morbidity Statistics, 11th Revision, (ICD-11), v2019-04 (2021) codes and describes Malingering as code QC30:

> Malingering is the feigning, intentional production or significant exaggeration of physical or psychological symptoms, or intentional misattribution of genuine symptoms to an unrelated event or series of events when this is specifically motivated by external incentives or rewards such as escaping duty or work; mitigating punishment; obtaining medications or drugs, or receiving unmerited recompenses such as disability compensation or personal injury damages award. (Reprinted from World Health Organization. ICD-11 for Mortality and Morbidity Statistics, 2023. https://icd.who.int/browse11/l-m/en#/http://id.who.int/icd/entity/1136473465.)

The DSM-5 guidelines used to indicate the condition of malingering are minimal and relatively broad. However, the *magnitude* of the dissimulation, that is, the creation and gross exaggeration of multiple false symptoms, must be present. There are no suggestions regarding chronologic age range or clear-cut demographic or epidemiologic findings because malingering has not been studied in the rigorous, scientific manner in which the mental disorders have been

researched. Also, because malingering denotes patient deception and unreliable information, it is difficult, if not impossible, to organize findings in a consistently coherent fashion. Clinical judgment, especially about inferred motivation and conscious intention to avoid perceived distress and achieve desired goals, must be sensitive to ambiguous, indeterminate presentations. Therefore, using careful and well-chosen terminology in reports suggests doubt or suspected lack of credibility (e.g., feigning, fabrication, noncredible, and dissimulation short of malingering). When present, it is essential to document this in diagnostic evaluations.

HISTORY

Examples of malingering can be found in literature, from Ulysses feigning insanity to escape the Trojan War to King David's biblical story. The image of street beggars and vagabonds who feigned disease to gain alms is familiar in early Western and Eastern cultures. It was not until about 1880 in Germany and about 1910 in the United Kingdom that malingering moved from the political, military, and social spheres to the medical profession's aegis. World War I reinforced the phenomenon of what already was known as *compensation neurosis*. At the time, medically prescribed removal from duty was added to address war fatigue, shell shock, and war trauma, particularly physical distress. At this point, physicians took or were given a leading role in the management of malingering because it presented as a symptomatic picture in the absence of typically associated material causative features. Because many symptom profiles were strongly suggestive of "mental" and emotional distress, psychiatrists and psychoanalysts then took the lead in trying to sort out genuine from feigned illness.

From its introduction in the DSM-III in 1980 to about 2005, there was an almost threefold increase in malingering scientific literature. Historical accounts have been written, and clinical and empirical case reports have appeared, but evidence-based research is still in its infancy. Hence, as a scientifically justifiable construct, malingering remains more in the context of discovery. The research phase in which evidence is brought to bear on objectively testable hypotheses remains in statu nascendi.

EPIDEMIOLOGY

The actual incidence, prevalence, and distribution features associated with malingering are imprecise. This uncertainty is because malingering has not achieved status as a formal psychiatric diagnosis with attendant studies examining validity and reliability in the context of clinically defined populations. Speculations suggest base rates can vary from 7.5% to 33%. In ordinary clinical practice, some have suggested a 1% prevalence; in military populations, a 5%

occurrence, and in litigious, criminal populations, up to 20%. A 2002 study of 131 clinicians of the American Board of Clinical Neuropsychology gave the following breakdown of base rates for different contexts of malingering: 29% for personal injury, 30% for disability or worker's compensation, 19% in criminal cases, and 8% in medical or psychiatric cases.

ETIOLOGY

The etiologic factors contributing to the spectrum of malingering presentations are broad. They are related to much larger questions concerning the structure of and motivations within human nature. A crucial element is "why" the illness behavior was deliberately manufactured. Cognitive development and refinement, introspection, insight, accurate self-analysis, ego defense mechanisms, adaptation and survival, moral development, openness to self-disclosure, honesty, and the capacity deliberately to lie all play into an assessment of the mechanisms contributing to malingering. Basic knowledge of child and adolescent development, especially the ability to lie, is useful. For example, lying is enabled for about 2 years and expands until 10. Lying is detectable by age 4. Malingering may be construed to carry a pejorative judgment, and so it poses significant professional and legal implications for the doctor if it is challenged. Hence, diligent, parsimonious, perspicacious, and paused approaches to a patient's motivations as intentions are essential ingredients. They should lead to fair and reasonable conclusions.

A thought-provoking 1994 study by Richard Rogers, Ph.D., a recognized leader in the malingering field, proposed the consideration of three explanatory models of malingering. He used a prototypical analysis and subjects who were trained psychologists with extensive experience with malingerers. Etiologic determinants showed adaptational attributes such as making rational decisions based on expected rewards, attempting to cope with challenging circumstances, weighing alternatives, trying to make the best of a bad situation, and facing an unsympathetic or adversarial system were first-rank factors explaining the behavior of response styles. Antisocial and criminologic factors were in the second rank. A psychopathological model was favored by only 3.4% of the forensic experts. This study emphasized that the choice of one's explanatory model may have important implications for treatment recommendations. For example, the adaptational and pathogenic models carried with them the sense of more positive motivation for recommending treatment. The fourth edition of Rogers' book (2020) again restates his explanatory, predicted-utility model: an adaptational and contextual position that flexible response styles over time are based on options available and desired outcomes. This perspective, rich and laudatory, differs from the current DSM-5 emphasis.

The biopsychosocial model in psychiatry, both theoretically and applied to individual cases, may be one of the best ways to consider possible etiologic factors until further research reveals more objectively verifiable causes. This approach includes the rational integration of data from clinical interviews and collateral information: biologic factors such as temperament and medical condition, psychological factors such as defense mechanisms, coping, adaptive styles, and social factors such as current stressors, interpersonal, occupational, and financial considerations, medical and legal matters, military obligations, and situationally specific challenges offering the patient pragmatic options.

DIAGNOSIS AND CLINICAL FEATURES

For the psychiatrist, the clinical diagnoses derive from several interviews with the patient during which an interpersonal and social field is established. Presenting problems, past history, and mental status are fundamental. Preexisting symptoms need clarification to discern if they are resolved, residual, or now being brought to the surface. Since the psychiatrist as a clinician might have only brief contact with one or several sessions, a highly detailed present problem survey with observable signs, reported symptoms, and the patient's detailed elaboration of these is crucial. Continuity versus gross contradictions over time must be noted. In this context and the specific situational demands, all aspects of the patient's demeanor are noted. Self-reports and response styles, complex and often nuanced, are carefully observed and explored. Concerning signals suggesting malingering include vague responses, little or no detail, and inconsistencies with reports and observed behaviors (e.g., having schizophrenia but showing no negative signs such as flat affect, a paucity of thought content and production, and anhedonia). Cognition, memory, social, and emotional responsivity, and behavior may be tested. Issues around the manner (e.g., passive and helpless versus more aggressive and grandiose) in which the patient views and may express a variety of emotions (e.g., envy and greed—with their implicit spoiling and destructive characteristics—have clinically relevant value). Initially, the patient's material may be considered raw data that only gradually undergo an evaluative and interpretive analysis and subsequent synthesis. All the patient's productions are initially taken at face value; some include sets of partial intangibles.

Conclusions can be drawn only after diligent consideration and further collation using collateral information when available (e.g., neuropsychological testing, medical reports, laboratory investigations, past medical history, past psychiatric history, and psychosocial and legal history). *Short of the only genuine gold standard for establishing malingering, which is the patient's full disclosure of deliberate intention to malinger, coding for malingering remains a matter of clinical judgment and professional opinion*. A judicious, prudent, and economical

approach lists the evidence suggesting malingering but does not reach a definitive conclusion unless the evidence is overwhelming and supported by clear-cut proof.

Projective Identification

Projective identification is a fundamental communicational and implicit information processing mechanism. Contemporary psychology recognizes it as implicit bias, which refers to the attitude or stereotypes that unconsciously affect our understanding, actions, and decisions—we don't know we're doing it.

Melanie Klein in 1946 and Wilfred Bion in the 1960s and 1970s in London first introduced the construct of *projective identification*. Their seminal framework exposed a modern information technology highlighting communicational dynamics. For example, "the medium is the message" includes explicit linguistic and implicit paralinguistic data, for example, facial microexpressions of emotions the patient communicates. The sway of outside influences (e.g., suggestions in collateral information and even theoretical training) cannot be underestimated. The evaluator must recognize the pressure from the adversarial divide and the referral source. Highly trained and sensitively attentive clinicians identify these visceral elements piecing them together to formulate such complex malingering presentations.

This theoretical construct is an informational and communicational processing transaction denoting the mobilization of partial aspects of an individual's implicitly conflicted emotions, thoughts, and wishes. These data become "split off" and "intrusively projected" (i.e., information transfers) into an unwitting receiver. Material communicational indicators, that is, response styles—language, gestures, demeanor, facial expression, even silence—are the medium of these data. The goal is a subtle yet aggressive manipulation persuading the receiver/examiner to believe the sender/examinee. The core aim is to control rather than to discover. The astute clinician, sensitive to this resonance, can parse this important *additional* factor as a subtle source of subliminal persuasive data in assessing all components of malingering presentations when formulating rational clinical judgments. Further aspects of *projective identification* are discussed in the treatment and management subsection.

Truth and Malingering

Malingering depends on the clinician's conception and assessment of truth—the truthfulness and veracity of the patient's clinical presentation, especially verbal descriptions of symptoms. This calculation rests, in part, on the patient's openness to accurate self-disclosure. The assessment of malingering challenges the trust inherent in the doctor–patient relationship. Comparisons make the detection of valid from feigned symptoms and disorders to accepted DSM standards thought-provoking. The normal development of a child's sense of

reality and capacity to intentionally misdirect (e.g., “lying”) is found in many child development texts. A lie is a misrepresentation of what is thought to be factual—without letting the other know that you are deliberately misrepresenting. The capacity to lie or deceive may be apparent at age 4 when the ability for perspective-taking and “theory of mind” (ToM) develops. Lies in this developmental era usually are prompted by self-preservation and the wish not to be punished.

Consistency in meeting standards, taken together with understandable atypical variations, reflects any clinical assessment’s fidelity. Marked discrepancies, mismatches, deceptive shifts of the diagnostic frame, and blatant excursions from established norms suggest deception. A high-index of suspicion is raised when the patient demands medication, divulges symptoms too eagerly or dramatically, and makes blatant conditional threats of self-harm, violence, or litigation.

Research has suggested that the following are representative detection indicators for feigned mental disorders: rare symptoms (a significant indicator), improbable combinations, symptoms that rarely occur together, spurious patterns, erroneous stereotypes, endorsing a very high-proportion of symptoms (an important detection indicator), endorsing a wide array of minor psychological problems, reporting symptoms of grossly extreme severity, and evidencing more significant impairment on reported symptoms versus observed behavior. Gross exaggeration is a detection indicator when its magnitude is strikingly amplified. When consciously deliberate intention and tangible gain can be assigned to illness deception, a malingering diagnosis can be entertained.

Table 28.1–1.
Contexts in Which Malingering May Present

1. Avoiding responsibility: Military service, child, or adolescent school avoidance
2. Criminal forensic contexts: Avoiding punishment, criminal liability, or seeking transfer from prison to a hospital (the base rate incidence in criminal cases is about 19%)
3. Medicolegal contexts: To obtain financial gain, compensation cases (personal injury, 29%; disability, 30%)
4. Emergency department or primary care outpatient clinic visits to gain admission to hospital as may be found in homeless persons seeking shelter
5. Outpatient settings: Medical requests to obtain drugs such as controlled substances, opioids, minor tranquilizers, or psychostimulants (e.g., ADHD medications: methylphenidate, dextroamphetamine, etc.)

Thus, signs of possible deception are inconsistencies and contradictions between reported history and actual facts, a clear record of misrepresentation, previous acts that are the same or similar to the current presentation, a rapid improvement when external incentives change, and absurd responses, contain

unlikely combinations, and blatant contradictions. Vague responses with little detail are suspect.

Diagnosing the condition of malingering is based on careful considerations of the best evidence available and astute clinical judgment. When reaching clinical conclusions, particular attention to configurations of factors associated with malingering is useful. When psychological testing is used as collateral evidence, neuropsychological profiles are constructed using multiple tests, each tapping a different area. There are no established unambiguous criteria. From the patient's side, good faith, openness to self-disclosure, and well-intentioned honesty are presumed present but examined for possible discrepancies. The extent to which such discrepant information is conveyed in what is suspected to be a deliberately deceitful manner lends itself to a high-index of malingering suspicion. Table 28.1–1 summarizes contexts in which malingering may present itself.

CONTEXTS IN WHICH MALINGERING MAY PRESENT

Avoiding Responsibility

Avoiding responsibility has developmental and social determinants. The current presence of international unrest and war makes the context of military service a continuing impetus for some to use malingering to avoid a personal threat. Avoiding responsibility may also appear in child and adolescent contexts in the frequently encountered condition of school avoidance. Although an anxiety disorder may be the underlying cause of such behaviors, many youngsters also intentionally feign illness to avoid going to school or leaving their homes. Malingering may not be an essential feature. Truancy may be associated with more salient disorders such as conduct disorder, learning disorders, or understandable environmentally based problems such as bullying or an impaired family situation in which neglect, abuse, or both exist.

Avoiding responsibility has shown itself in the workplace. Employees may seek leaves of absence or reduced work schedules because of claimed symptoms or illnesses. If these claims are not genuine and include a wish for payment, malingering is a consideration. However, in the current era of COVID-19, a new phenomenon has emerged in more explicit ways than before. Some have speculated about an unproductive and dangerous behavior loosely termed "reverse malingering." For example, genuine malingering occurs when a person believes they are well but feigns illness to obtain a hoped-for compensation for a leave of absence from work. Malingerers, well in general, use the deception of having distressing symptoms to avoid working. By contrast, health professionals say that people who know they are ill are told not to work if sick yet continue to work. This untruthfulness may be "reverse malingering." They reverse the direction of their health status from claiming illness to behaving as if they are well.

Unlike in malingering, they wish to receive “merited” recompense. Symptomatic people put themselves and their coworkers at risk if they have symptoms or are sick, do not mention it, and go to work, although advised to stay home. They want to continue working to maintain getting paid. This passive deception is used because they fear potential unemployment and income loss. Hiding actual illness is a medical deception to achieve the gain from working. This feigning may be a variant of *faking good.* Deception and questionable judgment are key. Such situations pose dilemmas in discerning the nuances of the dissimulation spectrum.

Criminal and Forensic Contexts

Criminal and forensic contexts in which adults and adolescents find themselves in situations in which malingering offers an option to avoid unwanted legal prosecution or confinement. Feigning psychiatric illness may offer a person convicted of a crime the opportunity to go to a psychiatric hospital rather than to jail. Malingerers might feign schizophrenic illness to avoid jail terms or, if in prison, to be transferred to better quarters. The issues surrounding criminal behaviors and psychiatric illness are complex. Appropriate assessment and recommendations require skilled forensic evaluators. Malingering has been seen in undocumented immigrants caught for illegal entry into a country and threatened with deportation back to their country of origin. Again, such situations must elicit a pause so that fair and judicious determinations are made.

The court referred a 15-year-old boy to a juvenile justice psychiatric evaluation clinic. He was being held at a detention center for multiple charges: possessing cannabis and crack cocaine, setting fire to his family's mobile home, expressing violence toward a parent, and resisting arrest. The arresting officers described him as uncooperative, at times belligerent, and communicatively unclear. Several years before this episode, they had known him since he and his mother had involved authorities because of an allegation of physical abuse by one of his mother's live-in boyfriends. He was brought to a local emergency department at the point of arrest. He was examined and found to be in good physical health; he became quiet and did not appear to exhibit any clear-cut psychiatric symptomatology. Shortly after, he was brought to the clinic daily for a series of psychiatric and psychosocial examinations and psychological testing. The patient was reticently compliant and demonstrated minimal expressive communication. He did admit to illicit substance use for several years, a history of school avoidance and failure, and a chronic family conflict history. When asked about the fire setting, he did not reply. Family interviews revealed a chaotic household; the biologic father was incarcerated. The mother had multiple male companions and a history of depression with suicidal attempts, and there was an overall lack of structure and home supervision. Psychological testing showed a full-scale intelligence quotient (IQ) of 75. Some disorganization and looseness of thinking, with pervasive deficits in adaptive and academic functioning, and projective tests suggested possible psychosis but no depression. He and his mother wanted to avoid incarceration and emphasized a history of abuse. The patient then claimed to be depressed; his mother vociferously supported this. The patient then tried to elaborate on what he thought were symptoms of depression: "I can't eat or sleep or play sports; I see monsters in my dreams." The patient, however, appeared robust, muscular, and engaged in soccer at school. Recent interviews, psychological testing, diagnoses of psychotic disorder unspecified, substance abuse disorders, borderline intellectual functioning, and PTSD were made from all the available past history. Conduct disorder was to be ruled out. Although both mother and son intentionally tried to establish a primary diagnosis of clinical depression alone to avoid prosecution, the evaluator did not concur. Moreover, adding malingering to the diagnostic profile was thought to be unhelpful in the context of this already complex group of psychiatric disorders. Recommendations were made for therapeutic services: long-term therapeutic residential placement, consideration of psychosocial therapy and psychotropic medication for PTSD, substance abuse, and psychotic symptoms.

Medicolegal Contexts

Medicolegal contexts can suggest malingering when issues of unmerited financial compensation are at stake. This situation may involve personal injury cases and disability claims for psychiatric or developmental problems. These complex cases have salient medical and neurocognitive components. Assessment requires medical specialists to weigh the merits of neurologic and musculoskeletal features and psychiatric and psychological evaluations.

Police brought a 16-year-old boy to the emergency department. He was wildly out of control, moving in a disorganized, hyperkinetic fashion, and speaking incoherently. Thinking showed loose associations. Initial physical examination was unremarkable, but laboratory investigations showed elevated liver function tests; drug screening was negative. The patient's mother said he had no prior medical or psychiatric history, and she was unaware of any indication of substance abuse or cigarette smoking. The patient was admitted to the psychiatric unit, where he was moderately agitated, demonstrated a catatonic-like excitement, and reported visual hallucinations. Atypical neuroleptics were begun; after several days, his motor behavior began to normalize, and he was more coherent. His cognitive functioning cleared but was slow. He denied using illicit substances but said he had recently started a summer job in a small paint factory; this appeared to coincide with his symptoms. A tentative diagnosis of inhalant-induced psychotic disorder was made. The patient was discharged on no psychotropic medication and seen 1 week later. He appeared to be stable and in no acute distress. His thinking was clear, with no reports of hallucinations. Sleep, appetite, and energy level were normal. Blood work was within normal limits at this time. He returned to school in the fall and was reported to be doing as well as before his decompensation. His mother then requested the hospital physicians support her contention that her son was permanently disabled, thereby certifying him to be eligible for long-term financial compensation. After further interviews, no evidence of changed or limited functioning from prehospital baselines could be found to support disability claims. The mother's attorneys brought the matter to a hearing. It was agreed that the paint factory would make a small settlement. This case demonstrates how patients may shift symptom history of a real disorder and its resolution toward exaggerated claims of continued impairment.

Emergency Facilities

Emergency departments and primary care facilities may be the only resource to which socially and occupationally impaired individuals have relatively easy access. Such persons may have complex chronic medical and even psychiatric illnesses, which do not warrant immediate hospitalization. Careful diagnostic assessment of emergent, urgent, and longer-term needs is critical. Social

services, particularly if an immediate shelter is needed, can be an essential resource. Whether malingering, in addition to other problems, is believed to be present, clinical judgment must dictate these cases' appropriate disposition.

Outpatient Settings

A common situation in which malingering may present itself can be seen in typical outpatient practice for the psychiatrist and all physicians. Patients may malinger about pain symptoms that are either untrue or deliberately exaggerated. The request for controlled substances such as opioids in excess of what the physician deems reasonable always needs careful attention. Patients may be habituated to or dependent on benzodiazepines and so demand ongoing prescriptions or excessively high daily doses. The physician's clinical judgment again must weigh reasonable risks and benefits, especially if malingering is suspected. A not infrequent request by adolescents and some adults is for psychostimulant medications such as methylphenidate and its derivatives and dextroamphetamine and its derivatives to treat alleged attention-deficit/hyperactivity disorder (ADHD) or attention-deficit disorder (ADD). Because these disorders are frequently diagnosed, careful clinical assessment is needed to discern legitimate cases from those persons wishing to get controlled substances for purposes such as weight loss or nonmedically justified stimulation, diversion, and abuse. It has been almost commonplace for adolescent girls and boys to be overly concerned about body weight and to request psychostimulant medications under the ruse of suffering from ADHD when, in fact, the underlying intent is to use the psychostimulant drug for effective weight loss. Adolescents and young adults may abuse stimulants to get through exams or merely to experience a temporary high. Of course, this represents only a subset of patients. Child and adolescent psychiatrists, and pediatricians, face this issue on an almost daily basis. Also, careful histories and assessments of the family context, particularly members with illicit drug histories or criminal backgrounds, are essential to rule out abusive use or diversion into the street for the illicit drug trade.

A 35-year-old attorney requested a psychiatric evaluation to treat what he claimed was his adult ADD. This meeting was the third such consultation he had requested in the last 6 months from different psychiatrists. The patient was a middle-class male, married with two children, and a practicing attorney for the previous 6 years. He had a reported past history of intermittent, moderate depressions since age 20 years, for which he received periodic brief psychotherapy and antidepressant medication. He stated he had not felt depressed for the last 5 years, although he described himself in the words he said his wife used: “a man who fears success.” He explained this was related to multiple law firms’ attempts at jobs that quickly ended with his sudden resignation when his intermittent bouts of worthlessness and anhedonia came to the surface. He now felt troubled with difficulties concentrating, staying focused, and completing tasks requiring attention, concentration, and perseverance. He said he was able to diagnose himself and believed he had ADD. He wanted to work and so sought a prescription for stimulant medication.

After several careful history sessions, diagnoses of anxiety and mild mood instability with possible depression were suggested, based on current and past history. After agreeing with the psychiatrist’s “skillful insights,” as he described them, he continued to assert the assessment was essentially wrong and missed understanding the core of his dilemma. He said that, although partly right, the judgment was “perfectly flawed.” However, he insisted he would come for further sessions to “show the doctor” how wrong he was and that the putative ADD required a prescription that “only the doctor had the power and authority to order. Whether or not I meet the criteria for ADD, I feel I can benefit from the drug.” Personality disorders were considered, but such diagnoses were deferred.

During about six sessions, he behaved similarly, and his uncooperative behavior increased. When it became clear that no psychostimulant medication would be prescribed, he said, “You just won’t open up and listen to me. It’s really very clear. I know myself better than you do. Even though I didn’t go to some fancy medical school, I’m competent enough to see things as they are.” He then added, “I guess we’re on different wavelengths.” Any sort of reasonable attempt to clarify his presentation, however tactful, was thwarted. The patient declared an “impasse” had been reached, and he would not return.

CASE DISCUSSION

The nature of the patient’s motivation was complex. Characterologic issues were principal. Envy of the therapist was a noticeable feature. He certainly intended to persuade the psychiatrist both of his ADD and his need for drugs. The extent to which he feigned or believed these to be true is unclear. His

almost arrogant insistence on his independently arrived at self-diagnosis, inability to consider another opinion, and constant comparisons between himself and the psychiatrist, evidenced rigidity and recalcitrance, hinted at a narcissistic pathologic, unconscious envy. He partially acknowledged the therapist's skill. Yet his insistence on the assessment being "perfectly flawed" pointed to his attempt at envious spoiling of what he sensed was skillful and insightful—that is, ideal. Such uncooperativeness thwarts constructive dialogue. Envy as implicit bias is powerful and can be an aggressive effort to influence the psychiatrist. Making this unconscious and implicit display of defensive omnipotence, that is, *projective identification,* conscious of oneself as an examiner, is critical to counter-transference self-observation. It is unnecessary to interpret the patient his wish to gain control to ward off and defend against feelings of inferred inadequacy and helplessness—in a short-term setting. His choice to leave the therapeutic field due to what he called an "impasse" further attested to the usual blocking of forwarding progress resulting from envy and narcissism in the therapeutic impasse. The boundary between malingering and factitious disorder, as seen in this case, is thin.

CLINICAL PRESENTATIONS OF MALINGERING

Physical Symptomatology

Pain and Medical Presentations. Malingered symptomatology may take various forms. Table 28.1–2 summarizes clinical presentations of malingered symptomatology. They may be divided into physical symptomatology (e.g., pain, medical with cognitive incapacity) and psychological symptomatology. Some think malingered pain and malingered amnesia are common in malingering contexts. Whereas factitious disorders often present with physical symptomatology and signs, malingering appears in psychiatric settings with psychological symptomatology suggestive of psychiatric disorders. Perhaps the presentation of pain and distress in suspected malingering is most often encountered in contexts in which financial or disability compensation is at stake, for example, lower back complaints in the work situation. This issue can be related to physical injury or degenerative disease states. Forensic and litigation disputes may be venues for this. If pain is malingered, it may typically take the form of an embellishment of the severity of pain and, subsequently, what appears to be significantly impaired functional capacity. Ordinarily, some degree of real pain is present, but the excessive degree to which it is intentionally exaggerated may suggest malingering. Because this is an extremely complex area and one in which malingering has been shown to be less prevalent than once thought, such presentations need careful consideration. When physical symptoms are in

question, medical specialists can help to rule out neurologic, infectious, musculoskeletal, orthopedic, and other primarily somatically based complaints. Also, one must carefully discern the presence or absence of pain disorder or the condition of pain (e.g., neuralgia, neuropathy, arthritis) associated with a general medical condition, the code for which is specifically selected based on the associated medical condition or the anatomical site.

Table 28.1–2.
Clinical Presentations in Which Malingered Symptomatology May Present

1. **Physical:**
   a. Physical pain and incapacity due to injury or chronic medical condition
   b. Psychogenic nonepileptic seizures
   c. Traumatic brain injuries
   d. Amnesia
   Dementias: *Alzheimer's, Frontotemporal, Lewy body, Vascular, Traumatic brain injury, HIV, Prion, Parkinson's, Huntington's, or due to another medical condition*
   e. Delirium
2. **Psychological:**
   a. Post-traumatic stress disorder
   b. Depression
   c. Amnesia
   d. Psychosis
   e.
   Neurodevelopmental: (unlikely)
      i. Intellectual disabilities
      ii. Borderline intellectual functioning
   f. Miscellaneous disorders: Attention-deficit/hyperactivity disorder; Ganser syndrome

Psychogenic Nonepileptic Seizures. Psychogenic nonepileptic seizures (aka PNES, pseudoseizures, psychoseizures, psychogenic nonepileptic spells, hystero-epilepsy) resemble epileptic seizures. Prevalence is suggested to be about 5% of presentations in emergency departments. Patients exhibiting PNES are unusually suggestible. They may also have real seizure disorders or a family history of epilepsy. Although they resemble tonic–clonic convulsions, no tonic phase is present; there is an asynchronous thrashing of the limbs typically lasting more than a few minutes, unlike in actual seizures. Consciousness may be normal or lost, and typical postictal phase or loss of continence, tongue bite, and

headache are variable. Laboratory studies show no electrocerebral changes. Serum prolactin, ordinarily increased between 15 and 30 minutes after a real tonic–clonic seizure, remains unchanged from baseline. Antiepileptic drug treatment has little, typically no, therapeutic effect.

In some cases, hysterical conversion reactions associated with acute emotional stress or chronic physical and sexual abuse produce PNES. PNES also have been seen in malingering. When there is clear evidence of incompatibility with neurologic disease and when malingering has been ruled out, DSM-5 terms PNES medically unexplained and therefore to be a functional neurologic symptom disorder (i.e., DSM-5, F44. a conversion disorder).

Neurocognitive Presentations

Neurocognitive functions include consciousness and information processing abilities–attention, concentration, memory, reasoning, problem-solving, executive functions, and language. This group of presentations is complex because it may entail the intricacies of multiple levels of cognition having medical, injury, and deterioration over time. Assessment demands specialized clinicians skilled in such cases.

Cognitive functions are closely linked to neural pathways and cortical networks. Impairments in these—DSM-5 (p. 591) "Neurocognitive Disorders (NCD)"—represent a decline, typically acquired, from a previously achieved level of functioning. The NCDs are syndromes whose etiology frequently can be potentially determined.

NCDs were referred to in DSM-IV-TR as dementia, delirium, amnestic, and other cognitive disorders. They may result from central nervous system injury, moderate-to-severe TBI with significant declines in previous performance levels, concussion whose traumatic effects may be transient, mild traumatic brain injury (mTBI), toxicity, disease, or deterioration. Clinical presentations may be classified as major NCD (i.e., a substantial decline) or minor cognitive (i.e., a mild to modest decline) disorders. They may present themselves as *delirium*, *dementias such as Alzheimer's, Frontotemporal, Lewy Body, Vascular, TBI, HIV, Prion, Parkinson's, Huntington's, or due to another medical condition (e.g., DSM-IV "amnestic disorder")*.

Neuropsychiatric symptoms may begin with social withdrawal and anxiety. Once a definitive diagnosis of dementia is made, significant agitation, aggression, hallucinations, and delusions of psychosis may emerge.

They may also appear as various intellectual and memory impairments, such as occurring after motor vehicle accidents or war trauma following concussion and TBI. Overlap with psychological symptoms is common. Trauma and injury events—head injuries—typically present themselves in the ruling out of possible malingering. Examples of typical venues are personal injury litigation, workmen's

compensation, and disability claims. Neuropsychological testing and the assessment of symptom validity are essential in these cases.

Cognitive assessment relies on the comparative measurement of responses: incorrect, partially correct, and correct answers. Estimations of reasonable effort, which may be difficult to assess, help in interpretation. Unlikely presentations, excessive impairment, and the magnitude of test error are useful detection strategies when malingering is suspected. Pain, depression, and PTSD represent the most common differential diagnoses when considering mild TBI or modest decline in the person's previous performance level. Various forms of the Mini-Mental State Examination can screen for dementia. However, several factors may render results unreliable: imprecise testing of executive functions and performance variations based on the patient's educational level and motivation or effortful willingness. Apathy in dementia, typically frontotemporal and Alzheimer's occurs and should be differentiated from depression, both of which influence clinical presentations. An experienced forensic neuropsychologist's expertise is essential in determinations. Findings may include data from standardized scales assessing levels of cognitive response and diagnostic category.

Psychological Symptomatology: Clinical Presentations

Psychological symptomatology and the suggestion of mental disorders are presentations the psychiatrist encounters, often by referral or consultation, in ruling out suspected malingering. A high-index of suspicion is raised when symptoms are clearly atypical, grossly unusual, nontraditionally bizarre, extraordinarily exaggerated, embellished, extravagantly elaborated, or alleged to occur in the future if some incentive or personal gain in the present is not met. Laypersons, for example, may decide to exhibit dramatic symptoms or to portray some florid clinical picture based on what has been seen in the popular media. Professionals who malinger might consult psychiatric texts and attempt to feign a bona fide mental disorder using every feature and criterion listed and their precisely given time frames. Such direct textbook presentations are rarely present in day-to-day clinical contexts. Detection strategies include close attention to the patient's description of when and how symptoms arose and their sequence. Clinical incongruities in symptom presentation—for example, an individual describing an anxiety disorder in a calm and composed manner at every interview—suggest feigning. Finally, the markedly atypical juxtaposition of symptoms and the presence of an external incentive may suggest malingering. Some examples of psychological symptomatology are discussed in the following.

Post-Traumatic Stress Disorder. PTSD is a common presentation in military and civilian populations. It first appeared in 1980 in the third edition of the DSM (DSM-III) and was associated with the Vietnam War's legacy. Earlier related terms such as "soldier's heart," "shell shock," and "war neurosis" were used in the World

War eras. For example, “war neurosis” was equivalent to the *nevrose de guerre* and *Kriegsneurose* of the French and German medical literature.

Genuine PTSD has clear-cut, very distressing signs and symptoms persisting for a month or more: exposure to actual or threatened severe harm, intrusive, recurrent traumatic thoughts, avoidance of reminders of the trauma, negative emotional states, alterations in arousal such as hypervigilance, and sleep disturbances.

Cases involving personal injury, automobile accidents, and those exposed to terrorism and traumas associated with military service and combat may present with features of PTSD. Combat-related and civilian PTSD needs to be differentiated. Although those in the military are prepared for the unexpected, they may experience genuine feelings of helplessness, vulnerability, and surprise. Suicide patterns in the military have increased over the last decades. Military suicides continue to be at high-rates. Veterans complete approximately 20% of national suicides. Megaorganizational complexity, time pressures, and feeling overwhelmed to act efficiently and reliably may contribute to stress factors. More than half the suicides occur in those never deployed. Those who have been exposed to combat may experience a variety of postcombat stress-related sequelae. Being in the combat zone, physical assault, and heavy fighting may cause 18% to 30% of PTSD. PTSD is also associated with the breakup of relationships and subjective feelings of isolation. “Moral injury,” which differs from PTSD, has been described in military personnel who experience feelings of guilt and shame that might be related to killing others or having friends killed in combat and causing the harm or death of civilians, knowingly but without alternatives, or accidentally. Other circumstances include failing to provide medical aid to an injured civilian or service member and following orders believed illegal, immoral, or against the Geneva Conventions’ rules of engagement.

Genuine PTSD has been correlated with the patient’s minimizing combat as causative, blaming oneself versus others, experiencing dreams with themes of helplessness, general reluctance to actively speak about combat memories, feeling survivor guilt and shame, and anger. Feigned PTSD diverts care from veterans and military personnel who genuinely have suffered mental and physical trauma and legitimately require services. Currently, genuine PTSD is common.

In civilian populations, with the onset of COVID-19 in the last few years, healthcare professionals are experiencing rates of PTSD higher than previously. Whereas *burnout syndrome* was recognized about a decade ago as a cause of physical and emotional exhaustion, depersonalization, and a loss of personal efficacy, burnout is now added to actual PTSD associated with the virus. High-stress emergencies over time raise cortisol levels that do not decline to baseline as in more typical situations. Doctors feel they cannot “decompress” and reestablish perspectives. In healthcare and other fields, most cases in frontline workers are genuine and need identification and multiple interventions.

COVID-19 has become a global health emergency, both physical and psychological. For example, healthcare workers are exposed to the virus, supply shortages, and patients suffering from the virus. Also, patients admitted to the hospital with COVID-19 are ill, fear for their survival, and experience social isolation. Fear of being intubated and put on a ventilator is real. 35% of ICU survivors and those with “postintubation syndrome” can go on to experience PTSD. After discharge, lack of immediate social support because of the need to self-quarantine is real. Thus, the rise in PTSD in healthcare and frontline workers and COVID sufferers is real and must be taken seriously.

One motivation for malingering PTSD *in the general population* is thought to be financial gain—unmerited recompense. Symptom presentations in feigned cases, by contrast, often appear dramatic and highly embellished. Dramatic positive symptoms, such as flashbacks and nightmares, are emphasized. For example, nightmares might be described as relentlessly persistent, whereas traumatic nightmares often dissipate over time. Feigned experiences are reported in ways inconsistent with DSM definitions; they may reflect unrealistic caricatures seen in the media. Subtle features and generally incapacitating anxiety are often absent. For example, to avoid occupational duties, psychological and physical incapacity (e.g., disability) may be claimed. Often, on further examination, this incapacity is found not to extend to other, more pleasant activities, such as social events, recreation, travel, vacation, or sports. A thorough history may reveal past occupational difficulties or frequent job changes. The general demeanor of uncooperativeness, withholding information, belligerence, or personality disorders (e.g., antisocial, borderline, or histrionic) may also suggest—though not confirm—malingering. A bland refusal to undergo treatment and to consider future re-employment is also suggestive. Using all available collateral information is essential regarding substantiating or disconfirming self-reports and detecting discrepancies.

Real predictors of PTSD include a “lifetime trauma load” of past trauma and a history of adverse childhood events, including physical, sexual, emotional, abuse and neglect, and witnessing violence in the family. Detailed collateral data and the examinee’s assessment using psychological testing make possible a more apparent distinction between genuine and malingered PTSD.

Depression. Depression may be malingered. Because depressive disorder and depressive variations (e.g., melancholic, atypical, and bipolar) have been so extensively researched, the psychiatrist is usually perceptive in detecting faking in this area. For example, the malingerer may be extremely fluent in descriptions of “feeling depressed” and “not sleeping” but may not report the typical details of impairment (e.g., diminished specific hobbies), anhedonia, worthlessness, inappropriate guilt, ambivalence, and the destructive and distressing trends common to these, For example, disruptive interpersonal relationships, limitations

in activities of daily living, and altered vegetative functions. The genuinely depressed person typically reports these symptoms. Appetite and weight may remain constant. The very loquaciousness often attending such presentations is inconsistent with depression. Bipolar depression must be ruled out. Also, malingered depressions may not permeate all aspects of a person's life and functioning. For example, the malingerer may continue to engage in going out to dinner, hobbies, and regular sports activities. Fatigue, loss of energy, degrees of anhedonia, worthlessness, and inappropriate guilt—all part of genuine depression—are absent.

Amnesia. Dissociative amnesia (F 44.0) is part of the DSM-5 category "Dissociative Disorders." This amnesia is the inability to recall important autobiographical information, usually of a traumatic or stressful nature inconsistent with ordinary forgetting. Autobiographical memory is a memory system comprising episodes recollected from an individual's life, based on a combination of two memory systems: (1) episodic, that is, personal experiences and specific objects, people, and events experienced at a particular time and place and (2) semantic, that is, general knowledge and facts about the world.

The disturbance is not attributable to any illicit substance or a neurologic or other medical condition Amnesia, with its cognitive and emotional dimensions, may be a form of malingering seen in forensic settings and is usually related to alleged crimes. Some suggest that up to one-third of homicide perpetrators claim amnesia. Because this is a grave situation, specialists in forensic psychiatry collaborating with other specialists are best suited to discern such presentations. Head injury after accidents also presents with degrees of amnesia. Such cases were historically referred to in the literature as *accident neurosis* or *compensation neurosis* and seen in a negative light until recent research suggested that genuine cognitive deficits might be present in large numbers of these cases. In assessing amnesia, highly selective, localized memory deficits, especially in the areas where the patient's motivation and liability are in question, may suggest feigning. Typically, genuine amnesic patients demonstrate impaired new learning and short-term memory, but procedural memory and premorbid semantic memory are preserved. If deficits are produced in immediate recall, digit span, autobiographical and self-memory, and new learning, this may suggest feigning if the broader context is corroborative.

Also, in genuine disorders (e.g., DSM-5 major or minor NCDs) with pathophysiologic concomitants, disorientation may be to place and to time. There may be a lack of insight into circumscribed memory deficits, and the patient may explicitly deny the presence of severe memory impairment. Apathy and emotional blandness, differing from depression, are common. Chronic substance abuse and alcoholism need to be ruled out. Dissociative states and histrionic personality

disorder tend to lessen the probability of malingering. In dissociative amnesic disorder, the patient does demonstrate an inability to recall important personal information, usually of a traumatic or stressful nature. Patients with genuine dissociative amnesia typically score high on standard measures of hypnotizability, unlike the case with malingerers.

DSM-5 states individuals with factitious and malingering have been noted to continue their deception even during hypnotic or barbiturate-facilitated interviews. An antisocial personality disorder is a feature of malingering according to the DSM-5 guidelines and needs to be considered in forensic contexts. Of course, neurologic examination and relevant studies (e.g., electroencephalogram [EEG] and magnetic imaging resonance [MRI]) should be considered.

A 25-year-old female was seen for consultation in a forensic neurologic in-patient unit. The question of whether malingering was present was raised by her neurologist. She had set fire to her boyfriend's trailer after a physical altercation, during which he struck her on the head with a blunt object several days ago. She was admitted for observation and holding. Neighbors called the police and firefighters. The trailer was demolished, and the boyfriend sustained severe burns and was unable to speak with authorities. The patient never lost consciousness; she sustained minor injuries. Her neurologic examination, EEG, CT, MRI, and blood work were noncontributory. The patient claimed amnesia for the event and asked for an attorney. After extensive interviews and the absence of a history of psychosis or mental illness, probable malingering was seriously entertained. When her boyfriend recovered after several weeks, he described her setting the fire. When she was told, she "broke down" in tears and admitted to the act.

Psychosis. Psychosis can be malingered. Examples include criminal defendants attempting to avoid trial or alter prison sentences, the homeless who present to the emergency department to gain entry into the hospital for temporary shelter and food, or those whose motivation is to avoid some clear-cut accountability they find undesirable, such as imprisonment for crimes. This behavior may be a more common malingered presentation in less sophisticated persons. It may not be challenging for the experienced clinician to differentiate true psychosis, as, for example, in schizophrenia, or bipolar mania, from deceptive illness. Persons with schizophrenia are often withdrawn and minimally verbal, not open to fluent descriptions of their symptoms. Individuals feigning psychosis often produce reports of very dramatic, perhaps melodramatic, hallucinations with bizarre content that is more characteristic of science fiction than ordinarily reported by those with genuine psychosis. Hallucinations may be uncharacteristically not accompanied by associated delusions. Feigned

hallucinations are constant, not intermittent; irresistibly commanding to action with no chastising content, always terrifying rather than manageable; and, if visual, seen in black and white or conversely in dramatic colors in cinematic fashion. Malingerers may speak of delusions in a forthright, open manner, unlike the guardedness often accompanying descriptions of genuine delusions. These persons may describe their delusions as having all-or-nothing features rather than the subtler and continuous tone characteristic of truly psychotic delusions. Also, malingerers feign only the contents that accompany psychotic states. They often demonstrate no irregularities in the form (e.g., derailment, looseness of associations, and disorganization) of their thinking processes, another essential characteristic of psychosis. Also, negative symptomatology (e.g., affect blunting, avolition, alogia, and asociality) may be absent. Genuine chronic thought disorder is typically distressing and confusing.

A 35-year-old male pharmacist was referred to an outpatient clinic by his internist for medication evaluation of his long-standing bipolar disorder. He was in apparently good health and worked over 60 hours per week but experienced anxiety, dysphoria, and increasing disorganization. He reported that the last year had been turbulent in his relationship with a girlfriend of 3 years. Sleep, appetite, and job performance were beginning to suffer. The patient had been on lithium and an atypical neuroleptic for 4 years with reasonable control of symptoms. When his symptoms had recently escalated, the patient suggested to his internist that his ADHD and bipolar disorder were not adequately addressed. A once-per-day, long-acting psychostimulant was then added by the internist. Although the patient stated he felt he could function more efficiently on the stimulant, his observable behaviors dramatically deteriorated, speech became pressured, and thinking became progressively more disorganized. His prescribing physician made the referral when he demanded benzodiazepines for anxiety, escalating irritability, and insomnia. At the psychiatric interview, the patient was thin and agitated; he appeared highly intelligent and articulate. At first, he asked for increases in his lithium and neuroleptics but then demanded increases in his stimulant and the addition of a benzodiazepine. Then, it was apparent he was hypomanic and escalating, and his judgment was progressively becoming impaired. After several sessions of attempting to target the worsening bipolar presentation and get blood work (which the patient failed to procure), a recommendation for inpatient hospitalization was made. He protested and reiterated his ADHD was his primary problem and stimulant medication was the only answer. A second psychiatric opinion was obtained, and it confirmed bipolar disorder with little or no evidence of ADHD. Again, hospitalization was strongly recommended, at which point the patient abruptly left the clinic. Attempts to contact him failed. After several weeks, it was discovered he had left the state, and his whereabouts were unknown. Six months later, a family member contacted the clinic to request records, stating that the patient had been found dead in suspicious circumstances, and an investigation was in progress. This regrettable case presentation shows complexity of actual psychosis and a malingered plea for obtaining inappropriate medications in the context of diagnostic difficulties and medication complications.

Intellectual Disabilities. Serious cognitive limitations, now referred to as “intellectual disabilities,” must be considered and identified. Intellectual disabilities connote substantially reduced cognitive capacities: a significantly limited age-appropriate capacity and use of thinking skills, memory, reasoning, abstraction, judgment, and decision-making. Such intellectual limitations have traditionally been referred to as ranging from the extreme of what had previously been termed

“mental retardation” to well below average or borderline intellectual functioning. These are not losses from a previously higher baseline level but relatively stable levels of cognitive functioning. It is also not very common for an adult to feign such conditions as an intellectual disability. Past history, especially academic performance, vocational functioning, daily living activities, and social adaptation, ordinarily appear in quite distinct ways as substantially impaired over extended periods in genuine cases of such disability. These impairments permeate all personality sectors and often require obvious caregiving, whether in childhood, adolescence, or adulthood.

The clinician may be presented with a malingering case by proxy, which suggests that the real malingerer (usually a parent) is alleging that their child has substantial intellectual disabilities that demand financial and other compensation. In these malingering cases imposed upon another, careful assessment of both child and caregiver’s past history is essential. Insofar as differential diagnoses to be considered, dementia in an adult (not an “intellectual disability”) represents a significant intellectual decline from a previously higher cognitive level. In neurocognitive dementias, there is a decrease in expressive language and marked perseveration; this is not a malingered condition. A person with mild dementia (mild NCD) may erroneously hold a false belief in a nonexistent illness and claim monetary compensation; this is not considered malingering.

Borderline Intellectual Functioning. Borderline intellectual functioning is a condition denoting an IQ between about 70 and 85, accompanied by significantly impaired adaptive functioning. The overall functioning is *well below average*. Average IQ ranges from about 85 to 110, with no need for adaptive supports in everyday living. Such persons often present as *slow learners* who may appear to be feigning their cognitive limitations to achieve an external gain, which is legitimately needed help from others. The often genuine needs of these persons should be differentiated from the deceptions of malingering. Also, persons of any intelligence level may innocently attribute an unlikely causative factor (e.g., allergies, job stress, or Lyme disease) to what they genuinely believe is a disorder. Such innocent misattributions should be distinguished from consciously motivated malingering. Cognitive decline, however, after a head injury, toxin exposure, or chronic substance abuse suggests a clear traumatic precipitant. Past history, medical examination, and laboratory screening for illicit substances and abnormal liver functions can help rule out legitimately understandable causes of genuine illness even if the patient misattributes cause and effect.

The single mother of an 18-year-old boy just graduating from a residential school for adolescents with academic, behavioral, and emotional problems requested documentation verifying her son was disabled on the grounds of "learning disabilities" to obtain financial assistance for college entrance. The mother immigrated from Europe and lived in the United States for over 10 years; the boy's father died in an automobile accident 5 years previously. There were no other children, and the mother could not work due to disability secondary to depression. However, she stated she took care of her son in many activities of his daily living. The boy had been enrolled in the school about 3 years previously because of public school failure. Psychological testing showed his intelligence to be below average (Full-scale IQ 80), and there was no evidence of primary attentional problems or specific learning disorders. His academic failure was deemed due to the primary situational conflicts between him and his mother, in addition to probable borderline intellectual functioning. For the last 3 years, his school performance and behavior approached normal parameters, but his relational situation did not improve. After comprehensive retesting and assessment of psychological and social factors, it was judged he was not disabled. While the mother's request may have been well-intentioned, it exaggerated her son's level of impairment with the goal of procuring financial resources based on partially plausible data. Whether or not these hints of exaggeration suggest malingering is debatable. Attendance at a supportive college that would accommodate his learning needs away from home was suggested. Appropriate resource help and access pathways were discussed and made available.

Ganser Syndrome. Ganser syndrome is classified as a DSM-5 other specified dissociative disorder. It is denoted as giving approximate answers (*Vorbereiden*) to questions when not associated with dissociative amnesia or dissociative fugue. Dissociative disorders connote disruptions in integrating consciousness, memory, identity, or perception of the environment. Ganser syndrome was initially described in prisoners who presented as confused. Although the utility of this diagnostic classification has been questioned, such presentations require ruling out genuine intellectual disabilities, borderline intellectual functioning, and forms of delirium and malingering. Considerations of both inferred motivation and assessing the prospect of external gain need to be considered.

Attention-Deficit/Hyperactivity Disorder. ADHD is a commonly made diagnosis. It is characterized by significant inattention, hyperactivity, impulsivity, several symptoms before age 12 years, and functional impairment in two or more settings such as school and home. Task avoidance and low motivation (e.g., as poor effortful willingness), which may be primary in such presentations, must

always be ruled out in assessing attentional difficulties. Because one aspect of the comprehensive educational, psychosocial, and psychopharmacological treatment of ADHD requires Class II controlled psychostimulant medication, adolescents, and adults have been known to feign symptomatology to gain these drugs for their perceived pleasurable and excitatory effects, which is drug abuse, or for diversion and financial gain. In *malingering by proxy* (e.g., malingering imposed on another), a caregiver might attempt to persuade the physician that the child or adolescent has ADHD symptomatology in the known absence of such to procure these controlled substances for personal use or illicit diversion. Drug use and abuse have strong associations with deceptive behaviors. Both DSM-5 and ICD-11 explicitly state that obtaining medications or drugs to gain a material advantage via deception suggests malingering.

An 8-year-old boy was brought to the clinic by his mother for medication management of his 2-year history of ADHD, which had been medicated by the family pediatrician until then. The referring physician reported he was unwilling to continue prescribing controlled substances because the mother had been unwilling to involve the child or herself in psychosocial interventions that included psychotherapy, behavior modification, parent management skills, family therapy, and adjunctive school interventions. Mother and child were interviewed both together and alone on several occasions. The mother reluctantly agreed to the release of school records. Previous psychological and academic testing showed the child to have low IQ scores but within normal limits. There was an adequate performance in all subjects except a clear-cut problem with reading. School personnel regarded this as probable dyslexia (i.e., a specific learning disorder of reading), not ADHD, and appropriate remediation was in place. The child was significantly below average in height and weight. He had multiple facial grimaces and tics and a history of insomnia and difficulty awakening in the morning. His medication regimen included dextroamphetamine in high doses and clonidine at night for sleep. His mother also requested the clinic verify the child's need for disability compensation based on his ADHD. The multidisciplinary clinic team assessment included social work home visits and an intensive evaluation of the mother's history. It was found she was on probation for a history of financial scams, writing bad checks, and involvement with the illicit drug trade. She gave informed consent for the release of her probation records. It was also discovered that state social services were in the process of investigating alleged child neglect. Before the psychiatric evaluation was completed, the clinic was informed that the mother had been arrested for possession of and dealing with illicit substances, some of which included stimulant medications. The child was put in custody of his grandparents. Recommendations were made for comprehensive psychosocial services for the child and his grandparents. They agreed that all medications should be tapered to get a new baseline of overall functioning and a new reassessment.

Child and Adolescent Illness Falsification

The importance of taking into account the developmental characteristics of the child or adolescent when considering whether a genuine illness is present cannot be overemphasized. Because individuals younger than 18 years fail to meet some guidelines used to code for malingering (e.g., antisocial personality disorder), the phrase *illness falsification* is best used to denote situations in which youth appear to feign a medical or psychiatric illness having some ulterior personal gain as a goal. Often, such *illness falsification* is associated with

symptomatic lying in this age group. Also, lying in youth may have temporary adaptive value, for example, under the duress of threatened abuse and trauma.

Does *Illness Falsification* Present Differently at Different Developmental Stages? In childhood, up to about 12 years of age, separation anxiety, school avoidance, and PTSD may be the leading disorders associated with a child's feigning illness (e.g., stomachache, headache, forgetfulness, intentional suppression of information of abuse, and pseudoseizures) to obtain a desired goal such as staying home from school, avoiding consequences for negative behaviors, or wishing to receive gifts or increased attention for being sick. Children who are bullied in school might also use *illness falsification* to avoid exposure to a context of trauma. Symptom coaching, sometimes a consideration when a child falsely attributes illness to a parent, may occur in the context of an acrimonious divorce and child custody dispute. One parent may coach the child to describe the other parent in an unfairly negative light. This dissimulation is an example of an *illness falsification* by proxy.

In adolescence, about age 13 to 18 years of age, the emotions of anxiety, fear, and guilt may prompt the teenager toward *illness falsification*. Anxiety and fear of attending classes may be related to anxiety disorders, social phobia, autism spectrum disorders, and bullying. School avoidance may result. As is discussed in the section on attentional problems, it is not uncommon for a subset of adolescents to claim to ADD and ADHD as an excuse to rationalize both low motivation and intentional task avoidance and so excuse excessively poor school performance. Juvenile offenders often carry a diagnosis of conduct disorder. This disorder strongly connotes the presence of lying and deception in possibly up to 50%. These youth have been noted to use *illness falsification* to avoid sentencing to jail, lighten sentencing severity, or divert their adjudication from jail to the mental health system for rehabilitation and treatment.

Antisocial Personality Disorder and Malingering

As described by Richard Rogers in 1990, 1994, 2008, and 2020, the criminologic model proposes that the DSM-articulated framework is used, perhaps inaptly, in Rogers view, to explain the primary motivations (i.e., reasons for acting) underlying malingering. It includes the diagnostic variables of antisocial personality disorder, the contextual variable of a medicolegal evaluation, and two presentational variables—uncooperativeness and discrepancies with objective findings. The strong association between antisocial personality and deceptiveness is emphasized in this implied DSM risk model. Although there are obvious correlations between these, some studies have questioned their validity. The prejudicial role of confirmatory bias must be considered in all assessments.

The Nonmalingerer's Dilemma. A significant consideration in any malingering assessment is an awareness of the patient whose symptomatic presentation is real, genuine, and not feigned, yet suspect. Ordinarily, such patients have genuine disease processes, bona fide diagnoses, obvious impairments, limitations, and restricted functioning. Such functional incapacity typically affects all areas of their life, including home, occupational, and social spheres. Their biopsychosocial functional capacity is significantly diminished, and actual disability leaves them handicapped. The context in which this appears may be work-related, injury-related, associated with a degenerative disease, or a mental disorder.

In the process of assessing a patient's genuine functional incapacity and current needs, the extensive and rigorous interviewing, at times perceived as an interrogation, and the implicit level of accusation that questions the patient's credibility and forthrightness are often sources that strain the patient's already compromised emotional resilience. Some refer to this as "litigation distress." While "stress" and extended interviewing can be a tool in malingering interview techniques, its use must be judicious and individually based on each case. The integrity of the working relationship between examiner, caregivers, and patients may become unduly encumbered. Iatrogenic factors may appear in the patient's presentation and confound correct evaluation and management in such cases. Here, the healthy and adaptive components of the individual's resources may be mobilized. Considerations of these factors are useful guidelines to help temper any tendencies to conduct evaluations in an inappropriately aggressive manner that, in itself, may be experienced as a trauma. Therefore, all assessments should be performed with respect, open-mindedness, and clinical grace.

CODING MALINGERING

When malingering is considered present, it is useful to indicate its inferred type since the response style lies on a continuum suggesting its significance.

- *Full malingering* denotes complete fabrication in the genuine absence of symptoms.
- *Pure malingering* denotes the feigning of disease when it does not exist.
- *Positive malingering* denotes the feigning of symptoms that do not exist.
- *Partial malingering* denotes the exaggeration of existing symptoms or the statement that extinct symptoms are still present; this level of malingering may be common.
- *False imputation* is a more nebulous type of malingering. The malingerer deceptively shifts the diagnostic focus frame by ascribing actual symptoms to a cause consciously recognized to have no direct causative relationship to those symptoms. Such obfuscation darkens and obscures diagnostic clarity yet may be often overlooked.

It may also be helpful to place malingering in a context that connotes its degree of certainty:

- Indeterminate
- Strongly suspected
- Provisional
- Probable
- Deemed likely present

The American Medical Association has stated that confirmation of malingering is challenging. Table 28.1–3 summarizes a range of degrees of certainty in coding for malingering. Finally, the inadvertent misattribution of linking symptoms with unrelated causes, as, for example, found in those with cognitive limitations, should not be considered malingering.

Table 28.1–3.
Degrees of Certainty for Coding Malingering

1. *Indeterminate*: Findings suggest the possible presence of malingering according to DSM-5 guidelines but are too ambiguous, insufficient, and unsupported by collateral evidence.
2. *Strongly suspected*: Findings are consistent with basic DSM-5 guidelines but lack typically associated features and contexts; collateral support is equivocal.
3. *Provisional*: Findings are compatible with primary DSM-5 guidelines, although they are partial or too brief, yet a strong presumption exists that further indicators will be brought to light over time.
4. *Probable*: Findings are consistent with basic DSM-5 guidelines; associated features and contexts are present, but there is a lack of strong confirmation from collateral sources, especially psychological testing.
5. *Present*: Findings are consistent with basic DSM-5 guidelines, associated features, and contexts and are supported by a preponderance of evidence from most collateral sources. If expressed, acknowledgment by the subject is definitive.

Table 28.1–4.
Clinical Decision Model for Coding Malingering

1. Intentional production of false or grossly exaggerated physical or psychological symptoms
2. Motivation by external incentives:
   - Avoiding military duty
   - Avoiding work
   - Obtaining unmerited financial compensation
   - Evading criminal prosecution
   - Obtaining drugs (e.g., for recreational use, abuse, financial gain, and diversion)
   - Adaptive behavior (e.g., feigning illness while a captive during wartime)
3. Medicolegal context
4. Marked discrepancy between a person's claimed stress or disability and the objective findings
5. Lack of cooperation during the diagnostic evaluation or in complying with treatment
6. The presence of antisocial personality disorder

Table 28.1–4 summarizes DSM guidelines indicative of malingering and provides a clinical decision-making model for coding the condition. Although these entire threshold-screening indicators are not essential, factors 1 and 2 are fundamental and should be accompanied by some other typical features. Although DSM-5 does list the presence of antisocial personality disorder in these coding guidelines, some have questioned the strength of this association. Others have called attention to the connection between the clinical findings of deliberate misrepresentation and lying, for instance, commonly seen in persons with an antisocial personality disorder and in persons with a borderline personality disorder, and similar findings of intentional deception in malingering.

Conclusions and case formulation should derive from five considerations:

1. Is the clinical evaluator acting as a short-term consultant in a setting that implies a medicolegal or, perhaps, an adversarial context?
2. Is the patient's presentation reasonably consistent with the presentation of genuine illness?
3. Is there a medical or psychiatric disorder that plausibly explains the signs and symptoms presented?
4. Are the final diagnostic conclusions based on evidence of consistency or marked inconsistency?
5. What is the best professional opinion about the patient's intentions and goals?

Central issues in evaluations should include:

- the specific situational demands challenging the patient.
- the clinical relevance (related to the above five considerations) that the dissimulation has or may have in the examinee's proposal of impairing problems.

Genuine medical and psychiatric illnesses have several features in common. Reported symptoms are typically not in excess of signs and measurable findings. Real illnesses demonstrate a regular consistency across an adequate database, including findings from different examiners, varied contexts (e.g., work, home, and recreation), and unmistakable presence when the patient is distracted. Disability specialists, for example, weigh these heavily in impairment determinations. Understandably, both forensic examiners and clinicians may be reluctant to give an opinion of malingering for various reasons, including litigation fear, concerns about errors, and the pejorative nature of the term. Partial malingering adds to the condition being far from clear-cut. Careful documentation of objective findings and facts in a nonpejorative manner is essential. A malingering diagnosis requires firm evidence.

COLLATERAL DIAGNOSTIC DATA

The finding of malingering may also be supported by getting information from collateral sources. These include data from interviews with people who know the patient, relevant records, psychological testing, and other care professionals. Informed consent issues need to be considered and meticulously documented. All authorizations need to be in writing and in the record. Interviews with family members and significant others, employers, past therapists, jail or prison personnel, and probation or parole officers may provide important information. Past medical records, psychiatric records, occupational and educational reports, court evaluations, and prior disability claims are also useful. There are no physical examination techniques that have been demonstrated objectively to prove the presence of malingering. However, internists and family practice physicians stress that warning flags include persistent noncompliance, striking inconsistency between physical findings and stated symptoms, and a referral from an attorney or an insurance company. Case formulations must include a culturally informed assessment. Although the psychiatrist has an essential clinical role in an overall assessment, the collaborative efforts of a team of medical, psychological (e.g., using neuropsychological testing), and legal specialists may be needed to provide corroborative evidence and hence a consensus to support psychiatric findings.

Psychological testing involves using standardized psychometric instruments by a trained and experienced clinical psychologist. These detection strategies can

establish feigning but not a person's underlying motivations, which are necessary to support malingering. The following summarizes a sampling of tests. The application of these sophisticated symptom validity tests (SVTs) and performance validity tests (PVTs) is best managed by those highly trained in their use.

Such tests are often used to assess competency to stand trial, child custody evaluations, criminal responsibility, violence risk assessments, and personal injury litigation. Tests must show validity and reliability to be admissible in legal contexts and adequate sensitivity to identify true positives and sufficient specificity to identify true negatives. These federally recognized criteria are known as the *Daubert* standard and are derived from the 1993 U.S. Supreme Court case *Daubert v. Merrell Dow Pharmaceuticals, Inc*. Tests with these features used to detect feigning will be reviewed. It is acknowledged that no one gold standard is considered definitive—using multiple test measures and other collateral data aids in providing converging supportive evidence suggesting malingering.

The astute clinician always considers the test taker's appearance of task avoidance, low motivation, poor effort, even time of day, and hunger status in assessing the results of psychometric tests. For that matter, any test result may be wrongly skewed in the presence of actual pain, headache, lack of sleep, fatigue, and so forth. Without a subaverage cognitive ability and substantial neurocognitive impairment, the malingerer may produce deceitfully feigned reports using dishonest, invalid, and intentionally motivated low effort to supply data.

The *Minnesota Multiphasic Personality Inventory-2 (MMPI-2*) is one of the most commonly employed instruments used to support mental illness malingering. Some of its subscales are particularly useful. The *F scale* detects symptom exaggeration or severe psychological disturbance such as deliberately exaggerated psychopathology. It is considered the best available discriminator of honest versus malingering feigned symptom profiles. It is not sensitive, however, to detecting neurocognitive dysfunction. The *K scale* is deemed good at detecting *faking good* or minimizing what the respondent perceives as incriminatingly negative symptomatology. This response shows mildly negative symptomatology an ordinary person would openly admit to experiencing. The *F-K scale* indicates a tendency to exaggerate symptoms. The F-psychopathology scale detects truly rare symptoms, and the D scale and FBS scale expose erroneous stereotypes of illness. MMPI-2-RF (2008/2011) is the restructured version currently used.

The *Wechsler Intelligence Scales* are also used to determine strengths and weaknesses in intellectual functioning areas from verbal comprehension, perceptual reasoning, working memory, and processing speed perspectives. Gross abnormalities in intellectual levels, such as intellectual disability forms and striking discrepancies in subtest areas, can be detected. Wechsler Memory Scales are also frequently used. Results are supplementary to the other tests of malingering described in this section.

The *Structured Inventory of Reported Symptoms (SIRS*), a prevalent instrument in use, is used to test for feigned mental disorders and truly rare symptoms. Some consider it the best measure or gold standard of whether someone is faking psychotic symptoms. The two underlying dimensions in this test are the Spurious Presentation used to assess symptom constellations unlikely to be true under any circumstances and the Plausible Presentation used to evaluate some symptoms that genuine patients are likely to endorse. *SIRS-2* (2010) is currently used.

The *Personality Assessment Test (PAI)* is also used to test for truly rare symptoms, unlikely psychopathology patterns, and screening out honest responders. It can be completed in less than 1 hour. The *Validity Indicator Profile (VIP*) is a psychometric instrument using verbal and nonverbal items to test cognitive feigning; it takes less than 1 hour. The VIP contains very easy and difficult items. Feigned profiles show easy items missed and difficult items responded to at chance levels by malingerers. Nonmalingerers, for example, typically pass these items. It should be noted that such tests are not suitable for those with significant intellectual disabilities because such cognitively limited persons may not try as hard or may give up easily and produce what are recognized to be careless and invalid profiles.

The *Test of Memory Malingering (TOMM*) is a more sophisticated malingering test. Also widely used, it assesses exaggerated memory complaints and the dissimulation of cognitive impairment, and it detects subtle forms of malingering. Its classification is based on the “floor effect,” a testing strategy relying on the nonmalingering individual’s easily passing most test items. Studies of its validation indicate excellent specificity and modest sensitivity. It has a very high accuracy rate, and its validity has been supported in a forensic psychiatric population. The *Millon Clinical Multiaxial Inventory (MCMI-III*) is a malingering test detecting tendencies to overstate emotional and personal problems. The *Fifteen Item Test (FIT*) is a test of recall; it evaluates feigned neurocognitive deficits.

The *Miller Forensic Assessment of Symptoms Test (M-FAST)* uses a structured interview and is considered most efficient at distinguishing feigned from bona fide schizophrenia. This tool is a screening device with highly validated studies confirming it has sound psychometric properties. The majority of its items represent psychotic or highly unusual or improbable symptoms.

Some experts state the two primary stand-alone measures for feigned mental disorders are the Miller Forensic Assessment of Symptoms (M-FAST) and the Structured Interview of Reported Symptoms (SIRS-2).

Using a polygraph or lie detector, drug-assisted (e.g., amobarbital) interviews, or hypnosis are not considered standardized in an adequately scientific fashion and are not ordinarily used to detect malingering. Ultimately, the only acknowledged gold standard undisputed in confirming malingering is full disclosure by the subject’s stating a deliberate intention to malinger.

DIFFERENTIAL DIAGNOSES

The malingering condition may coexist with actual mental disorders, such as major depressive disorder, anxiety disorders, bipolar disorders, and personality disorders. Careful assessment must discriminate genuine mental disorders and personality disorders from the pretense of malingering. Presentations are usually complicated and typically not straightforward. Often, more than one diagnosis and condition may exist together. Also, one must screen for intact cognitive status and rule out intellectual and developmental disabilities and dementias. These may inadvertently cause the patient to incorrectly describe what seems to be symptoms. These misidentifications are not deliberate deception—*feigning*. Such mistaken beliefs do not carry the motivation of intent to deceive and must be distinguished from malingering.

Malingering (not a mental disorder but a condition that may be a focus of clinical attention) has been contrasted with a group of mental disorders: "somatic symptom and related mental disorders," notably somatic symptom disorder, conversion disorder (i.e., DSM-5, F44. functional neurologic symptom disorder), illness anxiety disorder, and factitious disorder.

DSM-5 has a new category, *somatic symptom, and related disorders*, that includes these and other related disorders, and states their initial presentation occurs mainly in medical rather than psychiatric settings. Table 28.1–5 summarizes some aspects of the differentiation of malingering from factitious and somatic symptom disorders.

Factitious disorders imposed on self are characterized by physical, psychological, or mixed symptoms plus signs of illness intentionally produced or aggravated. Symptoms are not genuine but manufactured. The patient willingly agrees to any testing suggested. This disorder may or may not be associated with an unconscious psychological need to assume the sick role; yet, it is an apparent wish to receive medical care. Some have used the phrase: "the patient with factitious disorder looks for sympathy."

Emphasis on this diagnosis is on the objective identification of falsification rather than inference about intent, reasons, or possible underlying motivation. This diagnosis always implies psychopathology. Its prevalence is uncertain but said to be about 1%. Individuals with factitious disorder dramatically present their history but tend to be vague regarding details. Pathologic lying (i.e., "pseudologia fantastica") may be present. If frustrated by caregivers, these individuals may become uncooperative or abusive. Intentionally produced symptoms may include depression, amnesia, PTSD caricatures, infections, pain, fevers, or neurologic symptoms. Pain and requests for analgesic medications are widespread. The most severe and chronic form of factitious disorder, primarily with physical signs and symptoms, was referred to as *Munchausen syndrome*, which includes recurrent hospitalizations, peregrination (i.e., traveling), and pseudologia

fantastica. “Factitious disorder imposed on another” (previously termed *Munchausen by proxy*) refers to a form of maltreatment in which an individual in the parental or caregiving role fabricates or produces physical, psychological, or combined illness in another to assume the vicarious sick role. Other actual mental disorders and borderline personality disorder may also accompany this.

Table 28.1–5.
Differentiating Malingering from Factitious and Somatic Symptom Disorders

	Malingering	Factitious	Somatic Symptom Disorders
Presentation	Psychological/physical symptoms	Psychological/physical signs and symptoms	Physical symptoms
Deliberate feigning	Yes	Yes	No
Inferred motivation	Conscious desire for unmerited tangible gain	Sick role; to receive medical care	Multiple determinations

Malingering differs from factitious disorder because the malingerer’s intentionally manufactured symptom presentation is secondary to a clear-cut conscious motivation to attain a recognizable external reward, payment, or prize. The malingerer seeks a tangible external incentive, which is usually material, not an abstract satisfaction. The patient with factitious disorder, unlike the malingerer, can be shown to create an identifiable falsification of being ill, impaired, or injured in the absence of obvious external rewards. Dangerous, self-injurious, and self-handicapping signs often accompany symptoms. Malingering and factitious disorders typically are not to be diagnosed together. In psychodynamic terms, the inference is that the intentionally created signs and symptoms of any problem produce a *secondary gain*, a recognizable advantage, for example, being sick and needing some form of help. This idea has been challenged because it is not precise and its meaning confusing; therefore, “gain” concepts are no longer commonly used.

Somatic symptom disorders category (e.g., conversion disorder, somatic symptom disorder, and illness anxiety disorder) are characterized by real physical symptoms not intentionally produced and are not under voluntary control. These disorders are typically first seen in medical settings such as primary care and neurology rather than psychiatry.

In *conversion disorder*, also termed *functional neurologic symptom disorder*, somatic symptoms are present as the *absence* of a function. These real

symptoms are clearly incompatible with neurologic pathophysiology. In contrast to somatic symptom disorder, the patient does not express excessive thoughts, feelings, and behaviors about the disorder; the focus is typically on presenting a symptom of the loss of a function. In conversion disorder (e.g., blindness and paralysis), patients are cooperative, welcome evaluations, search for answers to their symptoms, yet present with historical gaps and vagaries. Some observers have commented on their "la belle indifference" attitude of almost bland indifference. Medically unexplained symptoms remain a key feature in conversion disorder. Neurologic symptoms that are found after appropriate neurologic assessment are incompatible with neurologic pathophysiology.

In *somatic symptom disorders*, complaints suggest a medical condition. The patient genuinely experiences the symptoms. Several real somatic or physical symptoms exist that are *positive*, for example, pain. Thus, positive symptoms, not the absence of a function such as sight or motor ability, are presented. Still, they cannot be fully explained by a general medical condition, by the direct effects of a drug substance, or by another mental disorder. One or more genuine somatic symptoms are significantly moderate to severe, distressing, and disabling. Thoughts, feelings, and behaviors about the seriousness of these symptoms are disproportionate and disrupt daily functioning. Most of the somatic symptoms in somatic symptom disorders cannot be demonstrated to be clearly incompatible with pathophysiology (e.g., pain and fatigue). The patient's preoccupation is distress at having a serious disease based on the misinterpretation of bodily symptoms. About 75% of these patients fall into the category of "hypochondriasis." The patient *focuses primarily on the distress about having the symptoms and not on the symptoms, usually pain; has a false belief they have a serious disease that has not been detected; this preoccupation impairs their ability to function in important areas of life.*

In contrast to the relatively more euthymic patients with conversion disorder, patients with somatic symptom disorder present as chronic worriers. Some have speculated that psychological factors, inferred to be dynamically unconscious, have an essential role in these physical symptoms. In this mental disorder, the patient believes their symptoms are real, and distress is based on having a serious disease. Approximately 75% of individuals previously diagnosed with hypochondriasis are subsumed under the diagnosis of somatic symptom disorder.

About 20% to 25% of those previously holding the DSM-IV term "hypochondriasis" may now be subsumed under *Illness Anxiety Disorder* (F45.21) in DSM-5. This disorder is seen in medical rather than mental health care settings. Characteristics are a *preoccupation with having or acquiring an as yet undiagnosed serious illness, that is, concerns about getting sick, not symptoms*; *somatic symptoms are not present* or, if present, few, mild, and not severe. There is a *high level of health anxiety*. With no or mild symptoms present, fear about having or acquiring a serious disease dominates thinking for at least 6 months.

Behaviors of avoidance or repeated body checks occur. A range from care-seeking to care-avoidance follows. All these patients misinterpret their bodily sensations. Another mental health disorder does not better explain illness preoccupation. Excessive health-related behaviors exist. The complaints are more than what one would expect from history, physical examination, or laboratory findings. There may be an absence of objective conclusions fully to explain the clinical presentation. Other mental disorders and genuine medical disorders such as depressive and anxiety disorders may coexist with somatic symptom disorders. Illness anxiety disorder (i.e., excessive worry about developing an illness) and somatic symptom disorder (i.e., excessive worry about the seriousness of one's physical symptoms) lie on a quantitative continuum, with the latter being more severe.

Since COVID-19 is now a universal part of our shared experience, issues related to it are plentiful. There are tests available detecting the presence or absence of COVID-19, even though patients may need repeat testing. Although respiratory symptoms may be present, numerous other symptoms and signs (e.g., fever, muscle pain, GI distress) may be found. The precautions, quarantine of those exposed, and isolation of those infected bring bouts of loneliness to the forefront. As with other concerns over illnesses, if the patient can show reasonable insight into their anxiety, this suggests a genuine concern. Insight into one's anxiety and refraining from extreme and unnecessary behaviors may obviate adding a tentative diagnosis of Illness Anxiety Disorder. Thus, differentiating real illness from its absence requires contextualizing individual patients and their realistic or overly extreme, preoccupying worries.

Malingering differs from somatic symptom disorders because the malingerer's intentionally contrived presentation of physical and psychological symptoms is under voluntary control and has an external incentive. In malingering, the patient does not genuinely experience the symptoms presented. The malingerer avoids agreeing to uncomfortable testing. If physical symptoms are present in somatic symptom disorders, they are not intentionally produced and are not under the patient's voluntary control. Conversion disorder within the somatic symptom disorder category is susceptible to symptom relief by suggestion and hypnosis, unlike malingering. Somatic symptom disorder may also exist with conversion disorder. If factitious disorder (does not seek obvious external reward) is diagnosed, malingering (does seek obvious external reward) ordinarily is not added as an additional condition. However, the presence of some factitious or malingered symptoms, mixed with other symptoms that are clearly nonintentional, may be found. When this mixed situation appears present, both somatic symptom disorder (referring to the nonintentional symptoms) and factitious disorder (intentional symptoms) or malingering (intentional symptoms) may be acknowledged.

COURSE AND PROGNOSIS

Malingering, when deemed present, needs to be assessed in the overall biopsychosocial context of the person's life. The presence of diagnosable mental disorders, their histories, and their response to psychotherapy and medications must be addressed. Any acute or chronic medical or surgical problems and their effect on the patient's overall functioning need to be considered. In forensic, hospital-related settings or military cases, *malingering may be context-specific and change its presentation or even disappear if circumstances and situational challenges change*. Because malingerers do not usually comply with treatment recommendations, the malingering status often remains unaffected. Research in this area is limited but shows that if reinforced, malingering may continue; if malingered goals are met, symptoms sometimes abate; if the malingerer becomes frustrated with current care, other providers are sought.

TREATMENT AND MANAGEMENT

Since malingering is regarded as a condition that may focus on clinical attention, no routine or standardized interventions have been devised and recommended. Collaboration among evaluators is useful and significant. A range of suitable management approaches having clarification as a primary goal includes the following:

1. A clear diagnostic delineation of any medical or psychiatric symptoms and disorders, if present, in addition to malingering.
2. A mindful consideration of legal and ethical issues, especially those reflected in the medical record, because malingering is unlikely to be proved conclusively.
3. If the psychiatrist is the treater or leading evaluator, a nonthreatening approach should include concerned neutrality and the avoidance of any abrupt confrontation or accusations of lying. Safety considerations should be present because angry reactions might escalate to dangerous behaviors. Explicit recognition of issues of implicit countertransference reactions (e.g., an unreasonable or exaggerated sense of annoyance at the patient) and an awareness of the possible subtle effects of *projective identification,* mentioned earlier*,* and any implicit biases on the part of all parties can minimize inordinate distortions and inadvertent psychological boundary violations.
4. The clinician might discuss that all findings indicate no medical basis for the patient's symptoms can be found. Hence, no medical or psychiatric diagnoses can be established. Suggesting that the patient's history appears incomplete or something significant has been left out may offer the patient the last opportunity to reveal the illness deception or devise an explanation now to save face. With tactful clarification, alternative strategies that are healthier

might emerge. Parsimonious, sensitive feedback might encourage the patient to shed further light on their intent or motivations. However, in some cases, the patient may become angry, respond defensively, and decide to leave, perhaps to go elsewhere. Rarely, a patient will openly admit malingering.

5. If the psychiatrist is a consultant, suggested recommendations and management strategies can be provided directly to the referring party for implementation.

FUTURE DIRECTIONS

The introduction of malingering–deliberate symptom falsification to obtain an external incentive or reward–into the DSM-III in 1980 caused many nonmedical specialists' vociferous reactions. This vigorous effort questioned the validity of this attempt to medicalize deceptive illness behavior. What had seemingly been an orphan condition was and is continuing to be the subject of intense debate. The medical model contrasts with an alternate view emphasizing the person having agency, free will, choice, and the ability to make consciously planned decisions. From this latter perspective, malingering as illness deception is said to be better regarded within the context of individual responsibility, accountability, conscious choice, and social action. According to such a framework, the emphasis on malingering should eschew an uncritical adoption of the medical model and instead consider legal issues and questions having to do with problems of intentional social deviance. Those who advocate this position state that patterns of misconduct that are, in fact, "bad behavior" are incorrectly being redefined as bona fide illnesses.

The psychiatrist views malingering as not a mental disorder but as a behavioral strategy that healthy or sick people might use in certain situations to attain an unmerited goal—using deliberate pretense. Persons with this condition may deem the behavior morally right or perhaps wrong but justified under their current circumstances. In contrast, factitious disorder is maladaptive because the induction of injury or disease is a central feature, making it a DSM-5 disorder rather than a condition. These considerations beg the questions:

- "What is injury, and who is harmed"?
- "Can we, as physicians, accurately document deception and motivation as reasons for the choice, let alone the degree"?
- "In what way is the suspected deception consequential"?

Many have debated the extent to which malingering has clear-cut legal implications, such as by equating it with criminal fraud. However, it can be argued that a medical expert's function is not principally to make a judgment on an individual's honesty. The medical expert's role is to assess a clinical presentation, evaluate reported symptoms, render diagnoses, and points of clinical attention

based on the best evidence possible. A treatment or management plan follows. This approach to malingering clearly gives the physician a medical rather than a legal or moral role.

The effort to introduce more objectivity into detecting malingering has produced sophisticated test measures from the medical field. Detecting deception has shown some success by mapping brain correlates of lying. Functional magnetic resonance imaging (fMRI) has demonstrated specific neurocircuitry in brain regions under conditions of simulated, mock crime such as stealing. For example, truthful, as opposed to deceptive responses, were correctly identified in 90% of the model testing group. Similar brain imaging studies have shown different cerebral activation processes are involved when a symptom is subjectively experienced as real compared to when it is feigned. Such objective data are intriguing but far from conclusive.

The entire area of malingering and assessing symptom validity with all it implies is complex. Partial malingering may be common and can add parameters to indeterminate conclusions. Obvious psychological, psychiatric, monetary, social, legal, moral, and philosophical issues, to mention a few, are at play. Although it is laudatory to understand malingering in an objectively accurate manner, as many in specialized fields are trying to do, the explosion of research, conjecture, simulation studies, and psychological testing has raised serious ethical questions.

At this time, no generally agreed-on consensus exists. With its relatively straightforward and presumed nonjudgmental guidelines, the psychiatric approach values a dedicated capacity for examining multiple sources of information, often ambiguous and indeterminate. Therefore, psychiatry striving for a nosologic reserve participates as a rational, even essential, player as one team member in the field.

28.2 Adult Antisocial Behavior, Criminality, and Violence

Dorothy Otnow Lewis, M.D., F.A.C.P., Harrell Woodson, Ph.D., and Robert J. Boland, M.D.

The acts subsumed under the terms "adult antisocial behavior, criminality, and violence" range from stealing candy from a baby to abducting, raping, and murdering a child. They cover a multitude of sins and a multitude of neuropsychiatric signs, symptoms, and behaviors. Despite the diverse aberrant behaviors included within these categories, official diagnostic manuals consider "adult antisocial behavior" to be a condition "not due to a mental disorder." For decades, criminals, violent and nonviolent, were deemed "bad." Those committing particularly heinous crimes were "evil." They posed a religious, not a medical question. There was nothing wrong with their brains. Professional thieves, racketeers, dealers in illegal substances, thugs, and even serial killers were regarded simply as mentally healthy malefactors. They were immoral, and their acts presumably represented their conscious choices of alternative lifestyles. Such assumptions presupposed the existence of supportive scientific evidence. Alas, there was none.

People tend to divide crime or antisocial behavior into two general categories: street crime and white-collar crime. But what about organized crime?

ORGANIZED CRIME

In the United States, organized crime, as defined by the Organized Crime Control Act of 1970, is "the unlawful activities of . . . a highly organized disciplined association." We call this structured criminal activity "racketeering.""

Until 1957, J. Edgar Hoover denied or ignored this violent if lucrative entity. Instead, Hoover focused his attention and workforce on uncovering alleged Communists at all levels of government, while the Mob (otherwise known as the Mafia or Cosa Nostra) flourished right under his nose. Prior to 1957, Hoover dismissed The Mob as hoodlums to be dealt with by local police. However, after a series of turf wars and murders, mob bosses from across the United States gathered for a meeting. This event was in the fall of 1957 at the palatial 58-acre Apalachin estate of Joe Barbara. A group of snazzy cars parked around the Barbara mansion caught the eye of the local police, who gave chase. The police caught several mobsters as they tried to run away through cornfields. Headlines the next day shouted, "Police Nab 67 Mafia Chiefs in Backwoods." However, the

courts convicted only 20 on minor charges, and the appeals court reversed all convictions. Such was the power of this theoretically nonexistent entity, The Mafia.

Although there are many books about "The Mob," its structure, rules, and alleged rituals, there is little, if any, formal research on the psychology of mobsters. In 2004, two Italian psychologists attempted a clinical description of the workings of the Mafia mind. Unfortunately, the vague, undocumented nature of their database made it impossible to generalize from their publication. Nonetheless, their description of the Mafia family structure was consistent with that of other Mafia observers. There is a consensus that at its height, many young men who joined The Mafia (or Cosa Nostra) were not joining in desperation (like their impoverished immigrant peers) but with admiration. Kingpins commanded respect. The toughest, strongest, most self-assured male children were, reportedly, groomed to take over positions of authority previously held by their fathers, uncles, or other powerful male relatives.

Absent vigorous data, Mafia psychology, is open to speculation. Some early criminologists asserted that these criminals suffered from a lack of self-control and sought only to satisfy their immediate needs or wishes. Others hypothesized the existence of a criminal personality characterized by risk-taking, unreliability, irresponsibility, and inability to tell the truth.

One systematic study compared Mafia-linked incarcerated criminals with incarcerated non-Mafiosi. The researchers found, to their surprise, that none of the Mafia-linked criminals scored in an abnormal range on a psychopathy scale, whereas "ordinary criminals" scored much higher on average. These results suggest that being a run-of-the-mill criminal is quite different from being a "made man." A fascinating finding was that Mafiosi's scores in interpersonal domains suggested that they were more caring and empathic than their everyday criminal jail mates. Many had stable marriages as well as mistresses. One expert on the Mafia concluded that the personality traits that predict leadership success (i.e., extroversion, controlled impulsiveness, a sense of adventure, megalomania, and narcissistic personality disorder) are equally suitable traits for a successful career in either business or organized crime. If the scales and methods were valid, we might conclude that the portrayal of mobsters in such shows as *The Sopranos* is surprisingly accurate.

WHITE-COLLAR CRIME

The line between legitimate business practices and racketeering often blurs and at times totally disappears. We merely have to scan through current news to marvel at the nature and scope of skullduggery perpetrated by heretofore upstanding businessmen who seem to be in their right minds. There are, it appears, hidden cracks in many pillars of society. It cannot be said with conviction

that, as a group, racketeers, embezzlers, and money launderers are free of psychopathology any more than we can say the same for doctors, lawyers, stockbrokers, accountants, senators, and even presidents. We know much less about the neuropsychiatric characteristics and brain function of so-called white-collar criminals than we do about violent criminals.

Edwin Sutherland coined the term *white-collar crime* at a 1939 meeting of the American Sociological Society. Sutherland took issue with his colleagues, who theorized that crime primarily resulted from poverty and socioeconomic inequality. Sutherland called attention to the improper business practices of individuals in positions of power, practices he felt should be regarded as criminal offenses rather than simply as civil wrongs.

The Federal Bureau of Investigation (FBI) has defined *white-collar crime* as illegal acts characterized by deceit, concealment, or violation of trust that are not dependent on the application or threat of physical force or violence. These crimes thus are treated as conscious, rational, and economic decisions.

Estimates of white-collar crime's cost range in the hundreds of billions of dollars per year, whereas street crime costs about 15 billion dollars per year. The human consequences of embezzlement and fraud are immeasurable and include losing one's home, pension, tuition, or physical and mental health.

To understand the increasing incidence and prevalence of financial crime, one must study the enormous changes in the technology used to manipulate economic transactions since the 1990s. For example, with very little oversight, corporate officers in publicly held companies with the stroke of a key can artificially inflate the price of a stock. New technologies have facilitated such practices at the expense of customers and employees. The more automated the victims (such as the digits of their retirement funds), the easier it is to defraud them. The farther away one is from the target, the easier it is to destroy it. It is easier to kill with drones than with knives. Also, the less human the target, the less troubled the conscience. Wall Street moguls, who would never consider holding up their clients at gunpoint, think nothing of tapping a key and transferring their clients' life savings into questionable, if not downright illegal, investment schemes.

Such moral compromises are not limited to the financial world. Most troubling is the degree to which the bottom-line economy has corrupted the medical industry.

An especially egregious example of corporate and medical malpractice was the marketing and dissemination of the Dalkon Shield, an intrauterine contraceptive device. Despite early warnings regarding the risky design of the product (it had a multifilament string with a tendency to wick and carry bacteria-laden fluid from the vagina into the otherwise sterile uterus), corporate officials went forward with promotion, production, and sales.

Shortly after that, the company began to receive complaints regarding cases of pelvic inflammatory disease and septic abortions. Nevertheless, it continued to market the device for over 3 years. By the time the corporation filed for bankruptcy, there were more than 300,000 lawsuits.

According to the National Health Care Anti-Fraud Association (NHCAA), a small percentage of health care providers commit most healthcare fraud. However, the NHCAA estimates that healthcare fraud's financial losses are in the tens of billions of dollars.

Epidemiology

As violent crime rates diminished during the first decade of the 21st century, government and private lawsuits for fraud and other financial violations soared. Scholars and law enforcement personnel have speculated that the surge in high-stake white-collar crime is a result, at least in part, of technologic advances such as the Internet, automated tellers, and plastic that facilitate certain kinds of offenses (e.g., hacking, identity theft, and embezzlement) and provide opportunities for new creative kinds of white-collar crime. The scope of white-collar crime is ever-widening. It has come to include criminal acts in violation of environmental and health laws. The Department of Justice has finally begun to focus on financial institution fraud, defense procurement fraud, health care fraud, computer crimes, telemarketing fraud, and international fraud.

Healthcare fraud is soaring as large healthcare programs, public and private, steal trillions of dollars. According to the Government Accounting Office (GAO), in 2011, Medicare and Medicaid paid a whopping $65 billion in improper payments. According to the FBI, one of the most significant trends in healthcare fraud is the participation of health care professionals—in other words, doctors—who in so doing risk their patients' lives, not to mention their patients' pocketbooks. The FBI has reported an upsurge in unnecessary treatments, including surgeries, the prescribing of unnecessary, potentially dangerous drugs, and overall substandard care.

Of particular concern to psychiatry are cases in which psychiatric/psychological professionals have engaged in fraudulent practices. For example, individual practitioners and hospital chains have pled guilty to providing unnecessary treatment to thousands of patients to collect insurance money.

When insurance reimbursements depend in large part on procedures performed, psychiatrists are at a disadvantage. Talk is cheap. There are a few procedures. At the same time, thanks to technologic advances, new procedural treatment modalities are now available (e.g., transcranial magnetic stimulation and deep brain stimulation). Electroconvulsive therapy, once rare, has experienced a rebirth.

One of the most devastating instances of white-collar crime in the United States involving the medical profession is the case involving Purdue Pharma, producer of OxyContin, an opioid touted by Purdue as being less addictive than other pain medications because of its time-release formula. Before marketing, internal documents circulated within the company indicating the product's potential for abuse. Nonetheless, sales representatives, reportedly under management's instructions, falsely assured doctors of the safety of their product. The U.S. Food and Drug Administration (FDA) approved the drug in 1995, and by the year 2000, parts of the United States, mainly rural areas, experienced soaring rates of addiction and crimes related to addiction. Although the pill as marketed was long-acting, the addict, by simply crushing the pill and swallowing the powder or diluting and injecting it, could experience an immediate, intense "high." At a news conference in 2007, a United States attorney stated that OxyContin's aggressive, untruthful marketing had resulted in rising crime rates, teenage drug addiction, and even deaths. This particular fraud was not limited to the pharmaceutical industry. Doctors reportedly were paid handsomely to promote the drug to colleagues.

White-Collar Violence

The more closely we examine corporate crime and criminals, the more we see that white-collar criminals cause tremendous physical damage. A graphic example is the production and sale of the Ford Pinto long after the corporation knew of the flaw in its design that caused it to explode in collision. The "bean-counters" at Ford concluded that the cost of lawsuits from injuries and deaths would be less than the cost of a large-scale recall, so Ford stalled the recall.

Another clear example of corporate violence, of obliviousness to human life, is the coal mining industry. In April 2010, an explosion occurred at the Upper Big Branch Mine in West Virginia, killing 29 of the 31 miners working there that day. The mine owners had previously received dozens of notifications of safety violations and had not rectified them. In its investigation, the West Virginia Office of Miners Health, Safety and Training (WVOMHS and T) issued 253 violations of safety standards.

According to the U.S. Bureau of Labor Statistics (BLS), there were 5,333 fatal work injuries in 2019, a 2% increase from 2018. That amounted to 3.5 fatal

injuries per 100,000 full-time workers. This percentage is only moderately lower than the 5.3 deliberate homicides per 100,000 population in 2017. Thus, corporate malfeasance has a mortality rate similar to that of deliberate homicide.

Etiology

We do not know what causes white-collar crime. The field is wide open to speculation. Sutherland believes these are learned behaviors resulting from an association with those who approve of them and isolation from disapprovers. Others have argued that white-collar crime, like street crime, results from a tendency of individuals to seek immediate, short-term gratification without considering the possible long-term consequences of their acts. Such individuals, they believe, are impulsive, aggressive, and motivated by the pursuit of pleasure and avoidance of pain. Comparing street criminals with other kinds of white-collar offenders reveals marked demographic differences (poor vs. rich). One magnetic resonance imaging (MRI) study reported hypertrophy of parts of the frontal cortex in white-collar criminals and suggested a relationship to "abstract monetary rewards." That is a leap! Although some have asserted that individual tendencies lead to all crime, others have argued that perceived incentives and disincentives like those described earlier are potent influences. Others have pointed to ethical deficits. For example, experiments on college students suggest that anyone will cheat when given a chance.

Why is white-collar crime so rampant? In his examination of this phenomenon, Callahan called attention to the trend in the United States toward an increasingly free-market, laissez-faire society with a focus on money. He posited that the bottom-line ethic (if it can be called that) had infiltrated areas of culture previously insulated from market pressures, such as medicine, education, journalism, and sports. In addition, he hypothesized that the greater inequality in America between the haves and the have-nots had weakened the social fabric—undermining the notion that everyone is in it together and bound by the same rules. Finally, Callahan suggests four critical reasons for the increased levels of cheating:

1. Increasing pressures to succeed in a society where we cannot count on job security.
2. Weakened safeguards against cheating. The FBI, Securities and Exchange Commission (SEC), and Justice Department currently have insufficient resources to stop white-collar crime.
3. Larger rewards for those who cheat, from the CEO who inflates company earnings to the baseball player who bulks up on steroids to maintain his million-dollar-plus annual income.
4. "Trickle-down corruption" in a society where the ordinary middle-class person perceives that the cards are stacked, and the rules are unfair.

Another factor may be the ever-increasing distance between perpetrators and victims. It is easier to harm someone on the internet than it is your neighbor.

MORALITY AND THE BRAIN

For millennia morality has been assumed to be an acquired capacity, developed with maturation and upbringing. Most religions include specific moral concepts, beliefs, and standards inculcated during childhood and encouraged throughout adolescence and adulthood. Pillars of the church and pillars of the community are considered fabricated of the same ethical stuff. Morality is, in reality, among the most sophisticated features of human judgment, behavior, social cognition, decision-making, and conflict resolution. It includes a theory of mind, meaning our ability to imagine another person's complex emotions and mental states. Scholars debate the relative biologic inheritance of this capacity versus environmental influences on it. It may be that infants are born with the innate capacity for implicit morality, whereas explicit morality requires ongoing instruction. Infants will cry when they hear other babies crying, but they cannot tell you why. This is the beginning of empathy.

In the 1990s and early 21st century, Damasio established an association between frontal lobe damage and immoral dyscontrolled behavior. Many studies have attempted to localize the areas in the brain and the pathways among them that facilitate moral thought and behavior. Greene and colleagues were the first to use functional magnetic resonance imaging (fMRI) to study moral judgments. In 2001 they reported a study that presented several different scenarios involving moral and neutral choices while subjects underwent fMRI. One example scenario was a variant of the trolley problem, developed by the philosopher Judith Jarvis Thomson in 1985 and familiar to ethicists and moral psychologists. In it, a person imagines seeing a runaway train and either doing nothing as it runs over five track workers or pushing a large man in front of the train, stopping it but killing that man. The dilemma, in part, is a challenge to utilitarianism: whether the end justifies the means.

Investigators found that certain brain areas were especially active when contemplating moral dilemmas such as the one above. These areas include the medial frontal gyrus, the posterior cingulate gyrus, and the angular gyrus. Some of these areas are more active in emotional processing than cognitive reasoning, and they were more active when subjects contemplated the "up close and personal" choices than when considering impersonal moral and nonmoral choices. Decety and Porges modified Greene's study by showing subjects scenarios in which a person was harming or helping another person. They instructed the subjects to identify themselves with the active (harming or helping) protagonist. Helping activity was associated with increased activity in the ventral striatum, while harmful activity resulted in a "strong signal decrease" in the

ventromedial prefrontal cortex (VPFC) and activation in the amygdala. Thus, Decety and Porges demonstrated that the subject's perspective profoundly affects the recruitment of different brain areas during moral considerations. Investigators have found that damage to the prefrontal cortex (PFC) interferes with the aversive response to harmful actions. They have argued that what some would call psychopathic behaviors result from damage to the PFC and an inability to develop an aversion to immoral behaviors.

Does it matter when in life damage to the PFC occurs? It does. Taber-Thomas and colleagues compared the moral functioning of individuals who experienced VPFO damage in adulthood with those who had similar injuries in childhood. They found that when they confronted adults with early childhood damage to the VPFO with self-interest decisions (e.g., whether or not to kill your boss for money), the subjects were less likely to condemn the act than were adults who had received similar results of damage to their brains during adulthood. The researchers suggest that the subjects with late-onset injury had, over time, developed affective responses that prohibited self-interested behaviors. What have we learned? Learning morality starts early. Absent early learning of morality, we may never be able to catch up.

Morality involves numerous other areas of the brain interconnected and connected to the PFC. These areas include the cingulate gyrus, the amygdala, the dorsolateral PFC, the temporal lobes, and even the cerebellum. Studies of the timing of reactivity from one area to the next exist. There appear to be different aspects of morality. This brief overview should tantalize the reader into exploring the findings, agreements, and disagreements, which swirl around the fascinating exploration of the neurologic foundations of morality.

VIOLENCE

What kind of animals are humans? Was Hobbes right? Is the natural state one of "continual fear, and danger of violent death"? Without a strong government or set of rules, "is the life of man, solitary, poor, nasty, brutish, and short"? Was Samuel Butler wise to caution, "Then spare the Rod and spill (sic) the Child"? Bad advice, at least according to current scientific data. Corporal punishment correlates with subsequent violence. No matter. Butler based his belief on the Biblical "He that spareth his rod hateth his son: but he that loveth him chasteneth him betimes." This instance is not the only time in this 21st century that science and God have found themselves at odds.

What about Wordsworth? Was he on to something when in *Intimations of Immortality,* he proclaimed that the human entrance into this world is one of purity and innocence? Humans come "trailing clouds of glory" only to be corrupted by the pressures of society, of living alongside other people. Rousseau agreed.

Locke disagreed. According to Locke, each person enters this world a blank slate to be scrawled upon by their environments and experiences.

Are all men (and women) created equal, or are some innately more aggressive than others? For millennia these kinds of questions were the provenance of religion, philosophy, literature, and politics. Now, these eternal questions have fallen into the lap of science. Think of current technologies, statistically validated neuropsychological test materials, positron emission tomography (PET) scans, fMRIs, the newly devised ability to chop up yards and yards of DNA, and discover what humans are made of—will these developing technologies lead to scientific answers based more on fact and less on faith? We have made a start. We already know that each person enters the world with certain innate but not inevitable potentials for behavior. What happens to each person makes the difference. No single factor or known constellation of factors accounts for violence. Instead, as will become apparent, various intrinsic and environmental influences come together, interact, and create matrices for violence.

Epidemiology

Just over a decade ago, Nelson Mandela stated, “The Twentieth Century will be remembered as a century marked by violence. It burdens us with its legacy of mass destruction, of violence inflicted on a scale never seen and never possible before in human history.” He blamed this extraordinary violence on “new technologies in the service of ideologies of hate.” Had he lived longer, he would be dismayed, although likely not surprised at the start we have made in the 21st century.

As of 2021, there are many ongoing conflicts in the world: 4 major wars (10,000 or more combat-related deaths in the past year), 19 other wars (1,000 to 9,999 combat deaths in the past year), and at least 25 other “minor conflicts” (between 100 and 1,000 deaths in that past year). Among the major wars, the Afghanistan conflict has been the most costly, killing as many as 2 million people from 1978 to 2020. The Mexican drug war has killed as many as half a million through direct (combat) deaths or related (organized crime) homicides since 1989. The Yemeni crisis has killed around 233,000 people since 2014, and the Tigray war has killed as many as 50,000 people since 2020. In addition to murders, wars leave countless refugees and abused and neglected children. Some of these children are recruited as child soldiers and taught to kill.

PEACE AND PEOPLE

In contrast to the straightforward documentation of worldwide conflict and homicidal violence, the documentation of peaceful societies is more complicated. One must almost literally beat the bushes to find data on peaceful societies. Those studying these kinds of societies describe tiny communities that avoid

contact with neighboring communities. They reported that adult members of such groups raised their children to be hesitant and fearful about the intentions of others. All physical violence was eschewed, including competitive games. One of the so-called “peaceful societies” is the Piaroa, a jungle people who live along the tributaries to the Orinoco River in Venezuela. The Piaroas society teaches children the evils of vanity, jealousy, arrogance, dishonesty, and ferocity. They are taught to protect themselves from unseen cannibalistic beings. Another reportedly peaceful tribe, the Semai of Malaysia, “see themselves as helpless in a hostile world that is beyond their control.” In truth, there is little evidence that idyllic, nonaggressive societies ever existed. Margaret Mead based her account of the peace-loving Samoan people on approximately 9 months of research on the island, most devoted to studying adolescent girls. Numerous accounts of Samoan life, written before and after Mead’s book, indicate that Mead’s generalizations about the peacefulness of Samoan life were simply wrong. It is surprising to learn that even now, the proportion of men killed by warfare in many primitive societies reportedly dwarfs the proportion of men in the United States and Europe who die in wars.

What about Buddhist societies? Tibet is a country long regarded as a model of nonviolence. The Dalai Lama is a symbol of peace. In 1912, Tibet, formerly a Chinese principality, declared its independence from China and ruled autonomously from 1912 to 1950. Then Mao’s army took over China. In 1958, following a series of uprisings in opposition to Chinese domination, a Tibetan army, made up predominantly of laypeople, was formed to fight the Chinese. Over the next few years, resentment of the Chinese grew among Tibetans, and in 1959 a full-blown revolt broke out, causing the Dalai Lama to flee his country. Despite their religious vows of nonviolence, Tibetan monks were active in protest movements. However, the extent to which even Buddhist monks participated in warfare remains unclear.

For years, the degree to which Tibetans, laypeople, and monks took part in training for battle and fighting remained secret. It is easy to understand why. Both monks and laypeople found themselves in an ethical dilemma. War violated the central principle of Buddhism, that is, to create no suffering for any sentient being. Even the Dalai Lama confessed his ambivalence, his personal and political quandaries. As he explained in his autobiography, “Nonviolence is not an intrinsic Tibetan trait. It is instead a philosophical component of Buddhism and a political component of state struggle.” Thus, one sees humanity’s difficulty in adhering strictly to nonviolence in its internal struggles. The source of this all too human dilemma will become more apparent when considering the complexities of brain structure and function.

Based on numerous studies of primitive and advanced societies, the consensus seems to be that violent conflicts motivated by jealousy, revenge, dominance, and sexuality (i.e., rape) are universal human behaviors and are

especially characteristic of men. These findings do not mean that violence alone characterizes the human species. Counterbalancing these aggressive drives are gentler instincts and a brain that, under optimal conditions, is often capable of moral reasoning and peaceful behavior. Then again, as will become apparent, moral reasoning does not always govern our behaviors.

HOMICIDE

Epidemiology

According to the United Nations' Global Study on Homicide (2013), the major forces contributing to homicide include economic crises, food insecurity, low levels of human development, and high levels of income inequality.

A study by the Geneva Declaration on Armed Violence and Development (GDAVD) estimated that in 2004 the global homicide rate was 7.6 intentional homicides per 100,000 inhabitants. In 2012, the United Nations Office on Drugs and Crime (UNODC) did a similar study and found a global average homicide rate of 6.2 per 100,000. UNODC's most recent data was from 2017, where the homicide was essentially unchanged at 6.1 victims per 100,000. Of these, men committed 90% of homicides, and 80% of the victims were also men.

Most homicides are in the Americas (17.2 per 100,000) and Africa (13 per 100,000). There are much lower rates in Asia (7.3 per 100,000), Europe (3 per 100,000), and Oceania (2.8 per 100,000). The countries with the highest rates are El Salvador (62.1 per 100,000), Venezuela (56.8 per 100,000), Honduras (41.7 per 100,000), and Brazil (30.5 per 100,000).

In the United States, the homicide rate increased by 14% from 2010 to 2017. This increase occurred after several decades of decline. The highest rates were in the central and southern United States, whereas the northeast United States had decreased murder rates. In the United States, most homicides involved firearms (77% in 2020), whereas, in countries where firearms are primarily banned, such as the United Kingdom, firearm-related deaths are infrequent.

Who gets murdered? In the United States, about 30% of victims were killed by someone they knew, and strangers killed only about 14%. Spouses and family members make up about 15% of all victims. Felony circumstances such as rape, robbery, and burglary accounted for only 22.5% of murders.

Murder rates in death penalty states were consistently higher over the years than in nondeath penalty states. Thus, it is unlikely that murderers consider the possibility of a death sentence when they commit a crime, and forensic evaluations seem to justify this assumption.

What about wars? Unfortunately, after a war ends, homicide rates often remain high. These increases seem to occur independently of the scale of the conflict or whether the nation was victorious in the war. Homicide rates increased with the

greatest consistency in nations that had suffered large numbers of combat deaths. Most of the wars studied occurred before developing the concept of post-traumatic stress disorder (PTSD), a mental illness familiar to psychiatrists practicing after the Persian Gulf, Iraq, and Afghanistan wars when mental health workers recognized numerous examples of homicides and suicides by traumatized soldiers. The extent to which these mental disorders contribute to postwar homicides is not well established.

Mass Shootings

In contrast with declining homicide rates by juveniles is the startling increase in mass or rampage shootings in the past several years. Between 1982 and 2005, most years had only one mass shooting. Several years had none. This number increased after 2005, the worst years being in 2017 to 2019 with 31 and 40 active shooter incidents respectively. About one-third of all mass shootings in the world occur in the United States. They have more mass shootings than any other country. However, the United States is also larger than most countries–it is more populous than most countries. Most school shootings are in the United States. The exact ranking of the United States among countries with mass shootings is a controversial subject, with different definitions, different ways to distinguish them from military conflicts, and different statistical approaches. Different approaches put the United States ranking in a range from 1st to 11th. However, it is notable that the United States is the most consistent in having mass shootings each year. Most other countries do not experience mass shootings.

It is hard to determine the comprehensive psychological profiles of mass shooters, as many die by suicide or are shot by first responders. Some have suggested typologies of mass shooters (e.g., psychopathic, psychotic, and traumatized). Some have reported that adult shooters tend to have experienced setbacks in social, family, or vocational domains as well as “autogenic components” (e.g., dysthymic reactions). Others have described shooters as having been bullied, being obsessional, grandiose, and harboring persecutory beliefs. We know that in most cases, the shooters are white, middle-aged men who act alone. Many mass shooters do suffer from identifiable mental illnesses. However, the relationship between mass shootings and mental illness is controversial.

The lead author of this chapter evaluated two teenaged mass shooters. Each of these young shooters (age 16 years) had long-standing histories of maladaptive school behaviors.

One of these youngsters had a history of auditory hallucinations dating back to the age of 12 years. He also, though highly intelligent, had specific learning disabilities for which he received special educational assistance. Of note, for years, he had been obsessed with war and guns. Periodically he came to school dressed in camouflage or all in black. The year before the shooting, he saw a psychiatrist (a gun collector himself) who diagnosed a depressive disorder and treated him with antidepressant medication. While in treatment and while taking his medication, he did well socially and academically. However, several weeks before the shooting, his parents decided he was doing well enough and should stop therapy and medication. Following cessation of treatment, his functioning deteriorated. His essays and presentations in class centered on war and shooting. At one point, he jumped up in class, clutched his head, and shouted, “Goddamn these voices in my head.” His teacher thereupon punished him, making him write out 100 times, “I will not swear in class,” completely overlooking his psychotic behavior. During the days prior to his shooting spree, he told his friends of his fantasies/plans of shooting up the school. No one did or said anything. One afternoon, following a bitter argument with his father (a high achiever who could not understand why his son had such trouble at school), the boy returned home and, using a firearm his parents had bought him, shot his father through the back of the head. When his mother came home, he shot her in the back (“so she wouldn’t see what I had done”). The following day he came to school with guns and ammunition, killed two classmates, and wounded several others. In addition to the prior author, a second psychiatrist evaluated him for the defense and diagnosed schizophrenia. However, as is often the case, the psychiatrist and psychologist who evaluated him for the state found no psychosis. On the advice of his attorney, the boy pled guilty to two counts of first-degree murder and was sentenced to life in prison.

The second shooter, a 16-year-old girl, also shot up a schoolyard of children, using a gun and ammunition gifted to her by the male relative with whom she lived. Shortly before the day of the shooting, at the request of her school counselor, she was evaluated by a psychiatrist who recommended hospitalization for severe depression. The male relative with whom she had been living refused to allow this. At that time, it was suspected that she was the victim of incest (she kept knives in plain sight around her room to prevent anyone from entering). When asked about being bothered sexually, she was evasive. She did not openly reveal that she had been sexually abused by the

male relative until a parole hearing 10 years later. The parole board ignored the relevance of this disclosure to mitigation.

During the psychiatric evaluation, the author learned that she had suffered a severe bicycle accident and had injured the left temporoparietal area of her skull. She also had a history of episodes of impaired memory for her actions and several symptoms consistent with possible complex partial seizures. In addition, her memory of the shooting itself was vague and distorted, and she lacked all memory for things she had said during an interview with police right after the shooting. Unfortunately, prior to her trial, she never had a neurologic or neuropsychological evaluation, although they had been recommended.

The psychiatrist for the prosecution found no evidence of mental illness. On the advice of her lawyer, she pled guilty to two counts of first-degree murder and, to this day, remains in prison. Several months after the shooting, the male relative with whom she had been living, married one of her girlfriends who was the same age as her. The author never saw this youngster after the initial interviews. However, years later, according to press releases, she was being treated in prison for what the press called a rare form of epilepsy.

Prior to the school shooting, she often talked about shooting and killing. Furthermore, approximately 3 days before her rampage, she warned her schoolmates that she would “do something big” the following week. Other shooters have made similar declarations that unfortunately are dismissed simply as ploys for attention.

In both cases evaluated by the prior author, sharing their thoughts of murder and mayhem appeared to be efforts to be stopped. In this author’s clinical experience, many murderers, young and old, indicate to others their homicidal thoughts days to weeks before they commit murder. Nobody gets the message.

Evolution and Violence

We cannot ignore the fact that, from an evolutionary perspective, *Homo sapiens* are apes. Because humans have uniquely large frontal lobes, humans seem to be the only creatures with the capacity to grow their foods, find shelter from extremes of climate, create new sources of energy, gain an understanding of their physiology, and invent specific cures for their ills. Humans are unique in our ability to try to understand the universe, mortality, and what we must do to protect ourselves from extinction. Our unique cognitive capacity allows us to distance ourselves and examine our behaviors as if we were studying another species. We can recognize our capacities for jealousy, hatred, vengeance, lust, and desire to dominate. We only need to consider the wars in our lifetimes to appreciate the advances we have made in our ability to annihilate one another.

For centuries, if not millennia, scholars assumed that humans were the only animals capable of forming groups to make war on each other, but humans are not alone. Jane Goodall documented raiding parties of male chimpanzees that perpetrate deliberate violence on other, more vulnerable groups of chimpanzees. Primatologists debate whether chimpanzee violence is innate or caused by human interference (e.g., feeding the animals and changing their habitats).

In a five-decade study of 18 chimpanzee communities, researchers reported that of 152 killings by chimpanzees in 16 communities, 92% of the attackers were male (as were 72% of the victims). Most killings involved intercommunity attacks in which the killers greatly outnumbered their victims. The investigators in this project asserted that variations in killing rates were unrelated to the impact on human beings. The researchers interpreted their findings as supporting the explanation that lethal violence among chimpanzees results from evolutionary adaptive strategies to increase access to food and mates. The primates did not catch it from humans. Other primatologists have questioned these conclusions.

There is substantial proof of human biologic closeness to the “other” great apes (chimpanzees, gorillas, orangutans, and bonobos). Advances in analyzing the structure and composition of deoxyribonucleic acid (DNA) have revealed that humans are genetically more closely related to chimpanzees than any other known species. From the perspective of chimpanzees, humans are their closest relatives. Their DNA is more similar to human DNA than it is to the DNA of other great apes. The question remains of whether the sizeable human cerebrum, which enables humans to devise weapons of mass destruction while simultaneously enabling humans to conceptualize moral codes by which to live, will, in the end, have survival value. How will people use their heads?

The recognition of our genetic similarity to chimpanzees has led to changes in the ways great apes are used for science. In the past, chimpanzees were used for experiments with toxins and infectious diseases. They were used by the Air Force and were subjected to extreme acceleration and sudden changes in atmospheric pressure. Early experiments tested the effects on primates of separation from their mothers and peers. These practices revealed the devastating effects of isolation. Ironically, though such maltreatment of chimpanzees is prohibited in the United States, immigration policies have separated human infants from their mothers.

Hormones, Gender, and Violence

Are all humans equally aggressive? Clearly not. Males of the human species, like chimpanzee males and males of most other species, are more violent than females. Whether measuring rough play during childhood or adult violent crime, the human male behaves demonstrably more aggressively than the female. These differences are not peculiar to a particular society but have been observed cross-culturally in societies as different as Ethiopia and Switzerland. In the United

States, men are about eight times as likely to commit murder, nine times as likely to commit armed robbery, and four to five times as likely to commit aggravated assault as women. Of note, men are also many times more likely than women to commit nonviolent crimes such as burglary, car theft, and drunken driving. Women are catching up to men in less physical forms of criminality such as fraud and embezzlement.

We can also witness the greater inherent aggressiveness of human males through the patriarchal nature of almost all human societies. For example, a 1971 survey of 93 societies around the world revealed that men retained all important political positions in 88% of them and that in the majority of societies, men also tended to hold all significant leadership roles within kinship groups. Most surprising is the finding that maltreatment of women by men (i.e., wife-beating) is more the rule than the exception in societies the world over. In addition, human males are more likely to commit rape than females. The human male is, in short, the predominant maker and breaker of the rules in human societies.

Much as many may wish to attribute most, if not all, of the differences between human male and female aggressiveness to cultural influences, overwhelming evidence exists that, long before birth, the die is cast; male and female brains develop differently in utero. The architectural and functional differences between male and female brains are, to this day, areas of controversy. While some investigators have noted marked differences in the “sexually dimorphic” areas of the hypothalamus and corpus callosum, others have highlighted the similarities across genders. However, human males have about 8% to 10% larger brains than females, although as we know from neurodevelopment, a bigger brain does not necessarily mean a smarter one as brain volume decreases with synaptic pruning while efficiency increases (and intelligence testing does not show a significant difference between the sexes). The most significant size discrepancies are in the cerebrum, that alleged repository of reason and impulse control.

Gonadal hormones play essential roles in the development of aggressive behaviors. Gonadal hormones are especially critical during fetal and neonatal development. In addition, these hormones affect sexually dimorphic areas of the brain, and their early presence is vital to the normal development of aggressive behaviors in such diverse species as fish, lizards, birds, and chimpanzees.

Androgens such as testosterone are metabolized in the brain to form estrogens. We now recognize that estrogens influence the sexual differentiation of the male and female brains and thus influence behavior. Estrogens influence dendrite formation at synapses. Thus, they have permanent organizing effects on the structure and function of the brain during critical prenatal periods. The transformation of testosterone to the estradiol essential to brain differentiation requires activating the cytochrome P450 aromatase enzyme. In vitro studies of neurons indicate that neurons from the male fetal hypothalamus have higher aromatase activity than neurons from the female fetal hypothalamus. We do not

entirely understand the relationship of the masculinization of the fetal brain to the production of neurotransmitters and receptors in the brain. However, we have documented the differences in the amount, turnover, and localization of catecholamines in male and female rat brains. The behavioral effects of gender differences in the central nervous system (CNS) are incredibly complex. The steroid derivatives progesterone, testosterone, and glucocorticoids, referred to as neuroactive steroids or neurosteroids, can also alter behavioral responses and are essential in sex-related differences. The behavioral effects of neurosteroids are numerous and include sedative, anesthetic, and anxiety-reducing properties.

Several MRI and fMRI studies have reported structural and functional differences between the brains of male and female homo sapiens. For example, investigators have reported sex differences in different parts of the orbitofrontal gray matter. This area is of particular interest because men in conflict with the law have been reported to have less functional orbitofrontal gray matter than their law-abiding peers. An exception: Raine has reported areas of hypertrophy in parts of the frontal cortices in white-collar criminals.

As technology has advanced, brain researchers have been able to identify other, smaller and smaller brain areas in which men and women differ. Investigators are zooming in on numerous brain areas affected by fetal testosterone (FT), including the right temporoparietal junction/posterior superior temporal sulcus, the planum temporale/parietal operculum (PT/PO), and posterior-lateral orbitofrontal cortex. Subregions of both the amygdala and hypothalamus are also reportedly sexually dimorphic.

Some of the literature on dimorphism reads like an exercise in political correctness. Papers on the subject of gender tend to soft-pedal any possible intellectual differences between men and women, especially if the differences seem to favor the male brain. One publication from the Proceedings of the National Academy of Sciences got directly to the point: “Sex differences in human behavior show adaptive complementarity. Males have better motor and spatial abilities whereas females have superior memory and social cognition skills.”

Males have one X chromosome and one Y chromosome, whereas females carry two X chromosomes. The Y chromosome contains a particular gene (SRY) that, during gestation, triggers the outpouring of androgens. Not only does this flood of testosterone affect the density of neurons in different parts of male and female brains, but it also results in sexually dimorphic *circuits* among different brain areas.

The study of brain formation and function has made a giant leap ahead with the new techniques of optogenetics and pharmacogenetics and innovations in researchers’ ability to track and record in vivo brain activity during complex social behavior. At this point, most of these new technologies study animal brain function, particularly the brain of the laboratory rodent. The assumption is that the

underlying neural mechanisms that drive aggressive behavior are likely to be conserved across species.

Using the new techniques of optogenetics and pharmacogenetics and newer in vivo recording methods, investigators have identified areas in the ventromedial hypothalamus and ventrolateral area (VMHvl) as a critical area for both the critical area intermale aggression and male-on-female sexual activity. David J. Anderson and colleagues identified a ventrolateral subdivision of the mouse VMHv1 marked by estrogen receptor 1 (Esr1+) that, when optogenetically stimulated, elicits attack behavior. However, to the researchers' surprise, weaker optogenetic activation of these same neurons promoted mounting (i.e., sexual) behavior. The finding that the same hypothalamic pathways associated with aggression are also associated with sexual acts at lower stimulation may shed light on the pairing of sex and aggression in human rape. Rape is not strictly a violent behavior. It is aggressive *and* sexual, and this research may help explain why that is. Research is also focusing more and more on the interactions of steroidal hormones and neurochemical systems. Many studies have looked at the relationship of hormones to serotonin (5-HT) function in males and the relationship of dehydroepiandrosterone (DHEA) to the modulation of gamma-aminobutyric acid (GABA) receptor function in females. A growing body of data suggests that serotonin, via its 5-HT 1A and 5-HT 1B receptors, significantly influences the regulation of aggression in species from crustaceans to humans. Increased 5-HT has repeatedly (though not consistently) been demonstrated to decrease aggression, whereas a lack of it is associated with increased aggression.

If particular hormones already give men a head start on violence, one can only imagine the possible consequences of their ingesting or injecting stimulants or steroids in the interest of bodybuilding and enhancing stamina. Anabolic-androgenic steroids and some of their metabolites and stimulants are associated with psychosis, disinhibition, aggression, and acts of violence.

A heretofore upstanding law enforcement officer, who stopped a young lady for an alleged traffic violation, then dragged her into a field of high grasses and raped her. Oblivious to her terror, he returned the victim to her car, gave her his card, and advised her to call him the next time she wanted to get together. The officer—a man with an impeccable record—then drove on to the department store where his recently estranged wife worked. He kept his gun in his holster when he entered the store. He just wanted to talk with his wife and win her back. While attempting to clear the store of customers, the officer brandished his revolver, which went off, killing a sales clerk. During the hours that followed, the officer kept several women hostage. He forced them to commit sexual acts with each other and with him. As time wore on, the captives got hungry, at which point the officer raided the till, took the change, and bought candies from a machine. When the police finally captured him, they charged him with felony murder (i.e., murder in the course of a robbery).

A psychiatric evaluation revealed that the defendant had periodic episodes of deep depression, which contrasted with his usual hypomanic state of mind. During the psychiatric examination, he was expansive and delusional about his powers to influence the police and the court to set him free. A detailed history obtained from close relatives and psychiatric records revealed a strong family history of bipolar mood disorder. Like many sexually violent offenders, the defendant also had a history of early, ongoing childhood sexual abuse by a neighbor.

The clinical team was nonplussed. Why had this upstanding officer of the law suddenly “lost it” and raped and murdered? After re-examining hundreds of pages of educational, social service, and medical records, the clinical team found a previously overlooked single allusion to the defendant’s recent use of “bodybuilding vitamins.” Before then, the clinicians had only inquired about alcohol and illegal substance use. When it finally occurred to the psychiatrist to ask about his bodybuilding “vitamins,” he readily admitted that over the past several months, he had been taking an over-the-counter potion called Ripped Fuel and an herbal concoction that at the time contained ephedrine and caffeine. He also had been consuming large amounts of a potentially mind-altering drug, chromium picolinate. In addition, to stay awake and work double shifts, he had been drinking dozens of cans of caffeinated sodas each day. As a result, he was wired and sleep-deprived. His wild sexual and aggressive explosion was a drug-induced, manic, psychotic episode in a man primed by early, ongoing sexually abusive treatment. The defendant was unaware of his predisposition to mania or that the “vitamins” could precipitate psychosis.

The man never ingested illegal substances. Thus, he had a solid defense of diminished capacity. An argument might even have been made for insanity because, at the time of his offenses, he could not have appreciated the nature

of his acts or that they were wrong (a legitimate M'Naughton defense). Would a man who thought he had done wrong have given his calling card to one of his victims?

Unfortunately, this man's manic braggadocio and his sexual advances toward one of his female defense attorneys alienated his entire defense team. This situation is not unusual, and many grandiose, manic murderers manage to alienate, particularly their male defense attorneys. They lock horns. They also compete with their psychiatrists, threatening their authority as "professionals." Their manic grandiosity often leads psychiatrists to dismiss them as having "antisocial personality disorder."

After the evaluation, the legal defense team learned of the defendant's mania and the effects of drug ingestion on his behaviors (offenses). The defense team, unable to overcome their antipathy, advised the defendant to plead guilty and throw himself at the mercy of the court. He was thereupon found guilty and sentenced to death.

Approximately 10 years later, a newly appointed, experienced public defender whose ego was strong enough to deal with the defendant's ego came upon the clinical team's neuropsychiatric evaluation and contacted the writer of this vignette. With the previous clinical findings, the new attorney was able to get a new sentencing hearing at which two psychiatrists, a psychopharmacologist, and a neuropsychologist, testified to the defendant's compromised state of mind at the time of the offense. At the time of this writing, the case is not decided.

Genes, Neurotransmitters, and Violence

Criminality runs in families. However, it is hard to tease out why this statement is true. A 1950s study of more than 1,000 Glasgow boys who left school at age 14 revealed that the greater the number of convicted family members, the more likely a boy would be convicted of a crime.

In David Farrington's Cambridge Study of Delinquent Development, he and his colleagues found that having a convicted father, mother, brother, or sister was associated with a child's convictions. In addition, same-sex relationships were more strongly associated with criminality than opposite-sex relationships, and having an older criminal sibling was more closely associated with a child's criminality than having a younger one.

Twin studies and studies of adopted away children of criminal biologic parents support a genetic component in the genesis of violence. A recent study of a large sample of twin pairs, using parent-reported data, found an association between early temperament and later aggression. Emotionality and high activity, especially in boys, were associated with subsequent aggressiveness.

Early studies of adopted away children of criminal biologic fathers and noncriminal biologic fathers revealed that the children of criminal fathers were more likely to become antisocial than noncriminal fathers' offspring. However, those children with both criminal biologic fathers and criminal adoptive fathers were at the most significant risk of becoming antisocial, suggesting that intrinsic and environmental factors contribute to antisocial behavior. Of particular importance is that the antisocial behaviors in these samples were reportedly nonviolent.

Others have compared identical twins (concordant for all genes) and fraternal twins and have found that identical twins are more similar in terms of aggressive behaviors than fraternal twins. Even identical twins separated at birth are more likely than fraternal twins or full siblings to become involved in criminal activities. These kinds of studies seem to support a genetic predisposition to antisocial behavior. The critical two words: "seem to."

Here is the hooker. What researchers find is limited to what they look for or ask. Studies are often large and impersonal. By large it meant studies of documented characteristics of hundreds, even thousands of subjects. Such studies are too large to allow for lengthy neuropsychiatric assessments of the subjects, much less of their families. Interviews in very large studies tend to be formulaic and conducted by trained interviewers rather than experienced clinicians. They gain in uniformity what they lack in the flexibility necessary to pursue areas of particular interest when they come to light. Subjects fill out checklists, as do interviewers and observers (e.g., parents and teachers). Investigators also rely on juvenile justice records or adult criminal records. Such studies allow for sophisticated statistical analyses. More often than not, they confirm that identical twins or fathers and sons are more likely than nonbiologically related relatives to get into hot water. The question is, why?

The answers to that kind of question depend not only on the records one locates but also on the time one spends interviewing the subject and relatives and the detail of the questions one asks. If one asks only whether a father, sibling, or another relative ever had trouble with alcohol or with the law, or even with mental illness, or if one looks only at arrest records, one will often find the names not only of parents but also of the defendant's "sisters and his cousins and his aunts" (Gilbert and Sullivan). However, one cannot simply ask about mental illness. The answer to that is usually "no." One must take the time to inquire about relatives who were "going and going and going," "too loud," "too talkative"; "too suspicious"; "too controlling"; relatives who were "performers," "tycoons," "big spenders," or "gamblers."

Having identified such relatives, one must then ask in greater detail about that person's behaviors. In that way, the researcher or clinician is more likely to come upon a family history of manic or hypomanic, or even psychotic signs and symptoms in relatives. After gathering such information, the next question must

be “who else in the family . . . and who else?” Suppose one takes the time to ask about people in the family with “moodiness,” “depression,” “suicide attempts,” “periods of isolation and withdrawal,” “over-suspiciousness,” “episodes of ragefulness,” as well as “alcohol” or “drug” problems. In that case, one is more likely to uncover a hitherto unknown family history of severe mental disorders that manifested themselves as aggressive antisocial behaviors and landed them in jail. Many of the relatives of the murderers the author has evaluated had documented family histories of severe psychiatric illness when an interviewer took the time to look for these data. Many had been imprisoned. Similarly, when taking a perpetrator’s medical history, one cannot settle for “Any serious accidents”? If the answer is “none,” one must pursue the topic (e.g., “How about bicycle accidents”? “Car accidents”? and “Falls”?). Any positive responses must be followed by “When else”? And “When else”? Ask. Look for scars on the face, head, or arms and the back, legs, the soles of the feet, the buttocks, and even on genitalia.

The secret is time. It takes much interviewing and record reviewing to uncover the extensive psychiatric and familial characteristics of perpetrators and their first, second, and even third-degree relatives. It takes more time to dig up the institutional records or find other family, friends, and relatives who can supplement and support indications of severe psychopathology and abuse in several generations of family members. Many of these psychiatrically impaired family members have come into conflict with the law at one time or another. That does not mean that the family carries a “warrior gene” for violence or criminality. It is tempting to settle for what one can get quickly and en masse (e.g., arrest and birth records). Extensive record review-based studies are a bit like buying in bulk at Walmart. Lots and lots of stuff, but the quality of the merchandise is pretty uniform. Now Tiffany is a different story. You pay a lot for a unique bauble, but boy, oh boy do you take your time studying the facets of those tiny jewels. Are there flaws? You will need a magnifying glass.

Some researchers who deal primarily with large cohorts or esoteric genetic concepts try to bring their studies to life with a colorful clinical example. Such was the case of Jeffrey Landrigan. Landrigan had twice killed and was sentenced to death in Arizona. After lengthy appeals regarding the failure of his lawyer to develop mitigating evidence, Landrigan was put to death. His case was used recently in scientific publications to illustrate the genetics of violence. He was said to have been adopted at birth into a loving middle-class professional family. The researchers stated that he was nevertheless a particularly troublesome child from the beginning. They said that even within this lovely family, his behavior progressed from temper tantrums at 2 years of age, abusing alcohol at 10 years of age, being arrested for burglary at 11 years of age, abusing drugs as a teenager, to killing his first victim at age 20 years. After escaping from prison, he again committed murder and was sentenced to death.

By chance, another inmate noticed that Landrigan bore a striking resemblance to another career criminal who also abused drugs and killed twice. This man turned out to be Landrigan's biologic father. With a bit more inquiry, the researchers learned that Landrigan's grandfather had been an "institutionalized criminal," but the nature of the institution remained a mystery. Alas, upon discharge from the "institution," grandpa was "shot by the police." According to the researchers, Landrigan's great-grandfather was "a notorious bootlegger." Now from bootlegging to murder is a long stretch (literally and figuratively). Nevertheless, the original researchers stated that Landrigan's case documented not just the intergenerational transmission of violence but also how "the adoption design separates the genetic influences of the biologic parents from the environmental influences of the rearing home." It did not.

At the beginning of Landrigan's trial, his lawyer had done little if any work investigating either his birth history, his medical history, or even his family history. In court, Landrigan was obstreperous, repeatedly interrupting his lawyer and boastfully telling the judge to go ahead and sentence him to death, which the judge obligingly did. Several accounts of Landrigan's behavior in court suggest that he was in an excited state and could not keep his mouth shut except to interrupt his lawyer and challenge the judge.

After the trial, Landrigan calmed down enough to realize the consequences of his court behavior and gathered mitigating evidence with the help of public defenders. His initial appeal for postconviction relief, based on his first lawyer's failure to present any mitigating evidence at all, was "summarily denied" by the Arizona Supreme Court. Eventually, in 2005, the United States Court of Appeals, Ninth Circuit, agreed to hear the petition of ineffective assistance. They stated, "We conclude Landrigan has raised a colorable claim that his counsel's performance fell below the objective standard of

reasonableness and that he was prejudiced by their errors." They deemed Landrigan's initial trial attorney ineffective because "Counsel is not deficient for failing to find mitigating evidence if, after a reasonable investigation, nothing has put the counsel on notice of the existence of that evidence . . . In this case, however, the initial investigation did reveal potential mitigating evidence . . . in addition to the evidence described above . . . Counsel did little to prepare for the sentencing aspect of the case."

A psychologist, who had interviewed Landrigan pretrial, recommended additional testing, but Landrigan's attorney failed to authorize any follow-up tests. The court also cited potential mitigators that the original defense attorney had evidence that Landrigan's birth mother was alcoholic and drug-addicted during her pregnancy with him and failed to inform the court. Furthermore, she did not give him up at birth but rather attempted to raise him until Landrigan was 6 months old, a crucial developmental period. She then abandoned him at daycare. One day she just did not bother to pick him up. Thus, Landrigan's adoption was not at birth. The state took custody of him and, at 8 months of age, he was adopted. However, further investigation brought to light the mythology that he was "adopted at birth into a loving middle-class professional family and was nevertheless a particularly troublesome child from the beginning." The court continued, "Landrigan began drinking at an early age because his adoptive mother was an alcoholic (at times consumed a fifth of vodka) and would walk around nude in front of him . . ." According to court records, she would frequently slap him and once even hit him with a frying pan. There was strong evidence that Landrigan suffered from severe psychiatric illness (i.e., Landrigan overdosed in class in eighth or ninth grade). After his trial, according to court records, Landrigan did undergo a thorough neuropsychological evaluation (which concluded) the concurrence of the factors mentioned above—Landrigan's genetic makeup, in utero exposure to teratogenic substances, early maternal rejection, and his troubled interactions with his alcoholic, sexually inappropriate, abusive adoptive family—resulted in disordered behavior that was beyond the control of Mr. Landrigan . . . and left him unable to function in a society that expects individuals to operate in an organized and adaptive manner. Thus, spoke the court. After his trial, Landrigan's appeals attorney arranged for a neurologic examination by Pamela Blake MD, at the time, an assistant professor of neurology at Georgetown. According to her report, Landrigan's mother "would come home from work and start drinking; she would drink until she would pass out on the couch." Dr. Blake stated, "The neurologic examination indicates several abnormalities consistent with impairment of the frontal lobes of the brain. The frontal lobes control higher level ("executive") function, impulses, regulation of behavior, and actions. . . . Numerous studies of brain function have demonstrated a correlation of this type of brain disorder with repeated

aggression." Dr. Blake documented "paratonia in all four extremities . . ." "inability to perform three-step hand movements (The Luria)," and "abnormal antisaccade functions." All of the above are signs of significant frontal lobe dysfunction.

Eventually, Landrigan's case reached the Supreme Court of the United States, where his death sentence was confirmed by a five to four majority. However, Justice Stevens wrote an eloquent dissent. Stevens said, "Significant mitigating evidence that may well have explained respondent's criminal conduct and unruly behavior at his capital sentencing hearing was unknown at the time of sentencing . . . correspondent's counsel failed to conduct a constitutionally adequate investigation."

On Tuesday, October 26, 2010, Jeffrey Landrigan was put to death. During the week preceding his execution, the sentencing judge from his initial trial told a clemency board that she would have given him a lesser sentence had she been aware of the brain damage caused by his mother's heavy drinking while pregnant and had she known of his turbulent childhood. She said, "The death penalty, in this case, is not appropriate and never has been." The clemency board reportedly split on whether or not to advise Arizona's Governor, Jan Brewer, to commute Landrigan's sentence to life without parole. She did not.

The author of this chapter chose to include this case study for two reasons: First, it illustrates the ease of dismissing violent defendants as inherently evil. Second, it calls into question the existence of a "warrior gene" that trumps the effects of a nurturing upbringing. The author's research team has evaluated hundreds of extremely violent individuals, most of whom came from chaotic, violent households. More critical, careful examination of first- and second-degree relatives usually revealed a family history of severe mental illness (e.g., bipolar disorder, psychoses, intrafamily violence, and physical or sexual abuse). Unfortunately, like the Landrigan case, many of the patients, particularly the men abused by fathers or mothers, withheld these data. The author is currently working on just such a case. She has seen murderers who go to their executions rather than reveal their mothers' and fathers' brutal, often sexually abusive behaviors. In two cases, families threatened to cease visitation if the person revealed the sexual abuse. One family cut off all communication with their son when he revealed his extraordinary physical and sexual abuse. Their son's death sentence was commuted, but he has not seen his parents in years. Because of confidentiality, the author has been obliged to remain silent in most of these cases.

This case was also chosen because, more often than not, what looks like a genetic transmission of violence is, instead, a predisposition to severe mental illness or a history of repeated CNS trauma that on clinical evaluation indicates frontal or temporal lobe/amygdaloid abnormalities. Landrigan had

frontal lobe abnormalities. Violence, child abuse, and mental illness are handed down from generation to generation, and thus, on the surface, violence appears to be genetic. Identifying these constellations is a mystery to be solved. Combinations of intrinsic and extrinsic interactions perpetuate what looks to outsiders like a simple genetic trait. The authors' team has encountered family after family to whom they can trace intergenerational mental illness, violence, child abuse, and institutionalizations. State prisons and county jails appear in the histories of violent families much as Harvard and Yale appear in the histories of intellectual/upper-middle-class families. Certainly, genetics plays some role in both pedigrees, but DNA is rarely the whole story. (Of note, one of the protective factors from violence is intelligence quotient [IQ].)

In the middle of the 20th century, at least partly in reaction to Lombroso's earlier theories that criminals represented a degenerate biologic phenomenon, investigators looked almost exclusively at society for explanations of criminality. The past half-century has seen an almost 180-degree about-face in the study of violence and criminality, as investigators have turned back to biology to explain deviance, especially violence. Advances in the so-called "hard" sciences (e.g., genetics, biochemistry, cellular biology, neuroanatomy, and neurophysiology) have increased the ability to identify, measure, and even visualize biologic similarities and differences among people thus encouraging this direction of research. Studies of the relationship of such neurochemicals as serotonin, norepinephrine, dopamine, vasopressin, GABA, glutamates, and nitric oxide to aggressive behavior in animals have encouraged similar studies in humans. Initially, the finding of a relationship between low cerebrospinal fluid (CSF) 5-HIAA (a metabolite of serotonin) and impulsiveness and aggressiveness in humans seems to shed light on why some individuals are more aggressive than others. Studies of men depleted of tryptophan, the amino acid precursor of serotonin, have indicated that they become more aggressive in a laboratory setting than men not so deprived. Of note, those men with a tendency toward hostility as measured on an aggression questionnaire reportedly responded more aggressively to tryptophan depletion than did nonhostile men. Chimpanzees with high blood levels of serotonin are reportedly nicer to their peers and more likely to groom them.

However, the relationship between serotonin levels and degrees of aggression is not simple. For example, a study of young (7 to 11 years old) aggressive boys with attention-deficit/hyperactivity disorder (ADHD) revealed a *greater* prolactin response to fenfluramine (i.e., greater serotonergic responsivity) in aggressive than in nonaggressive boys. In addition, a study of blood serotonin levels in adolescents diagnosed with conduct disorder reported that those with early-onset

maladaptive behaviors had *higher* blood serotonin levels than later offenders and that blood 5-HT correlated positively with ratings of aggressiveness.

Researchers included environmental factors in a study of the relationship of brain 5-HIAA levels in infants to subsequent behaviors. Clarke and colleagues followed a sample of children for their first 30 months of life and found only a modest correlation between 5-HIAA and aggression. In contrast, they found that environmental factors such as poverty and poor family cohesiveness were strongly associated with behavior problems at 30 months of age. Another study documented a relationship between low socioeconomic status, low prolactin response, and increased aggression. Finally, a meta-analysis of 39 studies linking 5-HIAA levels to violence in humans found that psychiatric patients as a group, whether violent or nonviolent, had similar 5-HIAA levels. The mean 5-HIAA level in both violent and nonviolent patient groups was lower than the mean level in groups of normal, healthy volunteers. Thus, serotonin levels may prove to be indicators of overall psychopathology that only occasionally manifest as aggressiveness.

One of the most critical and influential genetic studies was Brunner's 1993 report of a family in the Netherlands in which five generations had behavioral disorders, including arson, rape, exhibitionism, and attempted suicide. In addition, many individuals had been aggressive. Each affected family member had defective gene coding for monoamine oxidase A (MAOA), causing increased serotonin, norepinephrine, and dopamine. As these affect cognition and behavior, some refer to this gene as the "warrior gene." Only the male children of mothers carrying the abnormal gene showed behavioral abnormalities.

Piton and colleagues reported on a French family with a similar genetic abnormality and several family members suffering from various behavioral abnormalities. Piton reported that several affected males had cognitive difficulties, a 7-year-old boy was autistic, impulsive, and aggressive, and two maternal uncles had severely delayed psychomotor development and required placement in a special needs school. They, too, had autistic features, could not read or write, and were given aggressive outbursts. Of note, both of these family members were maltreated and sexually abused as children.

Since discovering the MAOA genetic abnormality, some clinicians/researchers have coined the term "Brunner Syndrome," designating the MAOA abnormalities as a recessive X-linked disorder characterized by impulsive, aggressive behaviors, and mild retardation. However, others have taken issue with this phenotypic concept because of the wide variety of signs, symptoms, and behaviors reported to exist among individuals carrying this MAOA abnormality.

Another gene, the serotonin transporter gene, has been associated with behavioral problems and with several different psychiatric disorders. Studies have focused on the short and long types of alleles of the serotonin transporter gene. People carrying the short allele appear to have lower-than-normal serotonin

levels in their blood. In addition, some studies have reported a greater predisposition to aggressiveness in individuals with low cerebrospinal levels of serotonin.

Dopamine, another catecholamine neurotransmitter, influences many mental functions, including cognition and emotion. The dopamine receptors belong to the family of G protein-coupled receptors (GPCRs). DRD1-type receptors are associated with stimulatory function, and DRD2-type receptors are generally associated with inhibitory functions. Investigators have identified more than 200 polymorphisms in the sequencing of this gene. Variants of the DRD2 gene are associated with alcoholism and addictive disorders, mood disorders, and psychotic disorders. In addition to genes, many other biopsychosocial influences and constellations of influences contribute to a violent lineage. Notably, although each cell carries the same load of genes, when, where, and how a gene will be "turned on" (i.e., activated) depends in great measure on environmental stimuli.

One of the most complex genetic studies illustrating the above is that of Hexuan and colleagues. They examined the possible relationships between youth delinquency and violence and 403 variants of 39 genes against what they termed high/moderate levels of social control in contrast to low levels of social control (i.e., high/moderate parental attachment vs. low parental attachment). Their theoretical underpinning was that changes in environmental conditions could influence the expression of genes related to different phenotypes in both animal and human studies.

They found that estimates of the total variance in serious delinquency attributable to the 403 SNPs were, in and of themselves, nonsignificant at the 0.05 level. The researchers then examined the collective genetic contribution of the 403 SNPs under low social control (LSC) compared with high/moderate social control (HMSC). They found that genetic risk for delinquency and violence was significantly greater for subjects weakly attached to parents and school and loosely disciplined by them. In addition, living in lower-income neighborhoods also increased the genetic risk for delinquency and violence. In short, their analysis showed "significant interactions of aggression-related genetic variants and socio-environmental variables . . . favorable social conditions are associated with smaller collective genetic contributions whereas adverse social conditions are associated with greater genetic contributions to adolescent delinquency and violence." This association amplifies when we consider the nature and interactions of child abuse with neuropsychiatric variables.

PSYCHOPATHY

To this author's mind, the concept and subsequent reification of the diagnosis "psychopathy" hamper the understanding of criminality and violence. Robert Hare spearheaded the term when, in 1970, he created a checklist of behaviors (based

in part on Hervey Cleckley's book, *The Mask of Sanity*), combinations of which Hare believed characterized a psychopath. He subsequently revised and updated the list. The list includes such items as "grandiose sense of self-worth," "need for stimulation," "promiscuous sexual behavior," "impulsivity," and "many short-term marital relations" as well as "early behavior problems," "shallow affect," "juvenile delinquency," "revocation of custodial release," "lack of realistic long-term goals," and "criminal versatility." Then come a series of clinically subjective criteria (e.g., "callous lack of empathy," "cunning manipulation," "failure to accept responsibility for one's own actions," "lack of remorse or guilt," and "irresponsibility") some of which come under the rubric of "pleading not guilty." Unfortunately, there is little guidance on how to ascertain cunning or callousness. What follows is a group of characteristics typical of many offenders with frontal lobe dysfunction, such as "poor behavioral controls," "impulsivity," "irresponsibility," and "shallow affect."

In reality, the items above, and their combinations, cover a multiplicity of different disorders. According to Hare, in many cases, one need not even meet the patient. Just rummage through his records to determine what items seemed to fit. Nonsense.

To this writer's mind, psychopathy and its synonyms (e.g., sociopathy and antisocial personality) are lazy diagnoses. As a result, the authors' team has seen scores of offenders dismissed as psychopaths. However, detailed, comprehensive psychiatric, neurologic, and neuropsychological evaluations have uncovered many signs, symptoms, and behaviors indicative of such disorders as a bipolar mood disorder, schizophrenia spectrum disorders, complex partial seizures, dissociative identity disorder, parasomnia, and, of course, brain damage/dysfunction.

Almost 20 years ago, this author evaluated a jittery, jumpy prisoner who had killed a policeman and whose psychiatric, neuropsychological, and neurologic examinations were consistent with frontal lobe dysfunction. Nonetheless, he was advised to plead guilty and was sentenced to death. He was dismissed as a psychopath. Almost 20 years later, he was lucky enough to have a very senior, experienced appeals attorney assigned to him, a man who read our old reports and wondered why they had not been introduced at trial, at sentencing, or at least on previous appeals. We re-evaluated him, and the signs of CNS dysfunction were even more severe than when we first saw him. However, this time, we obtained an fMRI. Figure 28.2–1 shows that this man had diffuse cortical atrophy, the most serious of which was orbitofrontal thinning (see Figs. 28.2–1 and 28.2–2).

FIGURE 28.2–1. Analyzed by Ruben Gur, Ph.D. (Courtesy of Ruben C. Gur, University of Pennsylvania, Philadelphia, PA.)

The mish-mash of different characteristics listed in the psychopath checklist has encouraged otherwise impeccable researchers, using sophisticated technologies (e.g., MRI, PET, and fMRI) to lump together criminals under the label "psychopaths" and compare them to noncriminals. Some have reported at least two different types of brain function or dysfunction in their psychopathic samples. The concept of psychopathy as described by Cleckley and "measured" by Hare just does not work. Nevertheless, in the experience of the authors' research team, just about every violent criminal they have ever examined has been diagnosed psychopathic or antisocial at one time or another. One of the criteria for diagnosing psychopathy is having been designated "conduct disordered" as a youngster. Many children labeled as having a conduct disorder have had many of the same psychopathologies as adult criminals. Thus, "conduct disorder" diagnosed in children smoothes the way to diagnosing psychopathy in adulthood. Unfortunately, clinicians use these terms indiscriminately to designate individuals young and old whose behaviors are unpleasant or dangerous and whom examiners would prefer to spend as little time as possible interviewing.

ENVIRONMENTAL INFLUENCES ON AGGRESSION

Intrauterine and Perinatal Factors

The position in utero of animals within a litter may influence behavior. For example, female mice that develop in utero between two males are more aggressive after birth than those positioned between other females. Thus, animals from the same litter who have shared the same uterus at the same time have not had identical prenatal environments. Maternal stress during pregnancy can affect the behavior of offspring long after delivery.

FIGURE 28.2–2. Analyzed by Ruben Gur, Ph.D. (Courtesy of Ruben C. Gur, University of Pennsylvania, Philadelphia, PA.)

In humans, there is strong evidence that different kinds of noxious prenatal influences ranging from minor viral infections to maternal anxiety and psychological stress correlate with childhood maladaptation. There is strong evidence regarding the adverse effects of maternal malnutrition, alcoholism, and other noxious substances on fetal development and subsequent postnatal social and intellectual functioning. There is a higher prevalence rate of histories of perinatal problems in the delinquent versus nondelinquent populations. Given the vicissitudes of life in utero and at birth, one should not conclude that even temperamental styles such as “emotionality” and early activity levels necessarily reflect genetic endowment. The pregnancies of mothers who release their children for adoption cannot have been uncomplicated. There is evidence that

even heightened maternal cortisol due to stress affects the fetus and increases aggressiveness postnatally. Thus, the adopted away children of criminal parents, in all likelihood, had rocky in utero experiences.

Moreover, the genes such children inherited may well have predisposed them to various mental disorders other than psychopathy or antisocial personality disorder. In other words, behaviors that at first appear to be genetic may not be.

Nurturing

Nurturing affects temperament. Animals bred to have a gentle nature, if cross-fostered by adult females of a violent strain, will become more aggressive than usual. Mice reared in their fathers' and mothers' company become more aggressive than those raised only by mothers. Isolation during critical postnatal developmental periods can engender aggression in otherwise gentle animals. Thus, there is evidence from animal studies that innate temperament can be modified and that the quality of parenting and environment influence adult behaviors.

Early experiences have potent and enduring effects on physiologic and psychological development and, therefore, on behavior. Social adaptation depends mainly on adequate parenting during the first days and weeks of life in animals and humans. Although many reptiles can defend themselves shortly after birth, most mammals require parental protection for more extended periods. And humans? Even longer.

In humans, the first months and years of life are periods of extreme vulnerability, emotionally and biologically. Although the auspicious neuropsychiatric and emotional cards nature deals with at birth may seem to predict a successful game, experiences can reverse what should have been a winning hand under other circumstances. For example, research on attachment has shown that how mothers and infants interact during the earliest weeks and months of life affects subsequent aggression in the child. Remember Landrigan. Adequate mothers sense their children's needs and respond appropriately. However, mothers who lack tenderness and harbor suppressed anger toward their babies seem to engender insecure, avoidant attachments. Avoidant attachment correlates with subsequent aggressive behavior in boys.

Poor mothering takes its toll intellectually as well as behaviorally. Infants with disorganized attachments lag in their mental development irrespective of maternal IQ. Lyons-Ruth and colleagues found that the combination of early disorganized attachment and lags in cognitive development were associated with aggressive behaviors at 7 years of age. Thus, it would appear that poor mothering affects brain function itself.

ABUSE

Copious literature attests to the association of maltreatment in childhood and aggression in adolescence and adulthood. The extent to which the category of "abused" children overlaps that of children who have suffered attachment disorders and the independent influences of each are difficult if not impossible to measure. Whereas complete emotional deprivation of infants leads to severe depression and even death, lesser degrees of neglect correlate with poor peer relationships and aggressive behaviors. Some research suggests that neglect can be as powerful an influence on the development of aggression as physical abuse. Research has repeatedly shown that severe ongoing physical or sexual abuse is associated with subsequent extremely violent behaviors.

Early repeated sexual abuse seems to have especially devastating consequences. Grotesque sexual crimes have been committed by men who, as children, experienced extraordinary sexual abuse. Many have been so traumatized that they do not remember the torture.

How does severe abuse and neglect engender aggression? The answer is not straightforward, and we must glean it from various studies and observations. What is clear is, for humans, maltreatment affects every aspect of functioning—cognitive, emotional, and physiologic.

A typical result of abuse or neglect is direct injury to the CNS. Almost any CNS trauma may be associated with hyperactivity, emotional lability, diminished intelligence, poor judgment, and impulsiveness. Children with these kinds of deficits and vulnerabilities have trouble thinking ahead or understanding the consequences of their behavior. In the author's studies of violent juveniles and adults, medical histories were so replete with evidence of CNS insults that it was usually impossible to ascertain the exact cause of brain dysfunction. We know that injuries to the CNS, even apparently mild concussions, can have a cumulative effect neurologically, cognitively, and behaviorally. Extremely violent juveniles have often experienced multiple accidents and injuries, many of them inflicted by those entrusted with their care. Of note, a recent study of perpetrators of domestic violence reported neuropsychological impairments of their executive functions, memory, attention, IQ, and empathy. In the author's studies, they could not distinguish between children exposed to domestic violence and physically abused children since they went hand in hand in most cases. Examining the heads, bodies, limbs, and even genitalia will often reveal traumas that the subject/patient cannot recall or will not reveal.

Psychological and Cognitive Effects of Abuse

Maltreatment has psychological consequences. Abuse changes how we perceive the environment. Studies of animals and children have shown that one of the consequences of maltreatment is the development of hypervigilance. Defeat increases defensiveness in laboratory mice, and conditioned defensiveness is generalized to other situations and other opponents. Likewise, abused children

seem to become hypervigilant, repeatedly misinterpreting their surroundings and perceiving ambiguous stimuli as threatening. Once a response has been established or conditioned (e.g., hormonal or neurophysiologic response to fear-inducing stimuli), it is easily re-evoked by exposure to similar stressors. Such recurrent, maladaptive physiologic responses seem to play essential roles in the hypervigilance and retaliatory aggression of many severely abused, violent children and adults.

Child abuse also contributes to violence by diminishing a child's expressive skills. Severely abused children manifest specific kinds of deficits in verbalization. For example, abused toddlers are less able to use words that reflect their inner states or feelings than normal children. In addition, the tendency of abused children to repress or deny their painful feelings as well as the pain of others, their inability to articulate emotions, their emotional lability and impulsiveness, their tendency to distort reality and perceive threats where they do not exist, and their resultant tendency to put angry feelings into actions rather than words can become a relatively enduring adaptational style.

Modeling of Abusive Behaviors

We also learn aggression. There is sound experimental evidence that modeling plays a vital role in the development of aggressive behaviors in animals and children. We learn aggressive behaviors (as we do more adaptive behaviors) through reinforcement. One of the most important contributions to the current understanding of the role of reinforcement in the genesis of aggression is Patterson's observation that when children's aggressive behaviors are punished severely by parents, they tend to continue. Farrington also found severe physical punishment to be a significant antecedent of aggressive delinquency. Murray Strauss has documented the aggressive behaviors induced by corporal punishment. Probably the most powerful generator of aggression in animals and possibly in humans is the repeated infliction of pain. It is, therefore, no surprise that children who have been painfully physically abused tend to behave in more aggressive ways than their nonabused peers.

To summarize, child abuse contributes to violence in several ways:

1. It provides a model of behavior
2. It teaches aggression through reinforcement
3. It inflicts pain, a known powerful stimulus to violence
4. It creates neurophysiologic responses in the brain that both damage the brain and affect its functioning
5. It damages parts of the brain related to impulses and their control
6. It increases paranoia
7. It impairs cognition and the ability to make judgments and foresee consequences

8. It diminishes the ability to verbalize feelings
9. It interferes with the child's ability to empathize with the feelings of others
10. In the extreme, it leads to dissociation

In short, early ongoing child abuse is the most potent known generator of child, adolescent, and adult violence.

SOCIAL FACTORS AND VIOLENCE

Courtwright, in his trenchant analysis of the sociocultural contributors to violence in the United States, observes, "other things being equal, the total amount of violence and disorder in society is negatively related to the percentage of males in intact families of origin or procreation ." He goes on to say, "Families rather than governments are the first best defense against violent and disordered behavior." He points out that the particular mixture of demographic, cultural, and social characteristics of the American frontier, its surplus of young, unparented, unmarried men, its code of honor, its racist attitudes, its heavy alcohol consumption, its lack of religious convictions or practices, its devotion to guns, and its lack of an effective system of law enforcement formed a matrix for violence. Moreover, the closing of the frontier did not eliminate the "national self-image" in that, to this day, Americans continue "to think a manly man is someone with a gun and an attitude." Courtwright states, "Indeed, it is possible to think of the urban ghettos as artificial, unusually violent frontier societies—vice-ridden combat zones in which groups of armed, unparented, and reputation-conscious young bachelors, high on alcohol, cocaine, and other drugs, menace one another and the local citizenry, undeterred." At this time, the United States is far more violent than most Western European and Asian countries.

In addition to the availability of guns, what else promotes violence? Material poverty and extreme economic inequality are associated with homicide rates; this is true if one compares violence in states, cities, or neighborhoods within cities. Whether the significant contributing factor is socioeconomic inequality or racial subordination is academic. Violence, poverty, and racial subordination cluster together in the same populations. Being somewhat low on the socioeconomic totem pole is not so much associated with violence as living in *grinding* poverty. However, poverty alone does not seem to account for violence. Sociologists believe that a strong influence on criminality springs from "social disorganization," the lack of extended families to support youngsters whose families lack the stability to nurture them properly.

Numerous studies from various parts of the world have documented an association between low or low-normal IQ and violence. It would be necessary to stress that neither impulsivity nor low IQ is necessarily inherited. The wealth of data cited above attest to the potentially adverse effects on intelligence,

temperament, and behavior of impaired attachment, child abuse, neglect, and neurologic insults. In summary, the kinds of external stressors and intrinsic vulnerabilities that play roles in individual violence (e.g., physical discomfort, lack of nurturance and stability, CNS dysfunction, increased rates of mental illness, and child abuse) are more pervasive in disadvantaged communities. They contribute significantly to the disproportional rate of violence in the most impoverished sectors of society.

BRAIN DYSFUNCTION AND VIOLENCE

The part of the human brain thought to be involved in sexual and aggressive drives lies deep in the areas often referred to as the *limbic system*. The areas of this region thought to be most closely involved in aggression are the hypothalamus, septal area, and amygdala. Lesions, electrical stimulation, and infusion of neuroactive substances into the amygdala have shown that those nuclei are necessary for animals to experience particular emotions, especially fear. In species as diverse as crocodiles and humans, the amygdala processes fear, stimulation of which elicits defensive, aggressive responses.

Humans can usually perceive a threat, assess it intellectually, and choose to act or not to act in response to the stimulus. The PFC allows humans to exercise some control over their instinctive responses. The reflexive, violent response of some repeatedly aggressive individuals to innocuous stimuli is often the result of paranoid misperceptions and immediate defensive responses. In the late 1960s, Vernon Mark and Frank Ervin in *Violence and the Brain* explored the association between electrical activity in the limbic system and aggressive behaviors in humans. Using electrodes inserted deep in the brains of recurrently aggressive subjects, they found abnormal electrical activity corresponding to episodic rages. Whether directed aggression can occur during a complex partial seizure generated within the limbic area remains a subject of debate among neurologists. However, investigators have reported aggressive behavioral changes in individuals with a damaged medial temporal lobe or brain tumors in the limbic system. Violence can also occur interictally in patients with epilepsy. The author's studies have indicated a high prevalence of various psychomotor symptoms and paranoid ideation in violent delinquents.

The serial killer, Arthur Shawcross, demonstrates the importance of obtaining a complete medical history and account of the offense(s). Shawcross had many dissociative symptoms and a history of early severe ongoing sexual abuse that could easily have influenced the rapes and murders he committed. However, a history of several severe blows to his head, evidence of which could be documented by the scars and indentations on his head, suggested the possibility that brain dysfunction might have contributed to his episodic violence. A detailed history of the offenses (i.e., what happened before, during, and after the offenses) revealed Shawcross's confusion and impaired memory of the acts. As Shawcross recalled, before the acts, he would be having a pleasant conversation with his victim. Then, out of the blue, something she did or said provoked a reaction. In response, he would start to sweat, and everything would turn bright white. A struggle would ensue and, shortly after that, his hands would close around his victim's neck. Shawcross would subsequently fall into a deep sleep. Hours later, he would awaken in his car, only to find a corpse in the seat beside him. Realizing what he must have done, Shawcross would drive around, seeking a place to hide the body. At least once, on a return visit to the body, he cut the victim's genitalia and ate them. Individuals with temporal lobe lesions have committed similar acts of extraordinary and bizarre viciousness (The psychiatrist for the prosecution opined that Shawcross's cannibalism was simply an effort to destroy the DNA. Surely, doctor, there must have been an easier way!)

The above account—an aura (bright lights and sweating), a misremembered act, followed by a deep sleep—had the hallmarks of a psychomotor or complex partial seizure. A review of prison records showed that Shawcross had been found unconscious in his cell on numerous occasions. An MRI of his brain revealed a cyst in the amygdalar area on his right temporal lobe and scars in the white matter of both frontal lobes. A single, routine electroencephalogram (EEG) was normal. The physicians advised his attorneys to obtain a more sophisticated neurologic assessment, including a quantitative EEG with hyperventilation and photic stimulation, but they refused. They chose instead to pursue a defense of dissociation. Such a defense is a big mistake when clear evidence of brain damage exists. Juries are more likely to believe what they can see (e.g., MRI and EEG printout). They can neither see nor hear dissociative states. For this reason, we try to videotape interviews in all cases in which dissociation plays a role. Predictably, Shawcross was tried, found guilty, and sentenced to life in prison for 10 of the 11 murders he had committed.

Before going to trial for the one remaining murder, Shawcross's second attorney decided to obtain a quantitative EEG. It revealed spiking, not only in one temporal lobe but also in both frontal lobes. Despite these findings, this

new confirmatory evidence of complex partial seizures and their relationship to the crime in question, Shawcross's attorney advised him to plead guilty to the last charge, which he did. Given the offenses, Shawcross was destined to be institutionalized either in prison or in a hospital. The tragedy was the failure of the defense to educate the judicial system and the public about how damage to specific parts of the brain and early, ongoing sexual abuse can engender extraordinary, repetitive sexual violence.

A recently published computed tomograpbhy (CT) and MRI study of 287 male prison inmates, comparing 162 violent offenders with 125 nonviolent offenders (none previously diagnosed mentally ill), and 52 noncriminal controls reported that offenders displayed a significantly higher rate of morphologic brain abnormalities, with violent offenders having significantly more abnormalities than nonviolent offenders. Differences were statistically different for frontal/parietal cortex, medial temporal structures, third ventricle, and left but not right lateral ventricles. The authors concluded that their findings raised questions regarding the culpability of violent offenders with brain abnormalities.

PET and studies of regional glucose metabolism have revealed hypoactivation in lateral and medial zones of the PFC in individuals given to impulsive aggressive acts. Findings from neuropsychological testing of patients with known prefrontal lesions also support the significance of frontal lobe deficits evident on PET scans.

In short, studies from various fields suggest that many impulsive, aggressive individuals have abnormalities in the structure or function of the brain and in circuits that interpret outside stimuli and regulate emotional responses.

We now understand what we once called schizophrenia to be a multiplicity of different psychoses with different genetic constellations and biopsychosocial correlations. Similarly, we have enough data on the biopsychosocial differences between aggressive and nonaggressive offenders to separate them into specific diagnostic categories that go beyond mere "psychopathy." It is vital to cease cramming them all into the same cubbyhole of psychopathy, or antisocial personality disorder. A review of the behaviors of the patients Cleckley described in *The Mask of Sanity* reveals that most were manic or hypomanic, and today we would treat them with mood stabilizers. Here is yet another distinct group of patients heretofore also dubbed psychopaths.

SEVERE PSYCHIATRIC DISORDERS AND VIOLENCE

Whether mentally ill individuals are more violent than people in the general population has become a politicized question. Thus, perfectly reputable scientists have sometimes turned statistical and intellectual somersaults to find ways to prove that severely psychiatrically disturbed individuals are no more a threat to

society than the little old lady living next door. Unfortunately, while well-intentioned, these politically correct efforts can have dire consequences for psychotic, brain-injured, impulsive, and aggressive patients and their neighbors. They get discharged from mental hospitals only to find themselves frightened, alone, homeless, and confused. When made uneasy (often paranoid) by their surroundings, they often lash out to defend themselves against real or imagined threats and wind up in jail more often than in the therapeutic settings they need. Moreover, their aggressive, disordered behaviors in prison and hospitals often land them in solitary confinement, a setting known to induce psychosis in normal people and exacerbate it in the mentally ill.

There is no question in this author's mind that the thrust of the 1998 MacArthur Foundation's Violent Risk Assessment, namely that with few exceptions, discharged patients from mental institutions are no more dangerous than other persons in the general population, is simply wrong. Indeed, most individuals with mental illness are not violent. Unfortunately, however, studies worldwide from more developed and less developed nations indicate that violence is more common among seriously mentally ill individuals than among mentally healthy individuals. These findings should not come as a surprise. After all, severe mental illness often distorts perceptions, increases suspiciousness, is accompanied by extremes of emotion, and impairs impulse control. When the brain is not functioning correctly, humans often take umbrage quickly and feel an urgency to protect themselves at all costs. It is called paranoia. Moreover, paranoia is part of almost every serious mental illness.

Studies have found that the prevalence of violence is approximately five times higher in individuals who meet the diagnostic and statistical manuals' criteria for an Axis I diagnosis than in people not meeting criteria for serious mental illness. The prevalence of violence in individuals with schizophrenia, major depression, or mania/bipolar disorders was similarly high (i.e., approximately 11% to 13%). Individuals with alcoholism or other substance abuse reportedly commit violent offenses (i.e., 25% and 35%, respectively) more often than patients with schizophrenia or major depression alone. Those with the highest prevalence of violence are young lower-class men with substance abuse disorders or major mental disorders. Almost all the differences in prevalence between violent and nonviolent patients are due to psychosis. Patients reportedly are no more violent than anyone else when they are not actively psychotic.

In the February 2008 issue of *Psychiatric Services*, E. Fuller Torrey and Jonathan Stanley reviewed the critical literature published since the MacArthur report and challenged their significant conclusions in a dialogue with two of the report's authors. The MacArthur study followed 951 psychiatric patients ages 18 to 40 after discharge from state and university psychiatric inpatient units.

Torrey and Stanley reported that the prevalence of violent, sometimes murderous behaviors among discharged patients was high. Among the 951

discharged patients, 262 (27.5%) committed at least one violent act over a 41-week follow-up. This group was responsible for 608 violent acts; 1% of the violent acts were homicidal, and there were 6 victims of these murders. The homicide rates in the United States during the MacArthur study were at a peak, ranging from 8.2 per 100,000 to 9.5 per 100,000. In the most impoverished, minority populations, among young adults, the rates approached 200 per 100,000. These numbers pale compared to the homicide rate in the discharged patient sample which was over 600 per 100,000 population. Thus, the contention that discharged patients are no more violent than others from disadvantaged communities is not correct.

There is a debate over which Axis I diagnoses are most closely associated with violence. In a study of a Danish birth cohort, hospitalized patients diagnosed with schizophrenia had higher arrest rates for violent crime than did nonpatients. A recent paper on the neurobiology of aggression in schizophrenia suggests a possible role of the catechol-*O*-methyltransferase gene that is involved in the metabolism of dopamine. Others have reported that patients with affective disorders have even higher rates of violence after hospital discharge than those diagnosed with schizophrenia. Some have found the onset of antisocial behaviors to coincide with the onset of affective disorders in many patients. Many so-called antisocial youths have unrecognized bipolar disorders. Their wild, antisocial behaviors are often dismissed as part of normal adolescent development. A glance at Hare criteria for the diagnosis of psychopathy reveals a plethora of manic symptoms (e.g., glibness, superficial charm, grandiose sense of self-worth, and promiscuous sexual behavior). Thus, use of the PCL-R criteria can lead to serious misdiagnosis.

Other psychiatric disorders associated with episodic violence, although usually not considered in the differential diagnosis, include PTSD and dissociative identity disorder. Violent behaviors may occur in reaction to flashbacks in cases of PTSD and in cases of dissociative identity disorder. Most patients with dissociative identity disorder develop aggressive alternate personality states early in life. In these states, they experience the actual pain inflicted and develop stoic but enraged and aggressive coping styles or personality states to deal with the pain. Subsequent stressors or threats, real or perceived, may evoke a switch into these aggressive personality states. At such times, these individuals may lash out, physically or sexually, and even become homicidal. Patients with dissociative identity disorder are often partially or completely amnesic for their behaviors and may vigorously deny responsibility for violent acts. Their stories may change frequently during interrogations, depending on their personality states and on what each state remembers of an event. These kinds of patients tend to be dismissed as pathologic liars. Because forensic psychiatrists and psychologists rarely entertain dissociative disorders as part of their differential diagnosis, dissociative individuals are routinely misdiagnosed as episodically explosive,

simply antisocial, or as “pathologic liars.” Because they do hear voices in their heads, they are sometimes diagnosed with schizophrenia. Alcoholic offenders, who, because of brain damage, do not recall parts of their behaviors, fill in the missing spaces with varying stories. They, too, tend to be dismissed as liars.

Again, it is important to restate that most mentally ill individuals are *not* violent. However, they are more likely than mentally healthy individuals to act aggressively when stressed, especially if they have endured early, severe, ongoing maltreatment.

Differential Diagnosis

The differential diagnosis of violent behaviors is as broad as the fields of psychiatry, psychology, and neurology. The diagnoses of oppositional defiant disorder, conduct disorder, and antisocial personality disorder are hodgepodges that, as stated, cover a multitude of sins and a multitude of different kinds of signs, symptoms, behaviors, and combinations thereof. These categories if used at all should be thought of as interim designations on their way to proper diagnoses. Because violence toward others is the final common pathway of so many different kinds of neurophysiologic vulnerabilities and environmental stressors, the clinician faced with the task of diagnosing and treating a dangerously violent person must work hard. Every aspect of functioning—behavioral, cognitive, emotional, social, psychiatric, neurologic, neuropsychological, and environmental—must be investigated thoroughly.

There is no single treatment or intervention for violence because it has a myriad of causes. What is more, because so much violence is grotesque and abhorrent, the perpetrator often is dismissed as simply evil or bad. One need not be a clinician to make that diagnosis. Evil is not a scientific or medical term.

OFF-COLOR CRIME? VIOLENCE BY THE MEDICAL PROFESSION

How does one pick a color for psychiatrists and psychologists who participate in torture, even death of prisoners? It is known that at the time of the Second World War, American and Canadian doctors worked with the government on methods of getting prisoners to reveal what they knew. The use of mind-altering drugs, the effects of sensory deprivation, and other methods were not only suggested but also implemented by respected individuals in the medical profession. Psychiatrists and psychologists at other times have consulted with the military on how to train soldiers to kill. (It does not come naturally to healthy people.)

The current wars in the Middle East seem to have further degraded the morals and standards of some in the psychiatric/psychological professions. The role of psychologists and physicians in the Central Intelligence Agency’s (CIA)torture program has been likened to the four main qualities of behavior of the Nazi

doctors. The report of the 2014 U.S. Senate Select Committee on Intelligence Report on the CIA's Detention and Interrogation Program revealed that medical professionals (1) experimented on detainees; (2) perverted medical procedures, turning them into rape and torture (e.g., giving their detainees enemas of fluids and pureed food substances in the guise of feeding and hydrating them); (3) induced disease in their detainees; and (4) provided enough medical care to put their subjects into condition to be tortured again. Only two so-called professionals were named, James Mitchell and Bruce Jessen; however, they were assisted by anonymous MDs. The use of torture was encouraged by the head of the United States' C.I.A. (George Tenet).

Although most of this chapter is devoted to the study of violence and criminality perpetrated by physically aggressive criminals and by greedy, flamboyant white-collar criminals and Mafiosi, next to nothing is known about what enables trained professionals to indulge in such brutality. Did they experience some sort of high? Some sort of sexual excitement while torturing? What were their incentives? According to government and newspaper reports, one incentive, money, may have been the draw. The sum of $ 81,000,000 has been bandied about. Was wealth the lure? Does that mean that for the right price, anyone could be turned into a sadist or murderer?

The people who indulge in such atrocities without blinking an eye are the ones who should be studied, if only to learn how to keep everyone else from falling into that inhuman (or all too human) trap.

ETHICAL IMPLICATIONS OF WHAT IS KNOWN ABOUT VIOLENCE

The diagnostic evaluation of the violent and/or criminal person is a weighty responsibility. The diagnostic evaluation for purposes of determining guilt, innocence, or mitigating factors in murder cases is weightier still. It can mean the difference between life and death. Remember Landrigan.

Extreme violence, even in war, does not come naturally. Soldiers must be trained to kill.

Studies of delinquents and criminals have shown that they can often conceptualize moral principles but are unable to behave in accordance with them. Bioethicists and philosophers have maintained that true autonomy, that is, the ability to make reasoned choices, requires the capacity not only to identify and reflect on basic, instinctual desires and impulses, but also to control them, and thereby to do the right thing (i.e., act virtuously). Part and parcel of that precept, of course, is the capacity not to do the wrong thing. Unfortunately, not all brains have the same capacity to judge consequences and monitor and control behavior. Some people by virtue of birth trauma, emotional neglect, brain injury, genetic predispositions to mental illness, and exposure to abuse and violence—by virtue

of what the bioethicist Rawls has called “the natural lottery”—are more vulnerable to emotional lability, distortions of reality, and loss of impulse control than are those who, by chance, have drawn a better hand.

This chapter asks the question posed by bioethicists Beauchamp and Childress: Do recurrently violent people, at the time of their violent acts, “have the capacity to rationally accept, identify with, or repudiate a lower order of desire or preference in a manner that [was] independent of the manipulation of desire?” Virtue, as conceptualized by Aristotle in *Nicomachean Ethics*, may spring from an innate capacity to do the right thing. However, according to Aristotle, in order for a person to make use of this potential for moral action, this capacity must be cultivated actively. It must be exercised with the same perseverance, intensity, and training necessary to perform well athletically. Aristotle recognized that virtue also required mentors, and models for controlled behavior. The ethical question posed in this chapter is whether defendants at the time of their offenses could have acted virtuously, or whether the combination of psychopathology, frontal lobe dysfunction, and the ongoing exposure to violent models of behavior prevented them from thinking once, much less twice, about what they were doing? According to one of the authors’ subjects, “Ain’t no thinkin’ anymore . . . it’s a reaction.”

These data call for a re-examination of the outdated 19th-century definition of insanity (i.e., “. . . if the party accused was labouring (sic) under such a defect of reason, from a disease of the mind, as not to know the nature and quality of the act . . . or, if he did know it, that he did not know . . . (it) was wrong”). Queen v M’Naughton (1843). This rule limits the defense to cognitive insanity, although it is known that cognition plays a limited role in violence. In this author’s experience, some of her colleagues have taught defendants how to parrot the M’Naughton answers and thus have enabled them to go to trial and on to execution. Numerous well-trained psychiatrists have declared chronic schizophrenic and unalterably brain-damaged people to have been “sane” at the time of their offenses. Did their psychoses temporarily remit? Did their damaged frontal lobes function briefly during their frenzied act? Given the biopsychosocial impairments that are now known to underlie many criminal, violent acts, has the time not come for the neuropsychiatric professions to assist the judiciary in redefining the criteria for mitigation and insanity?

28.3 Borderline Intellectual Functioning and Academic or Educational Problem

Frank John Ninivaggi, M.D.

This section introduces one of the most *clinically oriented* and relevant portions of this textbook: recognizing and treating borderline intellectual and adaptive functioning (BIAF). BIAF proposes that IQ and adaptive functioning are both *well below average*. This section's psychiatric focus rests on variable patient presentations—clinical expressions. Clinical medicine is the broader perspective encompassed by psychiatry to improve quality of life.

Mental abilities and adaptive performance skills being *well below average* is a hidden risk factor. When the threshold below typical and into BIAF is crossed, significant slowness, risk, and potential disability burden emerge. These important facts are known. Researchers across the world continue striving to expand knowledge and services for this population.

Borderline functioning, however, is neither currently viewed as a formal disability nor as representing clear-cut deficits in intellectual and adaptive domains. Thus, "borderline intellectual functioning" (BIF) is not a formal fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) disorder; it is a condition. DSM-5 only vaguely defines it. Yet, *the condition may indicate the probability of risk with potential harm and loss in the future. Marginal overall functioning is problematic. The chances of risk are present but can be prevented or lessened if identified and managed*.

Mindful awareness of BIF enhances the higher reliability of both remedial anticipation and building resilience. Such prevention improves cognitive reserve and disengages the trajectory for

cumulative impairments to solidify along the developmental line. Screening and assessment for risk factors, especially early adversity, predispositions to vulnerability, and stressful adverse life outcomes thwart developing disorders. Identification and good clinical care reduce often-underestimated residual burden. Considerations about risk, risk reduction, and intelligent performance (not identical to measured IQ scores) are discussed since risk and risk interventions have a protective effect and open the way for support providing growth and development. Comprehensive treatments—a detailed part of this section—can take the borderline person over the marginal edge so that life functioning can improve. This approach maintains patient-centered values at the heart of quality medicine.

Protection averts loss and builds a fence around resiliency. However, the following question remains: While duly respecting the currently limited state of evidence-based literature regarding BIF, does identifying clinically significant risk and addressing it merit inclusion of the now diagnostic gray zone, BIF, in official DSM-5 diagnoses? Such inclusion would recognize the evolving knowledge base of neuroscience and psychiatry and the limitations of current diagnostic criteria.

I suggest vanguard trends in primary prevention—eliminating or reducing risk—merit broadening risk assessment by expanding diagnostic thresholds. This refinement would identify cases with incipient clinical significance. Therefore, this inclusion's broadened scope may accommodate the natural diversity inherent in a population's heterogeneity. It would not artificially exclude groupings of heterogeneous syndromes with inferred different pathophysiologic mechanisms. Recognizing that *designated cutoffs may be better understood as flexibly moving targets* than as tipping points may be more realistic. This expanded vision would reflect the enhanced developmental focus of DSM-5. The magnitude of the net benefit of this spectrum flexibility remains to be seen. It may include authorizing coverage and making possible needed clinical services. Identifying such needs and providing resources is the essence of a prevention model that may thwart, if not obviate, additional complications, including costs. Such harm reduction, therefore, is a clinically salient

goal of excellent medicine. More significant strides toward precision medicine remain an ultimate vision.

The condition now termed BIF should be understood to denote BIAF. This phrase should be its proper designation. This inclusiveness reflects a realistic developmental, clinical, and functional understanding and diagnostic notation of the whole child and person. It is consistent with conceptions and definitions of intellectual disabilities (IDs) held by the American Association on Intellectual and Developmental Disabilities (AAIDD) and put forth in the World Health Organization's ICD-10 International Classification of Functioning, Disability, and Health.

Over the last decade, BIF has continued to be underrecognized. Lack of formal diagnosis makes reimbursement, qualification, and easy access to services sorely lacking. Thus, the trend of connecting BIF (has no qualification) and mild ID (has full qualification) in one grouping is now becoming more common, notably in Europe. This tendency is now prevalent because of the imprecise ability to distinguish between the two and their inescapable "overlap." Both may be developmental variants exhibiting substantial pleiotropy across intelligence boundaries. Many phenotypes—having one source with multiple outcomes—in intelligent functioning are to be expected and viewed as "the nuanced norm."

Epigenetics, molecular mechanisms regulating gene activity, is the complex interplay between genes and their products establishing the divergence of phenotypes. Studies show the tremendous diversity in the epigenome that allows for shifts in developmental trajectories. Epigenetic mechanisms are the basis of adaptation to environmental challenges. An optimistic interpretation would be that such pleiotropy could point to developmental risk pathways amenable to common therapeutic interventions. Perhaps, pleiotropy represents factors that reduce cognitive reserve or nonspecifically disrupt brain development. In either case, how phenotypic specificity occurs remains an open question.

A "borderline intellectual disability" diagnosis as part of "intellectual developmental disorders" (IDDs) would address the gaps in the DSM-5 BIF descriptions. Also, the qualification for needed services and

reimbursement would follow. Untapped abilities and newly developed skills can further social participation. This is more than a human right; *it is the right to be human to the fullest extent.*

The international community has taken a striking lead in research and has proposed bold initiatives about pursuing serious investigations concerning BIF's significance. A recent summary paper from Spain in 2013 by a 19-member panel documents the Catalan association's Nabiu (ACNabiu) CONFIL project begun in 2007. This comprehensive study funded by the Department of Health of the Catalan government draws from CONFIL 1, 2, 3, and 2010 conclusions. Using evidenced-informed clinical data, it advances BIF as a priority condition demanding an international consensus. This accord comprises construct, operational criteria, screening, coding, incidence, prevalence, effective interventions, and an integrative care model centered on the individual while also providing for the family and extended social, educational, economic, occupational, and environmental considerations. This wealth of research trajectories demands further expansion.

This movement is actively growing in Europe and internationally. For example, in the United Kingdom, Angela Hassiotis and colleagues continue to work on BIF, documenting significant future risks: a range of adverse health consequences and mental health disorders. In Spain, R. Martinez-Leal, and in the Netherlands, J. Weiland, P. Nouwens, I. Woittiez, and their colleagues continue unearthing quality-of-life difficulties for persons with BIF and mild ID. This prolific work has highlighted the heretofore underestimated intersection, overlap, and shared needs of persons with BIF and mild ID. Recognition and policy inclusion have immense practical value in establishing eligibility for needed services. For example, adverse childhood events, coupled with lower cognitive profiles, surround the newly recognized prevalence of substance abuse and offending behaviors in these populations. The toll on individuals and families, plus the economic burden on society, is sobering. Therefore, risk management includes harm reduction and an untapped plethora of treatments facilitating progressive development.

INTELLECTUAL FUNCTIONING

Whether intelligence is best regarded as a single general capacity (i.e., “g”) proposed by Charles Spearman in 1904 and 1927 or as a range of separate, modular capabilities as first proposed by Thurstone in 1938 remains an open question. No consensus prevails. Contemporary theorists view intelligent cognition as an array of abilities, strengths, and weaknesses across multiple information processing and adaptive domains. The Cattell–Horn–Carroll (CHC) theory of intelligence, one of the dominant models in modern psychology, reflects this view.

The very nature of intelligence and its multiple definitions lingers in an unsettlingly intriguing flux—the ongoing subject of intensive research. The “IQ” test was developed by Alfred Binet around 1900. As far back as 1916, American psychologist Lewis M. Terman recognized the spectrum of intellectual capacities and formalized the notion of “borderline” intelligence to indicate those who not only functioned *well below average* but were also not intellectually disabled. The emergence of rapidly developing disciplines such as cognitive science and its subspecialties is devoted to exploring the meaning and pragmatics of all aspects of human cognition (e.g., conceptual, emotional, social, practical, and motivational) bears out the central importance of these undeniable epistemologic realities. The role of powerful emotions such as envy in eliciting comparisons of superiority and inferiority cannot be overlooked. Envy triggers cognitive discrepancies, distinctions, and emotional dysregulation that attest to this. Here, envy is the bitter realization that someone else has more of something good (i.e., an ideal possession or capacity) than oneself who has less and wants. The sense of its being unattainable leads to hopelessness and an intolerable bitterness needing to devalue or destroy what is perceived as unreachable.

Intelligence—acquiring and applying knowledge—is broader than cognition—knowing—considered in isolation or merely by IQ scores. Intelligence and IQ scores, though related, are different conceptions. Intelligence first denotes the capacity for awareness and discrimination of relevant and novel environmental and subjective

stimuli. This information is then used in an integrated fashion in several ways:

1. To deductively make sense of complexity through analysis, synthesis, and reproducing meaning, primarily through perceptual reasoning.
2. To maintain mental and physiologic infrastructure.
3. To promote regulatory expansions in adaptive survival that includes flexible and effective performance interactively with the environment.

Language and effective communication facilitate executive functions—focused attention, selection, planning, organization, implementation, and refinement of both thinking and behavioral responses. Words become used as “signifiers” that represent something. These must be combined in the brain with the “signified” to form a meaning-imbued “sign.”

This unique human symbolic process correlates with the level of an individual’s capacity for abstract thought, which facilitates critical thinking and, in turn, executive functioning. Emotions and specific and nonspecific motivational urges give dynamic meaning to how these functions are integrated, experienced, and refined. Moreover, an individual’s intelligence does not exist in a vacuum; it is a function of interpersonal engagements throughout the life cycle. Real-life learning from experience contributes to eliciting strengths and accommodating to challenges. Respect for the mind’s life in the whole person underlies this quality-of-life consideration.

Intelligence or intellectual functioning is a complex construct (i.e., a measurable representation of a hypothesized abstraction) that does not necessarily manifest itself in a unitary fashion. It includes the following mental abilities: understanding relationships, adeptly and efficiently processing information, spontaneously applying problem-solving strategies, acting purposefully in novel, ambiguous, and complex situations, and learning from experience to refine adaptive and problem-solving skills. Intelligence is cognitive competence, the mental ability to function and perform successfully. *Intelligence is both*

intelligent cognition and intelligent adaptive performance. A range of latent inner resources and potential capacities can be developed by learning, experience, and a sensitively facilitating environment. Subsequently, real-time capabilities to perform a demanded task emerges. Pragmatic and efficient skill performance denotes adaptive functioning.

From a scientific and academic perspective, measurements of intelligence reflecting an individual's position or standing relative to others traditionally have resided on two quantitative indices:

1. Measurement by psychometric (i.e., "measuring the mind") instruments yielding profile arrays with numeric ranges of component scores of cognitional abilities, including a composite score—full-scale IQ.
2. A statement about the effectiveness of adaptive behavior as expressed by arrays of varied performance skills.

For both criteria, cutoff scores establishing normal ranges are approximately two standard deviations (SDs) below the respective assessment instrument's mean. These scores vary by test, subgroup, and age group while considering the standard error of measurement for the specific tool used and its strengths and limitations. Current testing uses complex neuropsychological examinations that yield arrays of profiles that eschew previously held reductionist assessments and single scores in isolation. Such results give full weight to the nuances of multifaceted cognitive and adaptive processes. Intelligence is neither a static given nor a single number. It is a dynamic and relatively changing confluence of phenomena affected by chronologic, maturational, developmental, neurologic, psychological, social, and contextual factors. In BIF, real-world reasoning and judgment are *well below average*. These atypical features are apparent in discernibly poor academic performance—an essential activity in childhood.

Taking the role of intelligence into serious consideration is vital in assessing health and well-being. This understanding derives, in part, from research demonstrating that intelligence plays a crucial role,

along with socioeconomic influences, not only in predicting academic success but also in promoting a variety of positive life outcomes. The pivotal role may have been underestimated or not relevant a century ago when the term “borderline intellectual” was first introduced. Today, it is self-evident. Along with the central importance of denoting intelligence as *mental ability*, including emotional intelligence as *emotional knowing* and motivational factors as real-life adaptation is essential in all considerations of intellectual functioning. The expression of intelligence and its limitations is multidimensional. It emerges from the dynamic and reciprocal engagement among intellectual abilities, adaptive behavior, health status, social participation, cultural context, individualized opportunities, and support availability. These considerations must temper, if not humble, any endeavors at reductionist measurements of this basic human functioning.

While this section’s primary thrust is on the cognitive and performance role central to intact intellectual functioning, emotional conflict undoubtedly affects daily life’s thinking and activities. When psychic conflict escalates, defense mechanisms are elicited. From a psychodynamic perspective, *intellectualizations* may block and constrain conflictual feelings, temporarily subduing anxiety. Avoiding and denying unruly emotional turmoil by using lofty, often specious, cognitive explanations normatively arise in adolescence as a way of managing newly emerging psychosexual impulses. If such strategies bring relief, they are carried forward and may become embedded as enduring character traits. However, those with BIF rarely become proponents of such abstruse, pedantic legalisms or present themselves as voluble, creamy intellectuals whose excessive verbosity mesmerizes the listener. Intellectualizations are cognitive obfuscations, rarely if ever, used by those with BIF. I raise these contrasts since they may sharpen attention to BIF’s typical presentations, more literal and concrete, as they tend to be.

Furthermore, the increasingly recognized protective effect that intelligence affords merits its appreciation as a powerful therapeutic focus. Protective factors increase the chances of resilience, healthy coping, effective action-oriented behaviors, and positive life

outcomes. Such knowledge has clinical utility by providing useful information needed to convey the patient's material, relevant to the clinical course, and comprehensive treatment planning. *Attention to IQ scores and adaptive strengths and weaknesses has provided helpers with a means of identifying persons who have developmental and other special needs. Only with this knowledge can services be offered to optimize social inclusion, equity, and personal empowerment. Moreover, these models influence research, policy, funding, access, and treatment reimbursement.* These considerations also comprise a vision aimed toward raising an individual's biopsychosocial quality of life with meaning and dignity. Cognitive and emotional capabilities pragmatically expressed as satisfying life skills in the real world are thereby enhanced.

BORDERLINE INTELLECTUAL AND ADAPTIVE FUNCTIONING AS A CLINICAL ENTITY OF SIGNIFICANCE

DSM-5, as have its previous renditions, recognizes and codes BIF as a condition or focus of attention and not as a disorder.

DSM-5 describes a mental disorder in the following way:

> "A mental disorder is a syndrome characterized by clinically significant disturbance in an individual's cognition, emotion regulation, or behavior that reflects a dysfunction in the psychological, biological, or developmental processes underlying mental functioning. Mental disorders are usually associated with significant distress or disability in social, occupational, or other important activities." (Adapted from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Text Revision, DSM-V-TR, p. 14 [Copyright © 2022]. American Psychiatric Association. All Rights Reserved.)

Clinical utility is emphasized: helping to determine prognosis, treatment plans, and potential treatment outcomes, and not a need for treatment. The need for treatment is a complex clinical decision that considers symptom severity, salience (e.g., suicidal ideation), distress or mental pain, disability, and risks and benefits of available treatments. Clinical significance emphasizes that the diagnostic threshold is vitally influenced by the disturbance's degree, causing

clinically significant distress or impairment in social, occupational, or other important areas of functioning at crucial developmental eras, for example, education in childhood.

By contrast, a *condition* is a focus of clinical attention that may affect the diagnosis, course, prognosis, or treatment of a patient's mental disorder. A condition draws attention to the scope of additional issues that may be encountered and affect or *impact* the individual's treatment or progress. Describing these conditions as "problems" or interferences strongly suggests some degree of distress, significant dilemma, trouble, or obstruction. Some examples of "conditions" are abuse, neglect, sexual violence, and adult antisocial behavior.

Practical utility in clinical practice is thus acknowledged, especially by definition of a condition, as it may impact clinical care and treatment progress. As far back as DSM-III (1980), the distinction between normality and psychopathology was seen as a gray area whose inexactness remains subject to continuous scrutiny and reexamination. The threshold for "caseness" and the "cut off area" concepts used to denote a diagnostic label of "mental disorder" is not yet deemed sufficient for BIF. While the real-world population abounds with persons having no apparent difficulties, individuals with BIF typically have noteworthy problems. BIAF, moreover, may exacerbate comorbid mental disorders. Yet, the psychological, educational, ID, and psychiatric literature meagerly yet valiantly strives to document this challenge convincingly. DSM-5 considers BIF worthy of inclusion since conditions such as these draw attention to a broad scope of problems encountered in clinical practice. BIF is coded both for its clinical importance and how it affects the diagnosis, course, prognosis, or treatment of the patient's co-occurring mental disorder(s). It is useful information that may affect patient care.

A consistent operational definition of BIF covering all or most situations, symptom presentation, structural pathology, pathophysiology, and etiology, along with valid and reliable studies, has been absent. This lack of data correlates directly with the absence of clear-cut measurement and defining criteria. To what extent BIF resembles a disorder, a disability, a deficit, or aspects of each remains indeterminate. How BIF shows features such as

distress, dyscontrol, dysfunction, malfunction, syndromal patterning, pervasive inflexibility, gross irrationality, severity level, disadvantage, social or occupational impairment, risk vulnerability, heterogeneity, and meaningful statistical limitations and deviations are questioned, debated, and controversial. From the platform of typical or average development, does BIF lie on the continuum of developmental atypicality, for example, average skills not emerging as expected for age? *These matters remain unsettled, as does labeling all IDs as disorders rather than conditions with significant demand for support levels*. For example, could disability be construed not as resulting from a deficit in isolation but from neurocircuitry in conflict that competes to create chaos resulting in marginally less disorganized or "well below average" or "borderline" outcomes? The Easterseals community has defined disability in 2020 contemporary terms: "Disability is defined as any visible, invisible, emotional, social and educational challenges that are a part of normal, everyday life. Disability can refer to a medical diagnosis, a barrier, and/or a person's identity."

BIF is, in fact, a boundary or transitional phenomenon—at least by previously accepted criteria (DSM-IV-TR), and now by rather broad, if not somewhat ambiguous, parsimonious guidelines ("careful assessment of intellectual and adaptive functions and their discrepancies," DSM-5, p. 727). Since BIF had been viewed as the transition from the ID spectrum to the average intellectual range, and since psychometric and adaptive testing shows some excursion from statistical norms in one or more essential areas, a "disability model" is suggested. One could also argue that the individual must have some internal "disorder" that is elicited or brought forward when interacting with an environment (animate and inanimate) not quite capable of meeting and supporting atypical needs, impairing, and thus causing distress. The last consideration that shall not be elaborated here is regarding the term "mental." Mental disorders assume the implicit split in an individual between the brain and mind. This dualism is not merely traceable to 17th-century Western Cartesian dualism but is recorded as far back as the extant Sanskrit literature of India and some Eastern philosophical systems. Contemporary Western science

now understands individuals from more unified, less anachronistic perspectives.

In psychology, psychometrics measures differences between individuals or an individual to an appropriate reference group. Measurement is key to scientific understanding because it puts the amounts measured into numbers for reference and comparison. For example, the range of normal IQs has been 90 to 109, following the Terman–Wechsler tradition. Sometimes it is defined as +/−1 SD from the mean of 100 (i.e., 85 to 115). Others consider average to be within 1 SD of the mean because the number of SDs from the mean or average norm has become an increasingly popular way of communicating test results. Of course, the sample of people used in these calculations should represent the testing standardization population.

BIF is a developmental limitation, not a psychiatric disorder. Not all persons with the condition of BIF or an IQ score of about 71 to 84 are impaired or dysfunctional. A *lower-than-average* IQ score is below the range of 85 to 115, with a mean of 100. This intellectual ability encompasses cognitive (i.e., analytical–conceptual–critical reasoning, verbal, and spatial) capacity. It is noteworthy to compare a DSM-5's criterion for Learning *Disorders* (LDs) (p. 69) that specifies substantial and quantifiable low academic achievement of academic skills "*well below average"* to be of at least 1.5 SDs below the population mean for age. This score is 78 or less. Having this *well below average* score qualifies the student for the formal LD diagnosis and many services.

The condition of BIF adds that well below average IQ must be present concurrently with significant *limitations in adaptive behaviors* and functionally restricted practical performance skills across several domains of everyday living. Clinical experience is consistent with BIF occurring in the developmental period before age 18. Integrating assessment of IQ scores with an individual's day-to-day functioning supports ecologic validity in interpretations.

Adaptive behavior domains include the following collection of conceptual, social, and practical dimensions of performance behaviors:

- Communication
- Self-care
- Social and interpersonal skills
- Home living
- Use of community resources
- Self-direction
- Health and safety
- Functional academics
- Leisure
- Work

Evaluation and treatment planning warrant serious consideration of adaptive performance criteria with particular attention to an individual's physical assets, strengths, limitations, preferences, and productive habits (e.g., exercise, sports, and other physical activities). Adaptive behaviors include a range of self-care and *instrumental activities of daily living*, notably skills needed to be reasonably successful at home and in the community. For example, personal hygiene such as bathing to minimize body odor, brushing the teeth to limit mouth odor and tooth decay, and trimming the nails create a positive appearance and minimize social signs that elicit perceptions of oddness and interpersonal distancing. Personal care includes a developing sense of wellness and mindful attention to good health and daily living activities. Uneven performance in adaptive skills, also in cognitional abilities, is common. Many distinguished contemporary psychologists whose work on intelligence testing is held in high esteem repeatedly emphasize the difficulties in adequately describing the ability levels of individuals whose IQ scores reside in the borderline category.

Therefore, BIF is a heterogeneous condition that, when dysfunctional, denotes the co-occurrence of clinically, significantly limited intellectual and adaptive functioning. Together, these deficits result in uneven and often marginal scholastic, practical, and social competence. In such situations, BIF acts as a functional neurodevelopmental disability, placing the individual at risk for failure and subsequent lowered self-esteem, dysphoria, and distress. As

these children grow, the gap between their capabilities and demands from school, the workforce, and society increases. Tasks of daily living become more challenging to fulfill successfully; hence failure and blame ensue. The impact that BIAF plays is typically overlooked. Missing BIF has perplexing consequences for all involved.

Such academically fragile persons have been referred to as “slow learners” and “hard-to-teach” children, especially since they typically have difficulty understanding and *learning* average schoolwork amounts. Dysfunctional BIF denotes a general life skill’s coping disadvantage and a heightened risk for maladaptive outcomes. Yet, it should not be regarded as a static condition. While it may be true that IQs stabilize after the childhood period, adaptive skills do not. They respond to environmental enrichment and supports. Overreliance on IQ scores alone incorrectly de-emphasizes the critical importance of viewing an individual’s functioning as the complex interaction of strengths, limitations, opportunities, and appropriate supportive interventions. The entire conception of supports—a contemporary and novel construct—includes resources, strategies, and accommodations that enable people to live successfully in community settings.

The essence of BIAF, therefore, descriptively indicates *ranges of abilities that are well below average*. Clinically, those with BIF are very slow to understand and problem solve across areas. Critical thinking and executive functioning reflected in planning, anticipating, performing, and self-correcting is well below average. This may manifest in the face of apparently adequate language skills. BIF, in effect, can become a significant developmental limitation in learning and real-life adaptation. Therefore, it can contribute to *marginal abilities* or inability to succeed in major life functions such as self-care, academic achievement, and social–occupational tasks. Limited ability to perform may be due to unavailable inner resources or inability to access and efficiently use what is already psychologically present but undeveloped. Sensitive environments can respond accordingly and enhance unsteady performance.

Last, as discussed in this section, the condition of academic or educational problem is coded, usually in addition to other diagnoses,

when scholastic performance is significantly impaired and becomes an outstanding feature of a patient's overall clinical presentation.

CULTURAL SENSITIVITY: A FRESH PERSPECTIVE AND AN ORIGINAL VOICE

The approach advocated here to recognize, screen, identify, and therapeutically work with persons with BIAF highlights direct clinical focus. This acuity is an astute individualized line of engagement. In part, it rests on the premise that the array and range of factors (i.e., conceptual, social, and practical performance skills, IQ scores, and details of an individual's culture, social context, and environment) are multidimensional and always varied.

Effective clinical work requires a center of gravity in clinical details with a periodic reflection on theoretical generalizations—sound clinical judgment. Acute clinical awareness and a high index of suspicion are needed to detect borderline functioning, indicating clusters of additional risk factors predisposing to limited and even impaired performance.

Recognition of cultural sensitivity in its broadest dimensions (i.e., language; styles of communication, movement, gesture, behavior; and the community environment typical of the individual's peers and cultural milieu) has been axiomatic of good clinical care. DSM-5 has updated its "Outline for Cultural Formulation Interviews" with field tests for diagnostic usefulness in many areas to obviate difficulties in communication that may bias diagnosis and treatment. In this spirit, clinicians who encounter persons with BIF and adaptive performance need to develop a higher level of sophisticated sensitivity and amplified empathy. This more intensive recognition will support a cultural formulation producing the following:

- Increased patient engagement
- A contoured comprehensive treatment plan
- Higher powered effectiveness
- Improvements in the patient's quality of life

Toward this vision, an acute, forwardly aware recognition and understanding of these cultural dimensions in the clinician and how they impact those served, including their families, schools, neighborhoods, and allied agencies, is essential. This partially self-reflective technique helps bring BIF's expression into sharper focus because BIF is typically "obscure." This instrumental perspective is the clinician's adding self-observing awareness as a primary tool to all assessments' repertoire. Evaluators and treaters undoubtedly experience some differences in perception, conception, and emotion—not themselves having BIF's personal experience.

Sharper *mindful self-awareness* provides the opportunity to recognize the transitional areas in the functioning and adaptive skills that approach theoretical ideals or "norms." This appreciation helps clinicians capture subtle impairments that may be severe enough to produce functional yet underrecognized disabilities. Effective clinical understanding may become more pragmatic because it traverses this transitional boundary between helper–helpee divides and typical versus slower or uneven mental abilities. The clinician's more intimate personal self-reflection and recognition of the individual with BIF and their distinctive profile of mental abilities, adaptive behaviors, and personality traits may be heard by the patient as an "original voice," fresh and empowering. The patient will experience the clinician not as an outside stranger but more as an inside ally, mentor, guide, and counselor. Such a motivated engagement magnifies care experience and may mitigate iatrogenic biases, enhance adherence, reinforce support, and bolster greater success chances.

BORDERLINE INTELLECTUAL FUNCTIONING

Definition

The DSM-5-TR describes BIF in Section II, "Other Conditions that may be a Focus of Clinical Attention," as follows [DSM-5 uses the older diagnostic terminology "mild intellectual disability (intellectual developmental disorder)"]:

This category may be used when an individual's borderline intellectual functioning is the focus of clinical attention or has an impact on the individual's treatment or progress. Differentiating borderline intellectual functioning and mild intellectual developmental disorder (intellectual disability) requires careful assessment of intellectual and adaptive functions and their discrepancies, particularly in the presence of co-occurring disorders that may affect patient compliance with standardized testing procedures (e.g., schizophrenia or attention-deficit/hyperactivity disorder, with severe impulsivity). (Adapted from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Text Revision, DSM-V-TR, p. 836 [Copyright © 2022]. American Psychiatric Association. All Rights Reserved.)

DSM-5 (ICD-10) coding: R 41.83 has significantly revised BIF's definition from that given in DSM-IV-TR in 2000. DSM-5 begins with acknowledging that BIF may be a focus of clinical attention or have an *impact* on treatment or progress. No numerical IQ scores (i.e., IQ 71 to 84) are now explicitly given as definitional criteria, as they had in DSM-IV-TR. Metrics for identification are suggested by indicating careful assessment of intellectual and adaptive functions and their discrepancies. Adaptive functions are now mentioned in the DSM-5 entry. DSM-IV-TR had contrasted BIF with mental retardation (MR)/ID. DSM-5 directly contrasts BIF with mild ID only. Co-occurring mental disorders now include attention-deficit hyperactivity disorder (ADHD) with severe impulsivity and mentions schizophrenia that may affect patient compliance with standardized testing procedures. DSM-5 does not give highly detailed coding instructions.

Since DSM-5 "requires careful assessment" of BIF (*well below average*) from mild ID (*significantly subaverage or* two or more SDs below the mean for the test), a brief discussion of this follows. Using traditional IQ scores based on Bell curves, a test norm or average is 100 as the mean; this norm extends to one SD above 100 and below 100. When one to two SDs occur, and scores range from about 70 to 85, this is considered *well below average or discernably subaverage*. At the 70 to the 55 mark or three SDs below the norm, this range is considered "significantly subaverage" or "severely, markedly, and seriously limited." At the 55 level and below, this range is deemed substantially impaired and extremely limited. Terminology that describes levels of support needed includes (1) mild ID, intermittent

supports;(2) moderate ID, limited supports; (3) severe ID, extreme supports; and (4) profound ID, pervasive supports.

Table 28.3–1
Clinical Features Associated with Borderline Intellectual Functioning

1. Mild, impairing global (not specific) learning problems
2. Well below average, limited ability
3. Uneven academic achievement and adaptive performance
4. Concrete mindedness
5. Well below average comprehension of functional relationships
6. Slowness in understanding, broad comprehension, and response
7. Poor attention, concentration, and organizational skills
8. Impaired ability to generalize and transfer learning
9. Low frustration tolerance
10. Intermittent dysphoria from perceived inadequacy
11. Low self-esteem
12. Variable social and adaptive behavior impairment
13. Task performance overcompensation (e.g., excels in physical tasks and sports)
14. Compensatory verbal fluency
15. Naiveté
16. Need for more-than-average direction

DSM-5 and others have shifted the emphasis in their current perspectives on IDs. Levels of severity are *determined by assessing adaptive functions and the levels of supports* required rather than by IQ scores. *Of great significance in the current Intellectual Disability literature is the serious consideration that mild ID characteristics may at times characterize BIF in more muted and less intense forms.* DSM-5's section on ID criteria (Table 28.3–1) discusses severity levels in the three adaptive domains: conceptual, social, and practical. The reader is referred to the DSM-5 discussion, mainly Severity Level Mild, to elaborate on such an individual's support

needs, intensity, and support systems. Supports enhance functioning and avert the risk burden.

Detailed elaborations of these comprehensive systems also can be found in AAIDD texts. AAIDD has made and continues to make contributions of inestimable importance, both theoretical and practical. The enormous significance of supports is reflected in the AAIDD User Guide statement: “The implication is that whereas the life functioning of the individual with ID can improve with personalized and sustained supports, a valid diagnosis will not change.” (2012, p. 2).

History and Comparative Nosology

BIF definitions’ history and development directly reflect evolving conceptualizations of MR, now termed ID. Significantly subaverage capacities characterize ID in intellectual functioning (e.g., reasoning, learning, and problem solving), and adaptive functioning (e.g., conceptual, social, and practical skills) emerges before the age of 18 years. Efforts toward reducing stigmatization and unfair segregation resulted in a federal statute in the United States (Public law 111–256, Rosa’s Law, 2010) replacing the term “mental retardation” with “intellectual disability.” Whereas BIF is a borderline cognitive and adaptive limitation, ID represents an array of mild, marked, severe, and substantial developmental disabilities below those of peers that include both intellectual and adaptive functioning deficits in conceptual, social, and practical domains. The DSM-5 (2013) definition correlates with that of the AAIDD 2010 definition except that the DSM-5 categorical definition includes the terms “disorder” and “deficit.” AAIDD instead uses the phrase “significant limitations” to denote and describe features of intellectual “disability.”

Of note is that ICD-11 (to be released in 2021) proposes to use the phrase “intellectual developmental disorder” to indicate ID as a disorder that involves impaired brain functioning early in life. The tentative name and coding are ICD-11: 6A00.Z, “Disorders of intellectual development, unspecified, Intellectual disability.” IDD is the term that characterizes persons with significant impairment of

cognitive functions associated with learning limitations, adaptive behaviors, and skills.

Since about 1973, in addition to an IQ score of between 70 and 75 up to 85 for BIF and onset before 18 years of age, classification schemes have placed significantly greater emphasis on functional adaptive skills, the elimination of the notion of borderline MR, and including the construct of BIF.

The following is a brief historical review of the coding and terminologic vicissitudes of BIF in the DSM. DSM-I (1952–1967), which correlated with ICD-6 of 1948, coding in Section V reads: “Code no. 60.0, mental deficiency (familial or hereditary), mild, standard nomenclature: 000-x901, international list: 325.3.” DSM-II (1968), which correlated with ICD-8, 1965, used the code and phrase “310. borderline mental retardation.” The name “borderline mental retardation” was eliminated in 1973 (official reclassification by the American Association on Mental Deficiency, now AAIDD). It was changed to “borderline intellectual functioning” at that time. DSM-III (1980), which followed ICD-9, 1975–1978 (ICD-9 clinical modification to increase the resolution of diagnoses and procedures, an adaption created by the U.S. National Center for Health Statistics, became official in January 1979 as “ICD-9-CM”). DSM-III first introduced the five-axis system and identified BIF on Axis I coded as “V62.89.” DSM-III-R (1987), still following ICD-9-CM, now shifted BIF from Axis I to Axis II and coded it as V40.00. DSM-IV (1994), working closely with ICD-10, 1992, maintained BIF on Axis II and coded it as V62.89. DSM-IV-TR (2000) maintained previous definitions, classifications, and coding. DSM-5 (2013), now intimately aligned with ICD-10, revised its description of BIF, eliminated all axes systems, and codes BIF as “R 41.83.”

Rapidly changing paradigms within the ID field have adopted an interaction-based ecologic perspective with an evolving vocabulary. For example, with the AAIDD’s 2010 publication of its 11th edition, *Intellectual Disability*, the nature and amount of support (i.e., frequency, daily support time, and type of support) that a person needs to participate fully in life is defined. As of October 1, 2014, DSM-5 codes ID based on both intellectual functioning deficits and

adaptive competencies, but specifiers will be based on levels of severity defined by adaptive functioning parameters. Although DSM-5 criteria remain broad, they state that identifying BIF requires “careful assessment of intellectual and adaptive functions and their discrepancies.”

Etiology and Epidemiology

As with other conditions that reflect intellectual and adaptive limitations, genetic, hereditary, congenital, health, environmental, interpersonal, sociocultural, and educational opportunities have been implicated as etiologic factors. For BIF, however, no factor in isolation has been shown to be definitively causative. Prenatal, perinatal, and postnatal medical conditions must be identified since they may provide more explicit explanatory and remedial information. With reference to a normal distribution or bell curve of psychometric intelligence on the general population, IQ scores in the borderline range (about 70 to 85) occur from between one and two SDs below the mean or average of 100, approximately 13.6% of the time. BIF’s clinical condition is strongly suggested only when noteworthy limitations or impairments in adaptive functioning accompany this finding. These considerations must be viewed in the cultural, educational, environmental, and economic context of a person’s life. Such a multimodal perspective adds needed clinical flexibility to assessments and determinations having significant consequences.

Identification and Clinical Features

Contemporary views stress the presence of *well below average* measured intelligence, limited adaptive functioning, and support requirement needs as the broadest dimensions within which dysfunction and needs arise. *Limitations and well below average performance may not be global and pervasive; areas of strength may be interspersed with marginal functioning*. Identification of BIF integrates clinical, academic, and common sense factors. There has been a shift from reliance on composite or full-scale IQ scores to an analysis of multiple subtests of cognitive functions together with

adaptive performance. Psychological and neuropsychological test assessments provide cognitive functioning scores, IQ profiles, and comments on emotional and behavioral functioning. These indicators offer objective measurements, helping to position the student in areas of strengths and weaknesses.

Specific cognitive abilities predict academic achievement and can be one part of evidence-based data for prescriptive, comprehensive interventions and individualized remediation. Because information regarding academic performance and testing, including psychometric testing, is typically available for persons younger than 18 years of age, BIF may be recognized more easily in the school-aged population. Initially, assessing adaptive functioning is done through clinical screening and thorough history taking. If needed, formal specialized testing may be performed. Intelligence testing and the conceptual, social, and practical life skills aspects of adaptive testing should be performed in a nonbiased manner with due attention to cultural contexts.

Fairness in adequately identifying and not misconstruing the presence of BIF remains essential in decision making. Attention to socioeconomic status (SES) and access to reasonable educational and school programs must be noted. This inclusion in case formulations underscores a culturally informed assessment. Motivational factors, effort, and fatigue affect test taking and affect real-time performance in life skills. The effects of psychotropic medications on performance must also be considered. Information from testing is correlated with all aspects of the individual's life functioning for conclusions to be rendered reasonably and reflect diligent clinical judgment. *For example, those with BIF are recognized implicitly as requiring more coaching early on in grade school. When this is successful, verbal skills are raised; hence, they may test at near average verbal levels, both empirically and on test scores. In such cases, verbal comprehension may eclipse well below average perceptual reasoning capacities, working memory, and processing speed deficits. A primary consideration of the presence of BIF thus may be missed.* A veneer of language may mask practical performance problem-solving abilities.

Common sense skills commensurate with chronologic age and educational level may be lacking.

Table 28.3–1 summarizes some essential clinical features associated with coding the condition of BIF. Familiarity with the basics of child and life cycle development, quickly gleaned from readily available texts on child development, offers inestimable pragmatic, clinical assistance in orienting the evaluator concerning presentations reflective of typical versus *well below average performance*. Clinical assessments and the psychiatric interview are based on firsthand observation. Seeing not only what a person can do but also *how they perform* is crucial for adaptive performance. Direct and detailed observation—*the patient's clinical expression*—is indispensable to the identification. The attentive clinician experiences that the individual's cognitional process—receptive and expressive—is slow-moving and lumbering.

These variable manifestations may show some of the following: mild but impairing global (i.e., not specific or isolated) learning problems; learning how to learn—the brain's "search engine"—appears limited; understanding is slow-moving; slow working memory; difficulty grasping functional relationships; once learned, materially performing an activity or task is intact, and may even be highly skilled; uneven academic and other skills performance; tendency to concrete-mindedness; perceptual reasoning (e.g., problem solving) may be impaired; some slowness in response time; difficulty with simultaneous management of multiple tasks; notable difficulties in understanding and learning, which may be displayed as task avoidance, insufficient attention, concentration, and organizational skills; difficulties integrating new knowledge with previously learned information and applying it to novel problem solving; impaired capacity to generalize learned information and skills; low frustration tolerance; intermittent irritability, dysphoria, and distress, mostly from poor achievement and perceived personal inadequacies; low self-esteem and low motivation; social awkwardness; mild-to-moderate social skills, although social interaction is sought (i.e., not apathetic); neither hypokinetic nor hyperkinetic motor activity; poor common sense; naivete; potential for

being bullied and for victimization; and a need for more-than-average direction and supervision in general, given chronologic and developmental status. Procedural memory and habitual task performance from past practice and repetition are typically intact. Uneven performance within each and between intellectual and adaptive domains may occur for several reasons, one of which is the individual's own compensatory processes. Verbal skills testing as average or better may compensate for *well below average* (i.e., *one to two SDs below the mean for the test*) perceptual reasoning and problem-solving abilities. Clinically, this may mask the real presence of BIF.

When a number of the aforementioned clinical features are moderately pervasive, dysfunction is inevitable. All these factors then contribute to a less-than-average rate of learning and understanding, frustration in an academic environment that expects average or greater-than-average performance and compliance, educational and social failure, some difficulties with activities of daily living, and a greater chance of emotional distress and behavioral dysfunction.

Other sources that support this diagnosis come from standardized intelligence tests (e.g., Wechsler Intelligence Scale for Children, Stanford–Binet test, and Kaufman Assessment Battery for Children), adaptive behavior scales, and school psychological and academic testing and achievement reports. Working memory seems to be significantly impaired. When these clinical features, integrated psychometric profiles of multiple cognitive functions and capacity measures, and adaptive and support needs are associated with an individual's biopsychosocial and academic dysfunction, BIF may be coded. If it is clinically deemed the principal or a significant cause of the individual's problems or visit, the terms "principal" or "reason for visit" may be indicated in parentheses. Although a strong presumption is present, such uncertainty can be shown by recording "(provisional)" after the code if not enough information is available.

Differential Diagnosis

The diagnosis of BIAF is an orphan entity. Rarely do clinicians consider it when faced with its presentation. Thus, a high index of

clinical suspicion needs BIF's signs and symptoms in mind. One must first rule out substantially significant forms of IDs, which can easily be detected by standardized intelligence tests, "adaptive skills" profiles, history of onset in the developmental period, and overall performance in various contexts. Table 28.3–2 summarizes the differential diagnosis of the clinical condition of BIF. A pivotal diagnostic question with significant treatment implications is whether the typically diagnosed disorders that often mask or are mistaken for BIF, such as ADHD, attention-deficit disorder (ADD), and LDs, are, in fact, present or absent. It is also essential to designate whether BIF is primary and comorbid or comorbid and secondary to the individual's presenting and fundamental borderline intellectual problems if comorbidity exists. Careful and diligent history from family and collateral sources such as school reports, including psychological testing, are indispensable.

BIF is typically underreported. The most frequently diagnosed disorders that mask, overshadow, or may be mistaken for BIF are *ADHD, ADD*, and *LDs*. Common features of all these are focusing attention and sustaining concentration that prevents adequate learning from occurring. However, there may be diagnostic overlap and definitional variations according to variable criteria used. ADHD, ADD, and LDs are often, though not necessarily, found in those with average or higher IQ scores (i.e., 85 and above).

Table 28.3–2
Differential Diagnosis of the Clinical Condition of Borderline Intellectual Functioning

1. Attention-deficit hyperactivity disorder; attention-deficit disorder
2. Learning disorders
3. Autistic spectrum disorder
4. Nonverbal learning disabilities
5. Conduct disorder
6. Antisocial personality disorder
7. Intellectual disability (previously termed "mental retardation")

In *ADHD and ADD*, impulsivity and behavioral inhibition impairments are primary, along with executive functioning impairments. Many psychologists emphasize that difficulties reside in *performing* academic skills, *not in learning* them. In ADHD, impulsive behaviors typically pose significantly disruptive problems and interferences with adaptation at home, school, and other contexts. In ADD and ADHD, academic functioning is notably affected by an impulsive need to rapidly get through the material, which is a deficit intimately linked to poor behavioral inhibition. Impulsivity leading to immediate action also prevents sufficient encoding into working memory. In BIF, academic learning is primarily limited since overall cognitive processing is well below average and concrete oriented, emphasizing physicality, not abstractions. Adaptive performance may match these limitations, including limited communication, social participation, or occupational functioning. In ADHD, organizing and skillfully executing a task is a clear-cut-weakness; in BIF, once an activity is learned, it is typically performed soundly; execution may be slow yet persistent and organized. Some studies indicate that on the WISC-IV Factor Index, Wechsler Perceptual Reasoning (Gv-Gf), those with ADHD attain average or better scores, unlike those with BIF. They score lower on solving novel nonverbal problems and fluid reasoning tasks.

Specific learning disorders (SLD) (present in up to 15% of the U.S. population) may manifest, not global, but in a specific fashion (e.g., reading, writing, mathematics, or combinations of these) and in those school-aged children whose learning and using academic skills are compromised by more modular, primarily cognitive, information processing irregularities. Samuel A. Kirk, an American psychologist, was the first to identify the construct and coin the term “learning disabilities” in 1963. DSM-5 implies IQ scores to be greater than about 70, thereby ruling out ID to better account for these LDs. These LDs may also occur in “gifted” individuals, those with IQ scores roughly above 130. DSM-5 also terms the persistent difficulties defined by LD as “disorders” rather than “disabilities.” They are localized to academic skills that are substantially and quantifiably below those expected for age. They cause significant interference

with educational or occupational performance or with activities of daily living. Details in memory function, mostly encoding and retrieval, play a significant role.

The entire construct of LDs has undergone radical revisions in the last several years, and its determination is dependent on multiple complex factors. A comprehensive process that includes developmental history, medical history, psychological and achievement testing, school reports, language and communication assessments, and especially the response to intervention (RTI) data are used to determine eligibility. LDs (commonly referred to as “learning disabilities” in educational contexts) qualify an individual for special education services and an individual education plan (IEP). Also, whereas ADHD and ADD may require psychotropic medication as one part of a comprehensive management plan that includes psychosocial therapies, behavior modification, specialized academic programming, and parenting strategies, LDs and BIF do not include a medication component as part of their comprehensive treatment plan. In specific LDs, *specific* academic skills performance is well below average for age (i.e., low achievement scores ranging from 1.0 to 2.5 SD below the population mean for age). Working memory and processing speed may be specifically impaired. In BIF, well below intellectual and adaptive functioning impacts functioning *as a whole*, not merely on specific or isolated academic skills, and so affects interventions and overall progress.

Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by persistent deficits in social communication and social interaction across multiple contexts together with restricted, repetitive patterns of behavior, interests, or activities. Reciprocity is severely constrained; pleasurable preoccupations rather than distressing obsessions are typical. DSM-5 codes three levels of severity. In higher functioning ASD (Level 1 severity), IQ scores are average or higher, and visuospatial competence may be high, unlike in BIF. Academic performance usually is impaired because of severe social skills deficits’ interference with learning, although social approach—awkward as it is—is attempted. Although eye contact is typically impaired, there is no social or emotional indifference.

Emotions can be powerful. Anxiety and dysphoria may emerge from social rejection and isolation. Those with ASD may appear dysmorphic and “quirky” because of difficulties modulating affect in response to social cues and irregularities in prosody and one-sided, egocentric, long-winded conversational styles. ASD Level 2 is less impaired but requires substantial support, while Level 3 requires very substantial support. In contrast, children with BIF appear typical, often quiet and exhibit modulated ranges of affect, unlike the more constricted facial expression reflecting impaired socioemotional reciprocity and perspective-taking exhibited by those with ASD. Those with BIF often show socially meaningful pragmatic language and developing empathetic perspectives, unlike those with ASD.

Nonverbal learning disabilities (NVLDs), a neuropsychological and academic classification and not a DSM disorder, are similar in presentation to higher functioning ASD, and both ASD and NVLD overlap in their clinical features. NVLD has also been called “right hemisphere deficit” and “developmental socioemotional processing disorder.” Prefrontal and frontal lobe executive functioning impairments manifest as cognitive, behavioral, and emotional dysregulation. Individuals with NVLD are characterized by less severe social skills deficits (i.e., “dyssemia”) than those found in ASD. Academic problems, for example, in mathematics and reading comprehension, take center stage. NVLD’s prominent features include overattention to details and missing main themes; intact linear cognitive processing but impaired gestalt comprehension; visuospatial perceptual deficits, especially left-side inattention and neglect; impaired pragmatic language use; and speech-related rhythm, volume, and prosody irregularities. Attentional style is desultory and wandering, in contrast to distractingly impulsive, as found in ADHD and ADD. Neuropsychological testing confirms clinical impressions and may show performance IQ scores, especially low scores on coding and block design subtests (i.e., poor visuospatial functioning), to be below verbal IQ scores, which are typically average. The capacity for abstract thinking is dysfunctional, regardless of average or higher IQ scores. Children with NVLD appear more motorically passive and not overactive. Anxiety and

depression, rather than disruptive behaviors, are more typical. Individuals with NVLD typically qualify for special education services more easily than those with BIF.

Disruptive, impulse-control, and conduct disorders (CDs) typically draw robust clinical attention and require treatment. CD is characterized by aggression and bullying to people and animals, destruction of property, deceitfulness or theft, and serious violation of rules. These behaviors in children and adolescents are often associated with school failure and an apparent impairment of comprehension of academic and social standards. BIF may be comorbid and contribute to the impaired ability to understand and comply with expected norms in youth with CD. Antisocial personality disorder (APD) is a pervasive pattern of disregard for and violation of others' rights that begins in childhood or early adolescence and continues into adulthood. As in CD in children, BIF can be associated with APD and impaired cognitive skills in adults, and its comorbidity, if present, needs to be identified. Any underlying psychotic disorder, whether endogenous or exogenously produced (e.g., illicit substance use), must be ruled out.

Also, it must be recognized that BIF, like other conditions found in the juvenile population, may be, and usually is, comorbid with (although usually not mistaken for) several different psychiatric disorders. Post-traumatic stress disorder (PTSD) associated with neglect, maltreatment, trauma, or abuse is now commonly encountered in children whose poor academic performance is primarily affected by anxiety, agitation, and preoccupation with traumas. Primary mood instability and cycling along with a driven, distracting, and hyperkinetic motor component (cognitive, speech, and physical activity) characterize mood disorder or bipolar disorder in children; "disruptive mood dysregulation disorder" with severe and recurrent verbal or behavioral temper outbursts and persistently (i.e., not episodic) irritable, peevish, and habitual angry mood may be seen in 7 to 18 year olds. Substance-related disorders such as cannabis use and other drugs that impair learning and memory must also be considered. Clear differentiation and targeted treatments are needed. Also, BIF has no correlation with borderline personality disorder.

Sluggish cognitive tempo (SCT) is a theoretical construct being investigated as a presentation of attentional cognitive impairment. It is not a formal diagnostic entity and has no standardized criteria. Most researchers, however, identify its most salient symptoms as including the following: daydreaming, trouble staying awake and alert, mentally foggy and easily confused, staring a lot, spacey with the mind seeming elsewhere, lethargic, underactive, slow-moving and sluggish, inability to process questions or explanations accurately, drowsy and sleepy appearance, apathetic and withdrawn, lost in thoughts, slow to complete tasks, and lacks initiative with fading effort. Although correlated with ADD and ADHD, it is thought to both be comorbid and possibly a different condition. While ADHD is considered a disorder of executive functions and externalizing correlates (i.e., disruptive behaviors), SCT is not. SCT is correlated with internalizing features such as anxiety, depression, and social withdrawal. Some have suggested renaming the condition "concentration deficit disorder," "developmental concentration disorder," or "focused attention disorder." Although problems in adaptive performance are evident, there are no data available regarding IQ scores, and, therefore, it would be premature to make correlations between SCT and BIF. The clinician must also carefully differentiate those with temperamental styles that are avoidant, reticent, and retiring (e.g., typically discernable by 12 months in infancy and onward) and schizoid personality styles from presentations having cognitive sluggishness as an isolated or primary feature.

Course and Prognosis

Specific studies showing the longitudinal course and prognosis of those with BIF continue as an evolving process. However, they detail the quality of life, risk, and potential impairments. Allied literature describing those with mild cognitive limitations reveals consistent negative trends. Studies show that the overall quality of life may be negatively affected when the condition is unrecognized, and no supports are given. *Quality of life* is reflected in the following domains of human functioning: social relationships, family relations,

employment, autonomy, recreation and leisure, personal competence, independent living, community integration, social status, health, finances, future parenting, and subjective well-being. With appropriate habilitation, remediation, guidance, and support, risk reduction may be achieved, and good quality of life is realized. Early identification and treatment are essential. A naturally facilitating environment that elicits strengths is found in a good family and reinforced with a mentor, a supportive school, and social community. These platforms support positive motivation and a sound work ethic—all of which continue to encourage success.

A 13-year-old boy was referred to a partial hospital program because of anger outbursts, temper tantrums, and moodiness in the home. He was in a regular classroom setting, and his grades were marginal. He appeared passive, but his overall demeanor brightened, and his performance improved when given adult attention and guidance in school and at home. Along with the psychiatric assessment, evaluation included a pediatric medical examination, blood work, and urine screening for illicit drugs. School psychological testing was reviewed. Results were unremarkable. There was no evidence to support diagnoses of ADD, ADHD, or LDs. There were no medical problems. However, verbal IQ was 80, performance IQ was 75, and adaptive skills proficiency was several years below that expected for age. A primary diagnosis of BIF was made. Treatment included intensive emphasis on special help with resource room and accommodations in school, psychoeducation for the family, and brief individual, group, and behavior modification for the patient. Mood and behavior at home significantly improved, self-esteem was enhanced, and school performance was strengthened academically and socially.

An 11-year-old boy was admitted to a residential facility to evaluate further, treat, and stabilize a long history of ADHD and intermittent explosive disorder. He had been on dextroamphetamine (Adderall), 20 mg in the morning and 20 mg at noon, and lithium (Eskalith, Lithobid) 300 mg three times daily. His clinical presentation showed a significantly small-for-age, underweight boy with a moderate degree of facial tics and grimaces, stereotyped behaviors (e.g., picking at the skin of the hands, arms, and legs), agitation, and constricted affect. Medical examination and blood work were normal, although tics were noted. A comprehensive assessment revealed a 3-year history of current behaviors, with no previous special education resources. However, grades had been consistently poor to failing, and chronic family strife because of the patient's intermittent irritability, oppositionality, and noncompliance at home, homework, bedtime, and difficulty getting up in the morning. Evaluation and treatment included a therapeutic trial of the gradual tapering to zero of all psychotropic medications in the context of a structured therapeutic milieu. After 3 months, the patient gained 10 lb, had considerably fewer facial tics, and had few to no explosive episodes. Sleep patterns began to normalize.

Stereotyped behaviors and moderate impulsivity remained, although school performance (behavior and academics) improved. A trial of 0.5 mg of risperidone (Risperdal) twice daily was begun to target residual agitation, impulsivity, stereotypies, and tics. Because of weight gain, risperidone was gradually cross-tapered to a small amount of aripiprazole and monitored carefully. After 2 months, these signs and symptoms resolved, leaving only mild impulsivity, which was easily redirected in the structured environment. During this stabilization period, psychological testing was done and showed a verbal IQ of 78, a performance IQ of 76, and an adaptive skills profile well below chronologic age expectations. A primary diagnosis of BIF was made. Because no specific learning disabilities were noted, his global school learning problems were addressed in a classroom with general, special

education accommodations. Furthermore, psychoeducation for the student and his family, along with family therapy, continued to help resolve much of the chronic strain between parents and the student, resulting from years of mutual frustration and apparent failure.

Treatment

Overview. BIF is a clinical condition showing significant risk vulnerability. Since few to no treatment guidelines exist, this section details a comprehensive summary. Risk management addresses the *whole person* who has the condition. Careful case formulations with culturally informed assessments and data from IQ and adaptive functions optimize quality treatment. Robust clinical and educational interventions follow from these. A whole-person focus sees the individual's inner resources—the terrain or field of resilience—as the platform upon which interventions depend. Although standardized techniques targeting those with borderline cognitive and adaptive functioning are not yet established, a *multimodal management approach* is best. Treatment is risk intervention and aims for harm reduction in BIF. Improvements beyond the marginal edge reinforce resilience. This comprehensive strategy centers on the individual, the family, and the school environment. As one part of an effective treatment plan, psychosocial therapies foster aptitudes eliciting innate resourcefulness—potentials for intelligent performance—and improved emotional resiliency are essential.

Psychotherapy and counseling, suitable to the developmental level and individual's receptivity, often help long-standing poor self-image. Many of those with BIAF feel they "do not fit in" with others. Many persons with borderline functioning are implicitly demoralized because of their typically undiagnosed, *well below average* condition. The emotional toll on those with BIF correlates with low self-esteem, low self-confidence, and a puzzling quality of alienation. Helping these children, adolescents, and adults identify their given strengths and amplify their inner resources is essential. Parents also need to come to terms with their child's BIF and *well below average*

functioning. Last, when the adult children of those with BIF finally realize their parent or caregiver was limited, insight and renewed compassion rather than frustration and resentment for unexplained less-than-optimal overall care can bring resolution and acceptance. Family work is essential. Psychoeducation and psychosocial management strategies to help parents understand, process, problem solve, and willingly reach out to professionals, notably educators and social service systems, round out multimodal care. Transition and long-range planning must be a part of all care models. Teaching life skills can be understood and internalized as early as age 12.

Initial Assessments. Since children, adolescents, and adults present with multiple problems, often with multiple psychotropic medications, careful medication assessments are crucial. Psychotropic medications have indications for psychiatric disorders or the symptomatic features of disorders such as anxiety, agitation, irritability, impulsivity, and mood instability. There is no explicit indication for BIF. Well-chosen, low doses of an appropriate medication may target distressing signs and symptoms and can support less dysphoric attitudes for educational, psychosocial, and behavioral interventions.

Clinical presentations may be confounded with iatrogenic medication side effects such as fatigue, sluggishness, cognitive dulling, lethargy, irritability, mood lability, anxiety, poor appetite, insomnia, tics, skin picking, and trichotillomania. These potential culprits pose distractions to evaluators that, when eliminated, make more transparent the child's actual profile of signs, symptoms, and cognitive baseline. Testing results are less adversely affected. The judicious use of psychotropic medications in the juvenile population is part of good clinical practice.

Therapeutic diversification—thoughtfully constructed, monitored, and refined over time—nuanced to identify and address individual needs is outstanding patient care. *A restructured individualized academic program is the framework of all interventions. The role of the school, whatever its context, is pivotal.* BIF's condition rarely qualifies an individual for special education services or an IEP—a

current shortcoming in official policies. Such plans outline specific and measurable educational and behavioral goals with quarterly and annually addressed objectives. Instead, a strong, compelling, and reasonable argument for an appropriate level of individualized academic intervention such as Section 504 remedial assistance can be requested to school boards. Acceptance may be successful.

After careful delineation of cognitive, emotional, social, academic, and adaptive strengths and limitations, comprehensive strategies should address the individual's specific needs and the educational supports required. Problems and interferences with adaptive activities of living are significant. The entire treatment plan should be user-friendly and not aversive in any way to the child, the family, or the academic environment. The treatment-determining context may be school based, within the family, or in a residential, independent living, or group home setting. Particular attention to significant developmental and other life transitions should be highlighted. This attention to lifelong needs includes early considerations of pragmatic vocational planning. Students graduating from high school, for example, might enter a community college transitional program specifically devoted to addressing the adaptive skills needed in adult life. Vocational training for adulthood is part of transition planning. Although interventions have emphasized attention to the intellectual domain, using the adaptive domains—including the physical body's role in kinesthetic activities such as sports and manual labor (e.g., prevocational exposure)—should not be underestimated. Procedural memory and forms of implicit learning typically remain potential strengths. Interpersonal communication skills, time management, organizational skills, career exploration, and workplace readiness are taught in such programs. For older adolescents and younger adults, referrals to bureaus of rehabilitation and vocational services, which may be associated with local and state Departments of Social Services, are appropriate vocational considerations. Treatment planning of resources and strategies must be reviewed regularly because needs and circumstances will change over time. The family and caregivers' role pervade school-based remediation, psychosocial therapies, behavior modification, and psychoeducation.

School-based remediation efforts in the developmental period up to age 18 years old are fundamental. These core interventions identify specific learning abilities, weaknesses, capabilities, adaptive skills, strengths, and limitations. Remediation first addresses increased overall academic and adaptive (i.e., conceptual, social, and practical) skills. Areas to strengthen include verbal comprehension and language use, basic problem-solving, and organizational strategies. The adaptive features of conceptual intelligence include reading, writing, mathematics, time awareness, and issues around using money. Adaptive social skills include teaching cues, communication, reciprocity, and situational judgment. Adaptive practical intelligence covers personal care, activities of daily living, and the instrumental activities of daily living—all of which are listed at the beginning of this section under Adaptive Behavior Domains. ID specifiers are based on the level of supports needed for adaptive functioning in three domains. The *conceptual* level in mild ID shows impairment in abstract thinking, executive functions, and the functional use of academic skills such as reading and money management. A concrete approach to problems and solutions compared to age-mates is evident. The *social* domain shows more concrete or immature than expected for age communication and social interactions with a limited understanding of risk in social situations. In the *practical* domain, personal care may be sufficient or need help. However, complex living tasks—the instrumental activities of daily living—grocery shopping, transportation, food preparation, and money management, require support and supervision. BIF and mild ID support needs overlap.

Moreover, *accommodations*, which are adjustments to the school program, do not change the curriculum level or performance criteria. They permit the student to use it more efficiently. Various forms of assistive technology have merit. *Modifications*, by contrast, change curriculum goals and performance criteria. Teaching adaptations and innovative workarounds to tasks must be individualized to afford the student reasonable participation and chances of success, especially since individuals perceive, interpret, and respond differently to new information. For example, public school programs in charter school

settings have been launched. They include modified curriculums considering the clinical features associated with BIF, customized educational course plans, daily assessments with ongoing plan revisions, and strong parental involvement. A treatment program with appropriate educational, behavioral, psychotherapeutic, counseling, and social interventions is then constructed. Since novelty and ambiguity may be experienced as stressors, learning is significantly enhanced when teaching styles change from relying on the individual's gathering, inferring, and generalizing information to styles that are more hands-on. Students benefit significantly from having a dedicated "go-to" person who can act as a personal mentor, guidance counselor, and mediator. All these acts as "stress inoculation," which is preparation by the exposure eliciting stretching to go above comfort zone reactions, learned to be controllable. Also, if psychotropic medication is deemed useful to boost attentional focus and reduce hyperarousability, FDA-approved guanfacine, extended release (ER) in from 1 to 3 mg by mouth once in the morning is helpful. Besides monitoring for baseline blood pressure and periodic checks, guanfacine ER has no appreciable side effects that the group of stimulant medications poses.

Psychosocial therapies focusing on the individual are essential. Various psychotherapy forms in the broadest sense, including counseling, guidance, mentoring, coaching, and support, may enhance greater social competence by strengthening social skills, especially communication, comprehension, and self-advocacy. Whatever the therapy style, feedback in the therapeutic conversation helps the therapist see where the patient is at the moment. This feedback helps the therapist structure questions and responses that "fit" the patient's ability to understand. These communicational guidelines help strengthen executive functions, which halo out and modulate the tendencies for impulsive choice—that is, decisions resulting in small, immediate rewards despite long-term negative consequences. A large part of this approach focuses on *risk reduction* because studies show that BIF is associated with *loneliness and poor social functioning, increased rates of psychiatric diagnoses, and drug use.* Recognizing boredom and redirecting energies are

skills taught through self-management techniques that target motivation, initial encoding competence, and sequencing. This approach also imparts strategies modeling learning in a step-by-step fashion and initially learned information in as many ways as possible to enhance generalization aptitudes.

The decisive role of helping children make sense of emotions and innovate their emotional intelligence has been underestimated in the past. We now know it can be instrumental in advancing their global performance skills. Precision medicine and effective interventions rest on developing emotional intelligence. Attention to social competence's vital role as allied with cognition and enhanced symbol formation in effective overall life functioning should not be underestimated. Its roots, in part, can be seen in the pioneering work of such distinguished psychoanalysts as Melanie Klein, who, as early as the first half of the 20th century, advanced important theoretical directions that underscored the significant interplay of cognition, symbol formation, social adaptation, and the reciprocal emotional influences within the parent–child relationship in clinical applications. Contemporary psychotherapies are pragmatic and solution focused. Therapists use various theoretical models and tailor techniques to real-time needs, interests, and patients' and families' responsiveness. As with other conditions that affect learning and successful interpersonal and social adaptation, effective contemporary methods built on precedents from the past must now also use multidisciplinary team approaches.

Behavior modification, especially useful in group and academic settings, has an essential place in comprehensive interventions. Whether the psychiatrist decides to work with the patient directly or in a team with other clinicians, the psychotherapeutic and behavioral components can be a powerful adjunct in promoting change. The child's quality of life in the extended environment expands.

An essential part of team treatment is the *family*: identifying its specific needs and offering pragmatic supports. The importance of enlisting the family as an active collaborator in psychotherapies, social skills, school programs, and allied interventions cannot be overstated. Recent meta-analyses show that family behavioral

therapy and parent management training have significant positive outcomes. Also, the child or adolescent, as a family member, should be offered an explicit collaborating role. A specified member of the treatment team, for example, should construct setting up benchmarks for future success in a coordinated fashion with the child.

Psychoeducation, which has a protective effect on many levels, denotes explaining the meaning and significance of the diagnosis and treatments of BIAF to families, therapists, and educators. BIF is typically underreported and unfamiliar to most professionals. Thus, knowledgeable evaluators must explain in a tactful and detailed way to caregivers of children, adolescents, and older adults its meaning and the practical limitations. Identifying appropriate resources and regularly applying them makes the potential for improvement significant.

Therefore, stressing to parents that their direct, *empathetic hands-on attentive care and guidance* are fundamental to their child's needs over time cannot be overemphasized. Clearly communicating this explanatory, attributional model is an essential task for the psychiatrist. Studies have shown parenting skills emphasizing genuine warmth and responsiveness augment adaptive outcomes. Because children with BIF are usually emotionally sensitive and responsive, especially to nonverbal communications, positive perceptions of genuine helpfulness from all caregivers effectively facilitate cooperation and change. Highlighting and reinforcing all indications of effort bolsters motivation and self-esteem. Motivation may be an underestimated explanatory factor for the question of why individuals "grow" at different rates. Motivation, more than just intention, is the energetic desire or *effortful willingness* to take action toward or away from a goal. Its emotional side is arousal. Its cognitive side entails persistence toward achieving despite challenges. Motivated performance goals are well defined and made pleasurable. The emphasis on motivation is willingness. The focus in the effort is an exertion to succeed. Both complement one another.

In working with those with BIF, *motivational messages* are communications sensitive to the developmental level, needs, "questions," requirements for guidance through transitions, self-

regulation, and containment. Whether implicit or explicit, such messaging becomes sufficiently powered when delivered with enthusiasm, hopefulness, and tempered optimism. This feedback to the student provides the scaffolding to support stepwise improvement rather than unrealistic perfection. A fundamental strategy for fostering the sustainability of desired behaviors is to call attention to them as they occur—“contingent positive reinforcement.” Pragmatic strategies emphasize “build first, refine after.”

All comorbid conditions must also be addressed in the comprehensive treatment plan. Behavior modification strategies (coordinated with techniques used in school) are essential in-home settings. Meta-analyses show that family behavior therapy and management skills training, and cognitive behavioral therapy for school-aged children are both clinically and cost-effective.

Mindfulness exposure is often part of interventions having both relaxation and an attention-focusing component. *Practicing deeper breathing*, a mindfulness platform, is sometimes called “watching the breath” or diaphragmatic breathing. The following guidelines are useful:

1. Sitting in a straight-back chair or lying down on a firm surface.
2. Closed eyes may be preferred.
3. Focus on breathing with attention to the abdomen/belly with a hand on it.
4. Relax the abdominal area and breathe slowly.
5. Slowly inhale through the nose for about a count of approximately 4 to 6.
6. Notice the abdomen rise; a hand on the stomach helps your awareness of this.
7. Try to hold the breath for about a count of 6 to 7.
8. Slowly exhale through the mouth or nose for a count slightly longer than your inhalation, for example, a count of 8.

To restate the breathing technique, in starting the breathing exercise, allot about 2 to 5 minutes to establish a calm breathing baseline that may or may not be maintained. While seated and

comfortable, erect posture with the spine vertically aligned, take a deep breath through the nose sensing, and noticing its course to expand the chest via the rise in the upper abdomen and diaphragm. A count of 4 to 6 is right. Putting a hand on the upper waist/belly helps center attention to this upward rise. Hold the breath in for a count of approximately 6 to 7, then gently exhale through the mouth or the nose, whichever is more comfortable in the beginning. The precise timing of in-breaths, holding, and out-breaths varies. In-breaths are shortest, out-breaths are most extended, and time holding the breath is in between these. Doing this breathing practice for 5 minutes once or more times per day is helpful. Physiologically, arterial baroreceptors are stimulated and modulate blood pressure. Also, the vagus nerve afferent stimulation to the frontal cortex increases parasympathetic tone—greater tranquility.

Given the fundamental platform of breathing, a summary of the essence of this *Learned Mindfulness* model founded on emotional intelligence, mindful awareness, and self-observation follows. Starting with a basic familiarity of how one's sensations emerge, one can be taught to label them as feelings. Grasping, releasing, contracting, and expanding attend these. Breathing affords a model of such fundamental dynamics. For example, releasing the breath follows the pause between inhalation and exhalation. This act establishes a sense of muting and not impulsively reacting that transfers to grasping, holding, and releasing objects arising in the mind. The emerging realization of gracefully letting go can progress further in the refinement of emotional processing: perception, conception, and performance. This emotional intelligence practice correlates the mind's "objects," for example, sensations, feelings, and thoughts, with their mindful management.

Special mention of the current widespread use of interventions derived from complementary, alternative, and integrative medicine may have a place in overall treatment because motivated families often first initiate these aids with enthusiasm not only to promote but also to enhance well-being. Healthy food choices, exercise, stress management, and even prenatal health measures (i.e., primary prevention) can be important components of a successful treatment

plan. When used adjunctively, rationally, and collaboratively, they may help sustain a positively engaged therapeutic trajectory.

Proper recognition, together with remediation, enhances both cognitive and adaptive reserve. This long-term perspective optimizes potentials that extend benefits beyond the identified individual's immediate needs with BIF. Risk reduction may reach across generations. The young children of such individuals are thereby given a significantly increased chance of success in all quality-of-life measures. The adult children of persons with borderline intelligence can be given a rational explanation of insights into parents' long-standing intellectual limitations. This epiphany may afford them a capacity for a forgiving attitude toward what might have erroneously been perceived as intentionally motivated, less-than-optimal parenting.

A 10-year-old boy was referred for consultation because of failing grades since first grade and disruptive classroom behaviors, including expressing aggression toward peers, breaking things, and having temper tantrums. He would purposefully break any toys or gifts he was given; he would tear his clothes at times. He was the only child of a single mother who reported normal gestation, delivery, and no medical problems in the child. The boy was mildly overweight in the interview and had some facial dysmorphic features but appeared otherwise healthy. His mood was sullen. In the past, his mother had been given a variety of diagnoses for the child by school and pediatrician: ADHD, bipolar disorder, ASD, and CD. No psychotropic medications had been helpful. A comprehensive assessment included multiple interviews with the child and the mother, school consultation with intelligence, adaptive and scholastic testing, and routine blood work. Verbal and performance IQ scores were in the low 70s, adaptive skills were marginal, and grades were 1 to 2 years behind. Laboratory values were within normal limits. A primary diagnosis of BIF with a mood disorder, unspecified, was made.

Intensive treatment was three pronged: child, mother, and school. School consultation provided psychoeducation about diagnoses and the need for special education, which was approved. Family therapy also included psychoeducation about borderline intelligence, the child's strengths and limitations, and his need for a structured, straightforward, and routine environment of expectations and behavioral performance. Individual therapy for the mother also began. His mother was eager to use a range of health-oriented dietary and exercise guidelines. This therapeutic alliance with the mother was crucial to holding and integrating all prongs in an effective and collaborative way. Intensive individual psychotherapy with the child included aspects of cognitive, behavioral, and age-appropriate psychodynamic work. The child's sense of self, self-esteem, peer relations, and the effects of his behaviors on others were reviewed. During play therapy, several conflictual problems

were uncovered. The boy revealed his envy of other boys on multiple levels. He envied their having a father, their perceived sense of being "smarter and not retarded," their physical competence in sports, and their acceptance and facile participation in peer-group activities. His envy created a hatred of, and a wish to destroy, both them and, moreover, aspects of himself, as illustrated in either spoiling his clothing or breaking gifts he received. He often stated: "I'm angry because I just don't fit in with everybody else." Even though he was cognitively limited, he showed an interest in and some aptitude for understanding the complex envy dynamic of excessive idealization, spoiling, destructiveness, and resentment—when put into simple language and delivered flexibly at his level of readiness over time.

Play therapy and interpretive discourse were sensitive to engage him on the specific and changing levels of cognition and affect that he presented at each session. Changes were slow but significant. This developing level of emotional insight, basic emotional and cognitive understanding, appeared to enhance his everyday cognition because it diminished a great deal of anxiety and preoccupying resentment. The acquisition of "envy management skills" over time helped him understand cause-and-effect sequences and constrain destructive behaviors. Once-weekly psychotherapy was supplemented using low doses of quetiapine (Seroquel) to target irritability, anxiety, and mood. After approximately 6 months, his behavior stabilized, his aggressive outbursts were significantly eliminated, and his academic performance began to approach chronologic and developmental expectations. His mother remarked that his demeanor appeared more relaxed and that his affect brightened.

ACADEMIC OR EDUCATIONAL PROBLEM

Definition

DSM-5 describes another condition (Z55.9) *academic or educational problem* as follows:

This category should be used when an academic or educational problem is the focus of clinical attention or impacts the individual's diagnosis, treatment, or prognosis. Problems to be considered include illiteracy or low-level illiteracy; lack of access to schooling owing to unavailability or unattainability; problems with academic performance (e.g., failing school examinations, receiving failing marks or grades) or underachievement (below what would be expected given the individuals intellectual capacity); discord with teachers, school staff, or other students; and any other problems related to education and literacy. (Adapted from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Text Revision, DSM-V-TR, p. 830 [Copyright © 2022]. American Psychiatric Association. All Rights Reserved.)

The title of this entry now includes the added phrase "…or educational problem." Unlike the DSM-IV-TR description, no mention is made of this condition not being "…due to a mental disorder or, if due to a mental disorder, is sufficiently severe to warrant independent clinical attention." About seven additional problems are now mentioned: illiteracy, low-level illiteracy, lack of access to schooling, discord with teachers, school staff, students, and other issues related to education or literacy besides the previous two in DSM-IV-TR: failing grades and significant underachievement. No mention is made of requiring the absence of a specific learning or communication disorder or any other mental disorder that would account for the problem, as DSM-IV-TR had required. Therefore, the term "illiteracy" is not defined in a specific fashion; some impairment in the ability to read and write is implied. Some of the associated factors causing academic or educational problems are remediable extrinsic agents (e.g., access, discord, implied bullying, and victimization) that, if addressed, would assuage or eliminate the designated academic problem. The way DSM-5 defines this condition suggests that it can be a focus of attention or a secondary problem affecting an already present diagnosis, its treatment, or progress. DSM-5 coding is Z55.9.

DSM-5-TR (2022) describes several specifically coded conditions under the single category, Educational Problems (Z55.0 -Z55.9) with the subcategory Z55.9, now called "Other Problems Related to Education and Literacy," that DSM-5, Z55.9, previously termed "Academic or Educational Problem" as described above.

DSM-5-TR now describes the entire range of Educational Problems as follows:

These categories may be used when an academic or educational problem is the focus of clinical attention or has an impact on the individual's diagnosis, treatment, or prognosis. Problems to be considered include illiteracy or low-level literacy; lack of access to schooling owing to unavailability or unattainability; problems with academic performance (e.g., failing school examinations, receiving failing marks or grades) or underachievement (below what would be expected given the individual's intellectual capacity); discord with teachers, school staff, or other students; problems related to inadequate teaching; and any other problems related to education and/or literacy. (p. 830)

Etiology

The presentation of significant academic or educational problems or those impacting diagnosis, treatment, or progress denotes this condition. Risk factors include genetic, constitutional, premature birth, congenital atypicalities, and various early and later environmental stressors, for example, poor nutrition, less than optimal care, and maltreatment. English as a second language may also be considered. DSM-5 also clearly lists several causatives and clear-cut associative factors, leading to academic and educational problems. Some of these may have intrinsic causes, such as illiteracy associated with dyslexia or LDs. Most related causative agents are apparent environmental difficulties such as lack of access to schooling (e.g., transportation, attendance in-school, online school, tele school access, tutoring, etc.), interpersonal conflict, and perhaps behavioral dissonance, as delineated in the DSM-5 description. Bullying and victimization must be primary considerations.

Identification and Clinical Features

Scholastic problems, acute or chronic, associated with the particular factors clearly mentioned in this code's description best characterize academic or educational difficulties. Specific medical conditions, disabilities, or primarily overshadowing psychiatric disorders such as psychosis, schizophrenia, bipolar, depression, ASD, substance-related disorders, or PTSD may be comorbid but not sufficient to account for this coding. Clinical judgment is required.

Differential Diagnosis

Adequate psychological and intellectual testing and academic performance profiles derived from standardized scholastic testing need to rule out forms of ID, BIF, specific LDs, and communications disorders. All medical conditions (including, e.g., vision, hearing, motor) and disabilities that might contribute to illiteracy, poor school performance, or access must also be explored. Major psychiatric disorders, along with severe oppositional defiant disorder, must be considered. Substance abuse or dependence and CD must be ruled out.

One must also rule out clinical and subclinical states of anxiety and depression, as well as environmental stressors, either hidden or explicit, which significantly affect the child in the family (e.g., marital discord, divorce, abuse, and mental illness in the parent), the socioeconomic environment (e.g., poverty, malnutrition), and the suitability of the school setting (e.g., accessibility, presence of bullying, and so forth). Significant medical conditions (e.g., anemia, seizures, hypothyroidism, chronic infections, heavy metal loads, motor and ambulation impairments, and genetic disorders) must be considered. Adolescent developmental concerns, such as preoccupation with burgeoning sexuality, identity issues, and peer relations, should not be underestimated as factors that contribute to academic problems. Typically, such preoccupations are highly significant and may contribute to academic problems. Also, motivational issues and associated family and socially influenced contextual values may directly affect scholastic performance. Socialization and developing social skills and exposure to community values take place in the school environment. With the onset of remote learning, many of these venues have been disrupted, thus posing additional risk exposure.

With the advent of COVID-19, remote academic learning is prevalent. Home learning with technology and electronics and access to these are used. Hybrid combinations, including at-home remote, partial attendance, and full attendance, are possibilities. Absenteeism, for various reasons, including illness in the child or family, needs consideration. Inappropriate or excessive use of individually chosen screen time, including the lack of needed

technologies such as electronics and lack of internet access, adds other emerging layers of concern related to academic or educational problems.

A 15-year-old boy was admitted to an intensive outpatient program to evaluate insidiously declining grades at school, isolative behavior, and incipient anhedonia occurring for the first time over the last semester in his second year in high school. The student told his family that he was being bullied in school. The patient had no previous psychiatric history and was in good health. School reports showed a full-scale IQ score to be 100 and no previous behavior or academic problems. Interviews with family and patient revealed that the boy had an intact family with no apparent or unusual conflicts noted. His mother found evidence of drug paraphernalia—cigarette papers, small pipe, matches, and a suspicious-looking dried substance—in the patient's bedroom. When confronted, the patient revealed a 6-month history of regular use of marijuana associated with his statement of being bullied in school. A primary diagnosis of cannabis abuse, along with an academic problem, was made. A secondary depression was to be ruled out. Referral to a therapeutic program with a drug and alcohol rehabilitation component was immediately implemented. A comprehensive school meeting was called to investigate and address the allegation of bullying.

A 10-year-old girl was admitted to an intensive outpatient program because of various disruptive, impulsive, hyperkinetic behaviors and intermittent rage reactions only in the home environment. The patient was well behaved in school and considered bright. Her grades, for the first time over the last year, were failing. Onset began about 2 years previously when her parents separated and her mother's new male companion moved in. The child's pediatrician made a diagnosis of ADHD and started methylphenidate (Ritalin). The child's condition worsened and was marked by mood instability and periodic temper outbursts, now also in school. The medical assessment showed the patient to be in good health, and she was referred for further examination. A psychiatric interview showed a guarded, hypervigilant child with a constricted affect. No other data were forthcoming. The patient's mother was reluctant to take part in treatment. The initial diagnostic impression was of disruptive behavior disorder, along with an academic problem. After several weeks and months, the patient revealed that she was sexually abused.

Further investigation and involvement with the Department of Child and Family Services uncovered that the home's adult male was the perpetrator. He was removed. Family and individual work began and continued for several months. All psychostimulant medication was discontinued. A primary diagnosis of PTSD was made, along with abuse and secondary academic problem. Over time, the child became less irritable, her rages stopped, and her grades in school improved.

Treatment

Identifying and addressing environmental—family, school, and socioeconomic—stressors are essential. Substance abuse and traumatic exposure must be ruled out. Any concurrent major psychiatric disorders require diagnosis and treatment. Since referred children and adolescents are typically prescribed multiple psychotropic medications, careful medication assessment is crucial.

Side effects, adverse drug effects, behavioral toxicity, and iatrogenic effects (e.g., hypothyroidism from lithium, or overactivation, irritability, mood instability, underweight, tics, stereotypies, and insomnia from psychostimulants) must be ruled out. When clinically indicated, taper and discontinuation or change of medications may be beneficial. With informed consent, school consultation can provide teachers with insight into the student's difficulties and suggest enhanced teaching strategies, especially conflict resolution techniques. Matters concerning bullying are now common and require careful consideration and treatment team coordinated efforts.

Child, family, school, and professional collaboration are essential. Illiteracy, underachievement, and failing grades need to be evaluated and appropriately addressed. If academic problems are severe enough, accommodations for individual educational programming, psychotherapeutic interventions such as counseling, guidance, family therapy, or residential schooling should be recommended even though this condition may not meet current stringent criteria for formal special education eligibility.

FUTURE DIRECTIONS

Intellectual *abilities*, social and emotional cognition, motivation, and successful adaptive performance skills coalesce through integrated thinking and behavior. Innovating emotional intelligence magnifies what I term *emotion performance utilization* (EPU). EPU is not a phase but the target of emotional intelligence. Viewing children and adolescents in this integral fashion calls for assessments and interventions that are comprehensive, multimodal, and flexible through the biopsychosocial paradigm.

In the introductory comments to this section, ongoing international efforts promoting evidence-based research and implementing recognition and intervention into BIAF are active. Perhaps, a case can be made for translating such patient-centered clinical practice into universally applicable research across the world. A global initiative is imperative to speed up BIF coordinated research, development, policy, and dissemination of pragmatic interventions.

In the United States, the AAIDD (2010) has proposed a rationale for formalizing a continuum of Intellectual and Developmental Disabilities. Included is a support framework spanning IQ limitations on either side of the definitional dividing line, typically full-scale IQ 70 to 75. AAIDD urges that individuals with BIF or persons with mild limitations falling marginally above this "cutoff" should become eligible for services already in place for those with mild ID. This bold yet accurate proposal attests to BIF being significant, let alone a vital area needing clinical intervention. BIF can, and usually does, interfere with activities of daily living and instrumental activities of living in the real world. This admonition for a broader breadth of the intelligence and adaptive continuum is consonant with this section's call to integrate BIF into the mainstream of official psychiatric nosology. This clinical improvement reflects the art guiding scientific psychiatry. Dimensional measures of severity between diagnostic entities transcend the limits of categories. The *Journal of the American Medical Association* (August 2014) advances the view that investing in prevention should be a strategic national priority to improve the United States' lagging population health compared with peer countries.

A new paradigm, the *biomental* perspective, has recently been introduced into psychiatric theory and has been applied to child development and parenting. The integral confluence of brain, mind, and behavior is proposed regarding neuroscience, developmental psychology, and pragmatic parenting strategies. Adaptive intelligence, a hypothetical construct, is presumed in this model. It denotes the central plexus subtending the wide range of conceptual, emotional, and motivational abilities underlying ease of effective response to change. This hub includes a tacit reserve of potential capabilities comprising an individual's innate resilience. We can make this intelligence potential active by therapeutic techniques that foster "instinctive resourcefulness," the repository of silent compensatory adaptive aptitudes. Here, "instinctive" is not impulsive but a visceral resilience made practical by a facilitating environment. These are learning-sensitive mediators between mental and emotional resources and their timely, spontaneous, and successful

implementation as practical problem-solving performance skills. This innate capacity of resourcefulness—possibly distinct from abilities currently measured by and solely dependent on IQ scores—is considered a fundamental life tool. Although its functioning may be significantly limited in those with borderline cognition and adaptive skills, therapeutic initiatives may activate its enhanced operation as described in the treatment section.

By integrating insights from genetics, neuroscience, and neuropsychiatry, behavioral and clinical studies aim to construct valid and reliable phenotypes. They span the heterogeneous range of typical to atypical and include “borderline” with its inevitable problems and interferences in daily life. The aim is not to medicalize or pathologize but to enhance BIF. Having a rational probabilistic mindset for risk provides for formal and resource-rich interventions. Circumventing quality-of-life hazards for these individual’s underdeveloped potentials expands possibilities. Incorporating such contemporary perspectives eschews considering only single categorical models. It pays tribute to heterogeneity as a fact in complex psychiatric presentations.

Studies show that emotional awareness is diminished in those with BIF, that is, alexithymia—the inability to meaningfully label emotions sensed and felt. Inclusive treatments for BIF may also embrace guidelines that recognize *emotional management skills*. These assets promote understanding, reduce cognitive and emotional dissonance, and foster greater cognitive clarity and emotional stability. This upgrade optimizes both intellectual and adaptive functioning and proficiency. Emotions are a common experience. Language offers an organizing principle to share our common experiences with one another. Helping those with BIF expand their understanding, and use of mindful language may be an underestimated, high-impact emotional management skill. These management skills and various mindfulness techniques are now commonly available. They may be adapted as part of BIF’s individualized support resources.

A paradox of COVID-19 is the need for physical distance and attendant social spacing to minimize the disease spread. This distancing has brought children apart and intensified their already

overinvolvement with electronic devices (e.g., the current need to use remote learning such as Zoom classrooms, etc.). In the COVID-19 era, the academic environment has undergone dramatic changes. The prevalence of distance, hybrid and at-home learning attests to this. Besides its inherent difficulties, the lack of regular socialization is paramount. Socialization includes material contact, interaction, and face-to-face feedback for correction and improvement. This interface comprises social learning with adults and a range of peers. Social learning fosters personal growth, maturation, and social skills development. Teamwork is enhanced. Being in a school setting also affords children access to both free and structured playtime. Play is essential to healthy development in childhood and those with borderline intellectual and adaptive skills needing improvement. COVID-19 has brought a new layer of multifaceted problems as an additional toll on marginally functioning persons.

Remote learning and home-based education are established in current educational approaches. Computer hardware, access, and having internet connectivity are potential problems. Improving accessibility and usability is evolving. Home-based education's complexity involves technology and teacher training to optimize access and the user-friendliness of educational materials. Addressing the social issues around remote learning remains and will continue to be a significant challenge.

The environmental embeddedness—*eco-corporeality*—of each individual is assumed in these approaches. Our entire corpus—human being—is embedded interactively in the fabric making up the world. The integrated use of inclusive interactional paradigms enhances a sustainable, successful, and satisfactory quality of life. This significant advance denotes a life imbued with meaning and dignity—disabilities becoming newfound abilities. This integration crosses multiple eco-contexts, including personal, interpersonal, social, academic, familial, occupational, cultural, and spiritual. Identification and active interventions cross the adaptive intelligence threshold; integrating those with BIF into this *nuanced norm* is necessary. More than a human right, this piece of social participation is the right to be human to the fullest extent.

28.4 Relational Problems

WILLIAM BERNET, M.D.

As social creatures, individuals cannot be completely understood without considering their interpersonal relationships. A person's identity is determined, in part, by how others see and value them. Likewise, clinicians cannot understand a person's symptoms out of the context of the individual's social relationships. These relationships can be promotive and protective of good mental and physical health—or neutral—or detrimental to health outcomes. There is a long history of competition—and perhaps some conflict—between the proponents of biologic psychiatry and the practitioners and researchers who emphasize the psychosocial and relational underpinnings of mental illness. No doubt, both these perspectives are essential in understanding and intervening with the mental disorders that trouble the individuals and the families with whom we work.

DEFINITIONS

Relational problems are maladaptive patterns of feelings, behavior, and perceptions involving two or more members of a relational unit. They can be distinguished from a broad range of interpersonal difficulties by four features: (1) repeated, fixed patterns of painful and destructive patterns of feelings, behavior, and perceptions can be clearly recognized; (2) the patterns are long-standing and are not a response to a recent stressful event; (3) the maladaptive patterns are nonresponsive to supportive features that may occur naturally in the social environment; (4) there is clear evidence of a major impact of these patterns on psychological functioning, physical health, social adaptation, and/or occupational activities in one or more persons in the relationship. A relational problem may come to clinical attention as the primary reason that the individual consults with a physician or therapist, or it may be a problem that affects the course, prognosis, or treatment of the individual's mental or medical disorder.

Relational problems are included in a chapter that occurs toward the end of the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and its text revision (DSM-5-TR), "Other Conditions That May Be a Focus of Clinical Attention." With regard to

terminology, the topics discussed in this chapter are called *problems* or *conditions;* in contrast, most of the topics discussed in other parts of DSM-5 are called *disorders,* such as delusional disorder and panic disorder. A common explanation for the distinction is that mental disorders are "located" inside the affected individual, while relational problems are "located" between the affected individual and another person.

Previous editions of the DSM employed a multiaxial system that included the documentation of mental disorders (Axes I and II), other medical disorders (Axis III), psychosocial and contextual factors (Axis IV), and level of disability (Axis V). Thus, relational problems were listed under Axis IV of the multiaxial system. As DSM-5 was developed, the Task Force decided to abandon the use of the multiaxial system. Mental disorders, other medical disorders, and relational problems are now included in one list, typically in the order of importance in understanding and conveying why the individual client is undergoing assessment and/or treatment. Some writers have had the misunderstanding that relational problems and other conditions (identified as V codes) may not be diagnosed because they are not mental disorders; that is incorrect since mental disorders, problems, and conditions may all be listed as diagnoses.

COMPARATIVE NOSOLOGY

Relational problems were not considered or alluded to in the first DSM (1952). In DSM-II (1968), however, a new diagnostic category was introduced called "social maladjustments without manifest psychiatric disorder." It was noted that "this category is for recording the conditions of individuals who are psychiatrically normal but who nevertheless have severe enough problems to warrant examination by a psychiatrist." One of the conditions included in that category was *marital maladjustment,* which was intended "for individuals who are psychiatrically normal but who have significant conflicts or maladjustments in marriage." The authors of DSM-II were prescient in saying, "The far-reaching implications of this set of terms for forensic

psychiatry and for insurance compensation will become clearer with time."

DSM-III (1980) featured a new chapter called "V Codes for Conditions Not Attributable to a Mental Disorder That are a Focus of Attention or Treatment." That chapter included several diagnoses that were precursors to conditions that ultimately were classified as relational problems: *uncomplicated bereavement (UB), marital problem, parent–child problem,* and *other specified family circumstances.* The last mental condition included sibling rivalry. DSM-III-R (1987) provided the same terms and definitions for those mental conditions.

In DSM-IV (1994), the title of the chapter changed to "Other Conditions That May Be a Focus of Clinical Attention." That chapter included a separate section called "Relational Problems," which included the following: *relational problem related to a mental disorder or general medical condition, parent–child relational problem (PCRP), partner relational problem, sibling relational problem (SRP),* and *relational problem not otherwise specified.* DSM-IV was criticized because the descriptions of these relational problems were overly vague. However, DSM-IV also featured the Global Assessment of Relational Functioning (GARF) Scale, which was included in the chapter, "Criteria Sets and Axes Provided for Further Study." The GARF was intended to indicate an overall judgment of a family relationship on a hypothetical continuum ranging from optimal relational functioning to a disrupted, dysfunctional relationship. It was analogous to the Global Assessment of Functioning (GAF) Scale that constituted Axis V of DSM-IV. The GARF and GAF Scales were continued in DSM-IV-TR (2000) but not in DSM-5 (2010).

Even before the publication of the DSM-IV, the Group for the Advancement of Psychiatry and the Family Psychology Division of the American Psychological Association was joined by 13 other professional societies interested in relational problems; they formed the Coalition of Family Diagnosis. The Coalition compiled further information about family dysfunction and relational problems and published the classic, *Handbook of Relational Diagnosis and Dysfunctional Family Patterns* (1996). The first sentence of the

Handbook stated, “Relational diagnosis is a concept whose time has come.” The contributors to that book were disappointed in the minimalistic presentation of relational problems in DSM-IV and hoped to influence the discussion of those topics in DSM-5. For example, they criticized the traditional principle in DSM that a mental disorder is something that occurs *in a person;* that approach seemed to exclude problems that emerge from disturbed relational patterns and dysfunctional family systems. Another consideration has been financial: “Other conditions” and V codes are typically not acceptable to third-party payers.

When the DSM-5 Task Force got underway, there was not a separate workgroup dedicated to relational problems. However, liaisons from the field of family therapy were included in some of the other workgroups. The *Research Agenda for DSM-5* (2002) included a chapter that emphasized both personality disorders and relational problems. It was suggested that relational problems should have the following features, which are ambitious goals not only for relational problems but also for traditional mental disorders:

- The diagnostic description must be of the relationship, not just of the individual.
- Relational problems should have distinctive features.
- Relational problems should cause severe emotional, social, and occupational impairment.
- Relational problems should have a recognizable clinical course.
- Relational problems should show recognized patterns of comorbidity.
- Relational problems are expected to appear in patterns of family aggregation.
- Relational problems should involve both biologic and psychosocial factors.
- Relational problems should show a response to specific treatments.
- Relational problems should be preventable.

A group of family researchers was organized to collect the scientific evidence and to create the conceptual frameworks necessary to

clarify the place of interpersonal relationships in clinical practice. That team of researchers, the Relational Processes Working Group, advised both the DSM-5 Task Force and the component of the World Health Organization (WHO) that was revising the *International Classification of Diseases* (ICD). The Working Group published a book, *Relational Processes and DSM-V: Neuroscience, Assessment, Prevention, and Intervention,* which DSM-5 personnel utilized in revising the chapter on "Other Conditions." The Working Group published a second book, *Family Problems and Family Violence,* which was directed more closely at ICD-11. In general, the importance and prominence of relational problems have gradually increased in both DSM-5 and ICD-11.

Eight relational problems—which all relate to psychosocial issues within families or couples—are included in DSM-5: (1) *parent-child relational problem (PCRP),* (2) *sibling relational problem (SRP),* (3) *upbringing away from parents,* (4) *child affected by parental relationship distress (CAPRD),* (5) *relationship distress with spouse or intimate partner (RDSIP),* (6) *disruption of family by separation or divorce,* (7) *high expressed emotion (EE) level within family,* and (8) *UB.* This is a rather disparate potpourri of mental conditions, which have a variety of manifestations, circumstances, and implications. The descriptions and definitions of relational problems in DSM-5-TR are more detailed and robust than those in DSM-IV, but there remains room for improvement in developing specific criteria for these mental conditions. These eight conditions are included in their own section, "Relational Problems," which distinguish them from "Abuse and Neglect," and the various additional topics that are included in the chapter, "Other Conditions That May Be a Focus of Clinical Attention."

Table 28.4–1.
Comparable Terminology for Relational Problems in DSM-5 and ICD-11

DSM-5-TR	ICD-11
Parent–child relational problem, V61.20	Caregiver–child relationship problem, QE52.0
Sibling relational problem, V61.8	Relationship with parents, in-laws, or other family members, QE50.4
Upbringing away from parents, V61.8	Removal from home in childhood Institutional upbringing, QE93
Child affected by parental relationship distress, V61.29	Problems related to primary support group, including family circumstances, unspecified, QE70.Z
Relationship distress with spouse or intimate partner, V61.10	Relationship distress with spouse or partner, QE51.0
Disruption of family by separation or divorce, V61.03	Disruption of family by separation or divorce, QE70.1
High expressed emotion level within family, V61.8	Problems related to primary support group, including family circumstances, unspecified, QE70.Z
Uncomplicated bereavement, V62.82	Uncomplicated bereavement, QE62

There was considerable discussion among the writers of DSM-5 and ICD-11 when those manuals were being developed, with the hope of coordinating definitions as much as possible. See Table 28.4–1 for comparisons of terminology regarding relational problems in DSM-5-TR and ICD-11. Relational problems are included in a much broader concept called social determinants of health

(SDOH), which the WHO has introduced. SDOH are the “conditions in the environments in which people are born, live, learn, work, play, worship, and age that affect a wide range of health, functioning, and quality-of-life outcomes and risks.”

PARENT–CHILD RELATIONAL PROBLEM

Definition

DSM-5-TR specifies that PCRP (V61.20) should be used when the main focus of clinical attention is to address the quality of the parent–child relationship or when the quality of the parent–child relationship is affecting the course, prognosis, or treatment of a mental or other medical disorder. The DSM-5-TR further explains that PCRP is associated with impaired functioning in behavioral, cognitive, or affective domains. Examples of behavioral problems include inadequate parent control, supervision, and involvement with the child; parental overprotection; excessive parental pressure; arguments that escalate to threats of physical violence; and avoidance without resolution of problems. Cognitive problems may include negative attributions of the other’s intentions, hostility toward or scapegoating of the other, and unwarranted feelings of estrangement. Affective problems may include feelings of sadness, apathy, or anger about the other individual in the relationship.

Etiology

There are multiple risk factors for PCRP. They include the child’s genetic predisposition, the child’s having a difficult temperament, parental psychopathology, parent–child attachment problems, inadequate supervision, parental relationship distress, family violence, negative peer interactions, poverty, neighborhood problems, and stressful life events. Maladaptive methods of parenting are frequently the cause of PCRPs. A common system of classifying parenting styles uses the two dimensions of parental *demandingness* (behavioral control, supervision, maturity demands) and *responsiveness* (warmth, acceptance, involvement). This model

results in subclassification into four parenting styles: (1) *authoritative,* with high demandingness and responsiveness, (2) *authoritarian,* with high demandingness and low responsiveness, (3) *permissive,* with low demandingness and high responsiveness, and (4) *neglectful,* with low demandingness and low responsiveness (Table 28.4–2). One can see that there is a broad range of adequate, good enough parenting, and problematic parenting can range from too much of a good thing (being overly protective) to too little (being neglectful). Most practitioners encourage parents to strive for an authoritative approach with their children. Parents who are overly authoritarian, permissive, or neglectful are more likely to create PCRP between themselves and their children.

Table 28.4–2.
Parenting Styles Diagram

		Parental Responsiveness	
		Supportive Parent is accepting and child centered	**Unsupportive** Parent is rejecting and parent centered
Parental Demandingness	**Demanding** Parent expects much of child	**Authoritative Parenting** Relationship is reciprocal, responsive, high in mutual communication	**Authoritarian Parenting** Relationship is controlling, power assertive, low in mutual communication
	Undemanding Parent expects little of the child	**Permissive Parenting** Relationship is indulgent, low in limit setting	**Rejecting–Neglecting Parenting** Relationship is rejecting, neglecting, uninvolved

Data from Baumrind D. The influence of parenting style on adolescent competence and substance use. *J Early Adolesc.* 1991;11(1):56–95.

Diagnosis and Clinical Features

PCRP pertains to the behaviors and attitudes of both the child and the parent; one or the other or both individuals may contribute to their dysfunctional relationship. Of course, this diagnosis may also apply to the relationship between the child and other caregivers who are actively involved in raising the child, such as extended family or even close family friends. The Semistructured Interview for Caregiver–Child Relationship Problem has been introduced, which may be useful in both research and clinical settings.

In cases of PCRP, it is common for one or both parties to experience personal mental health issues—such as depression in the parent or separation anxiety in the child—which drive the PCRP that occurs between them. In order to fully express what is happening in

the family, it is necessary to identify the mental disorders (if any) of both the child and the parent, as well as the dysfunction (if any) that occurs in their relationship.

The parent–child relationship is particularly important in infancy, and early childhood, when the development of the brain is essential and thus affects the child's mental maturation. A healthy parent–child relationship buffers and modulates psychopathologic risks arising from the child, the parent, or elsewhere. Impaired parent–child relationships can exacerbate and even create psychopathology. The organization, Zero to Three has focused on the assessment, diagnosis, treatment, and prevention of mental health problems in infants and toddlers. Their book, *DC:0–5,* is a diagnostic manual for young children that complements DSM-5.

Differential Diagnosis and Comorbidity

PCRP is intended to capture dysfunctional parenting, but not child maltreatment. If physical, sexual, or psychological abuse is occurring, those conditions should be the diagnosis, not PCRP. The parent participant in PCRP may have a mental disorder that is contributing to the problem, such as a substance use disorder, a mood disorder, or an anxiety disorder. The child participant in PCRP may also have a mental disorder that is aggravating their family relationships, such as oppositional defiant disorder or conduct disorder. Parents who are in conflict with their children may also be in conflict with each other, so one should consider an additional diagnosis such as relationship distress with a spouse or intimate partner or spouse or partner violence (SPV). Also, one should consider the possibility of parental alienation, where a child is manipulated by one parent to reject the other parent; that condition could explain symptoms that may occur in PCRP, such as negative attributions to the intentions of the rejected parent, extreme hostility toward that parent, and unwarranted feelings of estrangement.

SIBLING RELATIONAL PROBLEM

Definition

DSM-5-TR states that SRP (V61.8) should be used when the focus of clinical attention is a pattern of interaction among siblings that is associated with significant impairment in individual or family functioning or with development of symptoms in one or more of the siblings, or when an SRP is affecting the course, prognosis, or treatment of a sibling's mental or other medical disorder.

Etiology

Retrospective research indicates that the majority of adults have experienced sibling rivalry in some form. The birth of a new sibling usually results in an older sibling becoming competitive with the infant for the attention and affection of parents. Such rivalry becomes disordered when it is associated with extremely negative affects, overt hostility, or attempts to injure the new sibling or any other sibling.

SRP is exacerbated by marital conflict and parental displays of favoritism. When a child is idealized or is made a parental scapegoat, rivalry may become violent. Certain cultures may sanction favoritism, for example, favoring the oldest male, without increasing the risk for pathologic sibling rivalry.

A poignant form of an SRP may occur when a child experiences serious illness or death, which may be a life-altering event for that child's siblings and other family members. Such an event changes family dynamics, disrupts the family routines, and captures the parents' time and attention. The affected child's siblings may be marginalized just when they most need to feel like important members of the family.

Diagnosis and Clinical Features

Sibling rivalry refers to competition among siblings for the attention, affection, and esteem of their parents or for other recognition or reward. It typically consists of jealousy, competition, and fighting between brothers and sisters. The child may feel that they are receiving unequal amounts of the parent's attention, discipline, or

responsiveness. *Sibling rivalry* is a more general term that refers to common interactions among siblings; in contrast, *SRP* is a less common and more serious mental condition that—like all mental disorders and conditions—is associated with clinically significant impairment in functioning.

In cases of SRP, the maladaptive sibling relationship adversely affects family function, is the cause of significant impairment, or contributes to problematic behaviors in one or more siblings. Behaviors that occur in SRP include recurring arguments and conflicts that distract from the activities of daily life, avoiding interaction with the sibling who is causing the stress, threats of a child's running away, a pattern of anger toward a sibling that does not resolve because of a lack of conflict resolution strategies, and excessive jealousy between siblings. SRPs may occur between full, half, step, foster, or adopted siblings.

Although verbal and physical conflicts among siblings are common, major violence and abuse present a more serious challenge. There are no bright lines to distinguish them, but it seems obvious that extreme SRP may lead to sibling violence that becomes sibling abuse. The latter features injurious behaviors such as hitting hard enough to leave a mark, cutting, burning, and putting a child in dangerous circumstances; also, the victim becomes fearful of the perpetrator. However, parents may downplay fighting between siblings and regard it as child's play. Even the children are confused about what is abusive.

Differential Diagnosis and Comorbidity

In assessing for possible SRP, there needs to be a determination as to whether there is a partner relationship problem in the family that may have destabilized the family system, resulting in an intensification of sibling needs, parental needs, the showing of favoritism, or other more pathologic means of differentiating between siblings. SPV must be ruled out as well. The presence of serious psychiatric disorders or substance use disorders in the parents must be determined.

The siblings need to be evaluated for a variety of psychiatric diagnoses and psychosocial stressors. Being teased or bullied at school may exacerbate sibling violence at home. Having been sexually abused either within or outside of the family might predispose a child to be sexually abusive of a less powerful or younger sibling. Violent siblings need to be evaluated for past or current history of physical abuse, the witnessing of intimate partner violence (IPV), and specific psychiatric disorders. Specific disorders that might predispose a child to be abusive to a sibling include attention deficit hyperactivity disorder, conduct disorder, and mood disorders. Psychotic disorders, impulse disorders, and any neurologic conditions that might result in increased impulsivity or decreased inhibition and judgment should be considered.

UPBRINGING AWAY FROM PARENTS

Definition

DSM-5-TR states that *upbringing away from parents* (V61.8) should be used when the main focus of clinical attention pertains to issues regarding a child's being raised away from the parents or when this separate upbringing affects the course, prognosis, or treatment of a mental or other medical disorder. The child could be one who is under state custody and placed in kin care or foster care. The child could also be one who is living in a nonparental relative's home or with friends but whose out-of-home placement is not mandated or sanctioned by the courts. Problems related to a child living in a group home or orphanage are also included.

Etiology

Some children require out-of-home placement, most often due to parental neglect and inability to provide adequate care, less often because of physical abuse, sexual abuse, parental incarceration, and abandonment. Foster care—including shelters, orphanages, nonrelative foster parents, and relative foster parents—constitute a temporary form of out-of-home care; adoption is intended to be a

permanent assumption of parental responsibilities by individuals other than the biologic parents. Government data indicate that more than 420,000 children are in formal foster care—arranged and monitored by a social service agency—in the United States each year. The number of children placed through informal fostering arrangements outside of the public system, for example, with grandparents, is several times that.

Diagnosis and Clinical Features

Most children enter foster care with pre-existing handicaps and vulnerabilities, such as chronic medical and mental health problems. Separation from their families of origin and also the loss of peers, schools, and neighborhoods constitute enormous stressors. Although many children show resilience in the face of these stressors, the risk for continuing physical and mental health problems in children in foster care is higher than that of the general population. It is sadly common for children to experience multiple disruptions in placements over time, which add to their vulnerability for serious and prolonged mental health problems. Frequently the goal for the youngster is reunification with their biologic parents, which occurs in more than one-half of cases. However, many children who are reunified with their families of origin are subsequently placed again into foster care.

Various initiatives have been introduced with the goal of reducing the morbidity associated with foster care. For example, social service agencies strive to avoid unnecessary separation of children from their families in the first place by providing services for the prevention of removal. Permanency planning is a goal, with reunification, adoption, or long-term foster placement as possible options. Social service agencies also aim to free a child for adoption—by the termination of parental rights—sooner rather than later. All of these initiatives are intended to reduce the unstable and continuous cycle of children being in multiple foster homes over extended periods of time.

Kinship care—most often with the child's grandparents—is a popular option in lieu of reunification with the child's biologic parents. Typically, the grandparents hope that the child's parents will resolve the problem that led to the family crisis, such as substance abuse,

homelessness, etc. The advantages of placement with grandparents include the child's pre-existing attachment to the grandparents; preservation of a connection to the extended family of origin; greater stability and permanence; and maintenance of religious, racial, and ethnic values. There are also concerns regarding placement with grandparents: These are older individuals with health concerns and physical limitations; they may be unemployed and have limited financial resources, and difficulty maintaining restrictions on parental visitation. Fostering by grandparents and other relatives is often arranged informally rather than through a social service agency. In order for the family member to access medical care, educational services, etc., it may be necessary for the caregiver to secure guardianship or legal custody.

Practitioners will face other challenges associated with the relational problem, upbringing away from parents. (1) For example, children come to the United States from all over the world, fleeing desperate circumstances, becoming separated from family, and now experiencing a new culture and language. There is a surge of unaccompanied minors from the southern border of the United States, having been exposed to violence and severe deprivation. (2) A concern for child and adolescent psychiatrists is that children in foster care are prescribed a disproportionate amount of psychotropic medication. Prescribers and consultants try to put more emphasis on psychosocial interventions. (3) Finally, both practitioners and caregivers are concerned when foster children "age out" of the system. When that occurs—typically at age 18 or 21—everyone involved in their program should create an adequate transition plan, which relates to social supports, housing, education, employment, and medical insurance.

CHILD AFFECTED BY PARENTAL RELATIONSHIP DISTRESS

Definition

This diagnosis, CAPRD (V61.29), was new to DSM-5, which provided a very brief account of its meaning. DSM-5 simply states that CAPRD should be used when the focus of clinical attention is the negative effects of parental relationship discord (e.g., high levels of conflict, distress, or disparagement) on a child in the family, including effects on the child's mental or other medical disorders.

Etiology

About 55% of American marriages end in divorce. The divorce rate in second marriages is even high than for first marriages. Also, a large percentage of unmarried parents separate when they have young children. Approximately one-half of the children in the United States will experience parental separation or divorce.

A conflict between parents is common even in harmonious and stable relationships; most children, even in high-conflict homes, do not develop emotional or behavioral problems. Nevertheless, negative child outcomes are more strongly associated with parental conflict than with the parents' divorce. In fact, children from divorced families appear to have higher levels of well-being than children from intact, high-conflict families. Of course, continued conflict between parents after divorce exacerbates the children's poor adjustment.

Diagnosis and Clinical Features

Parental relationship distress may refer to persistent disparagement of one or both parents by the other parent; high levels of conflict; intimate partner distress (IPD: dissatisfaction with the relationship as well as difficulty resolving conflicts, lack of positive exchanges, coercive exchanges, or persistently perceiving negative intentions in the partner); and IPV (physical force such as hitting, slapping, and biting; extreme psychological manipulation; and/or coercive sexual acts). A CAPRD may display impaired functioning in behavioral, cognitive, affective, and/or physical domains. Examples of behavioral problems include oppositionality and the child's reluctance or refusal to have a relationship with a parent (contact refusal). Cognitive problems may include cognitive dissonance, attempting to maintain

affection for both parents simultaneously (loyalty conflict), and/or adopting the false belief that the rejected parent is evil or dangerous (parental alienation.). Affective problems may include anger, anxiety, depressed mood, and post-traumatic symptoms. Physical symptoms may include stomachaches, headaches, and exacerbation of general medical conditions.

Differential Diagnosis and Comorbidity

The scope of CAPRD includes the following four scenarios:

RDSIP, also called intimate partner distress, is the most common cause of acute emotional distress in treatment-seeking couples. RDSIP features relationship issues such as conflict resolution difficulty, withdrawal versus overinvolvement, chronic negative attributions of the other's intentions, dismissal of the partner's positive behavior, and chronic sadness, apathy, and/or anger about the other partner. Of course, the hurtful effects of marital conflict on children are well documented. Specifically, the level of marital conflict predicts children's internalizing and externalizing disorders.

SPV is also called IPV. SPV is always more serious than RDSIP. RDSIP is more amenable to treatment; SPV is more likely to be associated with antisocial personality disorder. The latter is a pattern of behavior in which one partner uses physical violence, coercion, threats, intimidation, isolation, or emotional, sexual, or economic abuse to control the other partner. There has been considerable research regarding the effects on children who have been exposed to IPV. It is traumatic for a child to witness persistent or substantial conflict between parents. When high levels of violence occur, the child may develop post-traumatic stress disorder. When low levels of violence occur over a period of time, the child may develop anxiety (such as separation anxiety disorder or generalized anxiety disorder) or depression. The clinician may use both terms together—for example, CAPRD with post-traumatic stress disorder—to convey clearly the child's condition.

A **Loyalty Conflict** occurs in a child when they try to maintain affection and good feelings toward each of their parents, even though the parents are angry and hostile toward each other. A child may

experience a significant degree of divided loyalty if parental conflicts are obvious and persistent. Also, a more serious loyalty conflict may develop if one or both parents pressure the child to support that parent's side. Children frequently develop physical and psychological symptoms—such as headaches and stomachaches—when they experience intense loyalty conflict stress. These physical symptoms typically occur when the time approaches for the child to transition from the household of one parent to that of the other parent.

Parental alienation is almost always more serious than a loyalty conflict. Those mental conditions involve different psychic mechanisms for coping with parental conflict. A child with a loyalty conflict puts mental energy into maintaining a good relationship with both parents; that effort evokes cognitive dissonance, which causes discomfort and anxiety. The child may resolve those uncomfortable emotional states by aligning with one parent against the other, especially if the favored parent was able to manipulate the child into believing that the rejected parent was abusive or neglectful. In cases of parental alienation, the child typically adopts false beliefs that the rejected parent was abusive or neglectful, which drive strongly expressed contact refusal and hostility. It is important for both clinicians and forensic practitioners to distinguish parental alienation (rejection of a parent without a good reason) from realistic parental estrangement (rejection of a parent for a good reason, such as a history of abuse or neglect by that parent).

Heather was a 6-year-old girl whose parents recently divorced, and her mother was the primary residential parent. Before the divorce, Heather had a close relationship with her father. Their relationship slowly deteriorated after the divorce to the point that Heather refused to visit her father and clung to her mother during the scheduled exchanges. Beginning when the parents separated, Heather's mother cried at the transition times and repetitively told Heather, "I love you. I miss you. I can't wait for you to come back." During her time with her father, the mother telephoned Heather repeatedly, asking if she was all right, and then said, "I miss you so much. I can't wait for you to come home." When Heather returned to her mother, her mother ran to her, became tearful, and said, "I'm so happy you're back. I've been worried sick about you. I don't know what to do when you're gone." The father noticed that Heather gravitated away from him. Just before Heather began to refuse visitation with her father, she told him, "Stop being so mean to Mommy. I hate you." This is an example of a child affected by parental relationship distress, specifically parental alienation. (Adapted from Lorandos D, Bernet W. *Parental Alienation: Science and Law*. Charles C Thomas, Publisher, Ltd; 2020.)

RELATIONSHIP DISTRESS WITH SPOUSE OR INTIMATE PARTNER

Definition

DSM-5-TR states that *RDSIP* (V61.10) should be used when the major focus of the clinical contact is to address the quality of the intimate (spouse or partner) relationship or when the quality of that relationship is affecting the course, prognosis, or treatment of a mental or other medical disorder. Examples of behavioral problems include conflict resolution difficulty, withdrawal, and overinvolvement. Cognitive problems can manifest as chronic negative attributions of the other's intentions or dismissals of the partner's positive behaviors.

Affective problems may include chronic sadness, apathy, and/or anger about the other partner.

Etiology

A satisfying marriage is one of the most important goals in life. Marital happiness is more strongly associated with overall life satisfaction than is satisfaction in areas involving health, work, and children. A survey in the United States found that the most frequently cited causes of acute emotional distress were problems in intimate relationships, including separation, divorce, and other problems with intimate partners.

General etiologic factors of RDSIP include genetic and neurobiologic contributions to temperament and style of interaction. Several studies have identified genetic factors related to partner relationship problems as modestly to moderately heritable, including divorce risk, marital satisfaction, conflict, and warmth. Most personality studies have focused on temperament, which is highly heritable. The most commonly used rating scale, the Five-Factor Model (FFM) of Temperament, categorizes temperament along five dimensions: neuroticism, extraversion, openness, agreeableness, and conscientiousness. High neuroticism and low agreeableness are the most consistent predictors of marital dissatisfaction, conflict, divorce, and abuse.

Childhood attachment patterns are remarkably stable through adulthood. Adult attachment patterns are described along two domains: seeking or avoiding attachment and fear of intimacy. Securely attached adults usually have a positive view of themselves and others; they feel loved, expect responses to self-disclosures, minimize negative affects, and engage in effective conflict resolution. Developmental factors, psychosocial factors, and sociocultural expectations within and outside the family, all contribute to stability in the partner relationship or lack thereof. A history of parental divorce increases the risk for partner separation, especially if both spouses' parents are divorced.

There is a circular pattern of causation between mental illness and stressful experiences such as relationship distress. For example,

individuals with symptoms of depression are less supportive toward their partner and have lower expectations regarding support from the partner. These negative behaviors and expectations lead to greater intimate partner distress. Then, the level of marital or partner stress predicts subsequent depressive symptoms. This feedback loop serves to maintain symptoms and reduce the effectiveness of interventions.

Diagnosis and Clinical Features

There are psychological tests that highlight possible marital or intimate partner relational problems. The Relationship Conflict Inventory consists of 114 items that ask how many times particular forms of conflict occurred and the distress level of each occurrence for the participant. The Marital Satisfaction Inventory-Revised (MSI-R)—which consists of 150 true/false questions—is designed to identify the nature and intensity of distress in distinct areas of partner interaction. A short form of the MSI-R can be used as a screening tool. It consists of only 10 questions, such as, “Does your partner often fail to understand your point of view on things?” Of course, if the screening test reveals a possible relational problem, a more complete assessment of RDSIP would include clinical interviews and perhaps more elaborate questionnaires.

Dysfunctional relationships are characterized by an increase in negative affects, cognitive distortions, communication problems, and difficulties in conflict resolution. Negative affect is the most significant sign of RDSIP, particularly when accompanied by negative reciprocity. Negative reciprocity exists when negative affect is countered with more negative affect, resulting in affect amplification. Dysfunctional couples tend to attribute hurtful encounters to events outside of their control, for example, their partner’s “unchangeable” personality traits, and view negative behaviors as undeserved, intentional, or malevolent. Attributions may also be affected by transference, with characteristics of a person’s partner being associated with earlier attachment figures, evoking re-enactments of earlier feelings and experiences. Relational stability is negatively affected by unrealistic expectations and conflicting personal and relational goals, for

example, the desire to have children, parenting strategies, money, sex, religion, and so on.

Strategies for problem solving are critical to relationship stability. The maladaptive characteristics of conflict resolution that are highly predictive of divorce in dysfunctional couples are harsh start-ups or arguments, frequent use of criticism and contempt, defensive reactions, withdrawal and stonewalling, and failed repair mechanisms. Abrupt criticism at the beginning of a conflict results in affective and autonomic flooding. Men are more prone to feeling flooded due to their higher physiologic reactivity; however, both genders may experience autonomic flooding. Cognitive cascading is another characteristic of dysfunctional relationships, with criticism turning into contempt and contempt triggering a loss of feelings of admiration and memories about positive aspects of the relationship, producing a loss of motivation for preserving the relationship. With escalating intensity, stonewalling and emotional withdrawal follow. Intervention is required if healthy communication patterns are to be restored.

Differential Diagnosis and Comorbidity

Having a successful intimate relationship is a major developmental task of adulthood. Consequently, the failure of a relationship affects a person's sense of self and self-esteem, resulting in sadness, despondency, and possibly suicidal risk. Because risk is high when there is a comorbid psychiatric illness, such as an affective disorder or substance abuse, a thorough psychiatric assessment is essential because untreated disorders may exacerbate the relational problem. Conversely, a relational problem may exacerbate a pre-existing psychiatric disorder.

Past history of violent behavior and the presence of a gun in the house pose significant risks. Personality characteristics associated with violence include pathologic jealousy, verbally abusive behavior, and progressive isolation of one's partner from family and friends. Risk is particularly high when separation is imminent, and the violent partner indicates, "If I can't have you, no one will." If there are children in the family, it becomes important to determine whether they

are being maltreated. It is likely that when there is an RDSIP, there will also be present relational problems such as CAPRD or PCRP, as children struggle to manage in the midst of their parent's difficulties.

DISRUPTION OF FAMILY BY SEPARATION OR DIVORCE

Definition

DSM-5-TR states that *disruption of family by separation or divorce* (V61.03) should be used when partners in an intimate adult couple are living apart due to relationship problems or are in the process of divorce.

Etiology

Marital distress predicts divorce, which is strongly associated with symptoms of depression for the parents and also child mental health outcomes. Separation and divorce are common: in the United States, 41% of first marriages, 60% of second marriages, and 73% of third marriages end in divorce. The median duration of first and second marriages is 7 to 8 years. The U.S. divorce rate varies by the occupation of the parties: dancers, bartenders, and massage therapists have the highest divorce rates; dentists, farmers, podiatrists, clergy, and optometrists have the lowest divorce rates. Between 2000 and 2019, both the marriage rate and the divorce rate in the United States have declined: the annual marriage rate fell from 8.2 per 1,000 population to 6.1; the annual divorce rate fell from 4.0 per 1,000 population to 2.7. This low rate continued during the pandemic, with 2.3 divorces per 1,000 population in 2020, and 2.5 in 2021.

Diagnosis and Clinical Features

Parental divorce places children at risk for a range of negative sequelae in childhood, adolescence, and adulthood. In childhood, parental divorce is associated with internalizing and externalizing

behavior problems, academic problems, social difficulties, and poor physical health. When parental divorce occurs during adolescence, there are continued academic, mental health, and physical health problems, as well as risk for substance use and pregnancy. Adults who experienced parental divorce during childhood have an increased risk for major depression, dysthymia, anxiety disorders, personality disorder, and alcohol and drug dependence. Parental divorce also predicts lower educational attainment, occupational problems, physical health problems, and poorer relationships with spouses, parents, and peers in adulthood.

HIGH EXPRESSED EMOTION LEVEL WITHIN FAMILY

Definition

DSM-5-TR states that *high EE level within family* (V61.8) should be used when a family's high level of EE is the focus of clinical attention or is affecting the course, prognosis, or treatment of a family member's mental or other medical disorder. *EE* is a construct used as a qualitative measure of the "amount" of emotion—in particular, hostility, emotional overinvolvement, and criticism directed toward a family member who is an identified patient—displayed in the family environment.

Etiology

It should be noted that contemporary perspectives on EE are distinct from early attempts at developing models of the influence of family processes on severe mental illness. While historical notions—such as "poor parenting," "double-bind messages," and "schizophrenogenic" mothering—were overly parent blaming, current terminology avoids censuring the family for a person's mental illness. For example, modern theories do not regard the family as the primary causal agent of the patient's illness. Instead, the emphasis is on how the family reacts to a psychiatrically impaired relative and how these reactions protect against or contribute to the risk of recurrence of illness.

Diagnosis and Clinical Features

An established assessment device for EE is a semistructured interview known as the Camberwell Family Interview (CFI), which is conducted with the parents or spouse without the patient being present. This instrument provides ratings on the dimensions of criticism, hostility, emotional overinvolvement, warmth, and positive remarks, which allow family members to be classified as high or low on EE. The CFI is a lengthy, complex process and is practical in research settings but not in clinical practice. The Five Minute Speech Sample simply requires the family to talk about the patient for 5 uninterrupted minutes. The speech is recorded and later coded for the overall level of EE, criticism, and emotional overinvolvement. The Level of Expressed Emotion (LEE) scale is a 60-item self-report, which is completed by either the patient's important relationships or by the patient themself. The Family Attitude Scale is a 30-item self-report measure of EE; either relatives or patients may complete it. Finally, the test of Perceived Criticism (PC) consists of only two questions: "How critical do you think [your relative] is of you?" and "When [your relative] criticizes you, how upset do you get?"

High levels of EE may be benign in many family contexts, and in other families may be elicited by the stress associated with physical and mental health problems. For example, parents or family members of severely mentally ill individuals may find themselves confronted with difficult situations for which they are poorly prepared, resulting in excessive EE by the family member toward the mentally ill individual. Thus, some serious mental disorders appear to be induced—in part—by high EE in the family. For instance, genetic load plus high EE in a patient's parents appear to predict the onset of schizophrenia. That phenomenon illustrates the biosocial hypothesis, that is, that major psychotic disorders are the result of the continual interaction of specific biologic disorders of the brain with specific psychosocial and other environmental factors.

It has been observed that relatives of individuals with a major psychiatric disorder tend to respond with negative and increasingly intense emotions to subtle symptoms and negative behavior during

the prodromal phase of the illness. As symptoms and functioning worsen, parents manifest more rejection and less warmth. Also, EE levels typically decline as patients are treated, and their condition improves. There are implications for interventions with these families, that is, that onset of illness might be delayed and relapses prevented if family members remain low in criticism and rejection of the patient. The family's therapist can help family members view the patient's behavioral symptoms as signs of their illness, not indications of an evil disposition.

During the first family session, JJ's father began with a list of all of the things JJ had done in the past several months to "destroy the family atmosphere." These included inconsistent school performance, staying up too late playing video games, being irritable, especially when asked to interrupt his game playing; being grumpy at the dinner table; getting into altercations with kids at school in situations where he felt insulted or left out; and more generally, "poisoning the atmosphere wherever he goes." JJ responded by intermittently crying and cursing at his father. In the next session, conducted just with JJ and his mother, JJ cursed loudly and repeatedly jumped out of his chair when his mother spoke, threatening to physically hurt her with pieces of cardboard, pens, or other implements he found in the therapy room. Despite this behavior, JJ showed some insight into his problems. He complained bitterly that his father "is always after me to do better… he never tells me I'm doing good enough." This is an example of a high expressed emotion level within the family. (Reprinted with permission of Hooley JM, Miklowiz DJ. UNCOMPLICATED BEREAVEMENT

Definition

DSM-5-TR states that *UB* (V62.82) may be used when the focus of clinical attention is a normal reaction to the death of a loved one. As part of their reaction to such a loss, some grieving individuals present with symptoms such as feelings of sadness and associated symptoms such as insomnia, poor appetite, and weight loss. The bereaved individual typically regards the depressed mood as "normal," although the individual may seek professional help for relief of associated symptoms such as insomnia or anorexia.

Diagnosis and Clinical Features

Questionnaires have been used for decades to screen for symptoms of grief. The Texas Revised Inventory of Grief (TRIG) assesses typical symptoms of UB, such as acceptance of loss, crying, and intrusive thoughts. The Inventory of Complicated Grief (ICG) assesses indicators of complicated bereavement, such as anger, disbelief, and hallucinations. Bereavement is also called "grief" and "mourning." After the loss of a loved one, the bereaved individual may experience sadness, loneliness, and perhaps anger. In some circumstances—for example, involving long-term caregivers—the process of bereavement may begin even before death occurs, which is called anticipatory grief. Cultural expectations may influence how a person experiences grief. In some cultures, a death in the family is manifested in a quiet and private manner; in other cultures, there may be loud, intense displays of emotion.

In contrast to the relational problem of UB, complicated or complex grief makes it harder for the bereaved person to adapt to the loss of the loved one. These individuals may ruminate over the timing or manner of the death. They may put excessive energy into avoiding reminders of the loss. They may question whether their own experience of grief is too much or too little. In complicated grief, these symptoms persist longer than 6 months following the death of the loved one.

Differential Diagnosis and Comorbidity

The DSM-5-TR discusses how to distinguish bereavement or grief from a major depressive episode (MDE). In UB, the predominant affect is feelings of emptiness and loss, while in an MDE, it is persistent depressed mood and the inability to anticipate happiness or pleasure. The dysphoria in UB is likely to decrease in intensity over days to weeks and occurs in waves, which tend to be associated with thoughts or reminders of the deceased. The depressed mood of an MDE is more persistent and not tied to specific thoughts or preoccupations. The pain of UB may be accompanied by positive emotions and humor that are uncharacteristic of the pervasive unhappiness and misery characteristic of an MDE. If a bereaved individual thinks about death and dying, such thoughts are generally focused on the deceased and possibly about “joining” the deceased, whereas, in an MDE, such thoughts are focused on ending one’s own life because of feeling worthless, undeserving of life, or unable to cope with the pain of depression.

CONCLUSIONS AND FUTURE RESEARCH

The relational problems are concepts that clinicians and research personnel will find useful once they become familiar with their meaning, scope, and implications. In clinical practice, it adds important information to say that a child with a generalized anxiety disorder is also experiencing the relational problem, high EE level within the family. Or to say that an adult with persistent depressive disorder is also experiencing the relational problem, disruption of the family by separation or divorce. Thus, traditional DSM-5-TR diagnoses focus solely on symptoms exhibited by individual patients, while relational problems identify the context and often the precipitating cause of the individual’s symptoms. Identification of the contextual component may lead to a more comprehensive treatment plan. The relevance of relational problems goes well beyond psychiatric disorders since they pertain to many disorders across all branches of medical practice. For example, the strategies for managing chronic medical illnesses may include an assessment of

family factors and interventions with families, which creates a role for the relational problems described in DSM-5-TR.

Researchers can achieve greater specificity by using both traditional diagnoses and relational problems in describing or classifying their study participants. For example, treatment studies for children with specific disorders—for example, anxiety, depression, or disruptive behavior disorders—can assess outcomes using the occurrence of IPD or IPV in parents as covariates to determine whether the presence of CAPRD affects treatment outcomes. Or, screening for parental relationship distress may be accomplished during well-baby appointments. If there are relational problems involving the parents, they could be randomized to couples therapy or treatment as usual, and tracking participant outcomes could test whether that intervention prevents the onset or progression of child mental health problems.

It seems counterproductive for clinicians and researchers to “choose sides” between biologic and psychosocial methods for conceptualizing mental illness. These are simply different ways of understanding the same reality, along with acknowledging that biologic and mental factors mutually influence each other. For example, genetic risk for major depression puts a person at risk for marital and family problems, which in turn are risk factors for depression.

Of course, there are opportunities for further research and improvements in the classification of relational problems, which may play out in future iterations of the DSM. Many family therapists would like to see a broader range of mental and interpersonal conditions included in this section. They would prefer more detailed descriptions of each condition, and they probably would like to include well-known terms and concepts such as triangulation and cross-generational coalition. Also, it is apparent that relational problems must be described in terms that are clearly operationalized. Studies can be designed to see if clinicians who observe the same interpersonal processes make the same relational diagnosis. It is important to distinguish relational problems from similar, perhaps overlapping, conditions: for example, what criteria distinguish PCRP from

CAPRD? Finally, researchers may be able to sort out how specific relational problems lead to specific mental disorders.

Cultural Concepts of Distress and Assessment

29.1 Cultural Concepts of Distress

Roberto Lewis-Fernández, M.D., M.T.S., Laurence J. Kirmayer, M.D., and Brandon A. Kohrt, M.D., Ph.D.

Cultural psychiatry has documented wide variations in the experience and expression of mental distress around the world. Historically, these variations were often characterized in terms of "culture-bound syndromes"—distinctive patterns of co-occurring symptoms and signs that were assumed to be rooted in or "bound" to local cultural or contextual features. With advances in research, this view has been challenged, and a more refined set of terms have been proposed to capture the ways in which symptoms, explanations, and expressions of distress vary across cultural contexts. This chapter reviews these newer concepts and approaches, which are included in DSM-5-TR, and illustrates how they can be used to better understand the causes, course, and consequences of mental health problems in the community and the clinic.

Contemporary cultural psychiatry and psychology recognize that all classification schemes are rooted in particular cultural and historical frames. In turn, the diagnostic language of psychiatry influences popular culture and everyday understandings of mental health problems, ensuring that professionally defined categories help pattern social experience. Hence, Western psychiatric nosologies need to be subjected to the same kind of social, historical, and contextual analysis applied to diverse local nosologies.

Despite local variations, however, similar forms of distress have been documented in many regions of the globe, resulting in clusters of symptoms or syndromes, such as depression or schizophrenia, that can be described at a level of abstraction that allows broad cross-cultural application. Local cultural variations in symptom interpretation and experience will nonetheless influence the recognition, response, and outcome of these disorders. Moreover, some local variations may depend on specific culturally based attributions, behavioral responses, and patterns of interpersonal interaction so that they only occur where those modes of explanation and interaction are present. These indigenous illness forms may occur in Western as well as non-Western contexts. The study of cultural variations in the presentation of illness and distress yields a valuable critique of Western classification schemes by highlighting the assumptions of existing nosology and identifying alternate, indigenous categories that may better fit the experience of patients from diverse backgrounds.

Terminology and Conceptualization

Cross-cultural mental health researchers have introduced several terms to refer to and describe culturally specific forms of expressing and diagnosing emotional distress, including cultural syndromes, popular or folk illness categories, idioms of distress, and illness explanations or attributions. The need for multiple terms reflects the complexity of the ways in which people experience, understand, and communicate distress.

The term “culture-bound syndrome” was used in the past to describe patterned behaviors of distress and/or illness that appeared to be distinct from existing psychiatric categories and were considered unique to particular cultural settings. The clear implication was that Western psychiatric categories were not culture-bound but rather universal and that proper characterization would disclose a simple mapping of non-Western syndromes onto the categories of international nosology.

The term “syndrome” generally refers to (1) a collection of co-occurring symptoms and signs with (2) a distinctive temporal course, which may include an immediate precipitating cause or etiologic context and response to treatment. Most of the entities described in the DSM as disorders are syndromes in that their identification depends on symptoms and signs since their underlying causes and mechanisms remain uncertain, and there are no reliable biomarkers. The categories are clinically useful largely because they have implications for treatment choice and prognosis. As underlying mechanisms become clear, new distinctions can be made, and specific symptoms, signs, and behaviors may be distinguished and given more diagnostic weight. However, the symptom cluster itself may remain important as a central feature of patients’ experience.

The notion of a syndrome being bound by culture is more problematic. The attribution of “boundedness” emerged early in the history of cultural psychiatry in colonialist contexts in which observers had limited understanding of local cultural contexts. Hence, there was a strong tendency to exaggerate differences, generate stereotypes, and “exoticize” the other. Reports that focused on a particular cultural group in a community noted patterns of problematic behavior, which appeared distinctive or unique to the (usually) Western observers, whether they were missionaries, anthropologists, or clinicians. In some cases, the behavior pattern had a specific popular label and treatment within an indigenous medical system. The foreign observers often believed that the communities in question had been socially isolated, and therefore, saw the patterns of distress as unique and locality bound. Considering the massive migrations and cultural diffusions that have occurred throughout

human history, this assumption of boundedness has rarely been tenable. For example, in the late 1950s, Raymond Prince described a Nigerian culture-bound syndrome of “brain fag” characterized by feelings of mental fatigue, difficulty concentrating, heat in the head, and myriad other somatic symptoms. Brain fag was found among students who were the first in their families or communities to pursue higher education and was linked to local ethnophysiologic ideas about the importance of central heat and the head in African psychology. However, recent historical evidence shows that “brain fag” was commonly described in England in the late 1800s, and presumably, traveled to Nigeria as part of the colonial system to be adopted as a local mode of expressing distress. Hence, while there may indeed be an important fit between the syndrome of brain fag and local cultural concepts, it must also be understood in relation to these colonial cultural influences.

It would be more accurate, therefore, to term these conditions *cultural syndromes*, de-emphasizing their boundedness because, while they originate in particular cultural areas, they spread with migration and communication and are incorporated into local concepts of illness and expressions of distress. In the contemporary global market of intensified cultural exchanges, exportable syndromes readily become detached from geographical areas. Whatever boundedness they have inheres not in specific locales but in their adoption by ethnic or linguistic groups and links to the sociocultural patterns of which they form part, whether in their countries of origin or in new homes.

The term “syndrome” implies a relatively fixed pattern of symptoms. Only a subset of culture-specific expressions of distress around the world shows this level of organization. Many are typified instead by a more diffuse set of complaints, symptoms, and predicaments that vary across situations and settings, age cohorts, and social subgroups. Rather than representing separate illnesses, they constitute a general category of distress, part of an indigenous system of classifying suffering, sometimes encompassing not only illness but also other forms of misfortune or adversity. Reports of *nervios* (nerves) in Latin America, for example, comprise a

continuum of conditions, labeled with different but related terms (e.g., “being nervous since childhood,” “suffering from nerves,” “being ill with nerves,” and “attacked by my nerves”), all denoting different gradations of vulnerability and of the effects of adverse events on the nervous system, including symptoms, signs, and causal attributions. As another example, Haitians may distinguish broadly between “*maladi dyab*” and “*maladi bon Dieu*”—the first referring to a set of illnesses (“maladi”) triggered in association with evil forces (“*dyab*,” literally “devil”), usually through spiritual means, and the latter referring to diseases of the natural order, sent by God (“*bon Dieu*”). A great diversity of human afflictions fall under these general headings. Anthropologists use the term *folk illness* to refer to local illness categories like these that are based on particular systems of medicine or broader cultural ontologies, independently of whether they are organized as discrete syndromes or not. A related term is *popular illness category*, which simply reflects the fact that these are labels or constructs commonly used by lay people in the general population.

Table 29.1–1.
Key Elements of the Constructs Used to Describe the Cultural Concepts of Distress

Folk Illness Categories	Cultural Syndromes	Idioms of Distress	Causal Explanations
▶ Encompass cultural syndromes, idioms of distress, and causal explanations ▶ May include afflictions and predicaments not considered illnesses in the local cultural context	▶ Organized as a collection of co-occurring symptoms and signs ▶ Have distinctive temporal courses, precipitants, causal attributions, and treatment responses	▶ Constitute a linguistic or nonverbal mode of communication ▶ Represent a local "language" for expressing distress ▶ Do not presuppose pathology	▶ Reference etiologies rooted in local systems of knowledge ▶ Are not necessarily linked to particular signs and symptoms ▶ Guide help seeking

One drawback to the term "folk illness" is that the descriptor "folk" tends to connote less affluent and formally educated sectors of society and ignores the fact that these categories are used in complex medical systems embraced by large segments of the population in modern, urban, industrialized societies. Thus, traditional Chinese medicine or Indian Ayurveda has many categories of illness defined in terms of the imbalance of energies or vital essences, respectively. Another disadvantage of the term is that many local illness labels are used to describe afflictions and expressions of distress that are on a continuum with folk illnesses but are not strictly illnesses themselves (much as the term "depression" refers to a psychiatric disorder as well as to lay descriptions of much milder

reactions to adversity). DSM-5-TR uses the more general term *cultural concepts of distress* to encompass folk illnesses, cultural syndromes, and two other types of cultural expressions of distress described below.

One of these is the notion of a *cultural idiom of distress*, a key concept in recent medical anthropology. Introduced by anthropologist Mark Nichter in 1981, the term "idiom" emphasizes the idea of a local linguistic or nonverbal mode of communication. It highlights the communicative function of the cultural concepts of distress, the notion that suffering is expressed in particular local "languages of distress," which are shaped by cultural understandings of what are appropriate and meaningful ways of denoting affliction. "Idiom" also does not presuppose pathology. Many idioms—like "thinking too much," "stressed out," or lay notions of "depression"—can be used to express everyday concerns or levels of distress that may be subclinical. However, idioms of distress also provide a way to express more severe suffering that leads to help seeking. Hence, the clinician must be able to decode the significance of such expressions to identify dimensions of the problem that require intervention.

A final cultural category encompassed under the term "cultural concepts of distress" involves the many expressions of distress pointing to *causal explanations* that are rooted in local systems of knowledge. These, in turn, may reference particular ontologies involving ethnophysiologic ideas about humors, energies, or other processes, ethnopsychological theories about the mind, sociomoral explanations in terms of problems in the social order, or spiritual or other religious and cosmologic systems. As etiologies, these causes are not necessarily linked to particular signs and symptoms but rather denote explanations for the source of the problem that usually guide help seeking. Table 29.1–1 summarizes the key elements of the constructs used in this chapter to describe the cultural concepts of distress.

Cultural syndromes, folk or popular illness categories, idioms of distress, and explanations commonly coexist, and the same local term, or closely related terms, may refer to more than one of these types of concepts. For example, *nervios* terms in Latin America can

be used to describe a syndrome (e.g., as the subcategory *ataque de nervios*, a stereotyped sequence of precipitants, behaviors, and sequelae), a folk illness category (e.g., when denoting an illness "affecting the nervous system," as in "she is ill with nerves"), an idiom (e.g., when communicating the nature of the affliction, such as, "my nerves are killing me"), or an explanatory cause (e.g., "he was born with emotional problems because his mother suffered from nerves during her pregnancy"). Moreover, usage may change over time, reflecting cultural changes and the influence of the health care system itself. Despite this complexity, the concepts provide a window into the ways that patients and their families understand their problems and are essential for accurate epidemiologic research, clinical diagnosis, and assessment, as well as designing appropriate and effective interventions. The following sections further trace the origins and use of these terms in psychiatric theory, research, and practice.

HISTORICAL BACKGROUND

Pioneering Work

In 1962, Pow Meng Yap, an early exponent of cultural psychiatry, introduced the term *atypical, culture-bound psychogenic psychoses* to denote what he later called "forms of psychopathology produced by certain systems of implicit values, social structure and obviously shared beliefs indigenous to certain areas." In response to changing nosologic paradigms, this term evolved over time into "atypical, culture-bound reactive syndromes," from which the label of "culture-bound syndromes" emerged. Yap's selection of the term "culture-bound" was based on his view that aspects of culture (i.e., implicit and explicit values and notions, social structure, and folk practices) pattern the expression of psychopathology to such a degree that particular forms of illness may be confined to the geographical boundaries of the cultural group in question. He expected that once analyzed further, these apparently unique forms of mental illness would prove to be atypical variations in generally distributed

psychogenic disorders. Basic to Yap's formulation was an acceptance of the universality of psychoanalytic constructs, on which culture could exert pathoplastic effects. This implied it should be possible to locate all of these "exotic" syndromes within the classificatory systems of clinical psychiatry, and Yap proposed a formal ordering of these syndromes within a universal nosologic schema for clinical, didactic, forensic, and administrative purposes. Yap also suggested that attempts should be made to distinguish "essential" from "accessory" symptoms as well as to establish the "natural history" of each disorder in its "elementary psychogenic form" in order to accurately parcel the syndromes among psychiatric and somatic illness categories. His expectation was that such studies would lead first to a consistent definition of each disorder in the form of modal symptoms and then to universally valid mechanisms of psychopathology, providing a firm basis for cross-cultural clinical research.

In the 1980s, Raymond Prince and coworkers expanded on Yap's writings. They proposed a definition of these phenomena as a "collection of signs and symptoms (excluding notions of cause), which is restricted to a limited number of cultures primarily by reason of certain of their psychosocial features." This definition attempted to narrow Yap's "culture-bound syndromes" exclusively to the medical denotation of "syndrome" as a collection of descriptively defined symptoms that are "a reasonably complete descriptive picture of nature, remain fairly constant over time and are verifiable by all investigators." This kind of nosologic entity was distinguished from "labels" and "causal notions" superimposed idiosyncratically on universal psychopathologic entities. In this view, these terms conveyed much less scientific accuracy and were prone to nonverifiable misconceptions. Prince attributed some of the controversy surrounding the "culture-bound syndromes" to the lack of focus on descriptive categories defined by recurrent symptom patterns. "Culture-bound syndromes" were portrayed as useful to medical anthropologists and cross-cultural psychiatrists as well as to epidemiologists. The former can use them to explain the relationships between symptom patterns and cultural processes,

while the latter need to take them into account to accurately and completely measure the full range of psychopathology in a given population.

Following on the methods of Yap and Prince, other authors continued to categorize “culture-bound syndromes” according to contemporary professional paradigms, usually adhering to Prince’s formula of stressing their descriptive aspects. For instance, Ronald Simons emphasized the phenomenologic similarity of groupings of these conditions across historically unrelated and culturally dissimilar times and places, despite differences in the meaning assigned to the experiences and behaviors. He contended that it is feasible to insert the “culture-bound syndromes” into contemporary diagnostic systems, particularly once they are grouped as a cluster of related syndromes. The term *taxon*, borrowed from biologic classification, was employed to denote a grouping of similar items, but without specifying the level of abstraction of the similarity or suggesting that the grouping as presently elaborated is in any way exhaustive or final. In their 1985 text, *The Culture-Bound Syndromes*, Simons and his colleague Charles Hughes used the taxonomic principle to group the cultural concepts based on their phenomenologic similarity across diverse cultural settings. For example, under a “Startle Matching Taxon,” they listed *latah* (from Malayo-Indonesia) and *imu* (from Japan), defined in purely behavioral terms, roughly as follows: someone is startled, after which they say things that are normally socially taboo, talks in a manner locally considered nonsensical and amusing, matches the movements of others, and obeys or defies commands in an exaggerated and stereotyped way. Like Yap and Prince, this kind of classification method focused on a verifiable cluster of behaviors and experiences as the defining elements of the cultural concepts of distress and de-emphasized other aspects of the illness experience, such as causal attributions or social meanings that are dependent on the context in which the cultural concepts arise.

Subsequent Work in Cultural Psychiatry

Ruth Levine and Albert Gaw distinguished several kinds of cultural concepts of distress. “True” “culture-bound syndromes” were organized as recurrent collections of symptoms, which should be classified according to their “predominant symptom or symptoms” and listed as culturally patterned versions of the most relevant DSM category (e.g., *amok* [from Malayo-Indonesia] under the dissociation phenomena and *boufée delirante* [from Western Africa and other settings] under the psychoses). By contrast, “illnesses of attribution” were organized around indigenous etiologic notions (e.g., *susto* [from Mexico and other Latin American regions] in which sudden fright will cause the soul to leave the body, making the individual vulnerable to a variety of ills) rather than discrete symptom clusters. And “idioms of distress” are more general terms that do not have specific correspondences to psychiatric categories (e.g., *nervios* [from Latin America], a general term used as an idiom for stress-related illnesses that can apply to disparate psychiatric disorders, from adjustment problems to psychosis). The authors themselves acknowledged some of the arbitrariness of this approach, however, as well as the technical difficulties involved in parceling out indigenous expressions of psychopathology into their three categories. For instance, in *hwa-byung*, suppression of anger is seen as a causative factor in the development of a somatic symptom cluster (indigestion, dyspnea, fatigue, and the sensation of a mass in the stomach) associated with emotional symptoms (anxiety and depression). The fact that this folk condition is organized around a Korean etiologic notion that ascribes to anger (*hwa*) the capacity to produce illness (*byung*) led these authors to categorize *hwa-byung* as an illness of attribution, whereas it has been described as a cultural syndrome by others due to its usual presentation as a recurrent symptom cluster. In fact, most cultural syndromes contain embedded notions of attribution as organizing elements for the symptom clusters.

Other authors have taken a more mixed approach, combining universalistic views with the notion that each social group creates unique forms of psychopathology that are fundamentally inseparable from the cultural preoccupations that gave rise to them. Notable among these is John Carr, who hypothesized that all forms of

psychopathology, including the folk illnesses, represent *culturally authorized final common behavioral pathways*. These are behavioral responses, part of a limited number of behavioral repertoires that individuals use in response to stressful conditions that are common to humanity. Although significantly shaped by cultural contexts, these pathways are mediated by universal mechanisms of learning and cognition. To elucidate the relationship between *amok* and depression, for example, Carr and his colleague Peter Vitaliano contended that these alternate expressions of distress are culturally determined variants of response to comparable life stress conditions. The critical question, in their view, is why some people respond with aggression, some with depression, and still, others cope adaptively to similar aversive events. Culture-specific and idiosyncratic responses to stress result from complex interactions between physiologic processes, predisposing personality styles, cognitive processes, and learned problem-solving skills.

Perspectives from Clinically Applied Medical Anthropology

Ethnographic studies of folk illnesses have approached them as indigenous expressions of distress found within specific cultural contexts. From the anthropologic perspective, these expressions represent local patterns of distress that reference common preoccupations or concerns of particular cultural groups. According to this view, all expressions of distress, including those incorporated into the DSM and ICD systems as diagnostic entities like major depression or schizophrenia, are culturally shaped and are thus equally “culture-bound.” This specificity does not negate the role of biology or personal biography in the formation of any of these concepts, much as universal biologic parameters constrain the features of all languages, yet cultural groups produce multiple variants of human speech.

Medical anthropologists and sociologists, such as Byron Good, Mary-Jo Delvecchio Good, and Margaret Lock, have noted that illness expressions may be organized culturally into nosologies not only on the basis of descriptive, symptom-based approaches but also

according to diverse cultural logics that are rooted in distinct ontologies (e.g., the reality of spirit-mediated illness). Many cultural groups use symbolic methods of classification, including the literate medical traditions of the ancient civilizations, in which illnesses are often categorized by analogy to various aspects of the cosmos, social relations, objects in nature, and other contextual factors. The Goods noted that current Western nosologic thinking is predicated on an empiricist theory of language, which posits the existence of a one-to-one correlation between *words* and *things in the world*, with the notion that the latter will remain fixed and unchanging despite evolving social situations. Other cultural groups and periods have considered instead that things in the world are mutable and depend for their meaning on their associations with the social, environmental, and even supernatural context and that human categorizations should reflect this fundamental embeddedness.

Ethnographic work reveals that cultural concepts of distress identify socially constructed patterns of interpretation of suffering that serve pragmatic communicative functions. Clarifying these functions requires what Good and Delvecchio Good called a "meaning-centered medical anthropology" that investigates illness forms from the perspective of *semantic networks*, the clusters of experiences, words, and interpretations that give rise to particular illness forms as modes of experience and expression. These meaning networks are called "semantic" because they reveal the role of interpretation and communication in shaping reality and may include "personal trauma, life stresses, fears and expectations about the illness . . . the metaphors associated with a disease, the ethnomedical theories, the basic values, and conceptual forms, and the care patterns that shape the experience of the illness and the social reactions to the sufferer in a given society." By taking this contextual approach, the basic organizational principle underlying a particular illness form can be established to assess the degree to which it is descriptive, etiologic, or expressive of particular concerns.

The anthropologist and psychiatrist Arthur Kleinman approached the meaning-centered approach through the concept of an *explanatory model*. This concept refers to the more-or-less

systematic explanations of an illness among different actors in any given illness episode (e.g., patient, relative, and caregiver). Kleinman showed how the explanatory model approach could be incorporated into clinical assessment through the use of practical questions about basic aspects of illness experience, addressing perceived etiology, time and mode of onset of symptoms, pathophysiology, course of sickness, and treatment that can be used by clinicians and investigators to clarify the interaction of cultural, physiologic, and psychological elements in an illness episode. The Explanatory Model approach was operationalized by Mitchell G. Weiss in the form of a semistructured instrument for clinical ethnographic research, called the Explanatory Model Interview Catalogue which can be adapted for research on any illness form.

In later work, Kleinman deepened this approach to explore the ways in which the intersubjective processes of interpersonal agency —communication, engagement, transaction, and negotiation—create the flow of *social experience* that links the body–self with collective meanings and social institutions. Individuals transact their lives, including basic processes of health and illness, within relational networks of social experience, which provides "the medium through which moral commitments and negotiations join the corporeal with the collective." For Kleinman, all of life is lived in "local worlds" that constitute the moral contexts of the illness experience. The importance of local categories of suffering then lies, not primarily in identifying discrete syndromes, but in understanding what is "at stake" for individual patients, families, and communities in terms of power, prestige, material resources, ethnic identity, social order, or survival. This intersection of vital interests and values was well illustrated in Kleinman's studies of neurasthenia in China, which revealed the importance of relational networks at the levels of supernatural and natural worlds, human interactions, bodily processes, and politics. In traditional Chinese thought, each level affects the functioning of all the other levels. This fundamental interdependence can be seen in the existence of illnesses whose pathology is at the network level, such as the concept of *shenjing shuairuo,* "weakness of the nervous system" in Mandarin. In this

cultural syndrome, the internal nervous system (*shenjing*) has become devitalized (weak or run down, *shuairuo*) in correspondence with a demoralized network of interpersonal and societal relations. The symptoms of *shenjing shuairuo* can thus be understood as embodied signs of a devitalized world, both internally and externally, which are linked by contextually located emotions.

Ethnographic fieldwork by Allan Young, Laurence Kirmayer, and their colleagues has shown the complexity of types of knowledge and modes of narration embedded in everyday explanatory accounts of illness. Individuals may link symptoms to explanations based on *chain complexes* because they were closely connected in time and space (contiguity) or as a result of logical shortcuts to denote complex experiences (e.g., metonymy), such as using the term "nerves" to refer to the anatomical and functional aspects of the nervous system, including the feelings and sensations it mediates, much as journalists use the term "Washington" to refer to the entire U.S. government. People also commonly use *illness prototypes*—illness episodes, experienced previously by the person or by others, that provide salient examples used to reason analogically about one's own experience. In effect, patients' illness narratives may combine models common to a cultural group, idiosyncratic assemblies of possibly disconnected events, and assumptions based on past experiences. These approaches were operationalized by Danielle Groleau in collaboration with Young and Kirmayer to develop the McGill Illness Narrative Interview, a semistructured interview designed to obtain illness narratives based on (a) contiguity of events, (b) cultural prototypes of the illness for the patient, and (c) explanatory models of illness.

Atwood Gaines's concept of *sickness history* was another important contribution to the anthropologic understanding of concepts of distress. Gaines's constructivist argument held that folk and professional notions of sickness evolve historically, in association with other aspects of culture, and that individuals' understanding and experience of illness are patterned on this accumulated social knowledge. In this way, cultural concepts of distress may reflect distinct cultural histories of societies. Gaines

presented the examples of *spasmophilie* (spasmophilia), *fatigué* (fatigued), and *triste/fatigué tout le temps* (sad/fatigued all the time) as sicknesses that are considered physical diseases in France but are unknown in the United States and would actually be considered nonpathologic forms of dysphoria if they came to the attention of American nosologists. Gaines showed how these concepts emerged from a common sickness history that evolved from medieval understandings of dejection as a sin (acedia) to a positive valuation of existential world-weariness as a sign of maturity and a possible and accepted etiology of a physical disease characterized by various states of fatigue, bodily aches, and irritability, among other symptoms.

Much recent work has pursued similar constructivist and historical approaches to both local constructs and the diagnostic entities of the DSM. Combining anthropologic and clinical methods, Roland Littlewood and Maurice Lipsedge traced the historical contexts of constructs like hysteria, medication overdosing, agoraphobia, anorexia nervosa, and shoplifting and linked their phenomenologies and demographic distribution to culturally patterned gender and class constraints prevalent in the United States and United Kingdom in the 19th and 20th centuries. They described these syndromes or idioms as deeply embodied expressions of societal conflicts about which the participants were frequently only marginally aware. The field of *critical medical anthropology* emphasizes the contribution of societal structures of oppression (e.g., racism, class hierarchies, restrictive immigration laws) to the prevalence, phenomenology, and course of mental health conditions, including their comorbidity with physical illnesses. The work of Nancy Scheper-Hughes, Merrill Singer, Philippe Bourgois, and others reveal the impact on the expression of illness of adverse social determinants of health that often go unnoticed or unaddressed in routine clinical care.

A constructivist approach to the ethnopsychologies underlying culturally specific expressions of illness and distress can be elaborated in terms of pragmatic, linguistic, communicative, and interactional processes, including (a) the handling of the gap between experience and expression; (b) the labeling of deviant

behavior as voluntary or accidental; and (c) the interpretation of symptoms as symbols or meaningless events. This conceptual grid helps explain why in North America, it is possible to privilege "psychologized" understandings of illness since these arise out of local commitments to individual autonomy, expressiveness, and personal goals. Commitments to other values in other cultural settings may produce different ethnopsychologies.

RELATIONSHIP TO PSYCHIATRIC CLASSIFICATION

At present, most investigators consider cultural concepts of distress to be *orthogonal* to psychiatric diagnoses; that is, the cultural concepts comprise alternate systems of classification that describe in distinct ways the same realm of suffering as professional nosologies. This means that, at the level of global categories, the cultural concepts cannot be easily subsumed into existing psychiatric disorders. Instead, each cultural concept exhibits a *degree of overlap* with a group of Western diagnoses, which can be represented by percentages or by a series of correlations, as with any set of comorbid relationships within professional categories.

Rather than one-to-one, the correspondence between diagnoses and cultural concepts tends to be one-to-many in either direction. Symptoms or behaviors that might be sorted by nosologies like ICD or DSM into several disorders—including across distinct diagnostic clusters—may be included in a single cultural concept, and diverse presentations that might be classified by Western nosologies as variants of a single disorder may be sorted into several distinct concepts by an indigenous diagnostic system. Therefore, cases identified by a single indigenous label often cut across diagnostic clusters. For example, the symptoms of *amok* in Malayo-Indonesia exhibit diverse combinations of anxiety, depressive, somatic, dissociative, psychotic, and characterologic symptoms. The obverse is also true; homogeneous psychiatric cohorts will appear locally diverse. In Latin America, for example, different cases of major

depression may be labeled as distinct conditions according to locally salient features of phenomenology, causation, context, or the healing ideology of the practitioner. These include cases of *padecer de los nervios* (suffering from nerves), *susto, fallo mental* (mental failure), *cólera* (rage), *facultades* (faculties, for *espiritistas*), and demonic influence (e.g., for Pentecostals), among other categories. Cross-cultural variation in the assembling of the "metastructure" of psychiatric disorders—the fact that different nosologies distribute individual illness categories into diagnostic groupings in distinct ways—as well as the changes over time in this classification process (e.g., the reassigning of post-traumatic stress disorder [PTSD] away from the anxiety disorders and into a new category of trauma and stressor-related disorders) reveals the cultural underpinnings and social evolution of any classification system.

The lack of one-to-one correspondence between diagnoses and cultural concepts is intensified by the substantial phenomenologic variation that exists even across individuals who endorse the same cultural concept of distress. A given instance of *ataque de nervios*, for example, may present as an acute dissociative episode, with seizure-like symptoms in a state akin to trance, for which amnesia is later reported. Other episodes may resemble cases of panic disorder, albeit with more suicidal and aggressive features, such as breaking things and verbally or physically attacking those around them. Some episodes may present as uncontrollable fits of nervous laughter, which evolve into bouts of crying and screaming and subsequent depression. Others may constitute episodes of acute grief at the funeral of a loved one without any pathologic sequelae. What links all four instances in the popular classification system in the Latino Caribbean is their presentation as acute episodes of uncontrolled emotionality, precipitated by interpersonal stressors that overwhelm the person's coping ability, usually in a context of insufficient social and familial support. Yet from the psychiatric perspective, these presentations would be considered phenomenologically distinct. Clinical translation between the cultural concepts and psychiatric diagnoses must therefore be conducted at the level of the *individual*,

describing for that person the overlap between both systems of classification.

Two other differences ensure that cultural concepts of distress and contemporary psychiatric nosologies overlap only partially as global systems. First, Western nosologies are based at present nearly exclusively on formal, descriptive definitions of psychopathology. Most indigenous nosologies, however, distinguish pathology from normality at least as much based on contextual characteristics and causal theories as on descriptive ones. These include assessments regarding the appropriateness of the symptom in the specific setting and time in question, the relative sufficiency of the precipitating stressors, and the nature and quality of the human, and sometimes spiritual, relationships of the sufferer.

Second, while psychiatric nosologies contain only pathologic conditions, cultural concepts of distress may apply to a wide range of severity, including presentations that do not meet DSM criteria for any mental disorder. As described in DSM-5-TR, “an individual with acute grief or a social predicament may use the same idiom of distress or display the same cultural syndrome as another individual with more severe psychopathology.” The indigenous classification systems thus tend to describe broader realms of behavior and adaptation than the narrower purview of psychiatric classification.

Despite the differences between local and professional nosologies, information on cultural concepts of distress is vital to clinical care for at least five reasons, which are outlined in DSM-5-TR. First, the use of cultural concepts in screening instruments or in reviews of systems may facilitate the identification of patients’ concerns and improve the detection of psychopathology, as individuals may be more familiar with these local concepts than with professional terminology. For example, including questions about “thinking too much” can elicit illness accounts that may not be evoked by typical symptom queries. Second, clinician awareness of cultural concepts may prevent misdiagnosis, as cultural variation in symptoms and explanatory models associated with these concepts may lead clinicians to misjudge the severity or a problem or assign the wrong diagnosis (e.g., socially warranted suspicion may be misunderstood as

paranoia). Third, cultural variations in symptoms and attributions related to the cultural concepts can be associated with particular features of risk, resilience, and outcome. Clinical exploration of cultural concepts can elicit information on the role that specific contexts play in symptom development, course, and coping strategies. For example, the interpretation of trauma-related symptoms as spiritual afflictions may prompt the use of effective forms of healing and self-coping, such as church-based social support or meditation. Conversely, the presence of a cultural syndrome may be associated with specific types of risk and morbidity —for instance, endorsement of *ataque de nervios* is related to higher suicidal ideation after adjusting for psychiatric diagnosis, demographic characteristics, and trauma exposure. Fourth, understanding the messages being communicated by the patient in the idiom of the cultural concept (e.g., social isolation, being overwhelmed) can improve clinical rapport and engagement and help patients and clinicians select a mutually acceptable treatment plan. Some patients come to care expecting to be treated for the cultural concept of distress and may become disengaged if their understanding is not negotiated effectively with that of the clinician. Fifth, cultural concepts can illustrate key psychological mechanisms which need to be understood and addressed to improve clinical efficacy. For example, catastrophic cognitions can contribute to symptom escalation into panic attacks in culturally specific ways, such as through the cultural salience of certain symptom–outcome pairings. The popular linkage made in the United States between chest pain and heart attacks can precipitate panic episodes when chest pain occurs as part of an anxiety reaction but is interpreted as a harbinger of myocardial infarction. In Cambodia, by contrast, the association is more commonly between neck soreness and stroke due to the interpretation of panic attacks as signs of disordered *khyâl* circulation, a wind-like substance important in local ethnophysiology. Being aware of these linkages can help clinicians identify how cultural interpretations can constitute the actual “cogs” of the disorder.

Attending to these aspects of the relationship between cultural concepts and psychiatric diagnoses can help clinicians meet patients' treatment expectations. Moreover, the inclusion of cultural concepts in research can reveal patterns of comorbidity—between the diagnoses linked by the idiom or cultural syndrome—and clarify the epidemiologic distribution of cultural features of the illness. Information on the cultural concept of distress can be incorporated into the process of diagnostic assessment and treatment planning by eliciting an account of the person's definitions of pathology, idioms of distress, unique symptoms, contextual embeddedness, and other associated factors that are contained in the experience of the cultural concept. A systematic approach for eliciting and documenting this information is the Cultural Formulation Interview, which is included in DSM-5-TR and will be described later in this chapter.

EXAMPLES OF CULTURAL CONCEPTS OF DISTRESS

Only a few of the thousands of cultural concepts of distress have received sustained research attention integrating cultural and psychiatric research methods. This chapter focuses on three concepts from diverse cultural regions that have been the object of intensive research, including studies of their relationship with psychiatric diagnoses: *ataques de nervios*, possession syndrome, and *shenjing shuairuo*. Other examples of cultural concepts of distress are included in the DSM-5-TR chapter on culture and psychiatric diagnosis. These three examples and the few cultural concepts listed in the DSM-5-TR are meant to be illustrative of the wide gamut of folk illness categories relevant to particular populations or contexts.

Ataque de Nervios

Ataque de nervios ("attack of nerves" in Spanish) is a syndrome indigenous to various Latin American cultural contexts, notably those of the Latino Caribbean (Puerto Rico, Cuba, and the Dominican

Republic). It has received considerable attention in the psychiatric and anthropologic literature since the mid-1950s, mostly in Puerto Rican communities in the Island and in the United States. Early reports of presentations in male recruits to the U.S. armed forces by military psychiatrists in Puerto Rico mislabeled *ataque* as "the Puerto Rican Syndrome." In keeping with psychoanalytic theory at the time, these investigators attributed the *ataque* to specific indigenous child-rearing practices allegedly predisposing to the hysterical discharge of aggressive drives. The power relationships embodied in the military, and the colonial situation represented by the presence of the U.S. armed forces in Puerto Rico, were usually left unanalyzed in these discussions.

Subsequent research focused on the role of *ataque* as a culturally recognized and sanctioned expression of emotion, mostly by women, that should be understood as a form of communication about family relationships in contexts of social and economic powerlessness. These investigations located the psychosocial etiology of *ataques* in experiences of acute family discord and individual suffering—such as grief, fear, and anger—in the context of collective distress—such as migration, poverty, and discrimination. This research emphasizes the role of *ataque* as an idiom of distress in Latino communities and illustrates how the same folk term may represent different kinds of cultural concepts—that is, a folk category such as *ataque* is a cultural syndrome that functions as an idiom of distress.

Contemporary clinical–anthropologic studies have further clarified the phenomenology, cultural meanings, epidemiology, and relationship of *ataque* to psychiatric diagnoses. The work of Peter Guarnaccia and Roberto Lewis-Fernández has identified loss of control of emotions, behaviors, and a social world out of control as the core experiences of *ataques de nervios*. Their work suggests a popular nosology based on various categories of *nervios* (nerves), several of which require more systematic research.

Phenomenology. Guarnaccia, Glorisa Canino, and colleagues surveyed a representative community sample of Puerto Rico residents (N = 912) for the presence of *ataque de nervios*. Qualitative

coding of general descriptions of the syndrome among a subsample of 145 respondents in this larger study—of whom 77 were *ataque* sufferers—yielded four domains of *ataque* experience. These were emotional expressions, bodily sensations, action dimensions, and alterations in consciousness. Based on these data, a prototypical *ataque de nervios* can be described as composed of the elements described in Table 29.1–2.

Epidemiology. A 1987 survey by Guarnaccia and Canino in a probability sample of the population of Puerto Rico (*N* = 912), using the Diagnostic Interview Schedule (DIS), found a weighted lifetime prevalence of *ataque* of 13.8%, making it one of the most frequently reported syndromes in the Island. Twelve percent of respondents had *ataques* that met DIS criteria for a positive psychological syndrome—that is, the *ataque* met severity criteria (consulting a physician or other professional, taking medications, or reporting some functional impairment) and could not be explained as resulting from physical illness or substance use. The Latino cohort of the 2002 to 2003 National Latino and Asian American Survey, led by Margarita Alegría, also obtained lifetime *ataque* prevalence in a nationally representative sample of U.S. Latinos using a diagnostic module that followed the format of the Composite International Diagnostic Interview. *Ataque* prevalence was 10.9% in Puerto Ricans, 6.2% in Cubans, 6.0% in Mexicans, and 5.4% in other Latinos, suggesting both that *ataque* is common across Latino subgroups and that it is more prevalent among Puerto Ricans.

Table 29.1–2.
Phenomenology of *Ataque de Nervios* (Attack of Nerves)

a. Exposure to a frequently sudden, stressful stimulus, typically eliciting feelings of fear, grief, or anger, and involving a person close to the subject, such as a spouse, child, family member, or friend. Severity of the trigger ranges from mild to moderate (i.e., marital argument and disclosure of migration plans) to extreme (i.e., physical or sexual abuse and acute bereavement).
b. Initiation of the episode immediately upon exposure to the stimulus or after a period of brooding or emotional "shock."
c. Once the acute attack begins, rapid evolution of an intense affective storm characterized by a primary affect usually congruent with the stimulus (such as anger, fear, grief) and a sense of loss of control (*emotional expressions*).
d. These are accompanied by all or some of the following:
    i. *Bodily sensations*: trembling, chest tightness, headache, difficulty breathing, heart palpitations, heat in the chest, paresthesias of diverse location, difficulty moving limbs, faintness, blurred vision, or dizziness (*mareos*).
    ii. Behaviors (*action dimension*): shouting, crying, swearing, moaning, breaking objects, striking out at others or at self, attempting to harm self with nearest implement, falling to the ground, shaking with convulsive movements, or lying "as if dead."
e. Cessation may be abrupt or gradual, but it is usually rapid, and often results from the ministration of others, involving expressions of concern, prayers, or use of rubbing alcohol (*alcoholado*). There is return of ordinary consciousness and reported exhaustion.
f. The attack is frequently followed by partial or total amnesia for the events of the episode, and descriptions of the following for the acute attack: loss of consciousness, depersonalization, derealization, mind going blank, and/or general unawareness of surroundings (*alterations in consciousness*). However, some *ataques* appear to exhibit no alterations in consciousness.

Guarnaccia and Canino found a prevalence of *ataques de nervios* of 8.9% in a representative sample of youth in Puerto Rico aged 4 to 17 years (*N* = 1,897). A second, community-based probabilistic sample of Puerto Rican children aged 5 to 13 years in San Juan (*N* = 1,353) and the South Bronx (*N* = 1,138), led by Héctor Bird and Canino, found a lifetime prevalence of *ataque* of 5.4% and 4.3%, respectively.

Risk factors for *ataque* span a range of social and demographic characteristics. Adults reporting an *ataque de nervios* in Puerto Rico are more likely to be female, over the age of 45, with less than a high school education, formerly married (i.e., divorced, widowed, or separated), and out of the labor force. However, 10% of the men in the sample reported an *ataque de nervios*, which indicates that some men express their distress through this cultural syndrome. Among Latinos in the United States—and like other psychiatric disorders—*ataque* is positively correlated with higher acculturation (e.g., U.S. birth and English proficiency), suggesting higher psychiatric vulnerability in this postmigration population. The level of neighborhood violence is also a risk factor for *ataque*. Risk factors among Puerto Rican youth differ somewhat by the site (New York vs. Puerto Rico) and by study; they include older age (especially adolescence in girls), single-parent household status, exposure to violence, stressful life events in the past year, and higher perceived poverty. In one of the community-based studies in Puerto Rico, multiple regression analysis also revealed an independent positive association between *ataque* status in the youth and a family history of the syndrome, suggesting the possible influence of intergenerational behavioral modeling.

Lewis-Fernández and colleagues estimated the lifetime prevalence of *ataque de nervios* in two clinical settings serving adult Puerto Rican psychiatric outpatients. The prevalence rate of *ataque* was 55.1% among immigrant Puerto Ricans (*N* = 89) in an outpatient Latino mental health clinic in New England and 51.5% among outpatient referrals to psychiatry (*N* = 97) in three rural Puerto Rico primary care clinics. In both sites, the gender distribution of *ataque* sufferers was nearly equivalent: 56.3% female in New England and

54.8% female in Puerto Rico. However, women were twice as likely to seek mental health care in both settings. Finally, in these rural clinics for low-income residents in Puerto Rico, *ataque* rates also did not differ by age cohort or level of education. All social groupings among this disenfranchised sector of the population appeared equally at risk for *ataque* episodes. Two large opportunity samples of Puerto Rican or Latino primary care patients in the Northeastern United States separately found a lifetime *ataque* prevalence of 26% to 28%, confirming the elevated prevalence of the syndrome in clinical populations. An elevated clinical prevalence was also observed among youth: lifetime prevalence of *ataque* was 25.5% in a representative sample of youth utilizing the mental health system in Puerto Rico (N = 767).

Precipitants/Etiology. Prototypically, *ataque de nervios* was linked by sufferers to an acute precipitating event or to the summation of many life episodes of suffering brought to a head by a trigger that overwhelmed the person's coping ability. In the Puerto Rico community sample studied by Guarnaccia and Canino, the first experience of an *ataque* was closely tied to a precipitating event. In 92% of cases, the *ataque* was directly provoked by a distressing situation, and 73% of the time, it began within minutes or hours of the event. A majority of first *ataques* (81%) occurred in the presence of others, as opposed to when the sufferer was alone and led to the person receiving help (67%). Finally, unlike the typical experience of persons with panic disorder, most respondents reported feeling better (71%) or feeling relieved (81%) after their first *ataque*. These findings suggest that first episodes of *ataque de nervios* are closely tied to the interpersonal world of the sufferer and that they result in an unburdening (*desahogarse*) of one's life problems, at least temporarily. One function of the *ataque* may be to rally the person's social network, including reversing the current interpersonal arrangement in favor of the sufferer. In one primary care study of 508 Latino adults in the Northeastern United States, partner support was associated with significantly lower odds of *ataque de nervios*, while

emotional strain from one's partner, family, or friends was each associated with higher lifetime prevalence.

Specific precipitants were varied but typically consisted of acutely stressful experiences resulting in feelings of loss, grief, anger, or fear. In general, the most frequent triggers identified by the Puerto Rico epidemiologic study included arguments with a spouse or other close relatives, the drunkenness of a family member, an accident that threatened the life of a person close to the subject, death of a close family member, natural disaster, or the passing of a fright (*susto*) through a person. Certain precipitants were obviously traumatic and were correlated with globally elevated prevalence rates in exposed subpopulations. For example, this survey showed a higher prevalence of *ataques* among those severely affected by a recent natural disaster (19%) than among nonexposed individuals (14%), and intermediate rates among subjects only moderately affected (16%). However, *ataques* have been reported after apparently minor stressors, such as family squabbles, adolescent romantic disappointments, or peer razzing. In these cases, the presence of underlying interpersonal or sociocultural conflicts of longer duration—such as a marital argument or abuse, migration, poverty, discrimination, precarious employment/source of income, or family discord—has been invoked by investigators to explain the enhanced *ataque*-producing power of superficially mild triggering experiences.

Studies in psychiatric outpatient samples of the relationship between childhood trauma exposure and the presence of *ataques* have yielded conflicting results. Daniel Schechter and colleagues found a positive association, whereas Lewis-Fernández and colleagues did not. In this latter study, childhood traumatic exposure was high across Puerto Rican psychiatric outpatients regardless of *ataque* status, suggesting that, in a clinical sample, factors in addition to childhood trauma accounted for this condition. In a different psychiatric outpatient sample of diverse Latino subethnicities with a history of traumatic exposure (N = 202), greater trauma severity was not associated with a higher frequency of *ataques*. More research is needed in samples with and without traumatic exposure to clarify the association between this risk factor and *ataque*.

Relationship to Psychiatric Diagnoses. Psychiatric evaluations of *ataque* sufferers have usually revealed the presence of some form of psychopathology. In the Puerto Rico adult epidemiologic survey, 63% of respondents who reported an *ataque de nervios* met diagnostic criteria for one or more psychiatric disorders measured in the DIS. This suggests that rather than being an expression of nonpathologic distress, most *ataques* are associated with a psychiatric disorder. Overall, *ataque* sufferers had 4.35 times the odds of meeting criteria for a psychiatric diagnosis than those who did not report the cultural syndrome. At the same time, 37% of *ataque* sufferers did not fulfill DIS criteria. This suggests that a substantial minority of respondents with this syndrome are describing milder levels of distress using the idiom of the cultural syndrome; alternatively, they may be reporting psychiatric disorders not assessed by the study instrument.

It is important to note that *ataques* do not correlate exclusively with one psychiatric diagnosis and cannot be treated as simply a culturally shaped version of a specific psychiatric disorder. The combined research findings support a strong relationship between *ataques de nervios* and mood and anxiety disorders in youth and adults, as well as disruptive disorders in youth and dissociative disorders in adults. Of particular concern is the strong relationship between *ataque* and suicidal ideation (odds ratio [OR] = 6.2) and attempts (OR = 8.1). In a U.S. nationally representative community sample of diverse Latino subethnicities (N = 2,554), lifetime history of *ataque de nervios* was independently associated with suicidal ideation (OR = 2.4) after adjusting for multiple covariates, suggesting that the cultural syndrome conveys additional risk beyond recognized risk factors such as psychiatric diagnosis and traumatic exposure. During *ataque* episodes, sufferers may make goal-directed or ill-formed attempts at self-harm, increasing the morbidity (and occasional mortality) of the syndrome.

While early speculation by psychiatrists focused on whether an *ataque* constitutes a culturally shaped version of a panic attack, Lewis-Fernández and colleagues systematically demonstrated that only 36% of best-remembered *ataques* met DSM-IV-TR criteria for

panic attacks and 17% met criteria for panic disorder. What mainly distinguished *ataques* that did not fulfill panic disorder criteria from those that did include the cuing of episodes by precipitants, symptom crescendo longer than 10 minutes, and feeling relieved rather than frightened after an episode. However, features that were common to both *ataque* and panic disorder included recurrence of attacks, the experience of fear or nervousness during an episode, and anticipatory or behavioral sequelae afterward. Patients who described feeling relieved after their *ataque* also reported significantly fewer panic symptoms than those without this feeling.

Specific characteristics of *ataque* profiles may be associated with distinct psychiatric diagnoses. A study by Ester Salmán and Michael Liebowitz of a sample of Puerto Ricans and Dominicans (N = 156) attending a Manhattan research clinic that was enriched with individuals suffering from *ataque de nervios* (N = 109) found a link between *ataque* features and specific psychiatric disorders. Among those participants in the study whose *ataques de nervios* were characterized by intense fearfulness and feelings of asphyxia and chest tightness, diagnoses of panic disorder were more common. Those whose *ataques* were more dominated by the emotion of anger and aggressive behavior, such as breaking things, were more likely to meet the criteria for co-occurring mood disorders.

Ataque is strongly associated with dissociative experiences. The severity of *ataques*, assessed as lifetime number of episodes, is positively and independently related to self-reported dissociative symptoms, measured with the Dissociative Experiences Scale (DES), and to clinician-diagnosed dissociative disorders, assessed with the Structured Clinical Interview for DSM-IV. Further evidence of the relationship between *ataque de nervios* and dissociation comes from the significant correlation between *ataque* and other Latino cultural concepts that are also related to higher dissociative capacity on the DES. One of these idioms is characterized by “pseudohallucinations” in several sensory modalities—hearing voices or noises, seeing shadows (*celajes*), and feeling presences when alone—that are popularly attributed to spiritual influences. In an outpatient U.S. Latino sample with high traumatic exposure (N =

202), *ataque de nervios*, pseudohallucinations, and a third Latino folk illness, “being currently ill with nerves,” were all significantly associated with each other and with elevated DES scores, forming a nexus of “nerves”-related cultural concepts linked to dissociative capacity.

In youth, *ataques de nervios* are associated with research diagnoses of mood, anxiety, and disruptive disorders. In a Puerto Rico community-based survey, youth aged 4 to 17 years with *ataques* had ORs of 7.6 for any mood disorder, 5.0 for any anxiety disorder, and 3.1 for any disruptive disorder, compared to youth who did not report an *ataque*. In the clinical sample of the same study, the equivalent ORs were 5.8, 3.5, and 2.0, respectively. Youth with *ataques de nervios* had 4.3 times the odds of meeting criteria for any psychiatric diagnosis in the community and 2.3 times the odds of doing so in the clinical setting. Moreover, impairment was likewise elevated among youth with *ataques* compared to those without, with an OR = 5.6 in the community and OR = 2.1 in the clinical sample. In another study, after adjusting for demographic characteristics and the level of psychosocial stressors, children aged 5 to 13 years with *ataques* in San Juan and the South Bronx had nearly 3 times higher odds of meeting criteria for an anxiety or a depressive disorder, nearly 2 times the odds of a disruptive disorder, and 1.4 times higher odds of global impairment.

Additional Clinical Features. Assessment of the phenomenologic features of *ataques de nervios* experienced by the 77 respondents in the Puerto Rico epidemiologic study with at least one lifetime *ataque* who were reinterviewed by Guarnaccia revealed that the largest number (28%) had suffered only one such episode over the course of their life. Thirteen percent had two *ataques*, 8% experienced three, 9% had four, and 4% had five. The second-largest number (23%) comprised those who had more than five lifetime *ataques*, while 15% were unsure about the total. The bimodal distribution of *ataque* frequency (one vs. six or more) suggests that persons with frequent episodes constitute a minority of *ataque* sufferers. This raises the question of whether having an isolated *ataque* in response to a

markedly stressful event—as opposed to recurrent *ataques*—represents a relatively normal expression of distress in Latino communities. However, the lifetime presence of one or more *ataques* is associated with disability and outpatient mental health service use among U.S. Latinos, even after adjusting for demographic characteristics, traumatic exposure, psychiatric diagnoses, and chronic health conditions. This suggests that experiencing an overwhelming reaction such as *ataque* may not be without clinical consequences.

The association between *ataque* and a sense of loss of control and of being overwhelmed highlights the importance of the relationship between the cultural syndrome and other behaviors associated with acute emotional dysregulation. Most concerning among these is the strong association noted earlier between *ataques* and suicidal ideation and attempts. Other behaviors related to this acute dysregulation include loss of aggression control, expressed as attacks on people or property, and dissociative experiences, both of which are related to the acute *ataque* experience.

Specific Cultural Factors. The complex relationship between *ataque de nervios* and psychiatric diagnosis may be further clarified by placing *ataque* within a broader Latin American popular nosology of *nervios* (nerves) of which it is part. Experiences of adversity are linked in this nosology to ensuing “alterations” of the nervous system, which result in its impaired functioning, including the peripheral nerves. This quasi-anatomical damage is evidenced in emotional symptoms, including interpersonal susceptibility, anxiety, and irritability, as well as in physically mediated symptoms, such as trembling, palpitations, and decreased concentration. Certain people are considered at greater risk for *nervios* when confronted with adversity, such as those with an inherited predisposition or with stressful perinatal experiences (e.g., mother’s alcoholism). But in all cases, the possibility that sufficient adversity will result in an alteration of the nervous system leads to the popular view that persons faced with experiences of suffering should “control” their reactions to avoid nervous system damage. This usually takes the

form of dampening the emotional impact of the experience so that the nerves will not be substantially “altered.”

Clinical and popular discussions about *nervios* and *ataques* in Latino communities thus typically reference cultural views about the importance of remaining in control and of facing adversity with *tranquilidad* (equanimity) regardless of the severity of a stressor. *Ataque de nervios* can therefore be understood as a behavioral syndrome stemming from general notions and practices about how to behave, rather than a peculiar cultural expression of a particular diagnosis. As a marker of being overwhelmed, *ataques* are associated with various forms of psychopathology, but the *ataque* itself cannot be reduced to just the psychiatric disorder; rather, it is a marker of the severity of the stressor, of the person’s reaction style, of their level of support, and of the resulting distress and pathology.

Aspects of Caribbean Latino cultural contexts may promote the observed association between *ataque de nervios* and dissociation since the appearance of dissociation during the *ataque* may be enhanced by the cultural perception that a mature social actor needs to be always in control. Dissociation may be particularly promoted by the popular view that when out of control, the person is no longer “themself” (“*ése no era yo* [that was not me]”). The uncontrolled behavior is disavowed as not being part of the self. This may facilitate the emergence of dissociative splits that allows the person to distance themself from the moral consequences of the *ataque* episode. Similarly, prevalent cultural concerns about the psychological and social dangerousness of strong emotions may reinforce the role of anxiety sensitivity in *ataque*. Individuals with high anxiety sensitivity appear to be at elevated risk for *ataque* prevalence and severity, possibly due to positive (adverse) feedback effects on *ataque* onset or persistence.

Community rates of *ataque* in adults are significantly higher in women than in men. The female-to-male ratio is 2:1 in Puerto Rico and 3:2 among U.S. Latinos. The gender difference may appear during adolescence since it is absent in both South Bronx- and San Juan-based representative samples of Puerto Rican children aged 5 to 13 years but is found in a Puerto Rico-wide representative sample

of youth aged 4 to 17 years. The gendered nature of *ataque* in adults has been attributed in part to traditional gender roles pressuring Latina women to restrict some emotions in social situations, especially around sexual, aggressive, or assertive needs. The gender-specific cultural directive to remain "in control" may predispose women to express suppressed feelings in situations of interpersonal conflict as acute paroxysms of emotionality and uncontrolled behavior, which can later be disavowed as unwilled or even ego-alien.

Treatment. No treatment studies of *ataque de nervios* have been conducted. Typical treatment in community settings involves, first, ensuring the safety of the person and those around them, given the association between *ataque*, suicidality, and uncontrolled aggressivity. "Talking the person down" is usually helpful, accompanied by expressions of support from relatives and other loved ones; the use of rubbing alcohol (*alcoholado*) to help calm the person is a culturally prescribed way of expressing this support.

"Telling the story" of what led to the *ataque* usually constitutes the principal therapeutic approach in subsequent stages of treatment. Since one of the main functions of the attack is to communicate a feeling of being overwhelmed, indicating receipt of the message and the desire to offer support are usually perceived as therapeutic. The person should be allowed to set the pace of disclosure and to give enough details and circumstances to feel "unburdened" (*desahogado[a]*).

In the case of single or occasional *ataques* in the absence of a psychiatric diagnosis, brief follow-up is usually sufficient. This may be discussed with the patient and the family as a way of ensuring a full return to the previous healthy state. For recurrent *ataques*, treatment depends on the associated psychopathology, the nature of the precipitants—including traumatic exposure—the degree of family conflict or support, the social context, the previous treatment experiences, and the patients' and family's expectations, among other factors.

Psychotherapy is typically the mainstay of treatment, usually with a family focus, given the usual source of the overwhelmed behavior in the interpersonal milieu. A social activism stance by the therapist that acknowledges the origins of adversity among low-income Latinos in socioeconomic disenfranchisement and ethnoracial discrimination is helpful in addressing the sociocultural roots of *ataque de nervios.* Pharmacotherapy may also be useful in the treatment of *ataque*-related psychopathology; the primary emphasis should be placed on treating the underlying disorder. Given the slow crescendo of many *ataques*, judicious use of short-acting benzodiazepines also has a role in helping abort an impending episode. However, this should not be the main form of treatment for recurrent *ataques* since it only forestalls the principal function of the syndrome as a mode of communication.

Possession Syndrome

Involuntary possession trance states are very common presentations of emotional distress around the world. Cognate experiences have been reported in very diverse cultural settings, including India, Sri Lanka, China, Japan, Malaysia, Niger, Uganda, Southern Africa, Turkey, the United States, Canada, Haiti, Puerto Rico, and Brazil among others. *Possession syndrome* is an umbrella English-language term used in the clinical and anthropologic literature on South Asian presentations of involuntary possession trance that encompasses conditions with many different names in regional languages and dialects of India and Sri Lanka. These presentations are seen as a severe affliction by the person's cultural group because they are involuntary, cause distress, and do not occur as a normal part of a broadly accepted collective cultural or religious ritual or performance.

DSM-IV-TR did not list possession syndrome or any other pathologic possession trance condition as a "culture-bound syndrome." Instead, this class of clinical presentations was included in Appendix B of DSM-IV and DSM-IV-TR under the proposed category of dissociative trance disorder (DTD), one of the "criteria

sets and axes provided for further study." Categories in this section of the manual fell short of full inclusion in DSM-IV as specified diagnoses but were included in the appendix to stimulate research for possible incorporation in DSM-5. Beyond its global prevalence, another reason why involuntary possession trance was given a special status in DSM-IV was its inclusion in ICD-10 as a subtype of trance and possession disorders (F44.3), a specified diagnosis under the dissociative (conversion) disorders in the section on neurotic, stress-related and somatoform disorders. The goal of making the ICD and DSM nosologies more compatible helped to promote consideration of involuntary possession trance in DSM-IV and DSM-5. In ICD-11, the main characteristics of possession trance disorder include the following:

A disorder characterized by a trance state in which there is a marked alteration in the individual's state of consciousness resulting in significant distress or impairment. During the trance episode, the individual's normal sense of personal identity is replaced by another identity attributed to an external "possessing" spirit, power, deity, or another spiritual entity, and the individual engages in behaviors or movements that are experienced as being controlled by the external agent. The trance episodes must be recurrent or, if single, last for at least several days and be involuntary, unwanted, and not accepted as a part of a collective cultural or religious practice. The episodes must also not be due to the effects of a substance or medication or be better explained by another disorder of the nervous system and must result in clinically significant distress or impairment.

In DSM-5 and DSM-5-TR, pathologic possession trance was included under dissociative identity disorder, leading to its redefinition as two variants: possession form and nonpossession form. This incorporation was due largely to the phenomenologic similarity between pathologic possession trance and dissociative identity disorder. Both are disorders of identity alteration that occur during a dissociative state of consciousness and are characterized by involuntary stereotyped and culturally determined behaviors or movements that are experienced as being under the control of an alternate identity. Among 119 possessed patients who visited

traditional healers in Uganda, for example, Marjolein Van Duijl and colleagues observed involuntary shaking of the head or parts of the body (attributed to spirits), talking in a different voice—which others recognized as the voice of a specific spirit—and feeling influenced by unidentified forces that cause unusual behavior. Nearly half of the possessed patients mentioned something holding the body, so they were unable to move or speak. Among traditional healers and local health workers in these villages, case vignettes of dissociative identity disorder were always attributed to spirit possession. In many healing traditions, patients or practitioners learn how to become possessed to serve as a vehicle for a healing deity or spirit, which then is able to diagnose and treat a wide range of health conditions and life predicaments. Such deliberately sought and socially regulated "executive possession" should not be seen as pathologic.

In both possession and nonpossession types of pathologic identity alteration, sufferers can report full or partial amnesia for the events of the dissociative state. Moreover, a history of exposure to traumatic experiences is common in both conditions. In the Uganda study, for example, individuals with pathologic possession scored higher on the Harvard Trauma Questionnaire and the Traumatic Experiences Checklist than 71 randomly selected healthy inhabitants of the same villages, and scores on both trauma scales were strongly correlated with symptoms of dissociation (r = 0.64 − 0.69) and pathologic possession (r = 0.51 − 0.64). To rule out the misdiagnosis of nonpathologic possession states, dissociative identity disorder requires the presence of amnesia, as well as the fact that the identity alteration states (a) be associated with clinically significant distress or impairment (criterion C) and (b) not be a normal part of a broadly accepted cultural or religious practice (criterion D). In addition, the text states that the pathologic possession episodes "present recurrently [and] are unwanted and involuntary."

Possession trance can occur in epidemic form. For example, in recent years, there have been many episodes of groups of school children in Nepal experiencing possession episodes characterized by involuntary movements and speech. Individuals who are affected in

these epidemics may be high on measures of hypnotizability and more likely to have a past history of peritraumatic dissociation.

The possession-form and nonpossession-form variants of dissociative identity disorder are not mutually exclusive: individuals in one cultural setting may experience either form, and a single individual may experience both forms. Typically, in nonpossession-form dissociative identity disorder, the alternate identities are experienced as *internal* aspects of the person, as other identity states. In possession-form dissociative identity disorder, by contrast, the alternate identities are typically experienced as *external* possessing agents, usually of supernatural or spiritual origin (e.g., demons and spirits). The main contrast between these two forms of dissociative identity disorder appears to be shaped by the patient's sociocultural milieu. That is, possession-form dissociative identity disorder arises in contexts where possessing agents are considered ontologically "real" (e.g., some fundamentalist religions in the United States or traditional South Asian cultures), as opposed to nonpossession-form dissociative identity disorder, which draws its alternate identities from individualistically focused experiences, such as stages of life (e.g., childhood) or biographical roles in the patient's life (e.g., protector and perpetrator).

The decision to subsume pathologic possession trance states under dissociative identity disorder is not without controversy, however. It is an open empirical question, for example, what proportion of pathologic possession states meets dissociative identity disorder criteria, which include substantial amnestic gaps in addition to identity alteration. The nonpossession form of the disorder is typically a chronic condition arising in childhood in the wake of prolonged and severe trauma. Some pathologic possession trance states follow this pattern, but others are triggered by nontraumatic stressors, such as romantic disappointments and work or religious conflicts, and present as single or recurrent episodes rather than persistent conditions. However, the absence of systematic assessment of childhood trauma precludes excluding this exposure from the genesis of dissociative disorders in these populations. With accumulating evidence, the placement of pathologic possession in

psychiatric nosology will be further clarified. Dissociative identity disorder may prove to be a heterogeneous condition, encompassing a gamut of identity alteration symptoms, courses, and precipitants across cultural contexts. Alternatively, the evidence may favor the inclusion of pathologic possession trance as a separate diagnostic entity in DSM, as in ICD-11.

Pathologic possession trance states thus constitute local presentations that are farther along the process of incorporation into Western psychiatric classification systems than the usual cultural concepts of distress. Their truly global prevalence makes them candidates for “universalistic” disorders, even though they are considered uncommon in modern Euro-American and European societies. Their status is still unresolved, however, given their inclusion as a variant of dissociative identity disorder in DSM-5 and as a distinct disorder in ICD-11. Moreover, since local presentations of pathologic possession trance vary substantially across cultural settings, possession syndrome is discussed here as a cultural concept of distress, focusing on its specific characteristics in South Asia.

Phenomenology. It is important to distinguish at the outset between possession syndrome, as an instance of possession trance, and the broader category of possession. The latter term refers to a general ideology describing the full range of direct spirit influences on human affairs, including effects on physical, psychological, spiritual, social, and ecologic realms. By contrast, as a subset of general possession experience, “possession trance” refers to specific alterations in consciousness, memory, behavior, and identity attributed to direct spirit influence. In addition to pathologic possession trance states, South Asian cultures authorize multiple examples of normal possession and possession trance in religious, healing, and other ritual contexts. When voluntary and normative, these states are typically seen as instances of religious devotion, mystical ecstasy, social commentary, asceticism, interpersonal relations, existential reflection, and the study of consciousness. This chapter discusses possession syndrome as a pathologic entity with

an established phenomenology, that is, as a special case in the general continuum of etiologic ideas regarding possession illnesses. A prototypical episode is composed of the elements in Table 29.1–3.

Data on the epidemiology, precipitants, and associated psychopathology of subjects with possession syndrome in South Asia is limited by methodologic considerations. These include a lack of representative community samples and nonsystematic definitions of the syndrome, which shows considerable regional variation.

Epidemiology. Period-prevalence rates among psychiatric cohorts in India conducted mostly via chart review have been variously reported as 0.2% over 1 year, 0.06% over 7 years, and 0.93% over 12 years. Patients with dissociative disorder accounted for 0.15% to 1.5% of outpatients and 0.15% to 1.2% of inpatients at a major psychiatric facility in India between 1999 and 2008; of these, 11.5% of outpatients and 5.4% of inpatients met ICD-10 criteria for trance and possession disorder.

Community-based surveys have yielded higher rates. In 1972, Morris Carstairs and Ravi Kapur found a 6-month period prevalence of 0.97% for involuntary possession syndrome in a South Indian village, using a symptom checklist in a 50% sample of all village adults (N = 1,233). They also reported a 6-month period prevalence of an additional 1.8% for voluntary possession states. V. Venkataramaiah and colleagues surveyed the total population (N = 1,158) of a school catchment area in another South Indian village during an epidemic of possession syndrome in 1979. They found a 1-year period prevalence of 3.5% for involuntary attacks, as well as a prevalence of 0.2% for voluntary possession trance episodes.

Anthropologic accounts of widespread occurrence and cultural barriers to discussing the supernatural features of the syndrome have suggested that the actual prevalence is likely higher than that reported in public surveys. The clients of indigenous healers currently provide the main source of comparative data. For example, 17% of those patients seen by one traditional healer during a 4-month period who met research criteria for psychiatric ailments (N = 30) received an indigenous label of possession syndrome. Finally, the periodic

occurrence of syndrome epidemics complicates the epidemiologic picture.

Possession syndrome is more common in women, with a female-to-male ratio of 2 to 3:1 in most community and psychiatric cohorts. The 1999 to 2008 cohort showed much higher female-to-male ratios among outpatients (4.7:1) than inpatients (1.3:1), suggesting that women with trance and possession disorder were significantly less likely to be hospitalized. Sex distribution may also vary historically, according to evolving cultural gender attributions, and show geographical or possibly idiosyncratic variation. Various studies conducted in India suggest that women experience considerable social disadvantage related to the typically patriarchal social system, including early marriage, childbearing as the primary social function, family and spousal violence, lack of social integration, poor social support from family members, and limited autonomy. These factors may contribute to the higher prevalence of possession syndrome among women. The age of onset is usually between 15 and 35, but many cases reportedly begin in childhood. Attacks may persist well into middle age, and geriatric cases have also been reported. The syndrome has been identified in all Hindu castes, as well as in Muslims, Christians, and tribal peoples; however, it is more commonly described among Hindus.

Table 29.1–3.
Phenomenology of Possession Syndrome

a. Onset occurs typically due to subacute conflict or stress and shows considerable variation. It may be gradual and nonspecific —e.g., diverse somatic complaints, such as dizziness, headaches, abdominal discomfort, hot–cold flashes, listlessness, or difficulty breathing—or sudden and specific, in the form of an abrupt transition to an altered state of consciousness. Onset may also vary by geographical region, presenting in certain areas of the country (e.g., parts of Uttar Pradesh) as a mounting series of rage attacks. If presentation is gradual and nonspecific, transition to the altered state may occur spontaneously or after contact with an indigenous healer specializing in the treatment of the syndrome.
b. Behavior during the altered state consists of some or all of the following:
   i. Dramatic, semipurposeful movements—such as head bobbing, bodily shaking, thrashing, gyrating, or falling to the ground—accompanied by guttural, incoherent verbalizations such as mumbling, moaning, or shrieking.
   ii. Aggressive or violent actions directed at self or at others, including spitting, striking, and impulsive suicidal or homicidal gestures. Verbalizations may be coherent, and consist of derogatory comments or threats of violence directed against significant others or against the subject (in the third person) and typically considered by observers to be uncharacteristic of the subject's usual behavior.
   iii. Specific gestures, comments, or requests denoting the appearance of a known possessing personality by (1) reference to standard attributes of culturally recognizable figures or (2) the name and degree of relation of deceased family members or acquaintances.
c. The altered state is marked by the emergence of one or several secondary identities distinct from that of the subject. Their specific identities, which may remain undisclosed for some time, typically adhere to cultural norms regulating permissible agents of possession, which vary by religion, region, and caste.

Acceptable agents include spirits of deceased family members, in-law relations, or known village acquaintances who died under specific conditions of distress, and minor supernatural figures of the Hindu pantheon (rarely major deities) and the Islamic spiritual world. They do not include the identities of alternate, living persons, nor apparently alternation of co-conscious multiple identities, as in nonpossession-form dissociative identity disorder, though consecutive possession by two or three agents is not rare, and one case of 21 successive possessions has been reported. On occasion, a single agent may possess several members of a family over time, or in succeeding generations.

d. Possession by the secondary identity(ies) is episodic, resulting in alternation between the usual personality of the subject and the altered state. The subject in their usual identity appears in a daze, exhausted, distressed, or confused about the situation and may report visual or auditory perceptual disturbances regarding the possessing agent, as well as “unconsciousness” and partial or total amnesia for the altered state. States of consciousness may alternate continuously within one episode over hours to weeks, with each state lasting minutes to hours. This pattern may persist intermittently over months or years.

e. Frequently, the specific identities of possessing agents remain undisclosed for some time, requiring the active ministrations of family members and the intervention of specialized indigenous practitioners. The process of disclosure is conceived as a struggle between the family members and the beneficent agents possessing the healer on the one side, and the troublesome possessing identities on the other. It is characterized by remarkable reactivity on the part of the subject to environmental cues, including direct questioning, strategic neglect, and aggressive manipulation. Often, this kind of ritualized intervention elicits the withheld disclosure, and leads to a process of negotiation between the family, the healer, and the possessing agent regarding the propitiatory treatment necessary for the resolution of the episode. Examples of this treatment typically consist of ritual offerings, admission to a possession

cult, resolution of family conflicts, cessation of abuse, and the postponement or precipitation of marriage.

f. Outcome is variable. Total recovery is often reported at the cessation of a single acute episode, which may be of several weeks' duration. Alternatively, prolonged morbidity may result, or even, rarely, death. The subject may seek exorcism treatment with multiple healers, or undertake a pilgrimage to a regional healing temple. At times, they are prescribed entrance into a ritual devotion cult offering programmed periodic possessions.

Caste distribution may fluctuate historically and respond to sociocultural determinants of the appropriateness and desirability of possession syndrome as an idiom of distress. It has been reported more frequently among disadvantaged castes, of low income and education, and rural residence. Nevertheless, some case studies revealed the prevalence of the syndrome among more advantaged groups, such as Brahmins, despite the cultural proscriptions against it. Case reports suggest higher rates among widowed persons, but a systematic study did not confirm this association. The presence of possession syndrome in other family members (or in ancestors) may be a risk factor, but this relationship has not been investigated systematically.

Precipitants/Etiology. Precipitants of possession syndrome are varied but typically include social or family conflicts and stressful life transitions that elicit strong feelings of vulnerability in persons without firm emotional support. Examples encountered in the literature include marital conflict, abuse, and neglect, at times associated with alcoholism; the arrival of a new bride to the home of her husband's family; delay in arranging a marriage, or in consummating it; forced marriage; widowhood; postpartum status; loss of family social standing; death of a family member; difficulty finding employment and financial difficulties; alienation from family support; and subordination to other family members and in-laws. These precipitants were identified in 67% and 73% of separate mental health cohorts.

Some older clinical studies stressed the pathogenic role of hysterical and histrionic ego defenses in possession syndrome. However, this ignores the fact that pathologic possession commonly occurs in settings where nonpathologic possession is a positive, socially mandated experience. What may distinguish pathologic episodes is the importance of traumatic precipitants—deaths of children, murder of husband, sexual abuse of a close friend, measles epidemic, physical abuse, the revelation of husband's incest with daughter. Social scientists such as Richard Castillo have emphasized the underlying context of violence against women in India—including selective abortion, infanticide, murder due to discovered premarital relations, rape, sale into prostitution, "dowry death" (the new bride is killed if dowry is considered insufficient), marital abuse, witch killings, and *sati* (widow burning). These data suggest that many instances of possession syndrome may arise not from intrapsychic vulnerability but from widespread undisclosed early trauma, an exposure that has been insufficiently investigated. Some researchers agreed on the etiologic role of childhood stress as a risk factor for possession syndrome but differed on the specific contributions of physical and sexual abuse as opposed to emotional or physical neglect. Alternatively, anthropologic investigators have argued that individual biographical data was insufficient to explain the specific association of spirit possession with marginal persons and transitional life phases, such as birth, menarche, marriage, pregnancy, widowhood, and death. They located the etiology of attacks in caste-specific cultural expectations linking social and spiritual vulnerability. Additional collectively defined precipitants of possession syndrome include certain acts and settings, such as crossing physical boundaries (e.g., the village limit, an empty field at night), which invite the attention of possessing spirits.

Relationship to Psychiatric Diagnoses. Psychoanalytically based evaluations of subjects with possession syndrome often reported evidence of hysterical traits predisposing to dissociative psychopathology in otherwise normal subjects. Others distinguished the intrapsychic origin of the acute behavioral syndrome—which they

attributed to hysterical processes—from the underlying personality formation and psychic vulnerability. These authors argued that attacks could arise in subjects with diverse personality structures and biologic propensities. Some research reported a substantial proportion of attacks among patients with a primary diagnosis of schizophrenia (40% to 59%) and manic depressive illness (11% to 13%), in whom the possession symptoms took longer to resolve, compared to patients without these disorders.

As noted earlier, DSM-5-TR includes most cases of possession syndrome under dissociative identity disorder. However, cases that do not fulfill the amnesia criterion should receive other DSM diagnoses, including other specified dissociative disorder. As with all cultural concepts of distress, there is no one-to-one overlap between the cultural label and any DSM disorder; psychiatric evaluation must proceed at the level of the individual. In ICD-11, possession syndrome cases would fulfill criteria for trance and possession disorders. Prior to the inclusion of possession phenomenology in dissociative identity disorder, possession syndrome did not have a diagnostic home in DSM: a study conducted in 1987 in a New Delhi outpatient psychiatric clinic (N = 1,517) found that 10% of cases with dissociative pathology received an ICD-10 diagnosis of trance and possession disorders, whereas none met DSM-III-R criteria for multiple personality disorder.

Additional Clinical Features. Rates of relapse are unknown, although anecdotal reports suggest it is not uncommon. Relapse within 15 years was not infrequent and has been recorded after two to three decades. Four of 15 subjects in one study were found to have suffered previous episodes, and 1 subject in another series reported three consecutive postpartum attacks. Entry into a ritual possession cult may reduce or eliminate relapse.

Specific Cultural Factors. Possession syndrome constitutes a folk illness category throughout India and Sri Lanka. It may present initially in a variety of forms, linked by the attribution of spirit etiology. When it presents in a nonspecific fashion, indigenous diagnosis is

confirmed by the appearance of the altered state during the therapeutic ritual. It is considered an affliction by its painful, involuntary nature and attributed to the intervention of specific spiritual agencies acting independently or at the behest of a witch. Certain castes and persons in transitional states (e.g., puerperium) are considered most vulnerable to spirit attacks, especially when deprived of emotional and material support. The degree of pathology ascribed to the sufferer, the therapy chosen, and the outcome attained depend on the interaction of several factors: psychological (e.g., traumatized ego), biologic (e.g., psychosis), sociocultural (e.g., caste status), and situational (e.g., family dynamics). For instance, when it presents in some Moger women of South India, possession syndrome may be seen as an affliction opening the door to a sacred practice in a possession cult. In some Havik Brahmin women, however, it may constitute the last step in a series of symptomatic expressions of acute distress instead, leading directly to exorcism and incomplete conflict resolution.

Treatment. Specialized indigenous practitioners and ritual therapies are generally available and widely utilized, but psychiatric treatment is typically avoided. Indigenous treatments include neutralization of the conflict or stress via the communal rituals involved in exorcism, as well as the reformulation of the suffering into beneficent individual and communal practice via initiation into a spirit devotion cult—such as the Siri cult of South India—or education into the roles of oracle (diviner), exorcist, or, rarely, avatar (divine incarnation).

Shenjing Shuairuo

Shenjing shuairuo (“weakness of the nervous system” in Mandarin Chinese) is a translation and cultural adaptation of the term “neurasthenia” (from Greek roots for “lack of nerve strength”), which was introduced to China from Russia in the early 1900s. As formulated by the American neurologist George Beard in 1868, neurasthenia denoted a heterogeneous syndrome of lassitude, pain, poor concentration, headache, irritability, dizziness, insomnia, and

over 50 other symptoms. At first, neurasthenia was considered an "American disease" resulting from the "pressures" of a rapidly modernizing society but was later adopted by European diagnosticians. Its pathophysiology was thought to derive from a lowering of nervous system function through a physical process due to excessive use, especially among the educated and wealthier classes. In Soviet psychiatry, buttressed by Pavlovian research, neurasthenia was a central component of mental health nosology, which became especially influential in Chinese psychiatry after the communist revolution of 1949.

While neurasthenia declined in importance in Western psychiatric nosology and practice during the 20th century, *shenjing shuairuo* underwent marked popular and professional development in mainland China, Taiwan, Hong Kong, in Chinese migrant communities, and in Japan, where a similar syndrome was labeled *shinkei suijaku*. From a peak in about 1980, when it constituted up to 80% of all "neurotic" diagnoses in Chinese societies, *shenjing shuairuo* has become less common. The diagnosis was included in the *Chinese Classification of Mental Disorders, Second Edition, Revised* (CCMD-2-R; 1993), under the section on "Other Neuroses." The CCMD-2-R diagnosis required three symptoms out of five nonhierarchical symptom clusters, organized as weakness, emotional, excitement, and nervous symptoms, as well as a fifth category of sleep disturbances. Like other neurotic disorders in the Chinese manual, the condition had to last at least 3 months and (a) lower the efficiency of work, study, or social function; (b) cause mental distress; or (c) lead to treatment seeking. Depressive and anxiety symptoms, which used to be central in previous professional definitions of *shenjing shuairuo*, became exclusionary in CCMD-2-R, probably due to the growing influence of Western nosologies. Physical weakness and mental fatigue, which are prominent elements of some neurasthenic presentations in other parts of the world, are not prioritized in the Chinese classification. The third edition of the CCMD (2001) retained *shenjing shuairuo* in the section on the Neuroses as a diagnosis of exclusion. This decision was

based on multicenter field trials in China on the discriminant validity and clinical utility of the neurosis subtypes.

The general category of “neurasthenia” included in ICD-10 (F48.0) emphasized the components of weakness and fatigue and relegated other possible symptoms to secondary characteristics. Although the evolving CCMD nosology has not emphasized these symptoms in its definitions of *shenjing shuairuo*, some controversy remains over the proper status of fatigue and weakness in the Chinese classification. Some investigators considered the centrality of fatigue in the ICD-10 definition of neurasthenia a misleading alignment of the international classification with the Western diagnoses of somatoform disorders and chronic fatigue syndrome. For example, Sing Lee estimated that the ICD-10 definition excluded over 80% of Chinese patients with *shenjing shuairuo* who reported prominent symptoms other than fatigue. ICD-11 no longer includes an entry for neurasthenia, apparently due to decreasing official support internationally for the category. The DSM-5-TR chapter on culture and psychiatric diagnosis includes an entry for *shenjing shuairuo*, as an example of a cultural syndrome, which follows the CCMD-3 definition and does not prioritize the fatigue component.

Phenomenology. Given the evolution of diagnostic practice regarding *shenjing shuairuo* in Chinese societies over the last decades, the phenomenologic description in this chapter is based instead on clinical histories of self-identified sufferers—or the “illness” aspect of the syndrome. The elements in Table 29.1–4 are prototypical.

Epidemiology. The changing professional definitions of ICD neurasthenia and CCMD *shenjing shuairuo* complicate the interpretation of the epidemiologic reports, which are in any case limited in European languages. Most studies have used ICD definitions, which in turn have evolved over time, or else refer to rates of “neurasthenia” without distinguishing between ICD and CCMD diagnoses. Therefore, the relationship between these reports

of neurasthenia prevalence and the folk presentation of *shenjing shuairuo* remains unclear.

Table 29.1–4.
Phenomenology of *Shenjing Shuairuo* (Weakness of the Nervous System)

a. Onset is usually gradual, sometimes spanning several years, and typically emerges out of a conflictive, frustrating, or worrying situation that involves work, family, and other social settings, or their combination. A sense of powerlessness in changing the precipitating situation appears central to most illness accounts of the syndrome.
b. Symptoms show substantial individual variation, but usually involve at least some of the following spontaneous complaints: insomnia, affective dysphoria, headache, bodily pains and distortions (e.g., “swelling” of the head), dizziness, difficulty concentrating, tension and anxiety, worry, fatigue, weakness, gastrointestinal problems, and “troubled vexation” (*fan nao*). This last emotion has been described as a form of irritability mixed with worry and distress over “conflicting thoughts and unfulfilled desires,” that may be partially concealed in Chinese communities for the sake of preserving social harmony.
c. The sufferer frequently seeks the sick role, attributing his/her difficulties in meeting work, school, or other social expectations to the syndrome. Sources of treatment vary substantially across Chinese communities, depending on the availability of formal and traditional service sectors. Typically, physical health services, such as general health or neurology clinics, or traditional Chinese medicine providers are preferred to psychiatric services, though this may be less pronounced among school-related presentations, especially in more Westernized settings such as Hong Kong.
d. Course is variable, and may respond closely to changing interpersonal and social circumstances. Amelioration of the precipitating stressor(s) typically brings about substantial improvement, although residual symptoms appear common.
e. Response to treatment may be strongly mediated by the illness role and its relationship to the intractability of precipitating stressors.

Several community studies have been conducted, but most are available only in Chinese. One community-based study conducted in 1959 in Chengdu City (*N* = 10,830) found a point prevalence of 5.9% for unspecified "neurasthenia" of greater than 3 months' duration. Prevalence rates from other community surveys prior to 1980 have been reported as between 6% and 10%. Several investigators noted a rise in presentations of *shenjing shuairuo* to medical services in the aftermath of the Cultural Revolution (1966 to 1976) when social space was opened for a public accounting of the traumas associated with this period. However, epidemiologic documentation of this likely upswing in community and clinical prevalence is limited. One nationwide community-based study from 1986 found a prevalence rate of 1.3% in the general population. Prevalence rates among students have typically been high, given the association of school-based stressors with *shenjing shuairuo*. In 1993, 5.1% of Chinese college students in Anhui, China, fulfilled the CCMD-2 criteria for the syndrome. Lee and colleagues reported a 6.3% prevalence of moderate or severe *shenjing shuairuo* among Hong Kong undergraduates in 1995. A 2014 household survey in Guangzhou by Brian Hall and colleagues, using the Patient Health Questionnaire (PHQ-9) and the neurasthenia criteria from ICD-10, found a prevalence of depression of 5.3% and of neurasthenia of 15.4%. The prevalence of neurasthenia alone or with depression did not differ significantly by any demographic characteristic studied, including age, gender, education, and income.

Clinical epidemiology studies have varied markedly over time. By numerous anecdotal reports, between about 1950 and 1980, neurasthenia, either in the ICD or the CCMD formulation, constituted probably the most common psychiatric diagnosis in China. The narrowing of the psychiatric definition of neurasthenia since 1980—such as by the exclusion of primary affective presentations—and its reduced application in diagnostic practice likely decreased prevalence rates in clinical epidemiology. Yet the prevalence of *shenjing shuairuo* in medical clinics remained high. A 1983 clinical epidemiologic study in a county general hospital in Sichuan province (*N* = 1,401) found a prevalence of 3.9% for ICD-9–defined

neurasthenia. From 1997 to 1998, 5.3% of adult outpatients using internal medicine, neurology, and traditional Chinese medicine clinics in a referral hospital in Hunan province met CCMD-2-R criteria for *shenjing shuairuo*. Rates of up to 6.3% have been reported in other general clinical settings. Psychiatric inpatients appear to have much lower rates, probably reflecting the outpatient nature of most neurasthenia care. In 1990, the prevalence of neurasthenia among 2,275 inpatients discharged from the Shanghai Institute of Mental Health was only 0.26. Due to the growing official acceptance of the ICD classification in China, the removal of neurasthenia from ICD-11 may lead to less use of the diagnosis of *shenjing shuairuo* in official clinical documentation.

The 12-month prevalence of ICD-10 neurasthenia among Chinese Americans in Los Angeles County was studied by Yan-Ping Zheng and colleagues. The prevalence of all neurasthenia diagnoses, regardless of diagnostic exclusions, was 6.4%. The rate of "pure" neurasthenia—those without any lifetime comorbid DSM-III-R diagnoses—was 3.6%, higher than any other DSM-III-R disorder. These "pure" neurasthenia sufferers did not differ on most sociodemographic characteristics from respondents without a psychiatric diagnosis, with "pure" depression, or with "pure" anxiety disorder. Further analysis of the study subsample (95%) who were foreign-born revealed that those with higher neurasthenic symptom counts were older, had less education, and were more likely to be formerly married (separated, widowed, or divorced). Lower acculturation increased the risk of neurasthenia, but only in the presence of financial stress (as an interaction term). Participants with lower acculturation were more likely than those with higher acculturation to express the syndrome when confronted with financial stress. The authors concluded that "neurasthenia is a unique form of expressing distress among low acculturated groups of Chinese Americans."

Precipitants/Etiology. An empirical assessment of the precipitants of *shenjing shuairuo* has found high rates of work-related stressors, which were made more intractable by the centrally directed

nature of mainland Chinese society. These included unwelcome work assignments, job postings that caused family separations, harsh criticism at work, excessive workloads, monotonous tasks, and feelings of inadequacy or incompatibility of skills and responsibilities. Students usually described somewhat less severe study-related precipitants, particularly school failure or anxiety over the mismatch between personal or family aspirations and performance. Other interpersonal and family-related stressors included romantic disappointments, marital conflict, and the death of a spouse or other relative. The work of Arthur Kleinman has emphasized the political nature of many precipitants of *shenjing shuairuo*, especially during the 1980s and 1990s as a result of the vicissitudes of the Cultural Revolution. This societal upheaval involved traumatic changes in social circumstances, family separations, acute humiliations, social ostracism, demoralization, and exposure to violence and deprivation.

A common theme to most precipitants of *shenjing shuairuo* involved frustration of a keenly held aspiration, glossed as "troubled vexation," to which social circumstances allowed no or insufficient solution. Loss of face (*mianzi, lianzi*), a key social value in Chinese communities, was also frequently noted as a trigger of *shenjing shuairuo*.

Chinese etiologic understandings of the syndrome commonly invert the Western view of "psychosomatic" presentations, whereby social–interpersonal precipitants cause psychological distress that is displaced onto bodily experience. In what Kleinman described as "somatopsychic" interpretations, many sufferers of *shenjing shuairuo* located the pathologic impact of external stressors directly onto physical functioning, producing somatic symptoms that only secondarily caused psychological distress. This schema permits sufferers to acknowledge a psychological contribution to their illness while yet locating the nexus of pathology on physical processes.

Relationship to Psychiatric Diagnoses. Several studies in Chinese communities found a strong relationship between *shenjing shuairuo* and mood, anxiety, and somatoform disorders. Kleinman found considerable overlap between *shenjing shuairuo* and these

disorder clusters in his studies in both mainland China and Taiwan. In the People's Republic, his study of 100 Chinese patients diagnosed with *shenjing shuairuo* found that 93 also had a depression diagnosis, with 87 meeting the criteria for major depressive disorder. Sixty-nine patients were also diagnosed with an anxiety disorder and 25 with a somatoform disorder. In Taiwan, 22 of 51 patients with *shenjing shuairuo* also met the criteria for major depressive disorder, which was the most common psychiatric diagnosis in this group of patients.

Subsequent investigations confirmed these associations, with rates of depressive disorders ranging from 30% to 70% in cases of *shenjing shuairuo*. The association with somatoform and anxiety disorders was also found repeatedly. The exact correlations with these disorders depended on whether the subjects came from community or clinical settings; in clinical studies, the correlations varied between general medicine and psychiatric clinics. Outpatient primary care settings tended to yield associations between *shenjing shuairuo* and the somatoform disorders. One study by Sing Lee and colleagues with 100 primary care patients in Hong Kong with unexplained fatigue of at least 6 months' duration that excluded patients already in treatment for a depressive disorder found that 72% endorsed a self-label of *shenjing shuairuo*. In the full sample, the most common diagnoses on the Structured Clinical Interview for DSM-III-R were somatoform pain disorder (47 percent) and undifferentiated somatoform disorder (35 percent). Fourteen patients met the criteria for depressive disorders, with the other diagnoses mostly in the anxiety spectrum.

A study conducted from 1997 to 1998 by Doris Chang and colleagues in three general medicine clinics in Hunan also found similar correlations. The study included 139 patients, mostly of rural origin, who presented with unexplained somatic complaints. Only 55 percent received any diagnosis on the Structured Clinical Interview for DSM-IV, all in the somatoform disorder spectrum. Undifferentiated somatoform disorder was the closest counterpart to *shenjing shuairuo* in DSM-IV, with a diagnostic concordance of kappa = 0.24 ($p < .001$). The fact that 45% of subjects with the CCMD-2 syndrome

did not meet the criteria for any DSM-IV disorder, however, suggested to the authors that *shenjing shuairuo* is a distinct clinical condition with only partial comorbidity with DSM diagnoses.

A similar conclusion was reached by Hall and colleagues in their 2014 community-based epidemiologic study in Guangzhou (*N* = 751). This study did not use the CCMD definition of *shenjing shuairuo*, however, relying instead on the ICD-10 criteria for neurasthenia, which had only a partial overlap with CCMD-3. The comorbidity between neurasthenia and PHQ-9-based depression was only 2.5%, but people with depression had nearly six times higher odds of having neurasthenia. Sleep latency was highest among individuals with neurasthenia and specific to this disorder, possibly linked to higher levels of worry. Zheng and colleagues, in their 1997 community-based epidemiologic study among Chinese Americans in Los Angeles County (*N* = 1,747), likewise used the ICD-10 criteria for neurasthenia. They identified 112 (6.4%) subjects with ICD-10 neurasthenia in the community. Over half (*N* = 63; 56%) did not meet the criteria for a DSM-III-R diagnosis. Compared with those with depression and anxiety diagnoses, these respondents reported fewer psychological symptoms on the SCL-90-R but similar levels of somatization symptoms.

The overlap with ICD definitions of neurasthenia has been assessed in a few studies. Chang and colleagues found an overlap of 53% between the CCMD-2 *shenjing shuairuo* category and ICD-10 neurasthenia. An even more limited overlap with the international classification was found in a 1989 study conducted at the Shanghai Psychiatric Hospital. Clinical diagnoses of *shenjing shuairuo* obtained by two senior Chinese psychiatrists yielded only a 22.5% overlap with the ICD-9 neurasthenia category.

Additional Clinical Features. The clinical course of the syndrome may depend on the associated psychiatric comorbidity and on the degree of persistence of the precipitating stressors. One longitudinal study found complete resolution of *shenjing shuairuo* symptoms and good social adjustment 20 years after the index diagnosis in 83 out of 89 cases. Only one case was receiving continued treatment, and

no subjects reported the onset of depressive disorder subsequent to the *shenjing shuairuo* diagnosis.

Chinese psychiatrists have carried out numerous studies of neurophysiologic and cognitive function in *shenjing shuairuo* patients since the 1950s. Most have reported abnormalities compared to normal controls, including in tests of polysomnography, EEG, psychogalvanic reflex, gastric function, and memory function. These findings need to be replicated with well-controlled samples using contemporary diagnostic instruments.

Specific Cultural Factors. The evolving definitions of *shenjing shuairuo* have emerged out of a tradition of syncretism in Chinese medicine between indigenous illness understandings and international contributions. Nineteenth-century Western notions of a weakened nervous system due to overuse (neurasthenia) found an ancient cognate expression in Chinese concepts of bodily meridians or channels (*jing*) binding vital organs in balanced networks along which forces (e.g., *qi*, vital energy, in *yin* and *yang* forms) could be disrupted from their normal, harmonious flow. This gave rise to *shenjing shuairuo*, an illness whereby the *jing* that carries *shen*—spirit or vitality, the capacity of the mind to form ideas, and the desire of the personality to live life—have become *shuai* (degenerate) and *ruo* (weak) following undue nervous excitement.

As noted by Kleinman, this Chinese conception is much more relational and contextual than the typical Western medical view. Bodies are seen as acting in the midst of specific contexts and social relationships rather than abstractly or individually. Physical networks are thus metaphorical representations of interpersonal and societal connections, with emotions acting as mediating channels. These social networks, just like bodies, “can be vitalized or devitalized, demoralized or remoralized. Indeed, bodies are networked, networks embodied.”

The result is an illness form, *shenjing shuairuo*, that tightly links social and interpersonal situations with bodily afflictions, such as the metaphorical linkage described earlier between dizziness and social dislocation due to revolutionary upheavals. Other contributors to the

persistence of this illness form include elevated stigma against mental illness in Chinese communities, which is forestalled by the primarily physical nature of *shenjing shuairuo*; the contributions of Pavlovian psychiatry and Japanese research to Chinese nosology, which emphasized neurasthenia beyond its role in Western psychiatry; the prominent use of the syndrome by the communist authorities as a health-based, treatable cause of reduced productivity during the 1950s and 1960s; and its popular acceptability as a veiled complaint against social deprivation and oppression at a time when direct confrontation would be harshly suppressed.

Treatment. Kleinman noted a discrepancy in treatment patterns between Taiwanese and Chinese *shenjing shuairuo* patients, with those in Taiwan more frequently resorting initially to self-help remedies, which included special foods, tonics, and dietary changes. He attributed this discrepancy to the availability of inexpensive care in the People's Republic.

When accessing formal sectors of care, most patients used both Western-trained physicians and practitioners of traditional Chinese medicine. Nonpsychiatric medical settings were preferred, including neurology and general medicine clinics, in concert with cultural understandings of the somatopsychic etiology of *shenjing shuairuo*, which emphasize its physical mediation. The modality of treatment was usually traditional Chinese medicines, which were prescribed by both Western-trained and traditional Chinese medicine practitioners. This conformed to the balanced status ascribed to both types of training among Chinese physicians. Polypharmacy was common, combining sedatives, traditional herbs, antianxiety agents, vitamins, and other tonics. In spite of active suppression of religious healing in China, almost a quarter of patients were also engaged in such treatment in the early 1980s.

ONGOING WORK ON THE RELATIONSHIP BETWEEN CULTURAL CONCEPTS OF DISTRESS AND PSYCHIATRIC NOSOLOGY

Research

In 1969, Yap challenged the field to learn more about “culture-bound syndromes” so that their relationship to psychiatric disorder could be resolved, yet much research still needs to be done. Without a more systematic and wide-ranging program of research on a broader range of cultural concepts of distress, current approaches that only focus on classificatory exercises are unlikely to further the current understanding. The strategy of trying to find the right classificatory scheme by basing it on the similarity between one or two symptoms of a cultural syndrome and of the psychiatric disorder is limited. It is particularly problematic when researchers privilege the DSM categories as the main organizing structure of relevance to the cultural concepts of distress. This approach is unlikely to produce new insights into these concepts on their own terms or in relation to psychiatric diagnosis. It ignores, for example, that many cultural concepts are not organized syndromically so that classifying them on the basis of prototypical symptoms is incompatible with their organizational structure. Comparing etiologic categories with symptom-based diagnoses on the nature of their symptoms is not only useless but counterproductive.

A simple, symptom-based comparison further ignores the function of cultural concepts as idioms or modes of expressing distress. Comparison of cultural concepts and psychiatric disorders as idioms should focus on the mutual compatibility of their intended communications (do they deliver the same message?) and the cultural fit between the idiom—whether indigenous or professional—and the situation in which it arises (is the message equally appropriate?). An idiom of distress intended as a sign of anger that is misinterpreted by the diagnostician as a sign of severe mental illness (e.g., psychosis) is not being accurately translated from the idiomatic perspective. Similarly, an idiom that is considered culturally appropriate to the situation (e.g., anger as a comprehensible reaction) would be well matched by a diagnosis that idiomatically conveys a similar sense of appropriateness.

In order to resolve the cognitive dissonance created by the complex relationship between the cultural concepts and psychiatric disorders, cross-cultural mental health researchers need to carry out an intensive research that illuminates these concepts rather than simply attempting to subsume them into psychiatric categories and obliterating them. Peter Guarnaccia and his colleague Lloyd Rogler proposed a research program on cultural concepts of distress to bring their study into the mainstream of mental health research. This framework is faithful to the holistic nature of the cultural concepts while at the same time applying current research approaches from several fields. It comprises a series of key questions that need to be answered in order to understand these concepts from the cultural as well as the psychiatric perspectives.

Guarnaccia Rogler's questions are organized into the following five broad dimensions:

1. **Nature of the phenomenon:** How is the folk category characterized within its cultural context? What are the defining features of the phenomenon? Is the folk illness organized syndromically? Does it refer primarily to an etiologic construct? What is the message it attempts to convey as an idiom of distress? How salient is the concept, defined as the rapidity and extent of its recognition within a cultural context?
2. **Location in the social context:** Who are the people who report the folk category, and what is their location in the social structure? What are the situational factors that provoke these conditions?
3. **Relationship to psychiatric disorder:** How is the folk illness empirically related to psychiatric disorder(s)? Does it cut across diagnostic groupings? What is the range of its overlap with psychiatric categories?
4. **Social/psychiatric history of the cultural concept:** When the onset and offset of the cultural concept and the associated psychiatric disorder(s) do not coincide, what is the sequence of onset? How does the life history of the sufferer, particularly the experience of traumatic events, affect the sequence? How many

episodes of the folk illness has the person experienced? How severe have they been?

5. **Treatments and outcomes:** Holistically, how should be person's suffering be addressed? If the folk illness is effectively treated, does the sufferer also experience relief of the associated psychiatric disorder(s)? And vice-versa, if the psychiatric disorder is resolved with psychotherapy or pharmacotherapy, does the folk illness resolve as well?

Clinical Application

Medical anthropology and cultural psychiatry, and psychology have developed tools and perspectives that are useful in assessing cultural concepts of distress in clinical work and in negotiating between the concepts and psychiatric diagnoses. One such model is the Explanatory Model Questions developed by Kleinman. Another model is the Outline for Cultural Formulation, included in DSM-5-TR along with its operationalization as a set of semistructured questionnaires known collectively as the Cultural Formulation Interview. These frameworks are designed to help clinicians inquire about and better understand the cultural dimensions of their patients' presentations of their mental health problems.

The key area of the Outline for Cultural Formulation is the section on cultural explanations of the individual's illness. The major elements of inquiry include the predominant idioms of distress through which symptoms are communicated; the meaning and perceived severity of the individual's symptoms in relation to the norms of the cultural reference group; local illness categories used by the individual's family and community to identify the condition; the perceived causes or explanatory models that the individual and reference group use to explain the illness; and past and current experiences with popular and professional sources of care. These areas can serve as a support for clinicians who seek to better understand their patients' perspectives on the symptoms, expressions, and difficulties they present.

In DSM-5, the Outline was rendered more operational for routine clinical practice by standardizing its implementation as the Cultural

Formulation Interview. This is composed of three types of semistructured interviews that offer clinicians concrete ways to carry out the cultural assessment of patients and their entourages. The three components of the Cultural Formulation Interview are a core 16-item questionnaire, an informant version of the core interview to obtain information from caregivers, and 12 supplementary modules that expand on these basic assessments. If used routinely to frame the intake evaluation, the Cultural Formulation Interview can help establish a foundation of person-centered information on the patient's context and perspective, and a working alliance, on which to build the rest of the diagnostic interview and treatment negotiation process.

There are several resources that clinicians can turn to for further guidance and examples using this formulation technique. The cultural formulation has been elaborated by the Cultural Committee of the Group for the Advancement of Psychiatry in their 2002 publication Cultural Assessment in Clinical Psychiatry. Illustrative cases using the cultural formulation and discussing the implications of cultural understanding of mental health problems have been available in select issues of *Culture, Medicine, and Psychiatry* starting in 1996. Key writings on the cultural formulation approach were assembled in *Cultural Formulation: A Reader for Psychiatric Diagnosis* (2008). The McGill Cultural Consultation Service published *Cultural Consultation: Encountering the Other in Mental Health Care* in 2014, describing the cultural assessment of over 400 cases with an expanded cultural formulation approach. Finally, the *DSM-5 Handbook on the Cultural Formulation Interview* (2016) describes in detail the components of the Cultural Formulation Interview, presents multiple clinical vignettes to illustrate its use, and suggests strategies for incorporating the interview into clinical training and routine practice.

Once the information is elicited, the next key step is for clinicians to lead a negotiation process whereby they and their patients come to understand each other's perspectives on the mental health problem and come to an agreement on how to proceed. Kleinman described this approach in *The Illness Narratives* (1988). The process that Kleinman developed is for the provider to first elicit and understand the patient's explanatory model and then to make clear the provider's

explanatory model. The process then focuses on developing a treatment plan based on negotiation between the patient and provider models. It may be useful to include the patient's cultural terms and explanations in case formulations and treatment plans, as they may help clarify symptoms and etiologic attributions that could otherwise be confusing. This approach has been further elaborated in a variety of cultural competence training programs for physicians to aid them in this negotiation process. The impact on the quality of mental health care from these approaches for assessing cultural understandings of cultural concepts of distress and for clinician–patient negotiation are pressing areas for research.

USING CULTURAL CONCEPTS OF DISTRESS TO IMPROVE MENTAL HEALTH SERVICE DESIGN AND IMPLEMENTATION

In the previous section, we discussed the added value of incorporating cultural concepts of distress into clinical assessment using the Cultural Formulation Interview. In this section, we discuss how attention to cultural concepts of distress can play an important role in culturally appropriate and effective mental health care more broadly. As we have emphasized, cultural concepts of distress are not simply placeholders for psychiatric categories—they have their own meanings and both personal and social consequences that may interact with many different clinical conditions and social predicaments. In many instances, cultural concepts of distress may be more meaningful to patients and families than psychiatric diagnostic terms because they represent shared experiences and expectations.

Many of the cultural concepts of distress previously described in this chapter have been used to improve mental health services. In this section, we will illustrate the clinical uses of cultural concepts of distress by focusing on the example of "thinking too much"—a cultural concept of distress characterized by both worry about future events and rumination about past events that has been observed in

various forms across many cultures and contexts. The qualification "too much" refers to the intrusive quality of these thoughts and difficulty controlling them once they have begun. "Thinking too much" may also be associated with sleep problems and negative perceptions of self. In some cultural contexts, experiencing "thinking too much" for a prolonged period is associated with a risk of more severe psychopathology such as delusions or hallucinations or a lack of self-control (e.g., an inability to abide by social norms). Coping with "thinking too much" varies cross-culturally, but it often includes strategies to control the intrusive thoughts such as by sharing them with others, engaging in prayer or other religious practices, using behavioral distractions, and seeking treatment from a variety of practitioners of traditional medicine as well as biomedical health workers. Local examples of "thinking too much" include *kufungisisa*, a Shona term in Zimbabwe; *reflechi twòp*, a Kreyòl term in Haiti; *pensando mucho*, a Spanish term in Latin America; *man maa kura khelne*, a Nepali term in South Asia; and *kut careen*, a Khmer term in Cambodia.

Cultural Concepts of Distress and Engagement with Mental Health Services

Challenges in mental health services are often categorized as *supply side* or *demand side*. "Supply side" refers to the availability of mental health services for a particular population and setting. "Demand side" refers to help-seeking behaviors to engage the available services. For many minority populations in high-income countries and for most residents of low- and middle-income countries, there are both supply-side and demand-side barriers. Culturally and contextually sensitive care is often lacking, and when services are available, there is a hesitance to engage such services because of lack of awareness about care, difficulties trusting providers due to prior experiences with poor-quality care, lack of recognition of a psychiatric illness, and stigma associated with using mental health services. The utilization of cultural concepts of distress can help to reduce demand-side barriers. For example, in Zimbabwe, although the label of depression

carries mental illness stigma, framing psychological treatment as care for *kufungisisa* makes it more acceptable and appealing. Similarly, in Haiti, describing psychosocial and psychological support as an approach to help with *reflechi twòp* helped lay community counselors encourage persons with psychological distress to participate in care. In Peru and other Latin American countries, cognitive behavioral therapy has been a treatment for *pensando mucho* in programs for women with perinatal depression.

Cultural concepts of distress can also be added to mental health screening tools or used to develop new screening instruments to identify persons who would benefit from services. Standard biomedical screening tools such as the PHQ-9 often lead to high numbers of false positives when adapted for use in a new cultural context. Adding a question about a cultural concept of distress can help identify individuals with forms of distress for which it may be appropriate to seek help. In Nepal, for example, adding a question about problems in the “heart–mind” (*man*) as a required symptom reduced false positives on the PHQ-9. Moreover, patients referred based on both heart–mind problems, and high PHQ-9 scores had the shared understanding that they all experienced a similar type of distress.

Another approach to using cultural concepts of distress to promote engagement with different types of mental health services is through proactive case detection. This approach uses consultation with community members to identify persons in the community who may need mental health services. For example, teachers can be consulted to refer students with distress. Health workers can refer persons they encounter when delivering vaccinations or reproductive health services. Religious leaders and traditional healers can refer members of their congregations and communities. Cultural concepts of distress can be an effective way to explain who would benefit from referrals when communicating with these community members who are not mental health professionals. For example, in Haiti, Vodou priests (*Hougan*) have been trained to refer persons suffering from ongoing *reflechi twòp* to be evaluated for mental health services. Similarly, in the Democratic Republic of Congo, community members

referred mothers who had *maladi ya souci* (a sickness of worry) to participate in a culturally adapted version of cognitive behavioral therapy. Recently, the World Health Organization has adopted the Community Informant Detection Tool (CIDT), which was developed by Mark Jordans and colleagues as a way of using cultural concepts of distress in a prototype narrative to train community members to identify persons with distress and link them with mental health services.

Once people are engaged through acknowledging their cultural concepts of distress, it is important to consider how these concepts may align with the available types of service. Traditional medicine systems or religious healers may recognize the same terms, and the cultural concept then may help direct the individual toward appropriate support. For biomedical services, it is important to further evaluate how the individual's cultural concepts of distress may map onto, modify, or obscure diagnostic criteria for specific psychiatric conditions. However, the increasing availability of transdiagnostic treatments means that individuals with specific symptoms or behavioral problems included in cultural concepts of distress may benefit from psychological interventions that target these symptoms or problems. Cultural concepts can also be incorporated into stepped-care services, as has been done in global mental health programs in low- and middle-income countries. In stepped-care services, patients who present with distress framed in terms of a cultural concept associated with limited functional impairment may be treated with a brief psychological intervention, such as training in stress management or problem-solving techniques. However, the presence of more severe impairment or urgent symptoms such as suicidal thoughts or behavior indicates the need for a higher tier of services, or potentially, emergency care. Similarly, endorsement of a cultural concept of distress among patients who also met criteria for a specific psychiatric diagnosis may require a disorder-specific pharmacologic and/or psychological intervention.

Cultural Concepts of Distress and Promotion of Collaborative Care

The efficacy of indigenous interventions may stem in part from their fit with local cultural explanations and expectations. Including elements of local concepts of distress in both the explanation of the treatment plan and in specific interventions may then increase effectiveness. For example, Tibetan, Mongolian, Chinese, and other related medical traditions have developed treatments for worry and rumination associated with “wind”-based and *qi*-based conditions, such as *rlung, yadargaa*, and *shenjing shuairou*. By understanding the healing theories associated with these cultural concepts of distress, biomedical mental health practitioners can better understand who may benefit from these healing practices. This runs counter to assumptions that traditional healing practices will have universal benefits for all types of patients and any type of depressive or anxiety disorder. Rather, the greatest benefit may be among those individuals who experience specific aspects of depression or anxiety but also endorse relevant aspects of the cultural concept of distress. Moreover, cultural concepts of distress can serve as a communication bridge among different types of care providers and support referrals when needed from one type of care system to another. In Haiti, persons suffering from *reflechi twòp* with suicidality report greater benefits when receiving care from a *Hougan* (Vodou priest). This suggests that care for suicidality may be optimal when both mental health specialists and *Hougan* are involved if that is the preference of the patient and family. While such cultural information can guide the development of collaborative care systems and services, in each case, it is crucial to move beyond cultural stereotypes and generalizations to determine individual patients’ experiences, expectations, and preferences.

Cultural Concepts of Distress and Monitoring and Evaluation of Mental Health Services

Another role that cultural concepts of distress can play is in monitoring the progress and outcomes of treatment. When biomedical interventions are evaluated, DSM and ICD symptoms are typically used to determine if treatment is progressing and deemed to

be successful. However, this may miss aspects of distress that are most salient to the person receiving care. Monitoring progress with measures that track culturally salient symptoms and outcomes can provide a more accurate assessment. For example, if a major concern of a patient is “thinking too much,” then this can be tracked during care to see if the individual feels that the distress is improving by monitoring the relevant local cultural concept. As described above in relation to the Cultural Formulation Interview, when clinicians prioritize the concerns of the patient, this will help promote patient engagement and guide decisions about what treatment will be most beneficial. At a systems level, an intervention or a whole system of care can be evaluated by monitoring changes in cultural concepts of distress. For example, in Haiti, *reflechi twòp* has been included in the Kreyòl Distress Inventory as an outcome measure. Similarly, in Zimbabwe, the Shona Symptom Questionnaire includes *kufungisisa* as one of the symptoms to evaluate the outcome of mental health interventions. For treatments of Cambodian refugees, the Cambodian Somatic Symptom and Syndrome Inventory (CSSI) was developed and used to determine the effectiveness of both medications and culturally adapted psychotherapy.

When evaluating interventions using cultural concepts of distress, it is important that results be transparently communicated. For example, in a study in East Africa of a group psychological treatment, the depression symptom measure was validated against a cultural concept for traumatic grief. However, when the study was published, it was reported as establishing evidence for treating depression. It would have been more accurate to describe the intervention as having local evidence for resolution of traumatic grief, as it was described in the local context because that construct is closer to the cultural concept of distress used to locally adapt the symptom–outcome measure. Again, the broad issue is that local cultural concepts should not simply be assimilated to standard psychiatric concepts and categories because they provide additional information about the personal and social meaning and consequences of distress.

Cultural Concepts of Distress and Adaptation and the Development of Mental Health Interventions

Finally, cultural concepts of distress can play an important role in the development and adaptation of clinical interventions, especially psychological and interpersonal or social interventions. One of the best predictors of effective cultural adaptation is when the adaptation addresses the explanatory models of participants. Eva Heim and Brandon Kohrt developed a cultural adaptation framework for psychological interventions centered around cultural concepts of distress as the core of the adaptation process. They suggest focusing the beginning of the intervention on cultural concepts of distress to present the intervention in ways that are readily understood by patients. The pathways by which the intervention alleviates psychological distress should consider the potential causes identified in cultural concepts of distress to the extent possible.

The Friendship Bench study in Zimbabwe provides a clear example of how a local cultural concept of distress for "thinking too much," *kufungisisa,* was central in developing, implementing, and evaluating a psychological intervention. The Zimbabwean psychiatrist Dixon Chibanda developed the Friendship Bench psychological intervention based on principles of problem-solving therapy, but the intervention is framed according to the concept of how to manage "thinking too much" (*kufungisisa*). In the intervention, problem solving is explained as an activity to reduce *kufungisisa*. Moreover, *kufungisisa* is not simply used as a substitute for depression but is linked to other aspects of Shona ethnopsychology in Zimbabwe. In particular, *kufungisisa* is ameliorated through the practices of *kuvhura pfungwa* ("opening of the mind"), *kusimudzira* ("uplifting"), and *kusimbisa* ("strengthening"). The intervention also makes use of cultural notions of social space and interpersonal interaction. The intervention is delivered on a bench outside the hospital. The person delivering the intervention is thought of as a "helpful grandmother-type" figure who listens closely to one's needs and provides sage advice. Discussing excessive thoughts with a trusted family member or other confidant is what one would typically do when experiencing

kufungisisa. Parts of the Friendship Bench intervention are delivered in groups. In this context, it is easy to explain the purpose of the group to all participants because they typically have a shared experience and understanding of *kufungisisa*. This focus is more comprehensible and less stigmatizing than framing the group as depression treatment. In a randomized controlled trial comparing the Friendship Bench with a waitlist control, participants in the Friendship Bench showed a greater reduction on the Shona Symptom Questionnaire, which includes *kufungisisa*. In addition, they showed improvement in depression symptoms. Six months after receiving the Friendship Bench psychological intervention, only 13% of patients were depressed, compared with 50% of persons in a basic treatment comparison group, which included a nurse-led evaluation, brief support counseling, option for medication, education, and support for common mental disorders, and referral to a psychiatric facility if appropriate. The Friendship Bench thus illustrates the power of framing a psychological intervention according to local concepts and the benefit this has both for reducing the cultural concept of distress as well as symptoms of a psychiatric disorder. There are similar examples of adapting interventions based on *pensando mucho* among Latin American populations, *kut careen* and other Khmer idioms for Cambodian refugees, and concepts of worries in the heart–mind and tension in South Asia.

CONCLUSION

Integrating cultural concepts of distress into mental health services is essential to culturally informed care. It is a deliberate process that uses information about the relationship between professional classification systems and local traditions of distress to accurately translate the person's experience into clinically useful formulations and diagnoses. Integrating this local information into clinical practice can also help identify individuals with psychological distress; enhance their engagement in mental health services; provide effective psychoeducation; facilitate collaboration among biomedical mental health specialists and traditional healers and helpers; monitor

individual patient-level and service-level outcomes; and guide the cultural adaptation and implementation of mental health interventions. This chapter has outlined key areas for this translation and implementation process.

29.2 Cultural Assessments in Psychiatry

Neil Krishan Aggarwal, M.D., M.B.A., M.A., and Roberto Lewis-Fernández, M.D., M.T.S.

Cultural psychiatry has been the medical subspecialty most involved in developing clinical, research, and educational methods for patient cultural assessments. Cultural psychiatry—also known as cross-cultural, transcultural, or anthropologic psychiatry—has typically focused on three areas: (1) the extent to which manifestations of psychopathology are similar or different across societies, (2) the provision of mental health services for underserved ethnoracial groups in multicultural societies, and (3) the cultural bases of psychiatric knowledge and practice to reveal how mental health systems reflect underlying societal concerns and values. Cultural assessments play a fundamental role in each area, clarifying the relative biologic and environmental contributions of symptom manifestations; patient preferences on how, where, when, and with whom to receive care; and cultural assumptions within the patient–clinician relationship such as communication and relational styles. The inclusion of the Outline for Cultural Formulation (OCF) in *DSM-IV* and the Cultural Formulation Interview (CFI) in *DSM-5* indicated

growing acceptance of cultural assessments within psychiatry, not just for underserved ethnoracial groups, but for *all* people, including those whose identities are defined through gender, sexual orientation, migration, and veteran status.

HISTORICAL OVERVIEW

Cultural assessments in psychiatry have evolved alongside changing definitions of culture, especially within disciplines such as anthropology and psychology. In 1904, the renowned psychiatrist Emil Kraepelin—one of the first to differentiate *dementia praecox* (schizophrenia) from manic-depressive illness—sailed to Java, Indonesia, and investigated symptom manifestations in 100 European, 100 indigenous, and 25 Chinese patients at the Buitenzorg mental hospital. Kraepelin found that Javanese patients with psychosis experienced fewer hallucinations and delusions than European patients. He concluded that “the Javanese mind” was more primitive than “the European mind.” Kraepelin carefully recorded patient symptoms to examine similarities and differences between both groups, assuming that the definition and expression of psychotic illness would be identical in both populations. Although his assumptions and interpretations were based on racist intellectual trends from 19th-century physical anthropology that posited hierarchical relationships among races based on supposed biologic differences, Kraepelin inaugurated the field of comparative psychiatry and was among the first psychiatrists to use interpreters.

Another landmark movement emerged in the 1920s and 1930s with the Culture and Personality School. Social anthropologists such as Gregory Bateson, Ruth Benedict, Margaret Mead, and Ralph Linton collaborated with psychoanalysts such as Abram Kardiner and drew from Sigmund Freud’s theories on personality structure and organization. Many researchers tried to apply psychoanalytical theories to ethnographic data. This school contended that culture molds personality types, especially during child development, and that different cultural contexts produce different personality types based on socialization practices. For this reason, its theorists held

that studies of individual personalities could lead to insights into general characteristics of prototypical national cultures. The school gained prominence during World War II with the American government using “National Character Studies” to understand the character and strategies of the Axis Powers, as exemplified by Benedict’s classic work on the Japanese, *The Chrysanthemum and the Sword*. Postwar, the school lost influence for suggesting that all members in a society act similarly through a prototypical personality, for assuming that culture is static rather than dynamically created and debated by society’s members, and for insufficiently demonstrating robust links between child development practices and adult personality traits.

These examples demonstrate how the process of conducting cultural assessments has changed based on contemporary understandings of culture.

Current trends in cultural assessments can be traced to the extensive collaboration among cultural mental health experts and interpretive medical anthropologists since the 1970s. A substantial scholarship has grown from this collaboration, which is based on the following principles: (1) formal psychiatric diagnoses may not be translatable across all societies, and empirical data must demonstrate their applicability in each society to avoid a “category fallacy,” the assumption that constructs (such as those related to mental health and illness) developed in one cultural setting are equally valid in other settings; (2) the clinician’s interview bears a resemblance to the anthropologist’s ethnography in attempting to reconcile personal lived experience with scientific theory; and (3) a clinical interview can approximate ethnography by understanding the patient’s explanatory model (EM) of mental illness, such as its causes, onset, mechanism, treatments, course, and severity. This orientation acknowledges that individuals belong and contribute to their cultural groups without assuming the homogeneity of cultural experience. In addition, this orientation acknowledges that professional biomedical theories and practices are also cultural products and that successful treatment requires negotiation between patient and clinician EMs. These principles have laid the foundation

for four main ethnographic interviews used in patient cultural assessments: psychiatrist-anthropologist Arthur Kleinman's EM framework (1980), the Explanatory Model Interview Catalogue (EMIC) (1992), the Short Explanatory Model Interview (SEMI) (1998), and the McGill Illness Narrative Interview (MINI) (2006). These cultural assessments identify key domains that can be used in evaluating all patients irrespective of their cultural background.

Kleinman's Explanatory Model Framework

Arthur Kleinman's work in medical anthropology and cultural psychiatry during the 1970s centered on EMs, the culturally based understandings of sickness and treatment that patients and practitioners use. Kleinman contended that the study of interactions among patient and practitioner EMs could introduce a method to understand cultural influences in clinical communication. He identified five themes in illness EMs: (1) etiology; (2) time and mode of onset of symptoms; (3) pathophysiology; (4) course of sickness, including the degree of severity; and (5) treatment. Differences in patient–practitioner EMs could be analyzed as the differences between illness and disease, the former referring to the patient's lived experience of sickness and the latter referring to the practitioner's professional knowledge. Kleinman believed that analyzing patient EMs could illuminate the personal meanings of sickness and help-seeking preferences. His framework was influential in cultural psychiatry, primary care, and medical anthropology as a form of readily applied ethnography in clinical settings throughout the 1980s and 1990s. Subsequent patient cultural assessment interviews have variously engaged with Kleinman's EM framework to expand in other directions.

The Explanatory Model Interview Catalogue

Psychiatrist-epidemiologist Mitchell Weiss and his colleagues developed the EMIC as a method for cross-cultural research in psychiatric epidemiology based on the EM framework. The abbreviation EMIC invokes the anthropologic distinction between

emic cultural knowledge rooted in local communities and *etic* theoretical knowledge of outside professionals, as in the illness/disease distinction mentioned earlier. Kleinman warned against a mechanical use of EMs that could reduce a patient's culture to decontextualized clinical information such as a lab result or physical examination finding; this may have prevented him from elaborating a research methodology beyond unstructured in-depth interviews. In contrast, Weiss designed the EMIC to operationalize the EM framework with a clear methodology, enable systematic comparisons across sites, and enhance diagnostic epidemiology with cultural epidemiology to analyze the relationships of illness understandings and practices with clinical outcomes. Based on research with patients having mental illness and leprosy in India, Weiss also created the EMIC to quantitatively rate narrative differences among patients; for example, noting whether a patient answered about a perceived illness cause in direct response to a question or in passing during a response to another question. EMIC instruments follow a tailored question format and set of domains rather than reproducing a single, unvarying interview; therefore, an EMIC instrument is customized for every research question. Starting from general introductory questions for each domain—which may be similar across EMICs—each iteration of the interview progresses to specific questions targeting a range of local illness experiences and interpretations. EMICs include assessment domains such as (1) patterns of distress, (2) perceived illness causes, (3) help seeking and treatment, (4) general illness beliefs, and (5) disease-specific queries. In addition to operationalizing Kleinman's EM framework, the EMIC introduces this final domain to assess the patient's general understanding of a specific disease. This domain is intended to ascertain the extent to which the patient's individual illness explanations resemble or differ from other explanations in the patient's cultural background to which the individual is exposed. This domain addresses a criticism of Kleinman's EM framework that it relies too heavily on individual explanations of illness without considering their degree of representativeness within a particular cultural grouping.

The Short Explanatory Model Interview

Criticisms emerged that the EM framework was underspecified and that the EMIC was too detailed and time-consuming. Psychiatric researchers in England developed the SEMI as a standardized, valid tool to assess common mental disorders in large-scale fieldwork and primary care settings. The SEMI covers five sections: (1) the patient's individual and social background; (2) the nature of the presenting problem; (3) help-seeking behavior, including contact with nonmedical healers; (4) interactions with the clinician/healer to clarify roles and expectations for promoting satisfaction; and (5) illness understandings, covered through a presentation of three vignettes for common mental disorders—depression, phobia, and somatization—followed by open-ended questions to capture the respondent's attitudes to the vignettes. The interview was tested in four primary care sites in England and Zimbabwe. In addition to assessing patient EMs and general views on mental illness, the SEMI expands cultural assessment to inquire about the patient's background and expectations of care to inform current treatment.

The McGill Illness Narrative Interview

The final ethnographic interview comes from researchers at McGill University in Canada, who raised concerns that the EM framework may be too unstructured and incomplete for systematic comparison and that the EMIC and SEMI may be too structured for narrative spontaneity. The MINI incorporates medical anthropologist Allan Young's critique that the EM framework assumes logical, coherent accounts of an illness experience. Young's work demonstrated that individuals use multiple representations and modes of reasoning to produce narratives of illness that can be complex, internally inconsistent, and even self-contradictory. Many patients may not be able to stipulate the causes of an illness, preferring explanations based on illness prototypes common to people in their communities (e.g., learned through popular myths or media accounts) or based on chain complexes in which people reason by association, such as through a chain of events (e.g., that a symptom and a potential cause

are related because they happened close together). The elicitation of illness prototypes recognizes broad social influences on an individual's meanings of illness, whereas chain complexes acknowledge reasoning based on categories salient to the patient rather than predetermined EM domains. To capture such variation, the MINI consists of open- and closed-ended interview components.

The *DSM-IV* Outline for Cultural Formulation

These four assessment interviews generated significant interest among mental health experts conducting cultural assessments in clinical practice. Anthropologists developed a related but independent scholarship demonstrating that the health care system can be analyzed as a cultural system and that psychiatric diagnosis is a form of clinical interpretation influenced by social networks and institutions. Throughout the 1980s, a consensus emerged among mental health clinicians and anthropologists that patients and providers—independently and together—routinely create and debate meanings of health, illness, and treatment. Psychiatrists and anthropologists have agreed that such acts of meaning making merit attention to close gaps between patient and provider understandings during any sickness. Mental health clinicians have found patient cultural assessments helpful to clarify mismatches between symptom manifestations and official diagnostic criteria or to engage patients in treatment based on their preferences for care; anthropologists have concentrated on the extent to which illness narratives reflect local patient worlds coming into contact with the biomedical system.

For the *DSM-IV* revision process, the U.S. National Institute of Mental Health (NIMH) convened a conference in April 1991 at the University of Pittsburgh among cultural experts, the *DSM-IV* task force, and workgroup representatives to enhance the new Manual's cultural validity. Cultural experts included cultural psychiatrists and psychologists, medical anthropologists, and members of underserved ethnic and racialized groups within the American Psychiatric Association (APA) leadership. Following this conference, the NIMH Group on Culture and Diagnosis developed recommendations for

DSM-IV, such as an introduction to the upcoming manual on the importance of culture, a section on cultural considerations for each diagnosis, a glossary of "cultural syndromes and idioms of distress," a cultural commentary on *DSM-IV's* multiaxial evaluation format, and guidelines for a cultural formulation. The NIMH group based the elements of its OCF on a literature review, demonstrating four domains that were common across patient cultural assessments: (1) cultural identity of the individual, (2) cultural explanations of the individual's illness, (3) cultural factors related to the psychosocial environment and levels of functioning, and (4) cultural elements of the patient–clinician relationship. A final domain was included to record how cultural information could influence diagnosis and care. Clinicians could use the OCF to supplement the multiaxial diagnostic assessment and to describe the patient's cultural and social reference groups in clinically relevant ways. Table 29.2–1 lists OCF domains for assessment.

Table 29.2–1.
The DSM-IV Outline for Cultural Formulation

Cultural Formulation Domain	Subtopics for Assessment
Cultural identity of the individual	▶ Individual's demographic and other socially and culturally defined characteristics ▶ Aspects of identity that are prioritized by the individual and how they interact (intersectionality) ▶ Degree of involvement with the cultural contexts of origin and the new cultural contexts (for immigrants and ethnic minorities) ▶ Degree of interaction and identification with own group and other segments of society (for those who identify with racialized and ethnic groups) ▶ Language abilities, use, and preference (including multilingualism) and their impact on access to and processes of care
Cultural concepts of distress	▶ Cultural constructs (idioms of distress, explanations, and syndromes) that influence how symptoms or problems are communicated ▶ Meaning and perceived severity of individual's distressing experience in relation to cultural norms

	▶ Priority symptoms, perceived seriousness of the illness, level of associated stigma, and anticipated outcomes ▶ Current preferences for and past experiences with professional and popular sources of care
Psychosocial stressors and cultural features of vulnerability and resilience	▶ Culturally relevant interpretations of social stressors, challenges, supports, and levels of functioning and disability ▶ Social determinants of mental health, including access to resources and opportunities, exposure to racism, discrimination, systemic institutional stigmatization, and social marginalization or exclusion (structural violence) ▶ Role of religion and interpersonal networks in causing stress or providing support
Cultural features of the relationship between the individual and the clinician, treatment team, and institution	▶ Individual differences in cultural background and identity between the individual and the clinician, treatment team, or institution ▶ Problems that these differences may cause in diagnosis and treatment (e.g., difficulties in eliciting symptoms and understanding their cultural significance, in determining whether a behavior is normal or pathologic, or in establishing rapport)

Overall cultural assessment	▶ Discussion of how cultural considerations specifically influence comprehensive diagnosis and care

The OCF's inclusion in *DSM-IV* provided an institutional mechanism for mental health experts and anthropologists around the world to appraise the current state of knowledge, harmonize efforts at patient cultural assessments, and suggest future directions. In contrast to the multiaxial evaluation with its standardized codes, the OCF was designed for clinicians to narratively describe the patient's account of suffering from an *emic* perspective rich with contextual details. The use of the word "formulation" was an attempt to stimulate the type of narrative analysis already familiar to psychiatrists trained in psychodynamic formulations who assess details of a patient's psychological conflicts in the context of life experiences. The formulation was also designed to standardize a methodology for cultural assessment and produce outcome studies in mental health services research. Field trials with various American ethnicities validated its utility and offered tangible clinical examples.

However, the OCF faced challenges right from its inclusion. Although the NIMH group recommended its placement at the beginning of the Manual, the OCF was placed in the ninth appendix. It was also combined with the *Glossary of Cultural Syndromes and Idioms of Distress* and renamed by the *DSM-IV* leadership as the *Glossary of Culture-Bound Syndromes*, a decision that tended to exoticize the OCF as if it should be used only with unusual cultural presentations rather than with every patient. Despite these obstacles, the OCF has been used worldwide since its publication in 1994. While much of this work has found the OCF a useful clinical tool, problems have been identified. Its format as a description of domains to be assessed, lack of implementation guidelines, and brevity—which required that clinicians already be familiar with cultural topics or social science theories—hindered widespread clinical use. Nonetheless, the OCF remains the most widely taught method of

cultural assessment in U.S. psychiatric residency programs. In addition, psychiatrists and psychologists in Canada, Denmark, England, the Netherlands, Sweden, and the United States have independently operationalized the OCF's implementation. These efforts range from brief semistructured interviews for individual clinicians to use with every patient to cultural consultation services that receive referrals from other health professionals and utilize cultural and linguistic brokers. A major contribution of the OCF has been to organize subsequent research along with its four domains of cultural assessment, facilitating its operationalization into the CFI in *DSM-5*.

KEY DOMAINS IN PATIENT CULTURAL ASSESSMENTS

Cultural Identity of the Individual

Cultural psychiatrists assume that understanding a patient's identity is indispensable to a thorough clinical evaluation. Early OCF guidelines suggested that cultural identity assessments be conducted through an "interpersonal grid" to record potentially relevant variables such as ethnicity, race, geographical origin, language, acculturation, gender, age, sexual orientation, religious or spiritual beliefs, socioeconomic class, and education. This suggestion can be seen as a precursor to contemporary understandings of intersectionality, the idea that individuals belong to multiple groups through which identities are ascribed and self-selected. However, the recommendation for an interpersonal grid faced criticism. The group raised concerns about stereotyping patients or minimizing sociocultural phenomena based on a clinician's determination of the patient's identity. Others have advocated a broader approach that accounts for changes in self-reported identity based on context (i.e., interviewer, setting), and that includes the patient's perception of the clinician's identity. Assessments of cultural identity can help clinicians discern whether forms of social belonging, stigma, and language

fluency impact symptom experience, expression, and interpretation in certain cultural contexts and settings.

Studies show that many psychiatric trainees may feel uncomfortable and invasive in asking patients about their identities without prior training. Nearly all OCF-inspired interviews include common elements to assess identity, such as the cultural groups with which a patient identifies; the levels of importance and meaning ascribed by the patient to these identifications; evaluations of language fluency and preferences; and assessments of patients' involvement in their cultural contexts of origin and the new cultural contexts in the case of immigrants, especially, including positive and negative experiences with involvement in both contexts. Aspects of identity in some OCF-based interviews included evaluations of whether patients experience multiple identities simultaneously or over time and how cultural identity impacts the clinical problem. Several OCF-based interviews also included detailed migration histories. All OCF-based interviews have used open-ended questions to encourage interaction and discussion, rather than closed-ended checklists. All authors have also warned against an oversimplification of cultural factors in which social processes such as adverse experiences associated with migration and discrimination are mistakenly understood as inherent and representative of the cultural group itself rather than as time-limited and context-driven reactions to social predicaments.

Studies published since the OCF have highlighted unique challenges for certain populations. Some refugees may be suspicious of questions about identity, and many migrants may not know how to discuss their backgrounds in new societies. Children and adolescents may have different cultural identities than their parents, depending on mixed parentage, adoption, and socialization or acculturation. The cultural identity of older patients may be shaped by cultural meanings of old age based on their social roles and status. For all patients, cultural identity should be explored with reference to social context, developmental phase, and the possibility of change over time. Clinicians should especially endeavor to clarify

which aspects of identity patients consider to be ascribed by others and chosen for themselves.

Cultural Concepts of Distress

EMs of illness have underpinned most studies on patient cultural assessments in mental health and anthropology. Compared to the original assumption of EMs as cognitively linear, later research has shown that EMs can exhibit metaphorical thinking, no clear causes, sequences of events linked by patients based on contiguity or metonymy in ways that may be unclear to others, and images or examples of illness used analogically to understand the current illness episode. EMs can change based on context, including the language, interviewer, and setting in which they are elicited; interactions with close associates, the community, or the health care system; acculturation status for immigrants and refugees; and experiences of discrimination within the health care system. Attempts to code illness narratives from patients with medically unexplained symptoms revealed three types of EMs: *nominal*, in which a condition was named without elaborating on causal attribution or mechanism; *causal attributions*, in which a symptom or illness was linked to a cause; and *process or mechanism explanations*, in which mechanistic or metaphorical devices linked cause and symptom.

Culture and context influence EMs. Clinical narratives reflect broader cultural norms affecting communications with mental health care providers, family, and friends. Access to the illness representations of crucial members in the person's extended social network (either directly or as reported by the patient) provides a range of possible views influencing the person's experience. The organization of health care services in a society may also determine patients' attitudes toward disease, diagnosis, and treatment based on familiarity with the health care system. For this reason, mental health clinicians should evaluate culture and context when working with *all* patients since the act of diagnosis still relies on linguistic communication within psychiatry.

Eliciting past treatment experiences and current treatment expectations are also important components of EMs. Cultural scripts associate a patient's illness representations with patterns of self-coping and help seeking, including perceived relevance, the efficacy of mental health treatments, and their potential dangerousness. Cultural adaptations of evidence-based therapies that take account of cultural scripts may improve patient engagement and response, highlighting the value of identifying cultural interpretations prior to treatment planning. Nonmedical forms of self-coping and help seeking are common, diverse, and merit clinical attention because they may complement or conflict with biomedical care. Barriers to utilizing mental health services are also determined by cultural priorities for care, family values and interactions, and local health system and socioeconomic factors affecting access to mental health services. A sound cultural assessment strives to situate EMs against the relevant social and health contexts of the patient.

Early theoretical guidelines on the OCF included the *culture-bound syndromes* in this section. *DSM-5-TR* substitutes the term "culture-bound syndrome" with three other terms: *cultural idioms of distress, cultural explanations,* and *cultural syndromes*. These terms denote the ways that suffering, behavioral problems, and troubling thoughts and emotions are experienced, understood, and communicated, either as symptom clusters, ways of expressing distress that may not involve specific symptoms, and/or as explanations or attributions. Key aspects of patients' clinical presentations may be patterned by such cultural concepts.

Nearly all OCF-based interviews include questions on illness-related idioms, the meaning and severity of symptoms, causes, expected course of illness, experiences with care, and treatment expectations. Nearly all interviews ask the patient to describe the views of close associates such as family and friends to situate the individual's perspective in the community context. This line of questioning attempts to operationalize the understanding of culture as shared and interpersonal. OCF-based instruments vary in assessing how the patient describes the clinical problem to close associates, the most troubling aspects of the clinical problem, the

contribution of illness prototypes within a given cultural context to the patient's understandings, the most useful treatments received, treatment recommendations of close associates, and the patient's use of traditional healers and alternative services.

Psychosocial Stressors and Cultural Features of Vulnerability and Resilience

This domain encourages clinicians to clarify the context of a patient's illness—especially cultural interpretations of the stressors and supports associated with onset and course—and fears and hopes affecting levels of functioning. OCF-based interviews have used open-ended questions, with some interviews asking questions directly of the patient and others instructing clinicians to identify these data based on patient responses. In all cases, the goal is to obtain a description of the life context in which illness emerges and to elicit responses from the patient, the family, and the community. The subjective, lived experience of the patient's and social network's response is crucial because culture shapes the perceived centrality, magnitude, and treatability of the problem as well as forms of stress and support. This approach synthesizes the person's subjective experience of risk, resilience, and protective factors and the clinician's analysis of the patient's social and cultural context. For example, the subjective–objective approach might rely on a functional assessment of key activities of daily living that the clinician conducts alongside the patient's and social network's cultural interpretations of normative functioning.

The OCF was partly developed to address the adverse experiences of disadvantaged ethnoracial groups. Since its publication, studies have elaborated on additional social stressors. A recurrent finding has been the effect of migration status on the mental health of refugees as a social determinant of health independent of premigratory trauma. The factors most associated with risk for psychopathology include low socioeconomic status, poor housing, unemployment or underemployment, lack of official residency status, linguistic barriers, limited social networks, racial or

ethnic discrimination, role strain, family conflict, status loss, acculturative stress, nostalgia, and bicultural tension. Acculturation issues may affect disempowered or marginalized ethnoracial groups, not just immigrants. Discrimination-related stress affects members of other social groups, such as religious minorities, lesbian–gay–bisexual–transgender–queer persons, those with lower socioeconomic status, and individuals who are differentially abled.

In clinical assessment, family, friends, and other close associates can provide valuable information about cultural context. Collateral information from relevant members of the patient's social network is critical for children and adolescents, older adults, and those with conditions affecting cognitive functioning such as dementia or psychosis that could interfere with the clinical interview. OCF-based interviews have varied in the extent to which they seek collateral forms of information, with some protocols for children and adolescents identifying multiple sources of information and perspectives. Although patient cultural assessments such as the OCF and its related interviews can accommodate the use of medical interpreters and cultural brokers, there is little guidance on how to operationalize this process in practice.

Finally, psychiatrists have reported that patients frequently turn to religion, spirituality, and secular moral traditions in understanding and responding to mental illness. A "religiosity gap" may exist among clinicians trained in empirical/positivistic scientific methods and patients searching for holistic treatments, especially within complementary and alternative systems. Cultural assessments should attend to the meanings of religion and other moral systems in crafting illness assumptions and beliefs, especially when a religious community provides emotional, social, and material support. Clinicians may be able to mobilize such information with patients to support recovery through groups and organizations aligned with these traditions.

OCF-based interviews have assessed stressors, supports, and levels of functioning differently. Variations include focusing on the impact of stressors, the views of the social network, the role of the person's partner, forms of religious/spiritual or moral support, barriers

to receiving help, and the views of the social network on subsequent levels of functioning.

Cultural Features of the Relationship between the Individual and the Clinician, Treatment Team, and Institution

Many OCF case studies have illustrated the challenges confronting clinicians who provide cross-cultural care. These include tensions between biomedical forms of treatment and other forms of healing, the failure of health systems to provide interpreters, and difficulties in cross-cultural communication. Clinicians have discussed their reactions to consider the patient as an individual and a member of a social group. Sincere clinicians may encounter obstacles in addressing discrimination, racism, and subtle forms of cross-cultural bias during the medical interview. This domain of the OCF provides an opportunity to consider how such experiences affect patients' perceptions of care and promote clinician self-reflection on the challenges of delivering culturally sensitive health care.

Existing OCF-based interviews address this domain differently. Some provide queries to the clinician in the form of introspection, such as questions on mutual perceptions of power and the social positions of the patient and clinician, including the history of relationships between their respective cultural groups. This work operationalizes the concepts of "cultural transference" and "cultural countertransference" to analyze patient–physician relationships. Other instruments suggest questions that can be directly posed to the patient, such as the quality of communication during the interview, the need for interpreters, important topics missed by the interview, the perceived impact of ethnic or cultural matching with the clinician or lack thereof, and the role of the patient during the interview. Although this is a sensitive topic, early, open inquiry into past negative experiences of care and potential miscommunications with clinicians may facilitate rapport, engagement, and a commitment to overcome treatment barriers.

Future Directions for the OCF

DSM-5 included the OCF as it was published in *DSM-IV* with only minor edits. Since then, mixed-methods (qualitative–quantitative) analyses of patient cultural assessments and debriefing interviews have suggested revisions to the OCF that would (1) combine the current third and fourth domains into a single domain on key social relationships and (2) create a new domain to cover the social, cultural, political, and economic contexts of care. This suggestion comes from one clinical site, particularly in response to growing calls throughout academic medicine for greater attention to the structural contexts of care, such as the social determinants of health and systemic racism. Further studies are needed to validate these findings with data from other settings. This work indicates the ongoing relevance of the OCF to contemporary research and practice in cultural psychiatry.

The Cultural Formulation Interview in *DSM-5* and *DSM-5-TR*

Nearly 20 years of experience with the OCF and its related interviews since 1994 led to the *DSM-5* revision. The *DSM-5* Cross-Cultural Issues Subgroup (DCCIS) developed corresponding semistructured interviews to operationalize the OCF for clinicians. This set of interviews is known collectively as the CFI and consists of a core questionnaire of 16 items, an informant version of the core CFI to obtain collateral material from caregivers, and 12 supplementary modules that expand the core cultural assessment based on topics of interest (i.e., explanatory models) or populations with specific needs (i.e., children and adolescents, immigrants and refugees). The APA has made these instruments available for free at http://www.psych.org/practice/dsm/dsm5/online-assessment-measures.

The DCCIS was part of the larger *DSM-5* Gender and Cross-Cultural Issues Study Group and included experts in culture and mental health from diverse countries and cultural groups. One goal of the DCCIS was to improve cultural assessment within psychiatric

diagnoses. The subgroup was charged by the *DSM-5* task force with making recommendations on ethnoracial, cultural, and contextual issues to the *DSM-5* workgroups, such as differences in risk factors, precipitants, symptom presentations, prevalence, symptom severity, and course of illness for each diagnosis. These recommendations have appeared within the text of *DSM-5* and were further expanded in *DSM-5-TR*.

In addition, the DCCIS undertook a critical review of the *DSM-IV* OCF. DCCIS participants prepared literature reviews on the OCF as a whole, each of its four domains, and key implementation questions raised by the use of the OCF in clinical care. Such topics included recommended guidelines for use, special populations in need of attention such as children, the older adults, or immigrants and refugees, and the format and content of previously developed interviews, protocols, and questionnaires operationalizing the OCF. DCCIS members provided recommendations on revising the OCF, including how to facilitate implementation through the CFI.

Based on these literature reviews and previous experiences of DCCIS members developing and using OCF-based cultural assessments, the OCF was revised slightly for *DSM-5*, mostly by making the *DSM-IV* text more explicit in places. Examples of this clarification process include the incorporation of elements of cultural identity not mentioned in *DSM-IV,* such as religious affiliation and sexual orientation, among others; clinician instructions to identify stressors and supports in the patient's social environment; and mention of the impact of racism and discrimination on the clinician–patient relationship. These clarifications were expanded in *DSM-5-TR:* for example, by referring under cultural identity to intersectionality, the interaction of various aspects of the person's identity, and by guiding clinicians to elicit the level of interaction and identification by individuals who identify with racialized and ethnic groups both with their own group and with other segments of society.

Other changes made the OCF more operational. An initial 14-item interview was developed largely from previous question lists, interview protocols, and interviews that operationalized the OCF; most of the authors of the OCF-based approaches were members of

the DCCIS. The content of the questions was formulated, discussed, and debated in 2010 and 2011 during biweekly conference calls, supported by the *DSM-5* development process. The resulting 14-item version of the CFI was tested in a field trial from November 2011 to November 2012 at 12 clinical sites in the United States, Canada, Peru, the Netherlands, Kenya, and India. This trial utilized a standardized training format (http://www.ucl.ac.uk/ccs/specialist-services/#cfi) and research design to evaluate the CFI's acceptability, feasibility, and clinical utility among patients and clinicians. Field trial results were used to finalize the 16-item version in *DSM-5*. An informant version of the CFI was prepared to elicit collateral information from parents, caregivers, and other close associates. Supplementary modules were also developed for a more comprehensive assessment. Some modules expand various sections of the core CFI, as mentioned above.

Definition of Culture

To facilitate the application of the interview, a definition of *culture* was included in *DSM-5* and updated in *DSM-5-TR*. *Culture* is defined as (1) the processes through which people assign meaning to experience, drawing from the values, orientations, knowledge, and practices of the diverse social groups (e.g., ethnic, faith, occupational, and veterans groups) in which they participate; (2) aspects of an individual's background, developmental experiences, and current social contexts and position that may affect their perspective, such as age, gender, social class, geographic origin, migration, language, religion, sexual orientation, disability, or ethnic or racialized background; (3) the influence of family, friends, and other community members (the individual's social network) on the individual's illness experience; and (4) the cultural background of the health care providers, and the values and assumptions embedded in the organization and practices of health care systems and institutions, that affect the clinical interaction.

This definition appears in the text of *DSM-5-TR* and emphasizes the all-encompassing effects of culture on individual subjective

experience, as well as the fundamental role of family and close associates in shaping conceptions of illness and help-seeking expectations. In the United States, culture is frequently conflated with ethnic and racialized categories, which may unintentionally stereotype patients. Other components of culture—for example, age cohort, occupation, and sexual orientation—are often not part of a cultural assessment. By contrast, the CFI encourages clinicians to elicit the contextual frame of each patient's experience—seeking to use information about the collective to understand an individual's perspective and to clarify how local environments influence the person's situation, including how sociocultural contingencies help pattern a set of events. In addition, the CFI focuses the cultural formulation on the patient's self-identified group rather than on visible group markers of identity that may inadvertently lead to stereotyping. Finally, the updated definition focuses attention on the cultural background of the clinician and the cultural assumptions that organize health care delivery as important cultural contributors to the clinical environment.

Table 29.2–2.
Cultural Formulation Interview (CFI)

Supplementary modules used to expand each CFI subtopic are noted in parentheses.

GUIDE TO INTERVIEWER	INSTRUCTIONS TO THE INTERVIEWER ARE ***ITALICIZED.***
The following questions aim to clarify key aspects of the presenting clinical problem from the point of view of the individual and other members of the individual's social network (i.e., family, friends, or others involved in current problem). This includes the problem's meaning, potential sources of help, and expectations for services.	*INTRODUCTION FOR THE INDIVIDUAL:* I would like to understand the problems that bring you here so that I can help you more effectively. I want to know about ***your*** experience and ideas. I will ask some questions about what is going on and how you are dealing with it. Please remember there are no right or wrong answers.

CULTURAL DEFINITION OF THE PROBLEM

CULTURAL DEFINITION OF THE PROBLEM

(Explanatory Model, Level of Functioning)

Elicit the individual's view of core problems and key concerns. *Focus on the individual's own way of understanding the problem.* *Use the term, expression, or brief description elicited in question 1 to identify the problem in subsequent questions (e.g., "your conflict with your son").*	1. What brings you here today? *IF INDIVIDUAL GIVES FEW DETAILS OR ONLY MENTIONS SYMPTOMS OR A MEDICAL DIAGNOSIS, PROBE:* People often understand their problems in their own way, which may be similar to or different from how doctors describe the problem. How would *you* describe your problem?

Ask how individual frames the problem for members of the social network.	2. Sometimes people have different ways of describing their problem to their family, friends, or others in their community. How would you describe your problem to them?
Focus on the aspects of the problem that matter most to the individual.	3. What troubles you most about your problem?

CULTURAL PERCEPTIONS OF CAUSE, CONTEXT, AND SUPPORT

CAUSES

(Explanatory Model, Social Network, Older Adults)

This question indicates the meaning of the condition for the individual, which may be relevant for clinical care.	4. Why do you think this is happening to you? What do you think are the causes of your [PROBLEM]?
Note that individuals may identify multiple causes, depending on the facet of the problem they are considering.	*PROMPT FURTHER IF REQUIRED:* Some people may explain their problem as the result of bad things that happen in their life, problems with others, a physical illness, a spiritual reason, or many other causes.
Focus on the views of members of the individual's social network. These may be diverse and vary from the individual's.	5. What do others in your family, your friends, or others in your community think is causing your [PROBLEM]?

STRESSORS AND SUPPORTS

(Social Network, Caregivers, Psychosocial Stressors, Religion and Spirituality, Immigrants and Refugees, Cultural Identity, Older Adults, Coping and Help Seeking)

Elicit information on the individual's life context, focusing on resources, social supports, and resilience. May also probe other supports (e.g., from co-workers, from participation in religion or spirituality).	6. Are there any kinds of support that make your [PROBLEM] better, such as support from family, friends, or others?
Focus on stressful aspects of the individual's environment. Can also probe, e.g., relationship problems, difficulties at work or school, or discrimination.	7. Are there any kinds of stresses that make your [PROBLEM] worse, such as difficulties with money, or family problems?

ROLE OF CULTURAL IDENTITY

(Cultural Identity, Psychosocial Stressors, Religion and Spirituality, Immigrants and Refugees, Older Adults, Children and Adolescents)

	Sometimes, aspects of people's background or identity can make their [PROBLEM] better or worse. By ***background*** or ***identity,*** I mean, for example, the communities you belong to, the languages you speak, where you or your family are from, your race or ethnic background, your gender or sexual orientation, or your faith or religion.
	8. For you, what are the most

Ask the individual to reflect on the most salient elements of his or her cultural identity. Use this information to tailor questions 9–10 as needed.	important aspects of your background or identity?
Elicit aspects of identity that make the problem better or worse. *Probe as needed (e.g., clinical worsening as a result of discrimination due to migration status, race/ethnicity, or sexual orientation).*	9. Are there any aspects of your background or identity that make a difference to your [PROBLEM]?
Probe as needed (e.g., migration-related problems; conflict across generations or due to gender roles).	10. Are there any aspects of your background or identity that are causing other concerns or difficulties for you?

CULTURAL FACTORS AFFECTING SELF-COPING AND PAST HELP SEEKING

SELF-COPING

(Coping and Help Seeking, Religion and Spirituality, Older Adults, Caregivers, Psychosocial Stressors)

Clarify self-coping for the problem.	11. Sometimes people have various ways of dealing with problems like [PROBLEM]. What have you done on your own to cope with your [PROBLEM]?

PAST HELP SEEKING

(Coping and Help Seeking, Religion and Spirituality, Older Adults, Caregivers, Psychosocial Stressors, Immigrants and Refugees, Social Network, Clinician-Patient Relationship)

Elicit various sources of help (e.g., medical care, mental health treatment, support groups, work-based counseling, folk healing, religious or spiritual counseling, other forms of traditional or alternative healing). *Probe as needed (e.g., "What other sources of help have you used?").* *Clarify the individual's experience and regard for previous help.*	12. Often, people look for help from many different sources, including different kinds of doctors, helpers, or healers. In the past, what kinds of treatment, help, advice, or healing have you sought for your [PROBLEM]? *PROBE IF DOES NOT DESCRIBE USEFULNESS OF HELP RECEIVED:* What types of help or treatment were most useful? Not useful?

BARRIERS

(Coping and Help Seeking, Religion and Spirituality, Older Adults, Psychosocial Stressors, Immigrants and Refugees, Social Network, Clinician-Patient Relationship)

Clarify the role of social barriers to help seeking, access to care, and problems engaging in previous treatment. *Probe details as needed (e.g., "What got in the way?").*	13. Has anything prevented you from getting the help you need? *PROBE AS NEEDED:* For example, money, work or family commitments, stigma or discrimination, or lack of services that understand your language or background?

CULTURAL FACTORS AFFECTING CURRENT HELP SEEKING

PREFERENCES

(Social Network, Caregivers, Religion and Spirituality, Older Adults, Coping and Help Seeking)

Clarify individual's current	Now let's talk some more

perceived needs and expectations of help, broadly defined. *Probe if individual lists only one source of help (e.g., "What other kinds of help would be useful to you at this time?").*	about the help you need. 14. What kinds of help do you think would be most useful to you at this time for your [PROBLEM]?
Focus on the views of the social network regarding help seeking.	15. Are there other kinds of help that your family, friends, or other people have suggested would be helpful for you now?
CLINICIAN-PATIENT RELATIONSHIP	
(Clinician-Patient Relationship, Older Adults)	
Elicit possible concerns about the clinic or the clinician-patient relationship, including perceived racism, language barriers, or cultural differences that may undermine goodwill, communication, or care delivery. *Probe details as needed (e.g., "In what way?").* *Address possible barriers to care or concerns about the clinic and the clinician-patient relationship raised previously.*	Sometimes doctors and patients misunderstand each other because they come from different backgrounds or have different expectations. 16. Have you been concerned about this and is there anything that we can do to provide you with the care you need?

The Core CFI

Table 29.2–2 presents the core CFI interview. The interview has been designed like other semistructured interviews, such as the Structured

Clinical Interview for DSM Disorders (SCID), in which instructions to clinicians appear next to questions for patients. As emphasized in *DSM-5-TR*, the CFI follows a person-centered approach to cultural assessment by asking the patient about their views and those of close associates to avoid stereotyping by ethnoracial background or clinical expectations for a given illness. Clinicians are encouraged to voice the questions in their own style and ask probes as necessary to understand patient answers completely. The CFI is designed for use in the initial assessment of patients in all clinical settings, regardless of the cultural backgrounds of the patient or the clinician. Even patients and clinicians who seem to share the same cultural background may differ in ways that are critical to care, such as by educational level, socioeconomic status, or role expectations. The CFI may be used in its entirety or incorporated piecemeal; however, its developers recommend obtaining the person's narrative as an unbroken flow before proceeding to the rest of the clinical interview. The CFI may be especially helpful when there is difficulty in diagnostic assessment due to differences in the cultural, religious, or socioeconomic backgrounds of the clinician and the patient; when there is uncertainty about the fit between patient symptoms and diagnostic criteria; when it is difficult to judge illness severity or impairment; when patients hold views of symptoms or expectations of care that differ from clinicians' based on their experience with other cultural systems of healing and health care; when patients and clinicians disagree on the course of care; when there is mistrust of mainstream services and institutions by individuals with collective histories of trauma and oppression; or in cases of suboptimal treatment engagement and adherence. In response to criticisms about the absence of guidelines for the OCF, the DCCIS specifies instructions to clinicians to facilitate cultural assessments.

The core CFI is divided into four main domains. The first domain is the *Cultural Definition of the Problem* and consists of the first three questions. Question no. 1 is a broad, open-ended inquiry about the patient's presenting concerns. The prompt invites patients to describe their problems and emphasizes an understanding of the patient's illness, even if these descriptions are "similar to or different

from how doctors describe the problem." Question no. 2 clarifies the patient's description of the problem as would be discussed with close associates, in recognition that culture influences information sharing according to the audience and social context. At this point in the interview, patients may be reticent to describe the problem in nonbiomedical ways that the clinician could find unusual and may therefore censor such descriptions. By framing the question in relation to the person's social network, the goal is to facilitate the patient's report of descriptions that are salient in the social environment. Question no. 3 on what troubles the patient most about the problem asks about what is most at stake for the individual during the illness.

Questions no. 4 to 10 belong to the second domain of the core CFI, *Cultural Perceptions of Cause, Context, and Support*. Questions no. 4, 6, and 7 focus the interview on the patient's EMs for the causes, social stressors, and social supports of the illness. Question no. 4 includes the placeholder "[PROBLEM]" to solicit the patient's preferred terms and phrases for how a problem is framed, known as *idioms of distress*. Once obtained, the patient's vocabulary can be substituted for the placeholder throughout the interview to build rapport and bridge patient–clinician linguistic differences in understanding the illness. In some cases, the patient may use biomedical vocabulary such as "I might have depression," but in other cases, terms referencing social determinants of health may be evident, such as "I worry about my rent, electricity, and phone bill." Terms communicating the presenting problem may vary greatly, and the CFI can reveal how patients frame issues so that clinicians can tailor treatment strategies.

Question no. 5 asks the patient to consider what close associates may understand as the cause of illness in response to the *DSM-5-TR* understanding of culture as the meanings and viewpoints transmitted within social groups. In this instance, the meanings being transmitted are the understandings of illness, and the social group is the patient's close associates. As with question no. 2 on the definition of the problem, framing the inquiry through members of the social network

encourages a fuller range of responses that may influence the individual's EMs.

Questions no. 8, 9, and 10 also belong to this second domain but orient the interview toward the patient's cultural identity. Question no. 8 begins with a brief introduction that clinicians can use to clarify the meaning of *cultural background or identity* as relevant to health care. The introduction provides examples of identities that may be important for the patient, such as language, ethnicity, religion, and sexual orientation. These examples are meant to be representative in order to stimulate thought, not a fixed set of identities from which the patient must choose. Question no. 8 then asks the patient directly about the most important aspects of background or identity. This method of allowing the patient to name the preferred cultural identity departs from previous models of cultural competence that have made assumptions about patient identities based on a group affiliation such as ethnoracial background without accounting for their importance to the individual. For example, one patient in the *DSM-5* field trial initially named his identity as "Cuban" but then explained that identifying as a Christian was more helpful in understanding his suffering existentially. A model of cultural competence that assumed ethnicity was the most important group affiliation—without accounting for the patient's self-ascribed identity—could have overlooked the role of religion in providing meaning to the illness experience. Question no. 9 asks the patient how this identity may impact the current illness experience or patient-centered definition of the clinical problem. Question no. 10 asks the patient to consider how identity may cause other problems in life that may not be as obviously related to the illness but may be nonetheless important, such as problems with migration, gender roles, or intergenerational conflict.

Questions no. 11, 12, and 13 form the third domain known as *Cultural Factors Affecting Self-Coping and Past Help Seeking*. This domain encourages patients to share past forms of self-coping and help seeking in recognition that most forms of help are sought outside of the biomedical health care system. Question no. 11 addresses the patient's coping practices, and question no. 12 considers help seeking broadly to include help inside and outside of

the biomedical system (i.e., religion-based support and support groups). An additional prompt for question no. 12 clarifies the types of help that have been most and least helpful. This information may aid the clinician in developing a treatment plan for the current illness episode. Question no. 13 asks about past barriers to treatment to help devise the current treatment plan around available resources.

The final three questions constitute the last domain of the CFI, *Cultural Factors Affecting Current Help Seeking*. Question no. 14 asks the patient about current treatment preferences, and question no. 15 explores treatment preferences recommended by close associates. As with questions on patient terms and causes for the presenting problem, this question is examined at the individual and social levels to explore how patients fashion cultural meanings within social groups. Question no. 16 begins with an open-ended statement to help the patient anticipate how perceived differences with the clinician can adversely affect care. By asking the patient about this potential barrier, the clinician can work to resolve such differences. Even if the question is not answered during the initial visit, the clinician's openness may empower the patient to raise concerns in future visits. The core CFI adopts an ecologic approach to culture by asking the patient about the illness, moving outward to views of the social network and the role of social supports and stressors, and then finishing with the illness in relation to the health care system.

The Informant CFI

The informant CFI (I-CFI) guides clinicians in conducting a cultural assessment of the patient's clinical problem from the perspective of a key informant such as a spouse, relative, or friend who may be present during the clinical encounter. Patients are often accompanied by relatives or other potential informants during clinic visits, providing clinicians with the opportunity to include them during diagnosis and treatment planning. Social relationships can have profound effects—positive and negative—on pathways to and through mental health treatment, including decisions about when or whether to seek care, participation in clinic visits, and implementation of treatment plans in

the home, such as adherence to medication. The roles of close associates and their perspectives on illness and treatment are informed by cultural meanings and practices.

Clinical care often requires consultation with family members, other kin, or friends. Certain aspects of culture may be shared among patients and others within the social network, but there may be differences within families. For example, an older immigrant man who is depressed and most comfortable speaking his native language may be accompanied by an adult child who speaks English and has different cultural values. In such cases, the patient and the informant may have different EMs for the patient's depression or view of treatment. In such situations, the I-CFI can assist clinicians with eliciting the perspectives of key informants through the lens of culture, enabling a deeper understanding of the patient's illness and the interpersonal dimensions of care. This can create opportunities for clinical negotiation and the development of shared understandings of illness and goals for treatment.

The I-CFI can play an especially important role in several situations when an informant is available. In some instances, the informant may be the primary or sole source of information to assess the role of cultural factors in diagnosis and treatment. This may occur when a patient is unable to give a meaningful or coherent history because of conditions such as severe cognitive impairment (i.e., from Alzheimer disease or a head injury), catatonia, severe paranoia, agitation, or substance intoxication. Alternatively, the patient may be a young child, and a cultural assessment of the parent or other caregiver's perspective may be helpful. In other cases, the clinician may seek clarification from the informant when the patient's responses to the CFI are ambiguous or partial (as when asking the patient about how others in their cultural group would view the symptoms). The clinician may also administer the I-CFI if there is a family member or friend who is influential in the patient's clinical care and decision making. Finally, the I-CFI may be useful when treatment hits an impasse, and an assessment of the social context may identify underlying causes.
