Other interventions embed ABA principles within naturalistic developmental behavioral approaches. These emphasize the importance of responding to the child's cues, building learning episodes on the child's initiative and choices, establishing emotional attunement and positive relationship between child and adult, and creating learning environments that resemble the "real world" where targeted skills would naturally be utilized. In addition, several intervention practices focus on the importance of environmental accommodations to create "autism-friendly" learning experiences, particularly in educational settings and workplaces. These include arranging spaces and using visual supports that capitalize on the visual processing strengths of those with ASD to facilitate understanding of expectations and communication (e.g., using pictures that illustrate what is expected in a specific space, or how to accomplish a specific task). Relatedly, many intervention programs include the use of visual and/or augmentative approaches to facilitate and teach communication. These include the use of visual cues (e.g., giving a partner a picture of an item in exchange for the actual item) or electronically generated sounds (e.g., pushing a button in a device that "speaks electronically" to request an item) that are designed to address difficulties in understanding language or using speech.

Although these intervention approaches are sometimes depicted as mutually exclusive, they are better characterized as falling along a multidimensional continuum from more structured to more naturalistic, from more adult directed to more child directed, from more focused on changing behavior to more focused on accommodating differences, and from more comprehensive to more targeted on specific skills. A growing body of literature has examined outcomes for different intervention packages along this continuum, identifying several elements that are in common across approaches shown to be effective. These include (1) timeliness (the earlier, the better), (2) intensity, (3) use of manualized and clearly operationalized instructional strategies, (4) focus on the core features of ASD, including sensory issues, as well as functional/adaptive skills, (5) assessment procedures to generate and update individualized

sets of goals, (6) collection systems to monitor progress and implementation fidelity, (7) involvement of caregivers in establishing treatment goals and delivering intervention, (8) developmental appropriateness and developmental sequencing of goals (i.e., teaching age-appropriate skills and their developmental prerequisites), (9) promoting the individual's active engagement and communicative intent, (10) incorporating intervention strategies and opportunities in everyday routines, (11) thoughtful environmental arrangements (including minimizing distractions/maximizing focus toward salient stimuli), (12) creating predictable and consistent routines and experiences, with a balance between structure and novelty to support flexibility, (13) incorporating the individual's special interests when possible, and provision of reinforcements that are meaningful to the individual, (14) use of task analysis to break down complex functional skills into teachable steps, (15) use of scripts, visual supports, and practice opportunities to remind the individual about the steps involved in the targeted skill (e.g., rehearsing the steps involved in buying groceries through visual scripts and supported role-playing), (16) focus on generalization skills (e.g., using the skills acquired in a therapy sessions at home and school), (17) addressing challenging behaviors through the systematic analysis of their function, and teaching more desirable behavioral alternatives, (18) using prompts to facilitate the individual's response to the instruction, while also fading supports over time to promote autonomy.

Although research has documented the beneficial effects of these practices, there are important gaps that require additional research effort. First, despite the increased number of studies evaluating interventions for younger children, there is limited knowledge on interventions for older individuals, especially those on the most severe end of the spectrum. In addition, most existing literature has tested the efficacy of interventions in the highly resourced context of clinical trials, with more limited knowledge on intervention outcomes when these are transported into community clinical and educational programs.

In addition, although contemporary approaches have shifted away from the use of psychodynamic psychotherapy to address autistic symptoms, cognitive behavioral therapy (CBT) has been shown to effectively address co-occurring anxiety and depression symptoms that

are common in children and adults with ASD. Several modifications have shown to facilitate the success of CBT for those with ASD, including using visual and multimodal teaching strategies, a focus on explicit problem-solving behaviors, and incorporating special interests into sessions. There may be an increased risk for suicidal ideation and suicide, and clinicians should be alert to this issue.

Psychopharmacology

The core social difficulty of ASD has, so far, proven resistant to treatment, although work is ongoing with agents such as oxytocin (a hormone involved in attachment). Medication can be of significant benefit for other features such as irritability, overactivity, aggression, and self-injury. Since children and adolescents are often enrolled in special educational programs, there may be opportunities to facilitate independent data collection of value in assessment of drug treatments. Potential benefits and side effects should be considered (e.g., with antipsychotic medications), and baseline laboratory studies (e.g., liver, kidney function, ECG, weight, and so forth) should be obtained. Depending on the agent used, it may be important to closely monitor for side effects, for example, tardive dyskinesia.

Antipsychotics. These agents have been extensively studied and, with relatively low doses, they may produce decreased irritability and agitation. This in turn may foster greater engagement in a treatment program. It is important to monitor for side effects. More recently atypical neuroleptics have been utilized. In one large double-blind, placebo-controlled study, risperidone was shown to quickly have a significant benefit in reducing agitation and other problematic behaviors. This and other atypical neuroleptics have now been approved for use in autism.

Selective Serotonin Reuptake Inhibitors. Interest in this group of agents arose given the awareness of higher peripheral serotonin levels in autism as well as in the increased risk for anxiety and depression. Several studies using placebo control methods have shown benefits for repetitive behaviors and impulsive aggression. Some children may have a paradoxical agitation.

Stimulants. Many school-aged children exhibit significant problems with attention and overactivity that may be responsive to the traditional stimulants and related medications. However, associated side effects, for example, agitation, may be higher than in the general pediatric population.

Other Agents. A number of other agents have been used in ASD. Often data is limited to case reports or open-label studies, and controlled studies are not available. Lithium has occasionally been used, particularly with family history of bipolar illness and clinical presentation suggesting possible bipolar disorder.

Complementary and Alternative Treatments

These are frequently used by parents although, by definition, they lack a strong evidence base. This evidence is based on anecdote and sometimes a case series. One claim was that the gut peptide secretin was suggested to produce marked improvement, but a number of double-blind, controlled studies, did not show benefit over placebo. Parents should be encouraged to pursue proven treatments and avoid those with some risk to the child, either directly due to side effects or more commonly due to lack of participation in effective treatment programs provided in schools. Some resources for parents on these treatments are available (see Volkmar and Wiensser, 2021).

Attention-Deficit Disorders

44.1 Attention-Deficit/Hyperactivity Disorder

Lily T. Hechtman, M.D., F.R.C.P., A.B.P.N., Margaret D. Weiss, M.D., Ph.D., and Philippe Hwang, M.B., B.Ch., B.A.O., M.Sc.

Attention-deficit hyperactivity disorder (ADHD) is the most common childhood behavioral disorder diagnosed in outpatient settings in the United States. It is a chronic disorder that can cause impairment into adolescence and adulthood. In 2007, Polanczyk and colleagues estimated worldwide prevalence of ADHD in children and adolescents to be 5.29% using a comprehensive meta-analysis including hundreds of articles and more than 100,000 patients. Similarly, a meta-analysis from 2012 by Willicut using full DSM-IV diagnostic criteria found the prevalence of ADHD to be 5.9% to 7.1%. The National Survey of Children's Health (NSCH) showed that 9.4% of U.S. school-aged children had been diagnosed with ADHD by 2016. It has been suggested that the increasing rates of diagnosis and treatment may be due to increased awareness and access to care as opposed to an increase in the number of children in the population meeting criteria for ADHD.

HISTORY

ADHD first was described by George Still in 1902, who wrote about children who were restless, impulsive, and inattentive, with intense affective responses and conduct problems. After the influenza pandemic and the epidemic of encephalitis lethargica from 1919 to 1920, children who survived the flu frequently developed severe behavior problems and are now thought to have suffered organic brain damage. For that reason, the childhood condition was termed “minimal brain damage syndrome,” even though brain damage could not be proven. In the early 1960s, the condition was renamed “minimal brain dysfunction.” Not only did these terms postulate unproven etiologic mechanisms, but they were also stigmatizing. The ninth revision of the *International Classification of Diseases and Related Health Problems* (ICD-9) and the second edition of the DSM adopted the same descriptive term for the condition—hyperkinetic syndrome of childhood. The 1980 version of the American Psychiatric Association (APA) classificatory system, DSM-III, renamed this diagnosis attention-deficit disorder (ADD) due to research suggesting that the main disability was the difficulty of maintaining sustained attention and problems with impulsivity. Much of the diagnostic criteria for ADHD have remained the same between DSM-IV in 1994, the text revision (DSM-IV-TR) in 2000, and the most recent version (DSM-5) released in May 2013.

DIAGNOSIS AND DEFINITION

The fifth edition of the APA’s *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), published in May 2013, describes ADHD under neurodevelopmental disorders as a pattern of inattentive and/or hyperactive–impulsive behavior inconsistent with developmental level which interferes with functioning in social, educational, or work settings. Symptoms are divided into two categories: inattention and hyperactivity/impulsivity. There are five main diagnostic criteria: (1) onset before age 12 years old; (2) duration greater than 6 months; (3) children must have at least six

symptoms from the inattention and/or hyperactive/impulsive symptom list, while older adolescents and adults must have at least five; (4) several symptoms must be present in two or more settings and interfere with functioning; and (5) symptoms that do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better accounted for by another mental disorder, such as depression. DSM-5 has no exclusion criteria for those with autism spectrum disorder (ASD), allowing both autism and ADHD to be diagnosed simultaneously in the same patient. Possible specifiers for the disorder in DSM-5 include combined presentation (criterion met for both inattention and hyperactivity–impulsivity), predominantly inattentive presentation, or predominantly hyperactive/impulsive presentation. Other specifiers describe current severity of the disorder being mild (few to no symptoms in excess of those required), moderate or severe (many symptoms in excess of those required), or to specify if the disorder is in partial remission (fewer than full criteria met in past 6 months, but still results in impairment).

The inattention symptom criteria list includes the following: (a) often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities; (b) often has difficulty sustaining attention in tasks or play activities; (c) often does not seem to listen when spoken to directly; (d) often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace; (e) often has difficulty organizing tasks and activities; (f) often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort; (g) often loses things necessary for tasks or activities; (h) often easily distracted by extraneous stimuli (or unrelated thoughts for adolescents and adults); and (i) often forgetful in daily activities.

Hyperactivity and impulsivity symptoms criteria include the following: (a) often fidgets with or taps hands or feet or squirms in seat; (b) often leaves seat in situations when remaining seated is expected; (c) often runs about or climbs in situations where it is inappropriate (for older adolescents and adults, feeling restless without the overactivity can apply); (d) often unable to play or engage in leisure activities quietly; (e) often “on the go,” acting as if “driven by

a motor"; (f) often talks excessively; (g) often blurts out an answer before a question has been completed; (h) often has difficulty waiting their turn; and (i) often interrupts or intrudes on others.

In the DSM-5, enhanced item descriptors were added to diagnostic criteria to demonstrate symptoms across the lifespan. For example, motor hyperactivity appears far less frequently in affected adolescents and adults, who continue to have attentional and organizational problems, poor anger management, job instability, and problems with social relationships and self-esteem. All 18 of the DSM-IV-TR symptoms of ADHD were retained in the DSM-5, but enhanced elaborators of each were added to better describe difficulties experienced by adolescents and adults. For instance, the inattention criteria "often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort" now includes specific examples of this symptom "(preparing reports, completing forms, reviewing lengthy papers)" to be applied to older adolescents and adults in addition to "(schoolwork or homework)," which is primarily specific to children.

COMPARATIVE NOSOLOGY

Previously, ICD-10 criteria differed from DSM-5 criteria significantly, with fewer children diagnosed with ADHD under ICD classification (called "hyperkinetic disorder" [HD]). In ICD-10, if a diagnosis of generalized anxiety or major depression was present, these disorders would be considered primary and HD would be excluded. For example, investigators in the United Kingdom applied an algorithm to the 579 children with DSM-IV ADHD combined subtype who had been recruited into the National Institute of Mental Health (NIMH) Multimodal Treatment Study of Attention Deficit Hyperactivity Disorder (MTA trial) in order to generate an ICD-10 diagnosis of HD. Only 25% of the MTA sample continued to meet the diagnostic criteria for HD in ICD-10.

However, the ICD-11 classification of ADHD is closer to that found in the DSM-5, removing this exclusion criterion. Therefore, the rate of diagnosis may increase following the adoption of the ICD-11 despite

the incidence remaining unchanged. Both diagnoses are now based on similar structures with presentations that are predominantly inattentive, hyperactive, or combined, and that have been present for over 6 months. The DSM-5 focuses on meeting criteria out of lists of symptoms, whereas the ICD-11 uses more generalized symptoms for each presentation, but both specify that these symptoms must be evident in multiple settings. The ICD-11 specifically describes essential characteristics of the disorder without providing a precise age of onset, duration, or number of symptoms necessary for the diagnosis.

ETIOLOGY

ADHD is a complex disorder of multifactorial etiology, thought to have multiple genetic and environmental variables of small effect acting together to produce vulnerability to ADHD. Although the etiology of ADHD yet has to be determined, there is a growing consensus that the condition involves functional and anatomical dysfunction in the brain's cortico-basal ganglia-thalamo-cortical circuitry. These areas support the regulation of attentional resources, the programming of complex motor behaviors, and the learning of responses to reinforcement. Theories involving these areas have been examined in studies involving neurobiologic studies of healthy humans, humans with ADHD, and animal models.

Genetics

Twin, sibling, adoption, and family studies, all suggest a strong genetic component in the development of hyperactivity, inattention, and impulsivity, with the heritability index estimated to range from 0.6 to 0.98. Heritability estimates include both genetic influences, as well as the effects of gene–environment interaction. ADHD-like behaviors have also been reported in rare genetic disorders such as fragile X syndrome, neurofibromatosis type 1, DiGeorge syndrome, tuberous sclerosis, Turner syndrome, Williams syndrome, Angelman syndrome, and Prader–Willi syndrome.

Twin Studies. Twin studies suggest that 76% of the variance in the transmission of ADHD is attributable to genetics, making ADHD one of the most heritable psychiatric disorders. Monozygotic twins have been found to be more concordant for ADHD symptoms of hyperactivity, inattention, and impulsivity than are same-sex dizygotic twins. The concordance rate among monozygotic twins ranges from 59% to 92%, whereas the concordance rate in dizygotic twins ranges from 29% to 42%.

Sibling and Half-Sibling Studies. Pettersson and colleagues reported on family data of 4,408,646 full and maternal half-siblings and genetic data of 125,533 cases and 208,215 controls in the Swedish sibling study. The strength of this study was the large sample size, and that psychiatric status was based on clinical diagnosis using standard diagnostic criteria. There was, however, the assumption that siblings and maternal half-siblings lived in the same household and thus shared the same environment. ADHD was one of the eight psychiatric disorders studied and was found to have a heritability estimate of 80%. An earlier sibling study found that 10 of 19 full-sibling pairs were concordant for ADHD, versus 2 of 22 half-sibling pairs; a significant difference supporting the genetic transmission of ADHD in families.

Adoption Studies. Studies have found that the biologic relatives of children with ADHD are more likely to have ADHD themselves. This relationship is not seen in adoptive relatives of children with ADHD. Adoptive relatives of children with ADHD have a risk of ADHD similar to relatives of control children, while the biologic relatives of children with ADHD are more likely to have ADHD or associated disorders. In a study of international adoptees aged 10 to 15 years, Van den Oord and colleagues estimated that genes accounted for 47% of the variance of inattention scores on the Child Behavior Checklist. Eighteen percent of biologic relatives of adopted-away children with ADHD were found to be at risk for the disorder versus 6% of the child's adopted relatives.

Family Studies. Family studies have shown that first-degree relatives of children with ADHD are two to eight times more likely to have the disorder. First-degree relatives of children with ADHD have a 20% to 25% risk for ADHD, compared with 4% to 5% for relatives of controls. If a parent has ADHD, 50% of their offspring are likely to have that condition. The increased incidence of ADHD is also extended to second-degree relatives.

Mode of Inheritance. Several hypotheses of ADHD's mode of transmission have been advanced. Omenn explored the possibility of sex-linked transmission because of the male preponderance in the condition. Other theories include a polygenetic inheritance model, including those of Morrison and Stewart, but limitations in sample size made this hard to prove. Rhee and colleagues postulated a polygenetic multiple threshold model after analyzing sex differences in an Australian twin and sibling-pair study. However, differences in fit between genetic models were modest, as is true for comparisons of multifactorial and single-gene inheritance. This led to the suggestion that symptoms of ADHD may be caused by several interacting genes of modest effect. This hypothesis is consistent with ADHD's high population prevalence and high concordance in monozygotic twins, but modest recurrence risk for first-degree relatives. However, diagnostic uncertainty impedes progress in developing genetic models of inheritance.

Molecular Genetic Studies. There has been increasing interest in attempting to identify the specific "risk" genes that may be implicated in the development of ADHD. This search has yielded generally inconsistent results due to complexity of the trait and heterogeneity across studies. Candidate genes have been chosen for study based on theoretical considerations related to their function, and the majority of studies have concentrated on dopamine-related genes given the implication of dopamine dysfunction in ADHD. Candidate genes discovered so far are responsible for less than 5% of genetic variation in ADHD.

The dopamine transporter gene (DAT1) codes for a sodium-dependent dopamine transporter protein that regulates reuptake of dopamine from the synaptic cleft. Cook et al. were the first to show an association between ADHD and DAT1 with 480–base-pair allele. Several studies have indicated that DAT1 might be more strongly associated with the hyperactive/impulsive or combined subtypes of ADHD. Another early gene studied was the dopamine type D2 receptor gene (DRD2). The gene is not specific to ADHD and is not believed to be a primary cause of the disorder. The dopamine-4 receptor seven-repeat allele gene (DRD4) has been linked to novelty seeking and connected to the impulsivity seen in ADHD. DRD4 has also been related to the inattentive subtype of ADHD. The synaptosomal-associated protein 25 gene (SNAP25) codes for a protein involved in neurotransmitter regulation and axonal growth. Researchers have found an association between SNAP25 and sensitivity to methylphenidate (MPH) adverse events in preschoolers with ADHD. Genes that code for dopamine β-hydroxylase (DBH), catechol-O-methyltransferase (COMT), dopamine 5 receptor gene, norepinephrine transporter gene (SLC6A2), serotonin transporter gene (SLC6A4), α-2A adrenergic receptor (ADRA2A), thyroid receptor B gene, androgen receptors, and factors in immune function and regulation have also been reported to correlate with ADHD symptoms. Subsequent studies and meta-analyses have not sufficiently supported the association between ADHD and these genes.

GENOME-WIDE SIGNIFICANT COMMON VARIANTS. Genome-wide association studies (GWAS) scan the entire genome to detect common DNA variants having small etiologic effects. GWAS assay hundreds of thousands or even millions of single nucleotide polymorphisms (SNP). Thus, genome-wide statistical significance must have extremely high “p” values and very large samples. Such a large sample was formed by the consortium of ADHD researchers who carried out a GWAS meta-analysis of 12 studies involving 20,183 people with ADHD and 35,191 children and found 12 independent loci (Demontis et al., 2019) which reached significance. Loci identified

include loci pertaining to dopamine regulation, educational attainment, and speech and language disorders. The GWAS analyses also showed that much of ADHD's heredity is due to the polygenic effects of many common variants each having a very small effect.

GENOME-WIDE ASSOCIATION STUDIES AND COPY NUMBER VARIANTS. Copy number variants (CNV) of the genome often delete or duplicate a large genome segment spanning part or even the entire gene. They clearly affect gene functioning. Such deletions and duplications are overrepresented in ADHD samples and significant effects have been found for small CNV. It has been shown that CNV affect the metabolism of glutamate receptor genes which may be associated with cognitive and clinical impairments of ADHD. Magnetic resonance spectroscopy showed dysregulation of glutamate–glutamine concentration in ADHD patients. The area of genetics in ADHD is evolving and the picture is far from complete. However, the strong heritability of this condition is clear.

Neuroanatomical Aspects

Investigators have postulated the presence of an anterior attention network for promoting multiple aspects of attention, including focusing, executing, sustaining, and shifting functions. The attention networks are widespread through the cortex of the brain and are closely related to the default mode network described by Castellanos and others. MRI studies suggest that there are structural abnormalities in the brains of children with ADHD, including differences in the frontostriatal areas, temporoparietal lobes, cerebellum, basal ganglia, corpus callosum, amygdala, hippocampus, and thalamus. A meta-analysis of voxel-based morphometric (VBM) studies by Nakao and colleagues of children and adults with ADHD found global reductions in gray matter volumes, especially the right lentiform nucleus extending to the caudate nucleus, with slightly larger gray matter volumes in the left posterior cingulate cortex. These areas were demonstrated to normalize with age as well as with stimulant medication treatment. Developmentally, children with ADHD

have a 3- to 5-year delay in cortical thickness maturation, particularly in the frontal and temporal brain regions. Diffusion tensor imaging (DTI) studies show white matter tract abnormalities and dysfunctional connectivity in ADHD during rest and while engaging in cognitive tasks.

Recent studies with larger samples by Hoogman et al. found lower surface area values in the frontal, cingulate, and temporal regions, with the largest effect being in total surface area and decreased cortical thickness in the fusiform gyrus and temporal lobes in children with ADHD. Neither surface area nor thickness differences were found in groups of adolescents and adults with ADHD, again suggesting some normalization occurring with age.

In a study using machine learning analysis of MRI data, significant differences were found in children and adults with ADHD compared to controls. However, prediction performance and effect sizes were better for the child versus the adult samples, suggesting greater differences in children versus adults with ADHD.

Deficits in neural activity within frontostriatal and frontoparietal circuits are consistent findings in ADHD. Functional MRI studies using cognitive tasks to target the neural circuits show significantly reduced frontal lobe activity in subjects with ADHD compared to controls. Meta-analysis shows hypoactivation in the frontoparietal and ventral attention networks in children with ADHD, areas that control goal-directed executive processes and decision making. Hart and colleagues found that right dorsolateral prefrontal cortex activation was reduced in medication-naive patients, but normal in long-term stimulant-medicated patients. Electroencephalography (EEG) studies have reported an elevated theta/beta ratio (TBR) in subjects with ADHD versus controls; however, increased theta band activity has also been associated with substance use and bipolar disorder. Recent meta-analysis determined that excess theta and elevated TBR was not a reliable diagnostic measure for ADHD but could have prognostic value for treatment outcome.

Neurotransmitters in ADHD

The nonspecific catecholamine hypothesis of ADHD posits that the psychophysiology of ADHD symptomatology emerges from an imbalance among various neurotransmitters, including norepinephrine, epinephrine, and dopamine. Human studies investigating the catecholamine hypothesis of ADHD produced conflicting results, possibly due to the difficulty of measuring brain levels of these neurotransmitters in peripherally obtained samples.

Dysfunction in brain norepinephrine systems, particularly a lack of inhibition of locus coeruleus neurons, could explain the inattention, cognitive deficits, and higher levels of gross motor activity seen in children with ADHD. Randomized clinical trials (RCTs) have suggested that the norepinephrine reuptake inhibitors (NRIs), tricyclic antidepressants (TCAs), and atomoxetine (ATX) are effective in reducing ADHD symptoms by restoring a more normal ratio of epinephrine and norepinephrine. Molecular genetic studies have targeted genes that code for dopamine receptors, and positron emission tomography (PET) scans in adults with ADHD have provided imaging data that correlate stimulant-driven increases in dopamine concentration. There is weak evidence for serotonin's role in ADHD. Medications that exclusively affect serotonin function, such as the selective serotonin reuptake inhibitors (SSRIs), have no efficacy in the treatment of children with ADHD. For that reason, serotonin is thought to play a secondary role in the pathology of ADHD.

Recently, the glutamate neurotransmitter system has also been implicated in ADHD. It has been reported that CNV in glutamatergic genes were associated with cognitive and clinical impairments of ADHD. In addition, a pharmacogenomic GWAS study found SNP in glutamate receptor genes (e.g., GRM7) was one of the most significant findings. Thus, the glutamate neurotransmitter system may also have a role in ADHD, and this impact needs to be elucidated.

Environmental Factors

ADHD has been associated with numerous environmental factors, although it is difficult to conclusively determine causality. In utero risk factors that have been associated include prenatal exposure to

alcohol, nicotine, recreational drugs, glucocorticoids, poor maternal diet, and maternal stress during pregnancy. Perinatal ADHD risks include prematurity, low birth weight, and obstetric complications. ADHD has been associated with childhood illnesses such as meningitis, encephalitis, cardiac disease, thyroid disease, epilepsy, head trauma and concussions, autoimmune and metabolic disorders, and in survivors of pediatric brain tumors. Psychosocial adversity including poverty, childhood maltreatment, negative parenting, family discord, and bullying have all been associated with ADHD. It has been difficult for investigators working with children affected by adversity to determine whether their ADHD symptoms reflect a response to negative parenting, a harsh environment, a genetically influenced biologic problem, or some interaction among these factors.

Dietary Influences. Dietary factors as a cause and possible treatment of ADHD are controversial. There have been reports of a connection between ADHD and nutritional deficiencies of essential fatty acids (omega-3 and omega-6) as well as mineral deficiencies (e.g., zinc, copper, and iron), but the beneficial effects of supplementation are inconclusive. Some studies have indicated that a small subset of children may have sensitivity to certain food additives, excess refined sugar intake, or nutritional deficiencies (such as fatty acids or iron), causing behavioral effects. There has been some previous support for elimination diets to treat ADHD, such as the Feingold (additive and salicylate-free) diet, oligoantigenic (hypoallergenic) diet, and ketogenic diet. However, in 2011, the U.S. Food and Drug Administration (FDA) determined that existing data do not support a causal link between additives and behavioral disturbance in children.

DIAGNOSIS AND CLINICAL FEATURES

The diagnosis of ADHD requires the integration of data from multiple sources, including clinical interview, direct observation, behavioral rating scales, and the subjective observations of parents and teachers. Most children with ADHD are referred for care because of

impairment in academic, family, and/or peer relationship functioning. Symptoms of impulsivity, overactivity, and inattention drive this impairment across the lifespan.

Clinical Features

DSM-5 Diagnostic Criteria. DSM-5 criteria were outlined previously in this chapter. We will here elaborate on key symptoms and their presentation.

Hyperactivity. Hyperactivity describes the inappropriate excessive motor activity observed in ADHD, including restlessness, fidgeting, and appearing to be “driven by a motor.” These behaviors are often first noticed when the child is a toddler but can be normative before age 4. The level of gross motor activity usually decreases with age, however, the inner sense of restlessness may continue into young adult life. Children with ADHD display sustained levels of high activity in different settings such as home, school, and playgroup. Activity increases occur during sleep as well. Hyperactivity may be absent in novel situations or when the child is engaged in an activity they find particularly engrossing, such as playing video games.

Impulsivity. Impulsive actions occur without forethought about consequences and may be associated with a desire for immediate rewards or to avoid delay. Impulsivity might be seen when the child engages in dangerous activities, yells out in class, or interrupts or intrudes on others during games or conversations. Impulsive behavior might also result in trouble with parents, teachers, or other children, including verbal or physical fights. Children with ADHD can demonstrate overly quick and error-prone performance on standardized tasks. Symptoms of impulsivity can persist into adulthood, even after hyperactive symptoms have diminished.

Attentional Difficulties. Inattention includes difficulty sustaining focus, trouble maintaining organization, and being easily distracted by extraneous stimuli. The symptoms of inattention often become prominent in elementary school, when the child is approximately 8 to

9 years old, and symptoms can be lifelong. Attentional difficulties are most often seen in routine settings in which the youth with ADHD must sit and carry out tasks that involve repetition under conditions of low levels of reinforcement and external motivation. Sluggish cognitive tempo (SCT) is a type of attentional difficulty that has been closely associated with the inattentive subtype of ADHD. SCT describes a constellation of symptoms such as daydreaming, staring, tendency toward confusion, mental fogginess, sleepiness, apathy, and physical hypoactivity. There is growing evidence suggesting that SCT is a condition distinct from ADHD; however, SCT is currently not considered a separate disorder or diagnostic subtype.

Associated Factors. Children with ADHD might have areas of impairment that are not listed under the DSM-5 symptom criteria covered exactly by the 18 symptom exemplars of hyperactivity, impulsivity, or inattention. Children and adolescents with ADHD often show difficulty with time management and do not develop an internal sense of pace in planning tasks. This poor sense of time leads to problems in estimating the actual difficulty of waiting in line, planning how much time a task requires, or even knowing when to come home when out playing with other children. Children with ADHD often lack persistence and can become bored playing interactive games with peers. They also find it difficult to delay gratification.

Neuropsychological testing and normalized rating scales such as the Behavior Rating Inventory of Executive Function (BRIEF) have found that individuals with ADHD demonstrate impaired executive functioning, including abnormal response inhibition. On any given measure of executive function, less than half of children with ADHD have been found to be impaired. Executive functioning problems also occur in other psychiatric disorders of childhood, such as depression, and are not specific to ADHD. It has been shown that academic functioning is more strongly affected by an impulsive need to get through tests quickly, a deficit closely linked to poor behavioral inhibition, rather than poor executive functioning.

ADHD is often associated with problems in emotion regulation, resulting in temper outbursts, mood lability, and reactivity. Moods can

change dramatically with no obvious connection with what is going on in the environment. Social skills are often significantly impaired in children with ADHD compared to controls. Individuals with ADHD may have problems accurately interpreting nonverbal social cues and have trouble cooperating with other children and following rules in games. Peers identify these individuals as intrusive, bossy, and insensitive to the needs of others. Children with ADHD often overreact and respond to frustration in social situations which can lead to verbal or physical aggression. This is a strong stimulus for peer rejection, which has been shown to be a reliable long-term negative predictor of development, particularly in adolescence.

MEDICAL AND LABORATORY EXAMINATION

Children with ADHD should be given a medical evaluation, including a thorough history and physical examination, to rule out physical disorders that can mimic the symptoms of ADHD. The medical history should cover the prenatal, perinatal, toddler, and preschool phases of development. Inquiries should be made about pregnancy complications, such as maternal illness (eclampsia, diabetes), maternal smoking, alcohol, or illicit drug use. The perinatal period should identify the presence of labor problems, delivery complications, prematurity, jaundice, and low birth weight. Feeding and sleeping routines during the perinatal and postnatal periods need to be described. Developmental milestones, illnesses, injuries, and symptomatology need to be reviewed. A detailed family, medical, and psychiatric history should be completed.

The medical history should include specific questioning about any past heart disease, syncope, dizziness, chest pain, shortness of breath, or palpitations at rest or exertion in the child. In addition, it is recommended to screen for family cardiovascular history including sudden death, early-onset cardiac disease, arrhythmias, or prolonged QT syndrome. It is also helpful to document a premedication baseline for common side effects such as stomachache, headache, insomnia, or rapid heartbeat.

The medical examination can identify physical problems that can increase the risk of serious adverse events should a stimulant medication treatment be initiated, including tachycardia, arrhythmia, or abnormalities in blood pressure. Height and weight at baseline should be recorded. Physical examination of a child with ADHD may reveal nonlocalizing neurologic signs, such as poor coordination, dysrhythmias, and overflow movements. Medical problems that might aid in the differential diagnosis, such as petit mal epilepsy, hearing and vision difficulty, thyroid dysfunction, and hypoglycemia, all need to be ruled out. No blood, genetic, or neuroimaging tests are available to diagnose ADHD.

RATING SCALES

Many standardized behavioral rating scales for ADHD have been developed. Rating scales should not be used independently to diagnose ADHD but can be particularly helpful in establishing the presence of core ADHD symptoms in more than one setting. ADHD-specific scales have been found to have greater than 90% sensitivity and specificity if used in the correct population. Clinical advantages of rating scales include the ability to obtain collateral information from different settings and to identify children who require further treatment because, although they are improved, they are not in remission. There are several commonly used rating scales in the public domain to assess for ADHD symptoms. The National Institute of Children's Health Quality (NICHQ) Vanderbilt Assessment scales for parents and teachers are now in their third edition and widely available on the internet (nichq.org), including a scale specific to the preschool population. The Vanderbilt scales also screen for oppositional disorder and conduct disorder (CD), depression, anxiety, school performance, learning, family, and peer relationships, and participation in activities. The Swanson, Nolan, and Pelham (SNAP) scale includes a 26-item form to look at ADHD and oppositional disorder and a 90-item version that includes a broad screen for other disorders and problems and which has been subject to psychometric validation. More recently, The Strengths and Weakness of ADHD-

Symptoms and Normal Behavior (SWAN) scale was developed to evaluate attention and behavior dimensionally, from below average to far above average. Proprietary scales such as the ADHD RS and Conners must be purchased but have the advantage of being consistent with DSM-5 and including psychometrically validated age and gender scoring paradigms. The Conners scales, now in their fourth edition, include forms specific to preschool, adolescent self-report, and comprehensive screening for a wide range of problems. The Weiss Functional Impairment Rating Scale has a parent and self-report version that evaluates the specific symptom-driven impairments a patient may experience. This is helpful in identifying those areas of functional impairment that may not respond to medication treatment alone and require other targeted interventions.

DIFFERENTIAL DIAGNOSIS

A clinician must make a differential diagnosis when judging whether a patient meets criteria for ADHD. The distinction between differential diagnosis and comorbidity is not well defined in the DSM-5. If the impairing condition is best accounted for by another disorder, that other disorder rules out ADHD. Conditions whose symptoms mimic those of ADHD should be considered and ruled out when possible, with attention to the possibility of either medical or psychiatric comorbid diagnoses.

For example, symptoms of inattention may be present in medical conditions such as hypoglycemia, petit mal epilepsy, substance abuse, sleep apnea, and hypothyroid or hyperthyroid conditions. Disrupted or poor sleep quality may present with tiredness, as well as difficulties with inattention, learning, and impulse regulation. Children undergoing ADHD evaluation should also be screened for clinical signs and symptoms suggestive of sleep apnea mimicking ADHD.

Symptoms of ADHD may also be present in psychiatric illnesses such as anxiety, depression, oppositional defiant disorder (ODD), and early psychosis in adolescents. The symptoms of children with oppositional defiant behavior must be distinguished from the reluctance and resistance that children with ADHD exhibit when they

avoid effortful mental tasks. For children with intellectual disability, inattention may be a natural accompaniment of the intellectual limitations, so the diagnosis of ADHD should only be applied if that symptom is excessive for the mental age of the child and the impact of intellectual challenges has been ruled out.

Furthermore, children who experience traumatic events (e.g., serious injury, physical/sexual abuse, neglect, violent acts, unexpected death of a loved one, life-threatening disasters, or parental divorce) can develop a stress response that mimics ADHD symptoms, including disorganization, difficulty concentrating, distractibility, and difficulty sleeping.

Symptoms of impulsivity, gross motor hyperactivity, or inattention may also appear during the use of medications, such as the akathisia that accompanies second-generation antipsychotics or from bronchodilators. Such children should not receive a diagnosis of ADHD, but one of other substance-related disorder.

COURSE AND PROGNOSIS

Parents often notice very high levels of gross motor activity when the child with ADHD is a toddler, just when the child has learned to walk independent of the parents' help. However, the energy, oppositionality, and curiosity of toddlers can be confused with the excessive, almost random motion of older children with ADHD, so that one must be cautious when applying the ADHD diagnosis to a preschooler. Usually, the ADHD diagnosis is first applied in primary school, during grades one to six, when adjustment to the sedentary learning style is compromised. School-aged children with ADHD may experience academic failure and peer rejection. Behavior problems at school and at home are not infrequent, with ODD being a common comorbidity.

During childhood, 65% to 75% of children with ADHD have one or more comorbid conditions, which in addition to ODD, can include conduct disorder (CD), anxiety and mood disorders, tics or Tourette syndrome, learning disorders, and autistic spectrum disorders. Many of these comorbidities continue into adolescence.

In adolescents, the external overactivity lessens but the internal restlessness does not. The adolescent with ADHD continues to have academic and social problems which erode self-esteem and at times promote the gravitation to a negative peer group. Thus, adolescents with ADHD who are untreated, compared to peers with no mental disorder, have a threefold increase in substance use and abuse, more frequent delinquent acts and trouble with the law, and increased rates of car accidents when they begin to drive. Adolescents with ADHD also start sexual intercourse earlier, with a higher number of sexual partners and greater frequency of unprotected sex and corresponding higher rates of sexually transmitted infections and unwanted pregnancy. The rate of depression and anxiety also increases in adolescence because of the many functional problems due to increasing demands and decreasing supports.

Approximately 60% of children with ADHD continue to be impaired well into adult life, with prevalence estimates suggesting that 4% of adults may suffer from ADHD. In adulthood, hyperactivity may be expressed by inner feelings of restlessness, inability to relax and excess talkativeness, fidgeting, and inability to remain seated for long periods of time, for example, in meetings, symposia, or in church. Impulsivity may be expressed in impatience, interrupting others, acting without thinking, and ending or starting ventures on impulse, for example, jobs, relationships, and at times sensation-seeking behavior. Inattention is seen in distractibility, disorganization, chronic lateness, or missing appointments. The distraction and disorganization often result in careless mistakes and forgetfulness. Procrastination is another important problem. Even when things are started, they are often not finished and so deadlines are thus missed.

The inattention and distractibility also make it appear that the adult with ADHD is not interested and not listening to what is being said. This can strain relationships at home and at work. Some adults with ADHD also suffer from labile moods and “short fuses.” These characteristics, coupled with the problems described above, result in more frequent losses of jobs and relationships. The consequences of this are lower job status, lower income, and a sense of underachievement or failure on the part of the adult with ADHD. The

inattentiveness and impulsivity also increase the likelihood of driving accidents, and infractions or other types of accidents are also more prevalent. In general, adults with ADHD may have an unhealthy lifestyle, with smoking, alcohol and drug abuse, risky sexual behavior, and chronic sleep problems frequently seen.

In adulthood, comorbidity is the rule, with more than 75% of adults with ADHD having at least one comorbid condition. Anxiety, depression, substance use, and some personality disorders are the most common comorbidities. Gambling and other addictions are also frequently seen.

Prospective follow-up has found that age is associated with a decline in symptoms, but less often with full functional remission. Hyperactive and impulsive symptoms tend to decline at a higher rate than inattention symptoms. It should be noted that even though the male/female ratio in children with ADHD can be 3 to 4:1, in adulthood it is 1:1. It is possible that many girls who tend to be less disruptive are not identified or referred in childhood but have significant impairment as adults and seek help then.

TREATMENT OF ADHD

The efficacy of both medication and psychosocial interventions for the treatment of ADHD has been well established. Treatment with ADHD medications reduces educational underachievement, accidental injury, bone fractures, traumatic brain injury, substance use, cigarette smoking, sexually transmitted infections, teenage pregnancy, depression, suicide, and criminal activity. Nonmedication treatments for ADHD are less effective than medication treatments for ADHD symptoms but are frequently useful to help problems that remain after medication has been optimized. The preferences of families and availability of services largely guide the choice of treatment.

Stimulants

Stimulants are considered first-line agents to treat ADHD symptoms based on decades of proven safety and efficacy. Therapeutic effects of stimulants include a decrease in hyperactivity, impulsivity, and

inattention, as well as improvement in associated behaviors. The two groups of stimulant medication that have received U.S. FDA approval for the treatment of youth with ADHD are MPH and amphetamines (AMP). There are approximately 30 stimulants on the market in the United States, many in both generic and branded versions (see Table 44.1–1 for brands, dose, onset, and duration of action). Stimulants are classified with drugs that can be abused or cause dependency under the category of schedule II–controlled substances by the U.S. Drug Enforcement Agency (DEA) (Table 44.1–1). In choosing between preparations, clinicians need to consider the needed duration of action, flexibility of dosing, time of day of impairment, time of day when maximum drug is released, whether the child can swallow pills, availability, and cost. Whenever possible, single-day dosing is helpful in improving compliance and coverage. Adherence and persistence with stimulant treatment have been problematic and can be managed by addressing efficacy and side effects and frequent follow-up. In addition, direct instruction, use of a pill box, and parental supervision, monitoring, or use of digital interventions can help patients to remember to take their medication.

Table 44.1–1. Methylphenidate Formulations

Generic Name	Formulation	Doses	Duration of Action	Comments
Methylphenidate Products				
Short Acting				
Methylphenidate immediate release	Tablet, chewable or solution	5, 10, 20 mg Solution 5 mg/5 mL Solution 10 mg/5 mL Chewable	2–4 hours	
Dexmethylphenidate Immediate release	Tablet	2.5, 5, 10	4–6 hours	
Intermediate Acting				
Modified release methylphenidate	Capsules	10, 20, 30, 40, 50, 60 mg	8–12 hours	Onset of action 1.5 hours
Methylphenidate Extended release	Chewable Extended-release suspension	20, 30, 40 mg 25 mg/5 mL	8–12 hours	
Long Acting				
Methylphenidate multi-layer release	Capsule	10,15, 20, 30, 40, 50, 60 mg	10–12 hours	Beads can be sprinkled
OROS methylphenidate	Capsule	18, 27, 36, 54 mg	10–12 hours	22% release in the morning, 78% release in the afternoon
Dexmethylphenidate extended release	Capsule	5, 10, 15, 20, 25, 30, 35, 40 mg	12–14 hours	Can be sprinkled
Methylphenidate extended release	Oral disintegrating tab Extended-release suspension	8.6, 17.3, 25.9 mg 25	10–12 hours	
Delayed release, extended release methylphenidate	Capsule	20, 40, 60, 80, 100 mg	22 hours	Given at night with delayed release of drug for morning onset of action
Methylphenidate transdermal system	Skin patch	10, 15, 20, 30 mg	Depends on how long patch is on	Onset of action 2 hours after applying patch. Patch must be removed at 9 hours.
Methylphenidate long acting	10, 20, 30, 40 mg		10–12 hours	
Methylphenidate extended release	Extended-release suspension	25 mg/5 mL	10–12 hours	
Methylphenidate multi-layer release	Capsule	25, 35, 45, 55, 70, 85	13–16 hours	Can be sprinkled

Pharmacology and Pharmacokinetics. Psychostimulants increase central nervous system activity in brain regions and increase blood pressure and pulse in the periphery. Although the exact mechanism of action is not completely understood, stimulants increase the concentration of dopamine and norepinephrine in the synaptic cleft. MPH appears to act primarily as a dopamine–norepinephrine reuptake inhibitor, while AMPs block the reuptake of both norepinephrine and dopamine as well as facilitate dopamine release. Some patients respond selectively to either MPH or AMP, with the majority of patients responding to both. AMP products are approximately two times more potent but may have lower tolerability in children. Dextro methylphenidate (d-MPH) is twice as potent as MPH, since it is the d isomer of the racemic mixture. Medication is introduced at a low dose and titrated up to optimize effect and

minimize side effects. There are wide differences in interindividual dose–response, so each individual needs to be titrated to their own optimal dose, and dose–response needs to be re-evaluated over time. When switching within the same class of stimulants (MPH or AMPs), direct switching is possible. However, when switching from one stimulant class to the other, decreasing the first class before switching to the second is recommended.

Formulations

FORMULATIONS OF METHYLPHENIDATE. Table 44.1–1 summarizes the commonly used short-acting immediate-release preparations (3 to 6 hours), intermediate acting (8 to 10 hours) and long acting (12 to 16 hours) of MPH and AMP drugs, as well as their availability as a tablet, capsule, suspension, chewable, or patch. These options increase the clinician's ability to provide individualized treatment for patients who need a short onset of action, a particular duration of action, patients who cannot swallow pills, patients who need more medication at the end of the day, or patients who wish to take medication in the evening rather than in the morning. These preparations differ in the pharmacologic mechanism they use to extend drug release. These include the osmotic release oral system (OROS) osmotic pump, use of beads with multiple layers, and drugs that combine immediate- and delayed-release beads. There are also differences between various formulations in the amount of drug released at a particular time of day. Choice between formulations depends on the length of time that a child needs medication and what time of day they are most impaired. There are also differences in time to onset of drug action, which is important in timing the early-morning administration of the drug to assure it is active at the time treatment needs to be effective.

Table 44.1–2. Amphetamine Formulations

Amphetamine Products				
Short Acting				
Dextroamphetamine Immediate release	Tablet, solution	2.5, 5.0, 7.5, 10, 15, 20, 30 mg Solution 5 mg/5 mL	4–6 hours	
Mixed amphetamine salts	Tablet	5, 7.5, 10, 12.5, 15, 20, and 30 mg	6–8 hours	
D, L amphetamine 1:1 ratio	Tablet Oral dissolving tablet	5, 10 mg 5, 10, 15, 20 mg	6–8 hours	
Intermediate Acting				
Dextroamphetamine extended release	Capsules	5, 10, 15 mg	4–9 hours	Onset of action 1.5 hours
d, l amphetamine 1:1 ratio	Tablet Oral dissolving tablet	5, 10 mg 5, 10, 15, 20 mg	4–9 hours	
Long Acting				
Mixed amphetamine salts extended release	Capsule Suspension Oral dissolving tablets	5, 10, 15, 20, 25, 30 mg 1.25, 2.5 mg/mL 3.1, 6.3, 9.4, 12.5, 15.7, 18.8	10–12 hours	Beads can be sprinkled
D, L amphetamine 1:1	Oral dissolving tablets	5, 10, 15, 20	10–12 hours	22% release in the morning, 78% release in the afternoon
Lisdexamfetamine	Capsule Chewable tablets	10, 20, 30, 40, 50, 60, 70 mg 10, 20, 30, 40, 50, 60 mg	12–14 hours	Can be dissolved in liquid

FORMULATIONS OF AMPHETAMINE. Table 44.1–2 summarizes the commonly used AMP medication for ADHD. Although absorption of MPH products is generally not affected by foods, some long-duration preparations of dextro amphetamine (d-AMP) show decreased concentrations when taken with high-fat meals. Whereas MPH is metabolized in the gut wall and plasma by esterases, the metabolism of d-AMP and mixed amphetamine salts (MAS) takes place in the liver. Variants in the human CES-1 gene coding for the hydrolyzing enzyme have led to interindividual variations in MPH metabolism and plasma level.

AMP product package inserts approved by the FDA warn that urinary excretion of AMP metabolites can be increased by foods of acidic content (vitamin C and orange juice), thus lowering plasma concentration. Conversely, foods that shift urinary pH higher reduce excretion and thus increase the plasma concentration of d-AMP or MAS.

Efficacy. A systematic and rigorous meta-analysis of randomized, double-blind, controlled medication trials in 10,068 children and adolescents demonstrated large effect sizes for both AMPs and MPH on parent ratings and large effect sizes for MPH on teacher ratings. Intercontinental Medical Statistics (IMS) data (2015) indicates that the

majority (52%) of children are on MPH products, whereas the majority (76%) of adults are on AMP products. The MTA study found that 77% responded to MPH, and an additional 10% of MPH nonresponders responded to d-AMP. Teacher rating scales showed significant reductions in ADHD symptoms for stimulants compared with placebo, with effect sizes ranging from 0.8 to 1.0 on behavioral measures and an effect size of 0.5 for cognitive measures for those children randomized to active drug. Placebo response rates in controlled studies have ranged from 17% to 40%, and for reasons that are unclear have increased over time. The Preschool ADHD Treatment Study (PATS) determined that preschool-aged children required lower optimal doses of immediate release (IR) MPH, experienced higher rates of adverse events, and had a diminished response as compared to school-aged children. Preschool children also had a slower clearance of the drug.

AMP and MPH both share the ability to reduce gross motor overactivity, increase sustained attention on tasks, and reduce impulsive responses on laboratory measures. Some individuals respond preferentially to MPH, whereas others respond preferentially to AMP. The majority of evidence indicates that MPH and AMP both have large effect sizes.

Cognitive and Behavioral Effects. Greater effects due to stimulants are found to occur in behavioral domains rather than in cognitive areas. Psychostimulant medications have been shown to reduce gross motor overactivity, out-of-seat behavior, calling-out in the classroom, disruptiveness, impulsive behavior, and noncompliance while improving self-perception, academic productivity, peer nominations of the child, and mother–child interaction. Stimulants have been shown to improve vigilance and reaction time, reduce variability, and enhance short-term memory and learning of verbal and nonverbal material in children with ADHD. The MTA Titration Trial showed a linear dose–response curve for behavioral measures between 0.5 and 1.0 mg/kg/day. Recent controlled trials revealed improvements in school-based productivity,

grade point average, test scores, and reading attendance in children with ADHD consistently treated with stimulants.

Adverse Effects

SHORT-TERM ADVERSE EFFECTS. Common side effects of the stimulant medications include decreased appetite, weight loss, delayed onset of sleep, headaches, stomach aches, and small increases in blood pressure and pulse. Most of the short-term side effects can often be dealt with by changing the time or dose of medication, change in diet, and sleep hygiene with or without use of melatonin to improve sleep-onset latency. Headaches tend to abate with time and stomach aches are decreased if medication is administered on a full stomach. Stimulants can also be associated with psychiatric side effects such as an increase in dysphoria, anxiety, irritability, social withdrawal, being “too quiet,” and emotional dysregulation.

Parents may complain of a worsening of behavior when medication is wearing off, sometimes called rebound. Rebound presents the sudden return of more severe overactivity, impulsivity, and inattention alongside increased irritability and emotional reactivity when medication is wearing off than was present at baseline off medication. Attempts to demonstrate their presence in full-day, laboratory classrooms have been unsuccessful, so these effects may be generated as the child interacts with task demands in their natural environment. Use of stimulants with a longer duration of action or a small booster dose of short-acting stimulant medication before the onset of rebound may be helpful. If these measures are not effective, a small dose of a short-acting α-blocking agent shortly before the onset of rebound can be useful.

Infrequent side effects include tics or the unmasking of Tourette syndrome. If the tics are functionally impairing, treatment with an α-blocker may be helpful.

Rare side effects include paranoia or other psychotic symptoms, priapism, choreiform movements, and self-directed behavior, such as lip licking, nail biting, and rubbing of sores. These problems are first

treated by discontinuing the medication until the adverse event disappears.

Two large recent studies in children and one in adults found that ADHD medications are not associated with an increased risk of severe cardiovascular events. General cardiac side effects of stimulant drugs are an increase in heart rate of approximately 1 to 2 beats/minute and an increase in systolic and diastolic blood pressure of 3 to 4 mm Hg. Stimulants have not been found to induce clinically significant changes in electrocardiographic parameters. The evidence suggests a potential for severe adverse cardiac events in some children with certain forms of congenital heart disease or arrhythmias. Routine electrocardiograms are not recommended prior to initiating stimulants in the absence of concerning physical examination findings or personal or family cardiac history.

Long-Term Adverse Events

EFFECTS ON GROWTH. The use of stimulants in children has been associated with growth suppression. Two large-scale NIMH-supported RCTs have shown that MPH can reduce the rate of height and weight gains in developing children with ADHD. The reductions in linear growth have been approximately 1 cm in height and 2.5 kg in weight during the first year of treatment with stimulants. Net growth loss in adulthood is greater with consistent than inconsistent use of medication, with a maximum loss of about 1.3 inches. Small, single-site studies are discordant concerning whether psychostimulants suppress human growth hormone (HGH) or affect prolactin levels. Clinicians need to regularly monitor the height and weight of children with ADHD treated with psychostimulant medication. Drug holidays during summer vacations increase the probability of growth rebound and thus may mitigate problems of growth deceleration when it occurs.

SUBSTANCE ABUSE. There is no evidence to suggest that the use of stimulants in young people increases the risk for later substance use disorders (SUDs). A meta-analytic study by Wilens and colleagues

suggests that stimulant treatment in childhood has a protective effect, bringing the risk down to the level of the general population. Other studies have revealed that stimulant therapy neither increases nor decreases the risk for subsequent SUD in children and adolescents with ADHD. Clinicians should take into consideration if family members are currently abusing prescription medication before prescribing stimulants for ADHD.

Stimulant medication can be misused or diverted for the purpose of academic performance enhancement or euphoric effects, with immediate-release stimulants more often misused compared to extended-release formulations. A systematic review of 21 studies indicated the prevalence of psychostimulant misuse in the year prior to the study ranged from 5% to 9% in grade and high school–aged children and 5% to 35% in college-aged individuals. Close monitoring, pill counts, or switching to long-acting, less easily abused formulations should be tried and, if not successful, nonstimulant medication should be employed by the clinician if misuse or diversion is suspected.

Summary of Stimulant Medication. Continuous treatment of children with ADHD with psychostimulants is both effective and safe over the first 2 years. Long-acting preparations provide the convenience of once-daily dosing, better coverage, and reduced stigma associated with taking medication at school and can decrease the potential for abuse. Short-acting forms are useful for younger children who often require smaller doses than are available in extended-release preparations. Many adverse events can be handled by adjustment of dose and/or the time of administration of the medication. Long-term adverse events such as growth rate suppression concern parents but may be managed by instituting drug holidays to permit growth rebound.

Nonstimulant Medication in the Treatment of Children with ADHD

Whereas psychostimulants constitute the first-line treatment for children with ADHD, other medications need to be used for the

treatment of patients who do not respond to or cannot tolerate stimulants. Some nonstimulant medications, such as Atomoxetine (ATX) and long-acting clonidine or guanfacine, have been approved by the FDA for the treatment of ADHD in children and adolescents. Advantages of nonstimulant medications include longer duration of action and the absence of psychostimulant effects such as behavioral rebound or delay of sleep onset. These drugs provide a moderate rather than a large effect size of stimulants but, nonetheless, provide clinical benefit.

Atomoxetine. ATX, a norepinephren reuptake inhibitor (NRI), is an approved alternative to stimulants. ATX may be considered in individuals where stimulants have failed or parents have refused stimulant treatment. In particular, for patients who are unable to tolerate stimulants because of worsening anxiety or tics, ATX is a reasonable alternative since it may ameliorate these comorbid conditions. ATX is well absorbed after oral administration and is minimally affected by food. At steady state, ATX provides 24 hours of coverage.

ATX is metabolized by the cytochrome P450 (CYP) 2D6 hepatic enzyme system. A fraction of the population are poor metabolizers of CYP 2D6–metabolized drugs. Such individuals may experience elevated plasma concentrations and extended plasma half-life; therefore, very slow initial titration may be required for all patients to prevent excessive dosing of these patients. Patients taking other medications metabolized by CYP 2D6, such as fluoxetine, paroxetine, and quinidine, might show signs of competitive inhibition, namely increased plasma levels of both ATX and the competing drug.

In order to mitigate side effects and to optimize the dose for individual patients with variable 2D6 activity, patients are usually started at 0.5 mg/kg and titrated up slowly with increases every 1 to 2 weeks up to 1.2 mg/kg. Patients who are slow metabolizers may require lower doses, just as patients who are ultrafast metabolizers may require higher doses. The time to therapeutic effect is in the range of 1 to 4 weeks, with full response at 6 to 12 weeks. Early signs of response in the first month are predictive of response at 3 months,

which can be helpful in encouraging parents to persist with treatment in the absence of the immediate benefits seen with stimulants.

ATX has been shown to reduce ADHD behaviors in children, adolescents, and adults with a medium effect size of 0.5 to 0.7. Common adverse events associated with ATX involve abdominal discomfort, nausea, decrease in appetite, sedation, daytime sleepiness, headache, dizziness, vertigo, irritability, and mood swings. To minimize the risk of stomach aches, ATX is best taken on a full stomach. Minor increases in blood pressure and pulse have been reported and thus should be regularly monitored. Rare adverse events in youth include priapism, disturbances in sexual functioning, increased suicidality, and liver toxicity. ATX has a black box warning of possible suicidal ideation, although more recent studies have questioned if this is actually a concern. Some patients may also experience adverse psychiatric side effects such as new-onset anger or irritability.

α-Adrenergic Agonists. The α-adrenergic agonist agents were initially approved for the management of hypertension in adults. The long-acting α-adrenergic agents guanfacine ER and clonidine ER have been FDA approved as monotherapy and adjunctive treatment of ADHD in children 6 to 17 years old. The immediate-release clonidine and guanfacine have not been approved to treat ADHD, although they are used as second-line or adjunctive agents. Guanfacine has also been found to be effective as an adjunctive agent in improving response to stimulants, particularly in decreasing blowups. The supposed mechanism of action of the α-adrenergic agents involves stimulating α-receptors in the prefrontal cortex leading to improvement of inattention, impulsivity, and hyperactivity. The α-adrenergic agonists are clearly less efficacious than the psychostimulants, with several meta-analyses suggesting a moderate effect size. However, a small multisite, double-blind, RCT showed that children and adolescents comorbid for ADHD and Tourette syndrome benefited from clonidine alone or in combination with MPH, in both cases significantly better than placebo. Guanfacine has proven

efficacy in reducing oppositional symptoms in children with comorbid oppositional behaviors and ADHD.

Common side effects of the α-adrenergic agents are sedation, fatigue, somnolence, headache, hypotension, syncope, and bradycardia. Clonidine is very sedating and has been used to treat sleep difficulties of children with ADHD, as well as to offset the delay in sleep onset caused by stimulant medications. Guanfacine is a more selective α-adrenergic agonist and is slightly less sedating than clonidine. The α-adrenergic agonists need to be discontinued very slowly to prevent rebound adrenergic overdrive, with hypertension, agitation, fever, headache, tachycardia, chest pain, sleep disturbance, nausea, and vomiting. Families need to be warned of the potential dangers of sudden discontinuation of this medication, even for holidays or weekends with another parent.

Bupropion. Bupropion is an antidepressant with dopaminergic and noradrenergic properties that has shown modest efficacy in ADHD but is less effective than stimulants or ATX. It is available in extended-release preparations that permit once-daily dosing. Bupropion may be considered as an option for patients presenting with significant depression. Starting dose for young adolescents is 75 mg twice a day to a maximum of 200 to 300 mg/day. The doses can be increased once weekly until improvement is noted. Bupropion usually takes 4 to 6 weeks at a therapeutic dose to show effect. Side effects of bupropion include fatigue, dry mouth, insomnia, headaches, nausea, vomiting, constipation, tremor, and skin rash. Seizures will reliably occur if the adolescent's dose exceeds 400 mg/day. This medication is FDA approved for the treatment of depression and smoking cessation, but not ADHD, in individuals older than 18 years of age. Bupropion is considered a second-line, off-label treatment for ADHD.

Other Alternative Medications. Anticonvulsants, including carbamazepine, lithium, and SSRIs have not been shown to be effective for the treatment of ADHD. Second-generation antipsychotic medications such as risperidone have been shown to be effective for

the treatment of aggression in children with disruptive behavior disorders, especially when combined with parent training and MPH.

Summary of Medication Treatments

Most children with ADHD respond to stimulant medication with good effect on all the core symptoms, making stimulant treatment the first-line medication treatment. If stimulants are ineffective or poorly tolerated, nonstimulant alternatives such as ATX can be used. Monotherapy with α-adrenergic agents is a third choice because they are less effective. Patients with a suboptimal response to stimulants or inability to tolerate an optimally effective dose may benefit from combination treatment with a stimulant and nonstimulant. Clonidine and guanfacine are sedating and have significant cardiovascular side effects. For all these drugs, careful monitoring and slow, cautious discontinuation are essential.

Treatment of ADHD Comorbidities

Tic Disorder. Stimulants alone or in combination with clonidine, guanfacine, or ATX appear to reduce ADHD symptoms in individuals with both ADHD and Tourette syndrome or tic disorders. Although stimulants have not been shown to worsen tics in most patients with tic disorders, they may exacerbate tics in some individual cases. In these instances, decreasing the dose of stimulants, adding α-agonists, or switching to ATX may be alternative strategies. Habit reversal therapy (HRT) and cognitive behavioral intervention for tics are evidence-based therapies that have been shown to be effective for tics.

Seizure Disorder. Children with seizure disorders may also suffer from ADHD. Although there are concerns about psychostimulants, particularly MPH, lowering the seizure threshold, experiencing a first seizure when starting a psychostimulant is extremely rare. Studies of EEG epileptiform activity, seizure rates, or interactions between antiepileptic drugs (AEDs) and psychostimulants have not shown any additional seizure risk. On the contrary, studies have shown that

children with ADHD and a seizure disorder that is adequately controlled on antiepileptic medications show reduced ADHD symptoms and no change in seizure frequency.

Aggression, Oppositional Defiant Disorder, and Conduct Disorder. Individuals with ADHD and comorbid aggression, ODD, and/or CD require comprehensive intervention which includes pharmacotherapy and psychosocial treatments. Stimulants have been shown in randomized, controlled trials to improve ADHD, aggression, ODD, and CD symptoms. α-Blockers (guanfacine and clonidine) alone or as adjuncts to stimulants have also been shown to decrease ADHD, aggression, and oppositional symptoms. Stimulants also reduced negative social interactions and covert antisocial behavior (stealing and vandalism but not cheating). However, one cannot solely rely on medication to treat children with ADHD and these comorbid conditions. A comprehensive treatment approach which may include parent training, social skills training, and anger management for the child, as well as an appropriate academic program and support, may also be needed. Adjunctive treatment with α-blockers (guanfacine XR or clonidine) can be helpful in managing extreme explosive outbursts. If these are not effective, replacing these drugs with risperidone or aripiprazole can be useful, although this benefit has to be weighed against the risk of the metabolic effects of the latter drugs. Careful metabolic monitoring is essential. Treating aggression, ODD, and CD early and effectively is critical, as long-term consequences of these disorders include later drug and alcohol abuse and antisocial behavior with involvement of the criminal justice system.

Anxiety Disorder. It had been suggested that children with ADHD and comorbid anxiety may be less responsive to and experience more side effects with stimulant medication. The large multimodal study of ADHD (MTA) did not find this to be the case. However, children with ADHD and anxiety disorder seemed to benefit significantly from psychosocial treatment as well as medication. Thus, for children with ADHD and comorbid anxiety, slow and careful

titration of stimulant medication for the ADHD symptoms is recommended. Evidence-based psychosocial treatments such as cognitive behavioral therapy (CBT), parent training, and social skills training combined with an appropriate academic program and academic support is suggested. However, should all these measures prove inadequate, SSRIs (fluoxetine or sertraline) to address the anxiety can be added.

Mood Disorder. In community samples, major depressive disorder (MDD) in youth with ADHD is more than five times higher than in youth without ADHD. Depressive disorders in youth with ADHD usually occur several years after the onset of ADHD and may be due to the cumulative effects of ADHD-related impairments and negative environmental circumstances they need to cope with. Youth with depression and ADHD have greater levels of psychosocial impairment than those with either condition alone. For individuals with both disorders, depressions start earlier, last longer, are more likely to recur, and have higher rates of suicides and hospitalizations than those who have depression alone.

A combination of pharmacotherapy and psychosocial interventions is recommended for patients who have both ADHD and major depression. In general, as per the Texas Children's Medication Algorithm Project (CMAP), it is suggested that the clinician begin with the most effective medication for the most impairing condition for the patient. Only after the full effect of this medication is determined for both conditions, should a second medication be added to deal with residual symptoms of the second condition. Thus, in some cases of the combination of ADHD and mood disorders, both stimulants and SSRIs may need to be used.

Psychosocial interventions both for the depression, for example, CBT, and the ADHD, for example, organizational, study skills remediation, and appropriate academic and/or vocational programs, may all be needed.

There has been controversy regarding the comorbidity of ADHD and bipolar disorder. Emotional dysregulation and irritability can be an important source of impairment in children with ADHD, and these

children may require additional and specialized intervention. DSM-5 introduced the diagnosis of disruptive mood dysregulation disorder (DMDD) to assist clinicians in attempting to characterize children who have chronic and frequent severe temper outbursts, anger, and irritability in multiple settings during latency or adolescence. Classical symptoms of bipolar disorder, such as severe elation of mood, grandiosity, racing thoughts, and hypersexuality, are used to confer the bipolar diagnosis. In these circumstances, the bipolar disorder needs to be stabilized with mood stabilizers and/or antipsychotics before stimulant treatment can be introduced.

Developmental Disorders. ADHD symptoms of inattention and hyperactivity are seen in children with intellectual and developmental delays, Autistic Spectrum Disorders (ASD) or both. Stimulants have been shown to be beneficial in both groups, particularly in those children with IQs greater than 50. MPH has been found to be more effective than placebo in reducing symptoms of ADHD in children with autism, and approximately one-third of children and adolescents with autism are on concomitant stimulant treatment. In the Research Units of Pediatric Psychopharmacology (RUPP) study, 49% of children with autism and ADHD responded to stimulants, with up to 18% unable to tolerate stimulant treatment. A trial of guanfacine found a 45% decrease in behavioral but not cognitive symptoms. ATX has also been found to be effective in the treatment of ADHD in autistic children.

Psychosocial Treatment of Children with ADHD

Psychosocial treatment of children with ADHD refers to nonmedication treatment. This type of treatment includes different modalities such as psychoeducation, academic organization skill teaching and remediation, parent training, behavior modification, CBT, social skills training, and individual therapy. Of these modalities, parent training, intensive behavior modification, social skills training, and academic organizational skills have shown efficacy for children with ADHD in controlled trials. Standardized parent training programs have been evaluated in systematic reviews including parent–child

interaction therapy, friendship coaching, and the positive parenting program. Children with ADHD may also have difficulties regulating emotions and anger management and would benefit from nonpharmacologic interventions to address these potential problems.

Behavioral interventions are the preferred choice of treatment for preschool children with ADHD and are recommended as adjuncts to medication in school-aged children and adolescents. Parent training and intensive behavioral interventions are based on principles that will enhance parenting techniques. These include parental psychoeducation about the course, risk factors, and long-term outcomes of ADHD, as well as education on and encouragement of the use of strategies that will address behavior both in and outside of the household. Techniques such as token economy, contingency management, setting small achievable goals, checklists, and closer attention to a child's behavior especially when the child is behaving appropriately are encouraged. While the effects on behavior and performance in the classroom have been shown, the effects do not tend to generalize to other settings. In practice, behavioral therapy is often carried out in consultation with parents and teachers to establish ideal in-school and home management. However, published trials tend to rely on parent and teacher ratings of improvement but do not have independent evaluators. There is some evidence in recent reviews that, even with blinded assessments, the effects of behavioral therapy persist for improving parenting and decreasing child conduct problems.

Academic interventions can take several forms to aid the child with ADHD. Organizational skills such as time management education are useful and have been shown to be effective. However, for some children, their academic difficulties may have put them behind their peers, and they might also require some level of academic support or remediation. A diagnosis of ADHD may qualify a child for special education or related services, as well as accommodations in a regular classroom. All these avenues should be explored to best support the child's learning.

Certain alternative interventions including physical activity and mindfulness may be useful supplements in the treatment of ADHD

but have not yet been rigorously studied. Other interventions such as dietary interventions, neurofeedback/biofeedback, and mineral and vitamin supplementations are still largely unproven. Recent studies suggest some benefit from fish oil.

Practice guidelines published for child and adolescent psychiatrists strongly suggest a combination of behavioral interventions, such as parent training or classroom management, alongside pharmacologic treatment in the management of ADHD. This is especially important due to the potential deficits along multiple axes in ADHD, and this combined multimodal treatment would benefit most the children who are responding only partially to stimulant medication or who exhibit a comorbid psychiatric disorder whose impairment is not responding to the stimulant medication.

SUMMARY AND CONCLUSIONS

ADHD is a prevalent condition that begins in childhood but often continues into adolescence and adulthood. It is accompanied by significant academic, occupational, social, and emotional impairment. The patients with ADHD often have other comorbid conditions. These comorbidities include oppositional defiant, conduct, learning, and anxiety disorders in childhood and anxiety, depression, and substance use and abuse in adolescence and adulthood.

Treatment must focus on both the ADHD and the various comorbidities. Thus, pharmacotherapy and psychosocial treatment as well as appropriate academic programs and support are needed for optimal outcome. It must be stressed that ADHD is a chronic condition for which ongoing long-term monitoring and treatment is required to optimize functioning.

SPECIFIC CASE OF CHILDHOOD ADHD

Ben is an 8.5-year-old adopted boy who lives with his parents and 11-year-old brother. He attends third-grade regular education in his local public school and received special services including speech, physical, and occupational therapy. Ben had suffered several upper respiratory infections at age 2 years requiring several rounds of antibiotics. Developmentally, some motor delays were reported, with crawling by 1 year and walking by age 2 years. He was speaking one word by his first birthday, but by age 3½ years, his expressive language was behind his peers in fluency. He demonstrated difficulties following multipart directions, even though his hearing tested in the normal range.

Ben has had difficulty with daydreaming and wandering about since kindergarten. His teachers complained that Ben did “not seem to listen,” had “poor concentration,” and was constantly “out of his seat.” Ben had never had close friends and other children seemed to avoid him because he could not stick with an activity for very long and he was always “in their space.” Ben’s adoptive parents were drained from the nightly battles over homework and discouraged by his lack of focus and “spaciness.” His inattention and impulsivity put him in danger and caused injury. He had run into traffic on several occasions, even after being hit by a truck with resulting injuries.

Ben’s parents and his third-grade teachers completed the SNAP rating scale. Clinician assessment revealed seven symptoms of inattention. His mother also endorsed all nine symptoms of hyperactivity/impulsivity. These symptoms were moderately to severely impairing across multiple settings, including school, home, peer relations, personal safety, and during athletics.

Ben was started on extended-release MPH at 18 mg daily, which was later increased to 27 mg daily. His teachers reported improvement in attention and hyperactive behavior at school. Homework was no longer such a struggle, and he was noted to play quietly with his toys in the evenings.

ACKNOWLEDGMENTS

I would like to acknowledge the contribution of Dr. Laurence Greenhill, who was a coauthor of this chapter in several previous editions. His contribution to this chapter continues to be felt and is much appreciated.

44.2 Adult Manifestations of Attention-Deficit/Hyperactivity Disorder

JAMES J. MCGOUGH, M.D., M.S.

Although attention-deficit/hyperactivity disorder (ADHD) was originally conceptualized as a developmental delay of childhood, it is now recognized as a lifespan neurodevelopmental disorder with widely acknowledged adult manifestations. Longitudinal studies indicate that

a majority of school-age children diagnosed with ADHD continue to have clinically meaningful symptoms and related impairments as young adults. Community epidemiologic studies suggest that prevalence rates of ADHD among adults are among the highest of all psychiatric disorders. Adults with ADHD have patterns of psychiatric comorbidity and neurocognitive deficits similar to children but suffer from a much broader array of functional impairments. Both structural and functional brain imaging studies demonstrate distinct abnormalities in groups of adults with ADHD compared to those without, and genetics studies conducted in adults have replicated pediatric findings. Adult ADHD is associated with significant medical, occupational, economic, and social impacts and has emerged as a major public health concern.

DEFINITION

ADHD was classified as a Neurodevelopmental Disorder in the 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and its text revision (DSM-5-TR), reflecting the disorder's initial emergence in childhood and common co-occurrence with other early-onset brain-based syndromes. In a departure from previous editions, DSM-5 fully acknowledged the persistence of ADHD across the lifespan with modified diagnostic criteria for older adolescents and adults to better reflect developmental changes in symptom sensitivity with increasing age. While criteria in younger patients require evidence of six or more inattentive or hyperactive/impulsive symptoms, this threshold was reduced to five symptoms in either domain for the diagnosis of patients aged 17 years and older. This modification recognized that the population prevalence of ADHD symptoms decreases with increasing age, but adults with as few as four symptoms suffer significant clinical impairments compared with similarly aged peers. As in youth, symptoms must have been present for a minimum of 6 months and exceed what is expected for the patient's expected developmental level. Additionally, there must be some evidence of symptoms prior to age 12 with concomitant functional impairments in multiple life settings, such as home, school,

work, social relationships, or personal activities. Current symptoms must be associated with a clinically significant level of functional impairment. Symptoms cannot occur exclusively during an episode of schizophrenia or other psychotic illness and cannot be better attributed to other psychiatric conditions such as mood, anxiety, dissociative, or substance use disorders.

DSM-5 eliminated ADHD subtypes. Instead, *specifiers* describe the overall clinical presentation evidenced in the prior 6 months. Adults with at least five symptoms of inattention and hyperactivity/impulsivity exhibit the combined presentation. Those with five or more inattentive but fewer than five hyperactive/impulsive symptoms exhibit the inattentive presentation. Those with a minimum of five hyperactive/impulsive but fewer than five inattentive symptoms exhibit the hyperactive/impulsive presentation.

Other specifiers describe disorder severity. *Mild ADHD* is specified when the minimal number of symptoms required for diagnosis occur and functional difficulties are at the threshold for clinical significance. *Severe ADHD* is specified when there are many symptoms in excess of the required threshold, or in the presence of marked functional difficulties in one or more settings. Moderate ADHD is specified when the number of symptoms and associated degree of impairment falls between “mild” and “severe.”

DSM-5 further permitted the diagnosis of “other specified ADHD” when an individual exhibits significant impairment due to ADHD symptoms but fails to meet full diagnostic criteria. In this instance, the clinician should specify which criteria are not met, for example, “other specified ADHD with insufficient symptom number.” Clinicians may also assign the diagnosis “unspecified ADHD” if they choose not to specify which criteria are lacking.

HISTORY

For the first half of the 20th century, the condition now recognized as ADHD was variably referred to as minimal brain damage (MBD), minimal brain dysfunction, or hyperkinesis. While these terms conveyed some expectation that the disorder arose from underlying

brain pathology, the syndrome was principally viewed as a developmental delay that was most often outgrown during adolescence. This position was maintained in the second edition of the DSM (DSM-II), published in 1968, which placed the diagnostic category *hyperkinetic reaction of childhood* within the grouping "Behavioral Disorders of Childhood and Adolescence." Unique among editions of the DSM, DSM-II further implied that core features of short attention span, restlessness, and hyperactivity were a reaction to unsupportive environments and/or inadequate parenting.

In the 1970s, concurrent with development of the third edition of the DSM (DSM-III), seminal work by Paul Wender and colleagues at the University of Utah identified a group of adults with persistent childhood ADHD symptoms. Wender asserted that symptoms under consideration for inclusion in the DSM revision were developmentally inappropriate for older patients. He proposed the Wender Utah Criteria for Adult ADHD, empirically derived from extensive experience with older patients, as an alternative to the DSM. Wender Utah Criteria required (1) retrospective diagnosis of childhood ADHD made on the basis of patient interview and, when available, confirmation by a third-party informant; (2) evidence of ongoing impairment in adulthood from hyperactive and impulsive symptoms adulthood; and (3) the presence of additional symptoms felt to be typical of adults with the disorder, including mood lability, irritability, impulsivity, disorganization, and poor stress tolerance. The diagnosis could not be made in patients suffering from severe depression, psychosis, or severe personality disorders.

DSM-III, published in 1980, continued to define attention deficit disorder as a childhood condition. However, with some deference to work by Wender and others, DSM-III allowed the diagnosis of attention deficit disorder, residual type, for adults previously diagnosed as children who had ongoing evidence of some symptoms. This category inherently implied that adults could not meet full diagnostic criteria. Text of the revised third edition (DSM-III-R) allowed that ADHD might continue through adulthood in up to 30% of affected children.

Throughout the 1980s and 1990s, and in the absence of clearly applicable DSM criteria, Wender Utah Criteria were used widely in clinical practice as well as research studies of adult medication response, brain imaging, and genetics. Concurrently, longitudinal follow-up studies of adults previously diagnosed with childhood hyperactivity reported ADHD persistence in 40% to 60% of cases. These converging lines of evidence influenced subsequent DSM revisions and increased recognition of ADHD in adults. Although Wender Utah Criteria had a tremendous impact in promoting initial acknowledgment and study of adult ADHD, their use was largely abandoned as DSM criteria were increasingly applied outside of pediatric age groups. More recently, building on Wender's contributions, there has been renewed recognition of difficulties related to emotional dysregulation in some adults with ADHD, which, while not diagnostic, predict increased risk for comorbidity and functional disability.

In the 1990s, emerging research and several best-selling lay publications spurred widespread public awareness of adult ADHD. These studies and resultant increases in public demand for clinical services catalyzed growing interest in the phenomenology, causes, and potential treatments of adult ADHD. Nonetheless, although the fourth edition (text revision) of the DSM (DSM-IV-TR) provided further leeway for adult diagnosis, it continued to maintain that ADHD symptoms are typically resolved by late adolescence.

Revisions in DSM-5 incorporated more than two decades of research and clinical experience in adults. Enumerated ADHD symptom criteria remained unchanged from those previously identified in field trials of school-age children, but text clarifications were added to reflect developmental changes in symptom presentation that occur with increasing age. The age of onset criterion from previous editions of the DSM was modified from requiring evidence of symptoms and impairment prior to age 7 to requiring some recognition of symptoms alone prior to age 12. In response to studies that demonstrated declining symptom prevalence rates with increasing age, as well as significant functional impairments seen in adults with as few as four ADHD symptoms,

DSM-5 required only five symptoms in either the inattentive or hyperactive/impulsive domain for diagnosis in individuals aged 17 and older. Finally, descriptions of typical impairments associated with ADHD were broadened to include the range of difficulties frequently seen in adults, notably problems with work, personal activities, social relationships, and general health maintenance. The text revision of the DSM-5, DSM-5-TR did not many any significant changes to this scheme.

Several birth cohort studies suggested the occurrence of adult-onset ADHD in individuals with no history of childhood symptoms, undermining the conceptualization of the disorder as a chronic neurodevelopmental syndrome emerging before age 12. These studies were largely symptom-based and did not require a demonstration of associated functional impairments. One subsequent investigation found that the failure to detect childhood ADHD was a function of higher IQ and lack of comorbidity. Other studies found that over 95% of supposed adult-onset cases failed to retain the diagnosis after comprehensive examination but instead generally suffered from other psychiatric disorders or functional impairments due to heavy substance use. Current evidence suggests that true adult-onset ADHD occurs rarely or not at all. Further research is necessary to better elucidate this question.

COMPARATIVE NOSOLOGY

The 11th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-11) harmonized with DSM-5-TR in renaming the ICD-10 category of hyperkinetic disorders as ADHD and moving it from the grouping of disruptive behavior to the neurodevelopmental domain. Consistent with DSM-5-TR, ICD-11 required *either* inattentive *or* hyperactive/impulsive symptoms, not both as in previous editions, and allows the use of predominately inattentive, hyperactive/impulsive, or combined presentation specifiers. Unlike DSM-5-TR, ICD-11 does not define a precise age of onset, specific symptom number, or duration. Also, unlike DSM-5-TR, ICD-11 continued to exclude the diagnosis in the presence of autism

spectrum disorder. ICD-11 is the principal classification system used outside the United States and generally relied upon within the United States for insurance billing purposes.

EPIDEMIOLOGY

Epidemiologic studies demonstrated that ADHD is the most common behavioral disorder of childhood, with prevalence estimates ranging from 5% to 10% of school-age children. Longitudinal studies suggest the persistence of the disorder from childhood to adulthood in approximately 65% of cases. The World Health Organization estimates the prevalence of adult ADHD to be 2.8%. However, there is a wide range of estimates across studies and countries (e.g., 1.1% in South Korea vs. 5.8% in Brazil). Differences in reported prevalence rates are deemed related to methodologic differences between investigations. These converging reports confirm that significant numbers of adults suffer from ADHD and related impairments. Unlike other common psychiatric conditions, such as mood and anxiety disorders that are typically episodic, adults with ADHD are apt to experience chronic and unremitting symptoms that require ongoing management.

ETIOLOGY

ADHD is best viewed as a neurodevelopmental disorder that arises from the interplay of genetic and environmental factors. Similar to studies in youth, meta-analyses suggest heritability estimates in the range of 70% to 80% in adults, with approximately one-third of this risk explained by polygenic effects of common variants with small individual effects. Adult genome-wide association studies (GWAS) identified a similar set of risk loci as seen in studies of youth, supporting the conceptualization of ADHD as a neurodevelopmental disorder with a significant genetic overlap with ADHD in children. Approximately one-third of adults with ADHD have at least one child with the disorder, and similarly, one-third of children with ADHD have at least one affected parent. Ongoing investigations will further

elucidate the genetic, environmental, and gene-by-environment interactions that affect ADHD risk.

Early structural and functional brain imaging studies in groups of adults with ADHD revealed localized dysfunctions in discrete areas of the prefrontal cortex and basal ganglia, similar to findings in children. Longitudinal imaging studies in youth demonstrated maturational delays in cerebral cortex myelination. Some have suggested that cortical maturation is associated with symptom attenuation in adulthood, whereas ongoing subcortical dysfunction predicts symptom persistence. Newer imaging research has shifted from examining distinct anatomical abnormalities to consideration of impaired functional connectivity in brain regions engaged in executive, attention, reward, and default networks. The heterogeneity of imaging findings reflects clinical heterogeneity, but ongoing research might provide insights into the persistence or desistance of childhood ADHD into adulthood

Meta-analyses suggest adult ADHD persistence in 65% of child cases, with some estimated variability due to differing methodologies. Approximately 15% of children demonstrate full diagnostic criteria as adults; an additional 40% to 60% show partial remission. Risk factors for persistence include the severity of childhood ADHD symptoms, the presence of childhood comorbidity, and parental mental health. There is no apparent impact from individual IQ, socioeconomic status, or quality of the parent–child relationship. Comorbid juvenile conduct disorder is the strongest predictor of severe adult outcomes, including increased risk for substance use disorders, criminality, and early mortality. Some evidence suggests that early and sustained medication treatment of childhood ADHD is associated with decreased risk for substance use disorders as young adults.

DIAGNOSIS AND CLINICAL FEATURES

Although parents and teachers generally serve as primary informants in the assessment of pediatric ADHD, adult patients themselves are usually the primary sources of information in their own assessments. Unfortunately, research showed that young adults are frequently poor

reporters of ADHD symptoms and associated difficulties, although reliability is much improved when patients reach their late 20s. Studies also revealed that both adults with ADHD and parents of these adult children exhibited poor retrospective recall of problems related to childhood ADHD, often reporting ages of onset up to 4 years later than documented in prospectively collected data. As with children, optimal assessment of adult ADHD depends on the clinical synthesis of all available information, including reports of childhood and current difficulties, symptom reports from parents and significant others, school and occupational reports, and a review of pertinent medical records.

Table 44.2–1.
DSM-5 Symptoms and Adult Correlates

Inattention		Hyperactivity and Impulsivity	
Younger Individuals	**Older Individuals**	**Younger Individuals**	**Older Individuals**
Fail to notice small details, make careless errors	Careless, inaccurate work	Frequently fidget, tap hands or feet, squirm while seated	Often fidgety or restless
Difficulty maintaining attention	Problems staying focused on boring work, mind often wanders, trouble with extensive reading	Frequently get out of seat or have trouble staying seated	Can't sit long at meetings or other activities where seating is required
Seem not to listen even when spoken to directly	Trouble retaining what people say even when addressed directly	Often run or climb at inappropriate times	Often feel internally restless or unsettled
Trouble finishing work or following through on instructions	Sidetracked easily, problems following directions or finishing tasks	Have trouble playing quietly; often too loud	Often louder than necessary or appropriate
Problems with organization	Can't prioritize, procrastinate, messy, miss deadlines, and bill payments	Often "on the go," as if "driven by a motor"	Difficulty unwinding or relaxing; always needing to be busy

Avoid activities that require sustained concentration	Delay and avoid work and other activities that are boring or repetitive	Get in trouble for excessive talking	Talk too much in social settings, don't tolerate silence
Lose or misplace things frequently	Often misplace things needed at home, work, or other activities	Often blurt out answers before questions are finished	Finish others' sentences or answers before questions are completed
Distracted easily when interrupted	Easily distracted by surrounding noises, interruptions, or extraneous thoughts	Have difficulties when waiting for turn or standing in line	Frustrated when needing to wait
Frequently forgetful	Fail to remember appointments, deadlines, and other obligations	Frequently interrupt or intrude	Interrupt others' conversations and activities, socially intrusive

Data from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022.

Consideration of an ADHD diagnosis should be given to any adult with long-standing difficulties from inattention or distractibility. A single DSM symptom, "Is often distracted by extraneous stimuli," correctly differentiated 97% of ADHD-affected adults compared with 98% of community controls. One additional symptom, "Avoids tasks requiring sustained mental effort," correctly identified 89% of ADHD cases when compared with other clinical cases without ADHD.

As with children and adolescents, the diagnosis of ADHD in adults is based on DSM-5-TR criteria. DSM-5-TR acknowledged developmental changes observed in adults by requiring only five

inattentive and/or hyperactive/impulsive symptoms for diagnosis, compared with six for younger individuals. ADHD symptoms in DSM-5-TR are identical to DSM-IV and were initially derived from field trials conducted in school-age children. However, text descriptions in DSM-5-TR provided adult correlates for these symptoms and allow greater applicability to older patients, as summarized in Table 44.2–1.

Diagnosis is based principally on information derived from a clinical interview with the adult patient. The self-administered Adult ADHD Self Report Screening Scale (ASRS), developed under the auspices of the World Health Organization and calibrated to DSM-5, is easily administered and has high diagnostic sensitivity and specificity. A related semistructured interview, the Adult ADHD Clinical Diagnostic Scale (ACDS), probes retrospective childhood and prior 6-month adult ADHD symptoms. ADHD assessment requires careful consideration of potentially comorbid psychopathology as well as a broad range of functional impairments. Common co-occurring conditions include lifetime histories of disruptive behavior and antisocial activities, nicotine dependence, substance use disorders, anxiety disorders, depression, risky behavior, and poor health maintenance. Typical impairments include difficulties in academic, occupational, social, and family functioning.

Many clinicians remain highly skeptical of the validity of adult ADHD and presume that most adults seek the diagnosis to obtain various academic or occupational accommodations or scheduled medications. ADHD symptoms are easily feigned. Clinicians should be particularly suspicious about adults claiming to suffer severe symptom levels without reasonable evidence of prior functional impairments. Several investigations compared individuals pretending to have ADHD with known adult cases and found that malingerers had atypically high rating scale scores and greater numbers of self-reported ADHD symptoms. This finding contrasts with the anticipated age-related symptom reduction typically seen in the disorder. Similarly, on computerized attention tasks, those feigning ADHD made many more errors in omission and commission than individuals with historically validated cases, suggesting deliberate attempts to perform poorly. Some have proposed that computerized performance

validity tests or symptom validity tests, such as the Exaggeration Index of the Connors Adult ADHD Rating Scale, aid in recognizing malingering, but evidence supporting this approach remains inconclusive. Clinical corroboration of self-reported ADHD symptoms and expected associated impairments with third-party informants, past records, and an overall life course remains the best approach for establishing the adult diagnosis.

Laboratory Studies

There are insufficient data to support the use of neuropsychological tests, computerized tests of attention (CPTs), or brain imaging modalities in the diagnosis of adult ADHD. Neuropsychiatric testing can be useful in differentiating ADHD from specific learning disabilities and other cognitive impairments, particularly with a predominance of inattentive symptoms or a history of school failure. Nonetheless, neuropsychiatric testing has no demonstrated value in assessing ADHD itself. Easily administered self-report measures, such as the Behavior Rating Inventory of Executive Function (BRIEF), can provide evidence of typical ADHD-related cognitive impairments supportive of the diagnosis but fail to identify deficits in half of the cases. Research studies using electroencephalography (EEG), functional magnetic imaging (fMRI), positron emission tomography (PET), and other imaging modalities reveal distinct features in groups of adults with ADHD compared with nonclinical controls. However, these findings have poor predictive value in assigning diagnoses to individual patients, and no evidence supports their utility in clinical settings. As with children and adolescents, adult ADHD remains a clinical diagnosis derived through careful history taking, adherence to clinical criteria, and differential diagnosis of other psychopathology.

Differential Diagnosis

Clinicians should consider a diagnosis of ADHD in any adult patient complaining of pervasive difficulties with inattention, hyperactivity, or impulsivity. Several ADHD symptoms, such as problems with

sustained attention, motor restlessness, increased speech, and acting “on the go,” are common in other psychiatric disorders. Clinicians must distinguish ADHD from other psychiatric syndromes while remaining sensitive to a high probability of coexisting psychopathology.

Depressive disorders are differentiated from ADHD in that problems with concentration and motor restlessness occur only during periods of dysphoric mood, anhedonia, or increased irritability. Discrete episodes of somato-vegetative symptoms, such as appetite changes and alterations in sleep patterns, further confirm a depression diagnosis. Patients with both ADHD and depression will report ongoing difficulties with core ADHD symptoms that persist outside of discrete mood episodes. Similarly, patients with bipolar I disorder report racing thoughts, rapid speech, and impulsive behaviors only in the context of sustained periods of elevated or irritable mood. Somewhat more controversial is the overlap of ADHD with hypomania and rapidly cycling bipolar disorder. A clear past history of discrete depressive episodes or strong family history might assist in clarifying the diagnosis, but some patients will meet the criteria for both conditions. Anxiety disorders are distinguished from ADHD by subjective worry that is either generalized and difficult to control or specific to situations or stimuli. Patients with substance use disorders and ADHD should have histories of ADHD symptoms that precede the initiation of substance use. Patients with histories of early school difficulties and childhood conduct disorder are likely to be comorbid for both ADHD and substance use. Adults with ADHD and a childhood history of conduct disorder might also exhibit antisocial personality disorders.

Adults with histories of school difficulties and inattentive symptoms in the absence of hyperactivity or impulsivity should be evaluated for specific learning disabilities or other executive functioning deficits. This generally requires a battery of neurocognitive tests to measure academic aptitude and achievement. Patients with significantly idiosyncratic interests and impaired social functioning might also be diagnosed with an autism spectrum disorder.

Although considerable research has described considerable psychiatric comorbidity in adults diagnosed with ADHD, far less attention has been paid to the prevalence rates of ADHD co-occurring with other adult psychiatric disorders. Evidence suggests up to 16% of adults currently suffering from major depression, 10% with current anxiety disorders, and up to 25% with current substance use disorders meet ADHD criteria. In view of its high overall adult prevalence and associated developmental risk for comorbid psychopathology, all adult psychiatric assessments should include routine diagnostic consideration of ADHD.

A 42-year-old woman was evaluated for complaints of distractibility and general nervousness. The patient had spent the past 16 years at home caring for her children. Her youngest child recently began elementary school, and she obtained part-time work as an assistant manager in a large retail department store. She was excited about the position, particularly the flexible work hours and the opportunity to earn extra income for the family. Nonetheless, she reported particular difficulty remaining focused on her job, had general trouble organizing her time, and was in danger of losing her job due to her failure to meet several deadlines. She was tense, irritable, had trouble relaxing, and described difficulty falling asleep because she was worried about what she needed to do the next day. She complained her “mind goes completely blank” when overstressed. She denied depressed mood, loss of pleasure in her usual activities, change of appetite, or suicidal preoccupations.

The patient reported that she was considered a bright student, particularly in elementary school. She enjoyed school but was generally shy and uncomfortable in unfamiliar social situations. Beginning in middle school and throughout college, she felt increasingly bored, easily distracted, and particularly frustrated with long reading assignments. She graduated with a 3.0-grade point average and subsequently worked for 2 years as a retail clerk. She became pregnant soon after her marriage and left her job to raise her family. She described her marriage as “typical,” generally stable and satisfying, with occasional marital tension due to financial stresses and child-rearing. Her middle child, a 12-year-old boy, had been diagnosed with ADHD, which was successfully managed with stimulant therapy and behavioral techniques learned through parent training.

The patient completed an Adult ADHD Self Report Screening Scale (ASRS), which suggested the presence of a high number of symptoms. An ADHD Rating Scale 5 (ADHD-RS-V) completed by her husband reflected a similar symptom pattern. Clinical synthesis of all available information supported an ADHD

diagnosis with a retrospectively determined age of onset in middle school, a history of impairment at school, work, and home, and a comorbid diagnosis of generalized anxiety disorder.

The treating clinician outlined several options for medication therapy, specifically an initial stimulant trial with subsequent selective serotonin reuptake inhibitor (SSRI) treatment for residual anxiety versus atomoxetine (Strattera) monotherapy. The patient agreed to a medication trial with the main target symptoms of distractibility, nervousness, and sleep disturbance.

On stable medication, she reported improved focus at work, better general organization, less general anxiety, and improved sleep. She was initially followed with monthly medication visits, which were reduced to visits every 3 months once her clinician deemed her to be stable. After 6 months of medication treatment, the patient was pleased to report that she recently finished reading a novel, her first since college. She resolved her initial difficulties at work and was given a commendable employment evaluation. She was feeling less stressed at home but remained troubled by what she viewed as her inadequacies and inability to manage all her responsibilities. In response, her clinician referred her for a brief course of cognitive-behavioral therapy (CBT) to address residual anxiety symptoms and organizational skills.

COURSE AND PROGNOSIS

The prevalence of ADHD symptoms declines with age. Many children with the combined presentation of ADHD exhibit fewer hyperactive-impulsive symptoms by midadolescence and subsequently exhibit the inattentive presentation as adults. Given the age-related decline of ADHD symptoms in the general population, adults can remain significantly impaired relative to same-age peers with fewer symptoms than are required for diagnosis in childhood. This suggests that reported rates of ADHD remission are more a function of syndrome definition than true syndrome remission. Long-term outcome studies of ADHD-affected children are limited, and there are

insufficient data to draw conclusions regarding the developmental course of ADHD from early to middle adulthood. Between 25% and 45% of ADHD children do not suffer ADHD-related impairments as adults. Nonetheless, many adults with ADHD continue to struggle with the consequences of the disorder throughout their lives.

Adults with ADHD have significant rates of co-occurring psychopathology and limitations in adaptive functioning when compared with unaffected peers. They exhibit higher rates of childhood conduct disorder, with a subset of these developing antisocial personality disorders. Significantly higher rates of substance use disorders are consistently reported compared with adults without ADHD. There is no clear evidence that adults with ADHD prefer one type of recreational drug compared to another, but those who develop drug dependency have a more difficult time achieving sobriety than individuals without ADHD. Similarly, adults with ADHD initiate nicotine use at earlier ages, demonstrate higher rates of lifetime nicotine addiction, and have more difficulty maintaining smoking cessation efforts. Adults with ADHD suffer high rates of lifetime mood and anxiety disorders. The differential impact of comorbid psychopathology on long-term ADHD outcomes has not been adequately studied.

ADHD confers a significant risk for lifetime functional impairments. Lower self-esteem, poorer lifetime academic achievement, less successful work histories, and more failures in long-term relationships are evident. Adults with ADHD often make poor choices regarding personal health, including participation in high-risk activities, unprotected sex, and unsafe driving. Conversely, some of these succeed in making lifestyle adjustments that minimize evidence of impairment. Individuals find occupations for which they are well suited, can live alone or find suitable close relationships, or can utilize other talents that compensate for ADHD-related difficulties. Additional research is required to identify predictive factors that mitigate these impairments.

A 26-year-old man was evaluated for severe distractibility after being involved in a minor traffic accident. In early grade school, he had particular difficulties making careless mistakes on tests, forgetting his assignments, and sitting still in class. Although he was considered intelligent, he earned average grades, and he had no college aspirations. After high school, he had several short-term jobs in the construction industry, which were enjoyable because he spent most of his time outdoors. In the past year, he obtained part-time work as a wedding videographer and found himself increasingly interested in making and editing videos.

During his clinical interview, the patient described ongoing difficulties maintaining his attention on uninteresting tasks, easy distractibility, problems with time management, generally feeling restless, and frustration when required to sit for extended periods. He endorsed six inattentive and five hyperactive/impulsive symptoms on a DSM-5-TR ADHD checklist of current symptoms. After a clinical interview, the patient was diagnosed with the combined presentation of adult ADHD.

After discussing the nature of ADHD with his clinician and receiving additional educational materials, the man agreed to a medication trial. A once-daily extended-release preparation of stimulant medication was prescribed in escalating doses over several weeks to determine the optimal dose that maximized symptom reduction and minimized side effects. At his follow-up visit, the patient described robust improvement in his ability to focus and was surprised at his increased motivation to attend to the technical details of video editing. After several months, he enrolled in a community college to pursue formal coursework in video production.

TREATMENT

Good long-term clinical care is contingent on adequate patient education about the nature of the disorder and the effects of treatment. Once a diagnosis is made, clinicians should provide

sufficient information to assist adult patients in choosing treatment options that meet individual patient needs. Given the degree of misinformation about ADHD from the Internet and other lay sources, patients are well served when clinicians guide them to appropriate reference materials. Many individuals are relieved to understand that they have a biologically based condition that is shared by a significant number of other adults. National organizations such as Children and Adults with ADD (CHADD, www.chadd.org) or the National Alliance for the Mentally Ill (NAMI, www.nami.org) provide access to local support networks and reliable educational materials.

Pharmacotherapy remains a treatment cornerstone. Medications found to be useful in the treatment of childhood ADHD are generally shown to be effective in adults. FDA-approved medications for adult ADHD include both stimulants and nonstimulants. Of the nonstimulants, atomoxetine has the greatest amount of clinical trial evidence supporting its use in adults. Medications commonly used off-label include bupropion, immediate alpha-2-agonists, tricyclic antidepressants, and the wake-promoting agents modafinil and armodafinil. Stimulants are the most frequently prescribed ADHD medications in adults, and their greatest clinical effects are seen with robust dosing. One noteworthy difficulty for adults is the frequent necessity for multiple daily dosing, even with extended-release formulations, in order to provide adequate symptom relief throughout the day. College students, in particular, have irregular daily class schedules and might not be best served with reliance on morning-administered extended-release stimulants. Well-considered use of immediate-release compounds is necessary at times to meet the clinical needs of these patients.

Many clinicians are reluctant to prescribe stimulants based on concerns about abuse, misuse, and illicit diversion. Misuse and diversion of prescribed stimulants among college students are common. In most cases, these medications are used with the expectation of improving academic performance, although there are no data to support this outcome. Approximately 30% of stimulant misuse among college-age students is for recreational purposes, that is, to cause euphoria. Misuse for academic purposes is highest

among white male students attending academically competitive universities, who are in fraternities, are in academic distress, and with prior histories of conduct-disordered behaviors and recreational drug, alcohol, and nicotine use. Several research reports recommend using prodrug and certain extended-release stimulant formulations, deemed less likely to be used for recreational purposes compared with older immediate-release forms if the clinician is concerned about potential misuse. Nonstimulant medications remain an option in patients at high risk for stimulant abuse or misuse. Proper record keeping and thorough documentation of prescriptions written are essential to good practice. When available, clinicians can verify that patients are not obtaining inappropriate amounts of controlled substances by checking prescription records on government-sponsored databases.

As they move toward independent living outside the structure of high school and their parents' homes, transitional-age youth, that is, those ranging in age from 16 to 26 years, have particular clinical needs. During these years, individuals with ADHD have an increased risk for substance use problems, academic underperformance, occupational failures, and relationship difficulties. Treatment adherence and responsible medication use might also be of concern. In working with this age group, clinicians should be particularly mindful of providing adequate counseling regarding responsible sexual activity, alcohol consumption, recreational drug use, and appropriate medication use.

Although many adults have significant lifetime histories of other psychiatric disorders, there have been few treatment studies for comorbid ADHD. Current evidence suggests that clinicians should first initiate therapy for the condition (i.e., ADHD vs. other psychopathology) that is causing the most distress. One example is sequential pharmacotherapy with either a stimulant or SSRI for co-occurring ADHD and anxiety or depression. A particularly vexing problem is whether stimulant medications should be provided to patients with known histories of substance use disorder. It is essential that physicians maintain proper documentation of patients' diagnostic assessments and prescription medication records. Some clinicians are comfortable initiating ADHD pharmacotherapy in the presence of

intermittent alcohol or cannabis use but are advised against stimulant pharmacotherapy in those patients with chronic use or the use of other psychoactive agents such as opioids or methamphetamine.

There is growing support for certain nonmedication treatments in adult ADHD. The strongest evidence exists for CBT, which has been administered successfully both in individual and group settings. Well-controlled blinded investigations of omega-3 fatty acid supplementation have also yielded small but significant positive effects on ADHD symptoms. Other nonmedication approaches, such as ADHD coaching, mindfulness training, meditation, yoga, cognitive remediation programs, EEG neurofeedback, and the use of digital technologies such as electronic scheduling and reminder systems, remain popular, despite a lack of sufficient scientific data to support their general use. Individuals are best served when psychosocial interventions are individually tailored to their own specific difficulties. For example, patients who suffer from marital or relationship difficulties might be referred to couples therapy. The emphasis in this treatment should be on the couple's relationship problems, not the individual's ADHD. Parents might benefit from participation in a parenting course, particularly if they themselves have children with ADHD. Insight-oriented psychotherapy might be useful for some patients with significant self-esteem or interpersonal difficulties.

Proper management of adult ADHD is also likely to include appropriate educational planning and consideration of academic and occupational accommodations. Occupational counseling and vocational training can be better options for some individuals than insistence on attending a 4-year college. Adults who attend college should be referred to their school's office for students with disabilities. The Americans with Disabilities Act (ADA) has particular implications for adults with ADHD. Regulations implementing the ADA require that *reasonable* accommodations be made in areas of education and employment for individuals with documented disabilities. Colleges and universities develop their own guidelines for the provision of special accommodations based on Federal mandates. At higher-grade levels and for standardized testing at the college level and beyond, it is generally necessary to conduct formal

neuropsychological testing to document ADHD-related learning impediments prior to granting accommodations. In occupational settings, the ADA requires that reasonable accommodations be made for persons with disabilities but does not require that anyone be hired for a position who is not otherwise qualified. It is essential that thresholds for disability be determined in reference to population or societal norms and not speculations about the individual's potential capabilities. *Reasonable* accommodations should have minimal impact on employer expectations, job performance, and coworkers.

A 19-year-old woman was evaluated at a drug rehabilitation center for methamphetamine dependence. In early grade school, she was extremely hyperactive, reckless, and prone to impulsive judgments. Her father suffered from alcohol dependence and was physically abusive to her and her mother. She began smoking cigarettes at age 11 and using alcohol and marijuana at age 12. At age 13, she was raped by a high school senior whom she had been dating. Two years later, she quit high school and ran away from home. She began smoking crystal methamphetamine the previous year and was court-ordered for drug evaluation after an arrest for prostitution.

A careful history of early school experiences revealed significant problems with distractibility, completing assignments, sitting still in class, and general irritability. On a DSM checklist assessing childhood symptoms, she endorsed six inattentive and eight hyperactive/impulsive symptoms. Currently, she endorsed five inattentive and six hyperactive/impulsive symptoms, general dysphoria, fatigue, anhedonia, and suicidal preoccupation.

The patient enrolled in a long-term, court-funded residential treatment program for drugs and alcohol. After several weeks her mood symptoms diminished, but she continued to suffer from marked inattention, distractibility, and restlessness. After careful consideration, her physician initiated nonstimulant medication treatment for ADHD. At discharge from her residential program, she resolved to stay in outpatient drug treatment and obtain part-time work. At the 1-month follow-up, she described a good response to treatment and had begun studying to obtain a general equivalency diploma (GED). Her physician continued to monitor her on a monthly basis with intermittent, unannounced drug testing to monitor ongoing sobriety.

FUTURE DIRECTIONS

Ongoing advances in neuroscience are apt to increase the acknowledgment of adult ADHD as a biologic syndrome. Changes in

clinical practice increasingly reflect a shift from viewing adult ADHD as a unique and rare phenomenon to routine consideration of ADHD both alone and as potentially comorbid with other traditional adult psychopathologies. There will be ongoing interest in developing medication treatments with less perceived potential for abuse and longer durations of effects. Concurrently, there will be sustained efforts to develop effective nonmedication therapies. Although revisions made to ADHD criteria for DSM-5 and DSM-5-TR better reflect the developmental aspects of the behavioral phenotype, ongoing research will increasingly focus on the identification and modification of underlying dysregulation in brain neural networks. Such discoveries would raise the possibility of early identification of risks and treatments that target specific dysregulated systems in individual patients.

Disruptive Behavior Disorders in Children and Adolescents

Erin P. Vaughan, M.A., Eva R. Kimonis, Ph.D., M.S., and Paul J. Frick, Ph.D.

Oppositional defiant disorder (ODD) and conduct disorder (CD) are included in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders, Text Revision (DSM-5-TR) in the chapter on disruptive, impulse control, and conduct disorders. The disorders included in this chapter all involve problems with the self-control of emotions or behavior. While many disorders included in the DSM-5-TR also involve problems with emotional and/or behavioral regulation, the disorders listed in this chapter are unique in that the problems in regulation bring the individual into significant conflict with societal norms (CD) or authority figures (ODD) or violate the rights of others (CD). Importantly, the DSM-5-TR and its global public health counterpart, the International Classification of Diseases 11th Revision (ICD-11), recognize the causal heterogeneity involved in the self-control problems of individuals who meet ODD and CD diagnostic criteria. Further, many of the symptoms that define ODD and CD occur to some degree in typically developing individuals, making it important to diagnose these disorders in the context of what is normative for a person's age, gender, and culture, while also considering the degree of impairment that is associated with the symptoms of the disorder.

Considered together, ODD and CD are among the most frequent reasons for children and adolescents to be referred to psychology and psychiatry clinics. This is because these disorders cause significant disruption to those around the child and are associated with a high degree

of concurrent impairment. Children and adolescents with ODD or CD are at risk for a variety of other mental health problems (e.g., anxiety, depression, substance use), social problems (e.g., peer rejection, conflict with parents, siblings, and teachers), academic problems (e.g., school suspension and dropout), and legal problems (e.g., arrest for illegal behavior). ODD and CD also increase risk for psychiatric disorders, physical health problems (i.e., cardiovascular disease, serious injury, and sexually transmitted diseases), poor educational and occupational adjustment, and legal problems in adulthood. As a result, ODD and CD are associated with higher rates of public expenditure (e.g., mental health treatment, medical treatment, incarceration) than other psychiatric conditions that are common in children and adolescents.

OPPOSITIONAL DEFIANT DISORDER

Definition

The essential features of ODD can be grouped into three symptom clusters: angry/irritable mood, argumentative/defiant behavior, and vindictiveness. Angry and irritable mood involves frequent temper outbursts, especially when the person does not get their way, and a general pattern of being angry, resentful, and easily annoyed. Argumentative and defiant behaviors are expressed by persistent stubbornness and unwillingness to compromise, give in, or negotiate with adults or peers. Defiance may also include deliberate or persistent testing of limits, usually by ignoring requests or commands, arguing, failing to accept blame, and blaming others for misdeeds. Individuals with ODD often do not regard themselves as oppositional or defiant but justify their behavior as a response to unreasonable demands or circumstances. Symptoms generally begin early in life at home in the child's interactions with the parents, other primary caregivers, and siblings. As the disorder progresses and increases in severity, angry/irritable and argumentative/defiant symptoms generalize outside of the home toward teachers or other authority figures at school or in the community. While significant symptoms of ODD at home are predictive of current and future impairment, displaying symptoms outside the home is an important marker for the severity of the disorder.

Given that ODD symptoms can be present to some degree in typically developing individuals, they are considered indicative of a disorder when

an individual exhibits four of eight possible symptoms over the past 6 months. Behaviors also must be present outside of interactions with siblings. While the required frequency of behaviors is not explicitly stated in symptom definitions (with the exception of vindictiveness, which must occur at least twice in the past 6 months), tentative guidelines are provided to distinguish symptomatic behavior from behavior within normal limits. For younger children (below age 5 years), behaviors should occur most days of the week in order to exceed normal behavior for young children. For individuals over the age of 5 years, behaviors should occur at least once a week. However, there is a degree of flexibility in these guidelines, in order to allow for clinical judgment on what is or is not within the expected range of behaviors for a particular individual based on their developmental level, gender, and culture. Importantly, the behaviors must also be associated with significant distress or impairment within the individual, their social context, or other important areas of functioning.

Disruptive mood dysregulation disorder (DMDD) shares several symptoms in common with ODD, including angry or irritable mood and temper outbursts. In fact, most individuals who meet diagnostic criteria for DMDD also meet criteria for ODD. However, the main differences between ODD and DMDD are in the frequency and intensity of symptoms and the pervasiveness of a negative mood between temper outbursts. That is, individuals with DMDD display more intense mood outbursts and do not have periods of normal mood between angry outbursts (i.e., anger or irritability is present most of the day every day). In individuals who meet diagnostic criteria for both ODD and DMDD, only a diagnosis of DMDD is given.

While ODD includes problems with emotional regulation (e.g., irritability, anger) that increase risk for later emotional disorders, these symptoms are not included in the diagnostic criteria for CD. As a result, when criteria are met for both ODD and CD, both diagnoses can be given. However, symptoms of ODD and CD are highly correlated and are often considered to represent a single dimension of disruptive or externalizing behaviors. In fact, most children who develop CD prior to adolescence begin by showing ODD symptoms, whereas most children with ODD do not go on to develop CD.

History

ODD first emerged as a diagnosis distinct from CD in DSM-III. Previously, the Group for the Advancement of Psychiatry had suggested the concept of childhood oppositional personality in 1966, emphasizing the symptoms of disobedience and pervasive negativism. Early conceptualizations of ODD emphasized the passive-aggressive nature of the oppositional symptoms. With the introduction of DSM-III in 1980, oppositional disorder was included with explicit behavioral criteria. Subsequent editions of the DSM added a defiant label and expanded the ODD symptom list from two of five possible items (DSM-III) to five of nine possible symptoms (DSM-III-R) and finally to four of eight total symptoms (DSM-IV, DSM-IV-TR, DSM-5, and DSM-5-TR). Although DSM-5 and DSM-5-TR include the same eight ODD symptoms as in DSM-IV-TR, they are newly grouped into three categories (i.e., angry/irritable mood, argumentative/defiant behavior, and vindictiveness) on the basis of factor analytic and longitudinal research showing that these symptoms show distinct patterns of covariation and the different symptom clusters uniquely predict different comorbidities and future problems. Specifically, the angry/irritable dimension is associated with greater emotional disorders, the argumentative/defiant dimension is related to attention-deficit/hyperactivity disorder (ADHD), the vindictive symptom is related to callous-unemotional (CU) traits, and all three dimensions are highly related to CD. Thus, DSM-5-TR conceptualizes ODD as a disorder with both emotional and behavioral dimensions. DSM-5 attempted to provide a more lifespan view of all disorders and, in doing so, eliminated the chapter on disorders first evident in infancy, childhood, or adolescence in which ODD was included in previous editions of the DSM, relocating this disorder to the disruptive, impulse control, and conduct disorders chapter.

Despite ODD being included in recent editions of the DSM, spanning many decades, the disorder has been somewhat controversial for two reasons. First, the oppositional and argumentative behaviors that form the criteria for ODD are commonly displayed in normally developing children, especially at certain developmental periods, such as in the toddler and early preschool years (i.e., the terrible twos) and in adolescence. Second, ODD is frequently comorbid with a host of other disorders and, in fact, is rarely displayed without symptoms of other disorders. As a result of these two issues, there were concerns that ODD over-pathologizes a normative behavior pattern and that, unless accompanied by another disorder (e.g., ADHD, CD), the symptoms of ODD are transient and benign and should

not be considered as a separate disorder. ODD was ultimately included in the DSM-5, however, based on research showing that its symptoms did predict impairment, even when controlling for comorbid conditions, and clearer guidance was provided on how to differentiate ODD from more normative displays of these behaviors.

Comparative Nosology

The DSM-5-TR and ICD-11 include similar descriptions of ODD. While the 10th edition of the ICD included ODD as a subtype of CD, ODD is classified as a separate disorder in the ICD-11. Similar to DSM-5-TR, ICD-11 defines ODD as a persistent pattern of defiant, disobedient, provocative, or spiteful behavior that is outside the normal range expected based on an individual's age and developmental level. The behaviors must be present outside of interactions with siblings and must cause significant impairment in functioning. The primary difference between the DSM-5-TR and ICD-11 criteria for ODD is their use of specifiers. In ICD-11, ODD is classified with specifiers to designate the presence or absence of chronic irritability-anger and the presence or absence of limited prosocial emotions (LPE). The presence of chronic irritability-anger requires a pervasive angry or irritable mood in addition to frequent temper outbursts, leading the diagnosis of ODD with chronic irritability-anger to strongly resemble DSM-5-TR's diagnosis of DMDD, which is not otherwise represented in ICD-11. The presence of LPE is defined by elevated levels of callous-unemotional (CU) traits. The symptoms for this LPE specifier include a lack of empathy, lack of remorse or guilt, lack of concern over poor performance, limited expression of emotions, and relative indifference to punishment. Although the LPE specifier applies to both ODD and CD diagnoses in ICD-11, it is only used for a diagnosis of CD in DSM-5-TR, excluding the fifth symptom related to indifference to punishment.

Epidemiology

DSM-5-TR cites an average overall prevalence estimate of 3.3% for childhood ODD, which is based on a review of probability estimates from school and community samples worldwide. Interestingly, this overall rate did not differ across countries that varied in their racial and ethnic composition. These prevalence rates were based on studies with children and adolescents, and there have been few studies estimating the

prevalence of ODD in adults, although it appears much rarer in this age group. ODD is more prevalent in males than females (1.6:1) in middle childhood, but this gender ratio is narrower in preschool children and adolescents. ODD is also more prevalent among children and adolescents from families of low socioeconomic status.

Etiology

One difficulty in interpreting the research on the causes of ODD is that, while the distinction between ODD and CD is made in clinical settings, most research combines symptoms of both disorders when studying risk factors and causal mechanisms. Further, most children who develop CD prior to adolescence show ODD earlier in development and, over time, start displaying the more severe CD symptoms in addition to ODD symptoms. Thus, the causal models developed to explain the development of childhood-onset CD, which are reviewed in the following section, are also relevant for explaining the onset of ODD. A critical piece of information that is currently unknown is what factors lead some children to develop ODD but not to go on to develop CD, and what factors lead other children to progress on to develop more severe CD symptoms.

What is critical to all theories of ODD is that it is a transactional disorder involving both dispositional characteristics of the child and problems in the child's psychosocial context. That is, ODD is related to factors within the child that make them difficult to socialize. As a result, the child evokes negative responses from others in their environment, in particular caregivers and authority figures, which further increases the child's defiant and negative behavior. Consequently, most causal theories for ODD involve gene-by-environment interactions and dynamic, interactive models involving reciprocal interactions between the child and their caregivers over time.

The degree to which ODD symptoms present within typically developing individuals differs across developmental stages, and several ODD behaviors are highly prevalent in 2- to 4-year-olds and adolescents. However, in addition to considering the child's developmental stage when diagnosing ODD, it is also important to consider the developmental processes that contribute to severe and impairing levels of ODD behaviors. For example, the defiance that is somewhat normative during the third and fourth years of life, as a child develops some degree of independence from caregivers, can lead to impairing behavior if it is met

by harsh and inconsistent responses from parents. Similarly, the questioning of authority that often accompanies identity development in adolescence can lead to severe and impairing behaviors, if supported by a deviant peer group or if the adolescent is not appropriately monitored and supervised by parents or other authority figures.

Biologic Factors. Twin studies estimating the genetic and environmental contributions to oppositional defiant behavior find support for additive genetic, unique environmental, and shared environmental influences for both boys and girls. However, these studies generally find support for a genetic vulnerability to oppositional and defiant behaviors that interacts with the child's environment across development to result in the expression of ODD. This research supports the clinical observation that oppositional and disruptive behaviors frequently cluster in siblings and biologic relatives of a child with ODD.

It is likely that genetic predispositions lead to ODD through the child's temperamental characteristics. Temperament is defined as the child's characteristic style of emotional and behavioral responses in a variety of situations and to a variety of environmental stimuli. Specific temperamental styles can be observed early in life and show a modest persistence over time, often developing into personality traits later in life. A cluster of temperament dimensions described as the "difficult temperament" has been shown to be a risk factor for ODD in children across a number of racial, ethnic, and socioeconomic groups. Although many definitions exist, the difficult temperament is generally characterized by emotional hyper-reactivity (especially through frequent and high-intensity responses of negative emotion), poor behavioral control (e.g., overactivity and difficulty sustaining attention), and low adaptability to new situations. This cluster of temperamental characteristics has been shown to predict a wide range of emotional and behavioral problems, and not only ODD. Whereas a difficult temperament alone is a relatively weak predictor of ODD, it becomes increasingly predictive when combined with various psychosocial stressors.

Psychological Factors. One psychosocial factor that is consistently linked with ODD is harsh, coercive, and inconsistent parenting. However, as noted above, this risk factor is usually considered in causal models along with the child's difficult temperament. An influential theory for the development of ODD that integrates both parenting and the child's

temperament is Gerald Patterson's coercion theory. Coercion theory applies learning theory, specifically negative reinforcement, to explain how oppositional child behavior develops. A problematic behavior is negatively reinforced when it allows an individual to escape from a noxious, aversive, or unpleasant situation or task. The negative behavior of one member of a parent–child dyad serves to terminate the ongoing negative behavior of the other, thereby negatively reinforcing the first member's original negative behavior. In the case of the child with a difficult temperament who expresses high-intensity negative emotion in response to parental demands (e.g., temper tantrums), this often leads the parent to use increasingly harsh and coercive discipline to change the child's behavior. The child's improved behavior negatively reinforces the parent's use of harsh discipline techniques. However, over time, the child learns that if they increases the negative behavior (e.g., longer and more intense temper tantrums), the parent will back down on their discipline attempts. This process reinforces the child's negative behavior. Thus, the child and parent become entangled in a coercive cycle in which they each use increasingly negative behavior to change the other's behavior. Over time, the child learns that aversive behavior "works" to solve social problems and may begin to generalize their angry and oppositional interpersonal behavior outside of the home to interactions with teachers and other authority figures at school and in the community, as well as to peers.

Sociologic Factors. Ecologic variables, including parental depression and other mental health problems, family discord, family stress, and poverty, are also associated with increased risk of developing ODD. However, these factors appear to have their influence on the development of ODD through their effects on parental discipline. For example, parents living in impoverished living conditions experience a large number of stressors and daily hassles that make it difficult to engage in positive parenting and to set and enforce consistent limits on their children. Similarly, studies of the relation between maternal depression and ODD find that depression in the mother reduces maternal–child interaction quality, making the parent less involved and responsive to their child's needs. Maternal depression can also lead to increases in negative parent–child interactions, including irritability or hostility between the mother and child.

Diagnosis and Clinical Features

Diagnostic criteria for ODD are listed in Table 45–1. The diagnosis is not limited to a particular age group, but most commonly emerges between the ages of 4 and 8 years old. While studies of ODD in adults are rare, there is evidence that adults can display this disorder as well. Impairment associated with ODD largely depends on the number of settings in which behaviors are present. Problem behaviors are usually first evident at home in relationships with those most familiar to the child. In more severe cases, ODD symptoms may also occur outside of the home, such as in daycare or school settings, usually in situations where authority figures set limits or place demands on the child. Thus, it is particularly important to investigate behavior in school, with friends, and in other settings to determine the degree of ODD severity. In addition, the child with ODD often does not see their behaviors as a problem and commonly places blame on others for any problems. Thus, the clinical evaluation should include multiple reporters including both parents (where applicable) and teachers, in addition to the child. Finally, given that the behavior associated with ODD can be displayed to some degree in typically developing children and adolescents, it is important that the diagnostic process involves some method for comparing the child's level of behavior to what is normative for the child's age, gender, and culture.

Jonah is a 7-year-old boy whose mother reports that he has been difficult to control at home since he was a toddler, with his behavior worsening when his younger sister was born. In addition to impulsive and hyperactive behavior, Jonah is often defiant and argumentative with his parents. Requests to clean his room, get ready for school or for bed, or share his toys with his younger sister are met with angry refusals that escalate into temper tantrums. His mother reports that her attempts to discipline him are unsuccessful, and she displays her frustration with his defiance by shouting and making threats that are not enforced. When Jonah began preschool, these negative behaviors began to be present with his teachers and peers as well. According to his second-grade teacher, he does not follow directions in class, blames other students for his mistakes, argues with adults, and loses his temper on a weekly basis. These behaviors have resulted in several discipline notes being sent home, and he has been kicked out of two afterschool programs due to his difficulty following rules and repeated conflicts with teachers and classmates. In addition to impairment at both home and school, reports from Jonah's parents and teacher on standardized rating scales reveal that his behavior is more severe than would be expected for a boy his age (over the 95th percentile compared to age norms). His performance on cognitive and academic testing indicates abilities within the normative range, and his mother reports an unremarkable developmental and medical history.

Table 45–1.
DSM-5-TR Diagnostic Criteria for Oppositional Defiant Disorder

A. A pattern of angry/irritable mood, argumentative/defiant behavior, or vindictiveness lasting at least 6 months as evidenced by at least four symptoms from any of the following categories, and exhibited during interaction with at least one individual who is not a sibling.

Angry/Irritable Mood

1. Often loses temper.
2. Is often touchy or easily annoyed.
3. Is often angry and resentful.

Argumentative/Defiant Behavior

4. Often argues with authority figures or, for children and adolescents, with adults.
5. Often actively defies or refuses to comply with requests from authority figures or with rules.
6. Often deliberately annoys others.
7. Often blames others for his or her mistakes or misbehavior.

Vindictiveness

8. Has been spiteful or vindictive at least twice within the past 6 months.

Note: The persistence and frequency of these behaviors should be used to distinguish a behavior that is within normal limits from a behavior that is symptomatic. For children younger than 5 years, the behavior should occur on most days for a period of at least 6 months unless otherwise noted (Criterion A8). For individuals 5 years or older, the behavior should occur at least once per week for at least 6 months unless otherwise noted (Criterion A8). While these frequency criteria provide guidance on a minimum level of frequency to define symptoms, other factors should also be considered, such as whether the frequency and intensity of the behaviors are outside a range that is normative for the individual's developmental level, gender, and culture.

B. The disturbance in behavior is associated with distress in the individual or others in his or her immediate social context (e.g., family, peer group, work colleagues), or it impacts negatively on social, educational, occupational, or other important areas of functioning.

C. The behaviors do not occur exclusively during the course of a psychotic, substance use, depressive, or bipolar disorder. Also, the

criteria are not met for disruptive mood dysregulation disorder.

Specify current severity:

Mild: Symptoms are confined to only one setting (e.g., at home, at school, at work, with peers).

Moderate: Some symptoms are present in at least two settings.

Severe: Some symptoms are present in three or more settings.

Pathology and Laboratory Examination

No laboratory tests are available for the diagnosis of ODD, and assessments are based largely on clinical examination and history. Several validated rating scales are available to assess oppositional and defiant behaviors. These scales document symptom severity relative to same-age and gender peers. Rating scales may assist in treatment planning by identifying specific targets for interventions and by documenting baseline disorder severity and subsequent response to treatment. Rating scales completed by both parents and teachers can aid in determining if the child's behavior is displayed in multiple situations and settings, and with multiple people. However, the cross-situational pervasiveness of behaviors can also be assessed through the clinical interview. Rating scales to measure the degree of functional impairment caused by symptoms are also available, although this too is often assessable through clinical interviews. Finally, observing parent–child interactions in young children can not only aid in determining the severity of a child's behavior but can also document specific parent–child interactional patterns and parenting practices that serve to maintain the ODD behaviors and could be targeted in treatment.

Differential Diagnosis

Children with ODD often have comorbid diagnoses of ADHD and CD. The behaviors associated with ADHD, especially the problems with impulse control, often lead children to have problems regulating their emotions and behaviors and make them difficult to discipline consistently. The diagnosis of ODD is added to the diagnosis of ADHD when the child shows active defiance and noncompliance that cannot be solely attributed to impulsive

acts. Over time, the behaviors associated with ODD can develop into the more serious behavior problems associated with CD (e.g., aggression toward people or animals, recurrent destruction of property, covert theft, or deceit). Maintaining the diagnosis of ODD alongside a CD diagnosis may be required to capture the emotional symptoms (e.g., angry/irritable mood) that can be part of ODD but not CD. Defiant and disruptive behaviors may occur after a major stressor such as a traumatic event or the loss of a loved one. If the behavioral disturbance lasts less than 6 months, an adjustment disorder with disturbance in behavior is the more appropriate diagnosis. In individuals with intellectual disability, a diagnosis of ODD is only given if the oppositional behaviors are markedly greater than is commonly observed among individuals of a comparable cognitive level. Irritable, defiant, and oppositional behaviors can be associated with mood and anxiety. However, in most cases of children who meet criteria for ODD, the emotional distress is caused by impairments associated with the child's behavior problems (e.g., disciplinary problems at school, conflict with parents, peers, and teachers). Bipolar disorder presenting in those younger than 18 years can include defiance of authority, oppositionality, and irritability, but the behavior problems are confined to the mood episodes. Also, oppositional behaviors may be a feature of psychotic illness in children and adolescents, but ODD is not diagnosed separately if the ODD symptoms occur only during the course of a psychotic or mood disorder. Refusal to follow the directions of authority figures needs to be distinguished from disorders of hearing and language. Children with hearing loss or receptive language disorders may look oppositional on the basis of a failure to hear or understand spoken commands.

Although DSM-5-TR classifies DMDD as a depressive disorder, DMDD shares several symptoms in common with ODD, including an angry or irritable mood and temper outbursts. The key difference between DMDD and ODD is that, while the angry/irritable mood and temper outburst symptoms of ODD are only required to take place "often" (typically once a week), DMDD requires an angry or irritable mood between temper outbursts that are present most of the day, nearly every day. Temper outbursts in DMDD must also occur three or more times a week on average. Finally, DMDD symptoms must be present for at least 12 months (rather than 6 months for ODD) and in two settings (while ODD symptoms can be present in only one setting for a mild severity). Diagnosis of DMDD

must also be made between ages 6 and 18, and symptoms must have emerged before age 10, while no such age requirements are needed for ODD. Despite these differences, research suggests that most individuals with DMDD would also meet the criteria for ODD. As such, DMDD can be conceptualized as a severe variant of ODD, with the primary problems being with emotional control rather than behavioral control. Thus, if criteria for both DMDD and ODD are met in an individual, DMDD is diagnosed as the more severe condition, and ODD is not diagnosed.

Comorbid Conditions

ODD often co-occurs with other psychiatric disorders and, in fact, it is rare for a child to show ODD without other comorbid problems. The most common comorbid diagnosis with ODD is ADHD. Studies have shown that 60% to 80% of children with ODD assessed in clinics may also meet criteria for ADHD, and about 50% of children with ADHD will also meet diagnostic criteria for ODD. Approximately 15% to 20% of clinically referred children and adolescents with ODD have comorbid depression, bipolar disorder, anxiety disorders, or language disorders. Concurrent substance abuse is also more common in individuals with ODD, especially teenagers with comorbid ADHD.

Course and Prognosis

The combination of ADHD and ODD confers risk for more problematic outcomes, including progression to CD. Children with an earlier age of onset of ODD (i.e., preschool or early elementary school) are also three times more likely than those with a later age of onset (i.e., later elementary school years or beginning in adolescence) to develop CD. Approximately 30% of children with ODD will eventually develop CD. Although the diagnosis of ODD is relatively stable over time, about two-thirds of children diagnosed with ODD will no longer meet diagnostic criteria within the following 3 years. Just as ODD confers risk for the eventual development of CD, CD confers risk for the development of antisocial personality disorder (ASPD) in adulthood. Longitudinal studies have shown that about 10% of children with ODD will meet diagnostic criteria for ASPD as adults. These are usually the children with ODD that progress to CD. Children with the angry/irritable mood symptoms of ODD are also at risk for developing anxiety and mood disorders later in life. The

development of mood disorders in children with ODD often results from the many impairments associated with their behavior problems.

Treatment

Research suggests that treatment of ODD is critical, not only for reducing the impairments associated with the disorder, but also to prevent the later development of CD, ASPD, and anxiety and depressive disorders. Treatment for ODD tends to be most effective when it is implemented early in childhood (i.e., prior to age 9 years). The most successful of these interventions is parent management training (PMT), also called behavioral parent training, which is based on social learning principles. There are several variants of PMT, such as Parent Management Training Oregon Model (PMTO), Parent–Child Interaction Therapy (PCIT), Helping The Noncompliant Child (HNC), Incredible Years, And Triple P, that have been successfully utilized in clinic, home, school, and online delivery settings and implemented with families in individual and group formats. There is recent evidence to support the effectiveness of various forms of self-administered PMT as well, including interventions provided via books, video, internet, and smartphone applications.

Although many different types of PMT exist, the underlying rationale for all programs is based on the general view that child oppositional problem behaviors are inadvertently learned, developed, and sustained in the home by chronic and maladaptive parent–child interactions. The goals of PMT programs are to teach parents how to develop and implement structured contingency management programs and to use more effective discipline strategies (e.g., increase consistency with and use of a variety of approaches). Roughly half of PMT programs examined in a meta-analysis were found to also integrate a positive parent–child relationship-building component (e.g., to increase parental warmth, sensitivity, and responsiveness). Several of these programs are implemented in two phases. The first phase focuses on improving the quality of the parent–child relationship by teaching parents how to interact with their child in a positive and responsive manner, how to use positive reinforcement to encourage compliant and prosocial behavior, and how to reduce coercive parent–child interactions using selective attention. The second phase focuses on teaching parents how to give clear and effective instructions to their children and to use consistent and noncorporal punishments, such as time-out, to decrease noncompliant, attention-seeking, and other

negative behavior. In many PMT programs, therapists model the skills for the parent during treatment sessions, in addition to providing didactic instruction and discussion. Some PMT programs involve real-time coaching of the parent during interactions with the child to practice the skills taught. Most PMT programs also rely on regular home practice assignments and exercises to support learning of parenting skills.

When the child with ODD has comorbid ADHD, which, as noted previously, is quite common, ODD symptoms often respond to psychopharmacological intervention with stimulant medications. However, there is little scientific evidence to suggest that ODD responds directly to medications when it is not accompanied by ADHD.

CONDUCT DISORDER

Definition

The essential characteristic of CD is a repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are repeatedly violated beginning in childhood or adolescence. These behaviors fall into four main groupings: aggression toward people or animals, destruction of property, deceitfulness or theft, and serious rule violations. To meet criteria for a diagnosis of CD, at least 3 of 15 criterion behaviors must be present during the past 12 months, with at least one behavior present in the past 6 months (see Table 45–2). The disturbance in behavior must also cause clinically significant impairment in social, academic, or occupational functioning. However, the level of severity of CD can vary greatly, from relatively mild lying and stealing to severe aggression involving serious harm to others involving a weapon or forced sexual activity. Severity is classified as mild, moderate, or severe based on the number of symptoms and the degree of harm to others caused by the symptoms. Except for requiring that the criteria for adult ASPD are not present if the individual is aged 18 years or more, there are no exclusionary criteria. Thus, individuals with any other diagnosable disorder, such as post-traumatic stress disorder (PTSD), depression, bipolar disorder, or schizophrenia can be additionally diagnosed with CD, if their behavior over the past year meets criteria.

Table 45–2.
DSM-5-TR Diagnostic Criteria for Conduct Disorder

A. A repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated, as manifested by the presence of at least three of the following 15 criteria in the past 12 months from any of the categories below, with at least one criterion present in the past 6 months.

Aggression to People and Animals

1. Often bullies, threatens, or intimidates others.
2. Often initiates physical fights.
3. Has used a weapon that can cause serious physical harm to others (e.g., a bat, brick, broken bottle, knife, gun).
4. Has been physically cruel to people.
5. Has been physically cruel to animals.
6. Has stolen while confronting a victim (e.g., mugging, purse snatching, extortion, armed robbery).
7. Has forced someone into sexual activity.

Destruction of Property

8. Has deliberately engaged in fire setting with the intention of causing serious damage.
9. Has deliberately destroyed others' property (other than by fire setting).

Deceitfulness or Theft

10. Has broken into someone else's house, building, or car.
11. Often lies to obtain goods or favors or to avoid obligations (i.e., "cons" others).
12. Has stolen items of nontrivial value without confronting a victim (e.g., shoplifting, but without breaking and entering; forgery).

Serious Violations of Rules

13. Often stays out at night despite parental prohibitions, beginning before age 13 years.
14. Has run away from home overnight at least twice while living in the parental or parental surrogate home, or once without returning for a lengthy period.
15. Is often truant from school, beginning before age 13 years.

B. The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

C. If the individual is age 18 years or older, criteria are not met for antisocial personality disorder.

Specify whether:

Childhood-onset type: Individuals show at least one symptom characteristic of conduct disorder prior to age 10 years.

Adolescent-onset type: Individuals show no symptom characteristic of conduct disorder prior to age 10 years.

Unspecified-onset type: Criteria for a diagnosis of conduct disorder are met, but there is not enough information available to determine whether the onset of the first symptom was before or after age 10 years.

Specify if:

With limited prosocial emotions: To qualify for this specifier, an individual must have displayed at least two of the following characteristics persistently over at least 12 months and in multiple relationships and settings. These characteristics reflect the individual's typical pattern of interpersonal and emotional functioning over this period and not just occasional occurrences in some situations. Thus, to assess the criteria for the specifier, multiple information sources are necessary. In addition to the individual's self-report, it is necessary to consider reports by others who have known the individual for extended periods of time (e.g., parents, teachers, coworkers, extended family members, peers).

Lack of remorse or guilt: Does not feel bad or guilty when he or she does something wrong (exclude remorse when expressed only when caught and/or facing punishment). The individual shows a general lack of concern about the negative consequences of his or her actions. For example, the individual is not remorseful after hurting someone or does not care about the consequences of breaking rules.

Callous-lack of empathy: Disregards and is unconcerned about the feelings of others. The individual is described as cold and uncaring. The individual appears more concerned about the effects of his or her actions on himself or herself, rather than their effects on others, even when they result in substantial harm to others.

Unconcerned about performance: Does not show concern about poor/problematic performance at school, at work, or in other important activities. The individual does not put forth the effort necessary to perform well, even when expectations are clear, and typically blames others for his or her poor performance.

Shallow or deficient affect: Does not express feelings or show emotions to others, except in ways that seem shallow, insincere, or superficial (e.g., actions contradict the emotion displayed; can turn emotions "on" or "off" quickly) or when emotional expressions are used for gain (e.g., emotions displayed to manipulate or intimidate others).

Specify current severity:

Mild: Few if any conduct problems in excess of those required to make the diagnosis are present, and conduct problems cause relatively minor harm to others (e.g., lying, truancy, staying out after dark without permission, other rule breaking).

Moderate: The number of conduct problems and the effect on others are intermediate between those specified in "mild" and those in "severe" (e.g., stealing without confronting a victim, vandalism).

Severe: Many conduct problems in excess of those required to make the diagnosis are present, or conduct problems cause considerable harm to others (e.g., forced sex, physical cruelty, use of a weapon, stealing while confronting a victim, breaking and entering).

Subtypes and Specifiers of Conduct Disorder

As with all disorders in the category of disruptive, impulse control, and conduct disorders, the behaviors associated with CD can be the result of a number of different factors. In an attempt to acknowledge the heterogeneity inherent in the diagnostic criteria for CD, a number of subtypes are recognized in addition to the severity criteria. DSM-5-TR indicates subtypes for CD based on the age of onset of the symptoms and the presence of LPE. Childhood-onset type refers to the onset of at least one CD symptom prior to the age of 10 years. This distinction is based on a long history of research in both mental health and criminology, showing

that the age of onset of antisocial behavior has important clinical, etiologic, and prognostic implications. Specifically, research finds that a relatively small group of children (generally boys) with the onset of antisocial behaviors in childhood (as contrasted with onset in adolescence) are more likely to be aggressive and to continue to display problem behaviors, including criminal behavior, into adulthood. Also, compared to the later-onset group, individuals with childhood-onset CD display more neuropsychological deficits, including comorbid sustained attentional deficits, failure to inhibit impulsive responding, chronic learning failure, and academic underachievement.

The second subtype of CD recognized in the DSM-5-TR, the adolescent-onset type, defines individuals for whom all symptoms begin after 10 years of age. The adolescent-onset group typically involves more girls than the childhood-onset subtype and is likely to show aggressive and violent behavior. The adolescent-onset subtype is less likely to show aggressive and violent behavior into adulthood but, importantly, are not completely free of risk for problems as adults. Their antisocial behavior in adolescence can result in continuing problems (e.g., school dropout, substance abuse, and criminal behavior) which can influence their adult adjustment.

It is important to note that while the importance of distinguishing between early and later onset CD has strong research support, the exact age at which to define the subgroups has been debated. Research has used ages ranging from 9 to 14 to make this distinction. Some have also argued that the distinction should be based on pubertal status or made continuously (i.e., the earlier the age of onset, the more severe the CD). The DSM-5-TR also recognizes that pinpointing the age of onset in a person through historical reports can be difficult and, as a result, CD unspecified onset is used when criteria for a diagnosis of CD are satisfied, but the age of onset of the first CD symptoms cannot be reliably determined.

While the distinction between childhood-onset and adolescent-onset CD is included in most recent editions of the DSM, the DSM-5 newly added another specifier to recognize that there can be clinically and etiologically important distinctions within the onset subtypes, particularly within the more severe childhood-onset subtype (DSM-5-TR continued this with identical criteria). Thus, a CD specifier called “with limited prosocial emotions” (LPE), which is defined by the presence of significant and

pervasive levels of CU traits, was added to the DSM-5. The LPE specifier is defined by the presence of two of the following four symptoms:

- a lack of remorse or guilt,
- callousness/lack of empathy,
- lack of concern about performance in importance activities, and
- shallow or deficient affect.

At least two of these characteristics must be present in multiple relationships and settings for at least 12 months. While this LPE specifier is new to the DSM-5, many of these symptoms were included in the definition of the undersocialized subtype of CD in the DSM-III. These traits are considered the affective components of conscience in developmental research, and the affective components of psychopathy in research with antisocial adults. The basis for adding the LPE specifier to the DSM-5 came from research showing that CU traits predict more aggression and poorer outcomes, even when controlling for the number of CD symptoms and age of onset. Individuals with CD and co-occurring CU traits typically show a childhood onset to their CD symptoms, which are more severe and aggressive, lead to more harm to their victims, and involve aggression that is more likely to be premeditated (i.e., planned) and instrumental (i.e., for gain) than other youth with early-onset CD. In contrast, children with childhood-onset CD who do not show elevated CU traits tend to show aggression that is confined to reactive acts occurring in context of high emotional arousal and in response to real or perceived provocations from others. In addition, although youth with CD and elevated CU traits do respond positively to many evidence-based treatments for CD, they often begin and end treatment with more severe behavior problems.

In addition to these clinically important differences, there are a number of other differences between children with CD with and without elevated CU traits that have implications for etiologic theories. For example, the conduct problems of children with elevated CU traits tend to show stronger influences from heredity. These children also show a number of deficits in how they recognize and react to emotional stimuli, such as showing poor recognition of fearful face stimuli and less emotional reactivity to signs of fear, sadness, and distress in others. In addition, children with CD and elevated CU traits tend to show reduced responses to cues of punishment and lower fear and anxiety relative to other children

with CD. In contrast, individuals with childhood-onset CD without elevated CU traits often show elevated rates of emotional reactivity, especially to others' distress cues and provocation from others, as well as other signs of difficulty in regulating their emotions and behaviors (e.g., high rates of anger and anxiety). Thus, these two subgroups of children with CD show very different emotional and cognitive correlates that are important to consider in etiologic theories and could also be important for tailoring treatment to the individual needs of individuals with CD.

History

Descriptions of youths with conduct, delinquent, and antisocial symptoms antedate the very existence of the field of child and adolescent psychiatry. As early as 1837, Prichard used the term "moral insanity" to describe young adult patients with recurrent patterns of antisocial behavior who were not overtly psychotic. Benjamin Rush, the father of American psychiatry, described cases exhibiting "innate, preternatural moral depravity" and speculated that these patients had a defect in the "moral faculties of the mind." In the 19th century, scientific thought emphasized the inherent traits and physical defects (i.e., phrenology) that appeared to mark the antisocial individual.

Beginning in the early 20th century, a shift in thinking occurred as clinicians, social workers, pediatricians, welfare workers, and academics began to consider the impact of the environment and adverse individual or social conditions on adolescents who commit crimes. Concern over keeping the youthful offender out of jail, combined with hope that advances in the new psychoanalytic and psychodynamic therapies being introduced into America in the first two decades of the new century might undo the psychological damage that early childhood adverse experiences might cause, lead to new optimism in the treatment of young people with antisocial behaviors. This shift in thinking combined with hope for new treatments led to the beginning of the child guidance movement in the United States with the opening of the Juvenile Psychopathic Institute in Chicago in 1909, and the Judge Baker Clinic in Boston in 1917. The initial purpose of these clinics was to advise the courts on the psychology of juveniles under arrest. In 1923, Karl Menninger brought together a group of psychiatrists concerned with youthful offenders and started the American Orthopsychiatric Association. Thus, psychiatry's concerns for youths with conduct problems and antisocial behaviors have been

intimately intertwined with shaping psychiatry's own development as a medical discipline over the past 100 years.

CD was first recognized as a mental health disorder in the DSM-II published in 1968. Continuing a focus on adverse experiences, this early definition of CD in the DSM-II was conceptualized as being a reaction to negative environmental factors, and three distinct reactions were described: runaway reaction, undersocialized aggressive reaction, and group delinquent reaction. Thus, from its very first definition in classification systems for mental disorders, there has been recognition that there are multiple distinct subgroups of individuals with CD who can be differentiated by the behaviors they display and the causes leading to these behaviors.

Over the years, the basic definition of CD as behavior in which the rights of others or major age-appropriate norms are violated has not changed much, but the methods for subtyping individuals within this category have been the major source of change in the diagnostic criteria over time. The DSM-III introduced a different method for subtyping individuals with CD according to whether or not they were (a) aggressive and (b) considered "socialized" (e.g., had lasting friendships, felt guilt/remorse). Relative to the socialized subtype, individuals with the undersocialized subtype of CD showed poorer outcomes in adulthood, and several unique neurophysiologic correlates to their CD, such as low serotonin levels and autonomic irregularities. While the undersocialized subgroup was defined by some characteristics shared in common with the DSM-5-TR's LPE specifier (e.g., does not feel guilt or remorse), the undersocialized label created considerable confusion as to its core features and most suitable operationalization. Some definitions focused on the child's ability to form and maintain social relationships, whereas others focused primarily on the context (alone or with a peer group) in which antisocial acts were typically committed. Few definitions focused directly on the LPE themselves.

In an attempt to address this definitional confusion, the next revision of the DSM (i.e., the DSM-III-R) revised how CD was subtyped. The criteria for the undersocialized subtype were changed to focus solely on whether the antisocial acts were committed alone and whether the pattern included aggressive symptoms, both of which were judged to be more easily assessed than the CU features included in the original undersocialized definition. This change was accompanied by relabeling the specifier as

the solitary-aggressive subtype. The criteria for the second subtype focused solely on whether the antisocial acts were committed with other antisocial peers, and this subtype was assumed to be primarily nonaggressive in nature, leading to its renaming as the group subtype.

In the DSM-IV, these subtypes were replaced by the childhood-onset and adolescent-onset distinction that was retained in the DSM-5. The focus on onset was intended to capture the distinction between early and later onset of antisocial behavior that had been long studied in research on criminal behavior and proven to be important for predicting different outcomes. Also, given that the childhood-onset subtype was more likely to be aggressive, the distinction based on onset was viewed as adequately capturing the distinction between aggressive and nonaggressive subtypes. Since the publication of the DSM-IV, substantial research supported that CU traits could be assessed reliably in children and adolescents and their presence designated a unique group of children, primarily within the childhood-onset category. An estimated 25% to 35% of children and adolescents with childhood-onset CD show elevated CU traits. However, this minority of children with early-onset CD show a more severe, stable, and difficult-to-treat pattern of behavior, as well as distinct risk factors that have led to etiologic theories for different causal pathways leading to CD in those with and without elevated CU traits.

Comparative Nosology

The ICD-11 description of conduct-dissocial disorder strongly resembles diagnostic criteria for CD in DSM-5-TR, describing a persistent pattern of behavior that violates the basic rights of others or major age-appropriate norms, rules, or laws. While previous editions of the ICD classified CD as either CD confined to the family context, undersocialized CD, socialized CD, or ODD, ICD-11 brought its classification more in line with DSM-5. The ICD-11 definition includes specifiers based on the age of onset (childhood or adolescence) and level of prosocial emotions (limited or typical). One difference between the ICD-11 and DSM-5-TR specifier for LPE is that the ICD-11 includes a fifth symptom defined as “insensitivity to punishment.”

Epidemiology

The worldwide prevalence of CD is estimated to be 2% to 2.5%, with about 10% of individuals affected at some point during childhood or

adolescence. There is little evidence that the prevalence of CD differs by world region, and findings of differences between racial and ethnic groups are mixed and not easily teased apart from socioeconomic factors. The prevalence of CD increases from childhood to adolescence, with the median age of onset of CD in the United States being 11.6 years old. Overall, boys show higher prevalence rates of CD than girls at approximately a 2:1 male-to-female ratio. However, like ODD, the sex ratio for CD varies across development, being narrower in early childhood and adolescence than in middle childhood. This narrowing of the sex difference in adolescence is due largely to the finding that girls typically show an adolescent onset to their CD.

Etiology

The vast body of research on antisocial and aggressive behavior generally or on CD specifically has produced several clear conclusions. First, the development of CD typically results from a host of risk factors in both the child's biologic and genetic background, as well as problems in their social environment. Thus, focusing on any single risk factor or even a single class of risk (e.g., biologic risk, familial risk, neighborhood risk) will likely be inadequate to explain how the vast majority of children and adolescents develop CD. Second, research on CD has clearly documented that children can develop CD through many different causal processes, which is reflected in the multiple subtypes of CD that have been proposed, each of which is associated with at least somewhat distinct risk factors.

Table 45–3.
A Summary of Risk Factors for Conduct Disorder

General Risk Factors	Risk Factors Unique to Specific Subtypes		
	CU Traits	Childhood-Onset	Adolescent-Onset
Prenatal exposure to toxins and birth complications	Stronger genetic contribution	Stronger evidence for shared and nonshared environmental influences	Low traditionalism
Socioeconomic disadvantage	Structural and functional deficits in amygdala	Frontal lobe dysfunction	High rebelliousness
Physical and sexual abuse and neglect	Insensitivity to punishment	Low executive functioning/verbal IQ	Poor parental monitoring and supervision
Deviant peer affiliation	Low fear and anxiety	Emotional dysregulation, including anxiety	Few bonds with prosocial institutions
Parental depression and substance use	Low reactivity to cues of distress in others	High reactivity to threat and provocation	
Community and media violence	Deviant social goals	Hostile attributional bias	
	Low parental warmth	Harsh and inconsistent parenting	

While research has historically focused on simply uncovering the multitude of dispositional and environmental factors that can place an individual at risk of showing CD symptoms, more recent work is focused on developing theoretical models that can explain both multiple risk factors and the heterogeneity of causal mechanisms. Further, many of

these theories have attempted to embed this research on CD within research on normal development. That is, current theories of CD not only attempt to describe dispositional risk factors that have been empirically linked to CD, but also propose and test how these risk factors can affect important developmental processes in the child that make them more likely to display antisocial and aggressive behavior. These etiologic theories could have important treatment implications because, even if a child shows a historical risk factor that cannot be changed (e.g., prenatal exposure to toxins), if one can document what effects this exposure has had on the developing child, these effects could be the target of treatment.

This developmental psychopathology approach to explaining the causes of the various subtypes of CD, as defined in the DSM-5-TR, has led to theories specifying very different developmental mechanisms underlying adolescent-onset CD, childhood-onset CD with LPE, and childhood-onset CD without LPE. Adolescent-onset CD is viewed as an exaggeration of the normal process of identity formation, which leads to rebellious behavior as an attempt to establish autonomy and results in the rejection of traditional status hierarchies. This view explains why the CD behavior in this group does not onset until adolescence when this need for autonomy becomes more prominent, and why there is greater desistance from antisocial behavior in adulthood for individuals in this group. While most adolescents show some level of rebellious behavior, only a small minority show CD. The exaggeration of the normal process of rebellion can be due to associations with deviant peers who encourage maladaptive forms of rebellion, poor supervision by adults, a lack of connection to prosocial institutions, or simply a rebellious temperament. In contrast, childhood-onset CD is viewed as more of a characterologic disturbance because these behaviors start earlier in development and persist across multiple developmental stages. However, the different correlates to CD in children with versus without elevated CU traits suggest that the type of disturbance may differ for these groups. Children with elevated CU traits show deficits in how they process emotional stimuli that are evident very early in development, which can make it difficult for them to develop empathy, guilt, and other aspects of conscience. In contrast, children in the childhood-onset group without elevated CU traits show elevated levels of emotional reactivity and cognitive deficits (e.g., lower verbal intelligence and deficits in executive functioning) that can make it difficult for them to learn to regulate their emotions and behaviors.

Thus, this theoretical model specifies at least three common causal pathways to CD corresponding to the subtypes recognized by the DSM-5-TR, each involving different developmental mechanisms and somewhat different risk factors. This research is summarized in Table 45–3. In the subsequent sections, discussion of the various types of risk factors that have been associated with CD is organized within this framework.

Biologic Factors

HERITABLE FACTORS. Research has long shown that antisocial behavior, aggression, and conduct problems tend to cluster in families. Familial clustering can reflect shared environmental factors (i.e., factors that all siblings in a family share such as socioeconomic status), genetic factors, or the interaction between genetic vulnerability factors and adverse environmental experiences (i.e., gene-by-environment correlations and interactions). However, there is clear evidence from twin and adoption studies that there is a genetic influence on CD. Adoption studies have shown that biologic children of antisocial parents who are adopted away at birth to nonantisocial adoptive parents show elevated rates of CD. Further, twin studies have consistently shown that about 50% of the variance in CD symptoms are due to genetic influence, with the rest accounted for by shared and nonshared environmental influences. Importantly, there appears to be a different pattern of genetic influence across the subtypes of CD. Specifically, children with CD and elevated CU traits show stronger genetic influences compared to other subtypes.

Recent research has focused on gene-by-environment interactive effects in the development of CD. Several of these studies specifically investigate the gene for the enzyme monoamine oxidase type A (MAOA), which is involved in the metabolism of several central nervous system (CNS) monoamine neurotransmitters that are important in the etiology of many psychiatric disorders. Polymorphisms in the MAOA gene explained variance in the eventual development of CD for boys who experienced sexual or physical abuse. That is, abused boys with a gene variant for low MAOA activity were twice as likely to develop CD as those with a gene variant coding for high MAOA activity. In boys without an abuse history, variations in MAOA were unrelated to the eventual development of CD. This research demonstrates the importance of examining both

environmental risk factors and genetic vulnerability factors, along with their interactions, in order to understand the etiology of CD.

PHYSIOLOGIC FACTORS. CD is associated with a number of physiologic factors related to activation of the autonomic nervous system and how it responds to emotional stimuli. The different developmental pathways to CD are particularly important for interpreting this research because the subtypes of CD can have very different and even opposing patterns of physiologic arousal. Specifically, CD in children with elevated CU traits is associated with reduced physiologic arousal to various emotional stimuli, such as signs of emotional distress in others or cues to punishment. These findings have been consistent across studies using very different measures of physiologic arousal, including the child's self-report of arousal, attentional orienting to pictures of emotional stimuli, skin conductance changes in response to visual or auditory emotional stimuli, changes in startle reflex following exposure to emotional stimuli, and paradigms that measure physiologic and behavioral responses to changes in reward and punishment contingencies. These physiologic correlates to CD in those with elevated CU traits are combined with neuroendocrine and neurocognitive differences that can also reflect emotional underarousal to certain stimuli.

Importantly, not only do children with CD without elevated CU traits not show this same consistent pattern of underarousal as is seen in those with elevated CU traits, but they often show the opposite pattern of arousal by being hyper-reactive to emotional stimuli. This includes emotional reactivity to provocation, which could help to explain the reactive aggression that is often displayed by children in the low CU group. From this research, it is apparent why using the DSM-5-TR LPE specifier to designate those with CD and elevated CU traits from those without elevated CU traits is critical when studying psychophysiological correlates to CD. Since some individuals with CD show overarousal and others show underarousal, grouping them together could lead to the conclusion that arousal plays no role in the development of CD since these two opposing patterns could cancel each other out. Further, these patterns of arousal could be critical for understanding how other correlates can influence the development of CD in children from the two subtype groups. The reduced emotional arousal may make children with elevated CU traits less likely to develop empathy and guilt because they do not

become aroused to signs of distress in others and therefore are not motivated to avoid hurting others. The lack of response to punishment could also make many forms of discipline less effective for children with elevated CU traits, such that a focus on positive reinforcement becomes more important. In contrast, the overarousal in those without elevated CU traits may make them more likely to evoke reactive and hostile discipline from parents, leading to harsh and coercive interchanges between the parent and child.

NEUROENDOCRINOLOGIC FACTORS. Several studies have examined neuroendocrine risk factors associated with CD subtypes. The hypothalamic–pituitary–adrenal (HPA) axis is a major stress-regulating system in the body, whose final product is the release of cortisol, a stress hormone, into the bloodstream. Cortisol has many effects on biologic arousal systems, preparing the organism to respond to environmental threats. Research has studied basal, diurnal, and stress-reactive levels of cortisol in children and adolescents with CD, with somewhat mixed findings. These inconsistent results may be due to a failure to consider the subtypes of CD. Consistent with other biologic risk factors, there is some support for differences in emotional reactivity by CD subtype, such that those with elevated CU traits tend to show blunted cortisol activity in response to a stressor.

NEUROTRANSMITTER FACTORS. Research identifying specific neurotransmitters in relation to CD has been inconsistent, again possibly due to the failure to consistently consider differences across subtypes. However, three classes of neurotransmitters have been found to be associated with CD. First, there is some support for a relationship between lowered catecholaminergic activity (dopamine and norepinephrine) in the CNS and increased risk for aggressive behavior, ODD, and CD. Second, serotonin is a ubiquitous CNS neurotransmitter that plays an important role in stabilizing information processing in neural systems, resulting in coherent behavioral, emotional, and cognitive outputs. Disturbed serotonin neurotransmission is associated with disinhibited, aggressive, and impulsive behavior in humans, perhaps by increasing sensitivity to cues that elicit irritation and aggression and by diminishing sensitivity to stimuli that signal punishment or consequence for one’s actions. Decreased sensitivity of the serotonin 1A receptor (5-

HT_{1A}) is associated with increased impulsive aggression, whereas sensitivity of the serotonin 1B receptor gene (5-HT_{1B}) is associated with CU traits in boys. Thus, the exact nature of serotonin involvement in CD may differ depending on the subtype. Third, recent studies have found associations between methylation of specific sites on the oxytocin receptor genes and lower levels of circulating oxytocin in children with elevated CU traits. Oxytocin has been associated with a range of biologic and psychological functions, including greater attention to emotional stimuli.

NEUROANATOMIC FACTORS. Structural MRI studies of children and adolescents with CD or aggressive behavior consistently document reductions in grey matter volume across various cortical (i.e., ventrolateral, medial prefrontal, middle/superior temporal, and anterior insular cortices) and subcortical (i.e., amygdala, caudate, and putamen) regions. The most consistent abnormalities in CD are reduced cortical thickness in the ventromedial prefrontal/orbitofrontal cortex, superior temporal cortex, fusiform gyrus, precentral gyrus, and precuneus. These regions are implicated in moral and affective decision-making, face processing, motor functions, and self-referential processing, respectively. Most structural imaging studies have failed to consider the subtypes of CD. However, there is some evidence of a negative correlation between CU traits and cortical thickness in the right superior temporal cortex and lingual/fusiform gyrus, which are both involved in moral decision-making and face processing.

Functional MRI (fMRI) studies of CD have focused on emotion processing, using tasks involving viewing emotional images, facial expressions, or empathy-eliciting stimuli. These studies have reported lower activation in the dorsal and rostral anterior cingulate cortex (ACC), anterior insula, medial prefrontal cortex, ventral striatum, and amygdala in youth with CD. Reduced neural activity in the amygdala, anterior insula, and ACC have been specifically related to elevated CU traits in children with CD. These regions are implicated in fear conditioning and processing distress and pain cues in others. Few studies have directly compared CD children with and without CU traits on fMRI tasks, but those that have done so have found clear differences in brain activation, similar to those found for measures of physiologic arousal. That is, children with CD and elevated CU traits show reduced emotional reactivity in the amygdala in

response to distress cues in others, whereas those without elevated CU traits show enhanced arousal in the amygdala.

PRENATAL AND PERINATAL FACTORS. There are a number of prenatal and perinatal risk factors that have been associated with CD, largely through their influence on the CNS of the developing child. Maternal smoking, drinking, drug use, and stress during pregnancy are the most consistently documented prenatal risk factors for CD. Perinatal risk factors for CD include birth complications and malnutrition. Hypoxia during birth can disrupt white matter tracts that have been associated with CD, and malnutrition could contribute to neuronal loss that has been associated with risk for CD.

Psychological Factors

COGNITIVE FACTORS. Some of the biologic factors associated with CD could have effects on the developing child through their influence on the child's cognitive functioning. Lower intelligence, particularly verbal intelligence, and executive functioning deficits, are some of the most frequently studied cognitive correlates of CD, particularly for childhood-onset CD. These cognitive deficits could explain why some children with CD have difficulty anticipating the consequences of their behavior, as well as why CD is often linked to academic difficulties. Some children and adolescents with CD also fail to appropriately attend to and accurately encode social cues from others in the environment. For example, children with CD often attribute hostile intentions to others, even when the expressed cues are neutral and nonthreatening. Such deficits in social cognition are thought to explain the high rate of reactive aggression displayed by some children with CD.

These cognitive deficits seem to be most strongly related to children with CD who do not show CU traits, while children with elevated CU traits show a different set of cognitive deficits. Relative to other youth with CD, children, and adolescents with elevated CU traits display an insensitivity to punishment cues, which includes responding more poorly to punishment cues after a reward dominant response set is primed, responding more poorly to gradual punishment schedules, underestimating the likelihood that they will be punished for misbehavior, and being less sensitive to potential punishment when peers are present. Youth with CD and elevated CU traits are also more likely to view

aggression as an acceptable means for obtaining goals, blame others for their misbehavior, and emphasize the importance of dominance and revenge in resolving social conflicts.

FAMILY FACTORS. Various forms of parental mental health problems have been associated with CD. As noted above, because antisocial behavior tends to run in families, parents of children with CD often also show antisocial and aggressive behavior. Higher rates of parental substance use and depression are also consistently linked to CD. Some of the most common parenting styles that are associated with CD involve low levels of positive parenting (i.e., infrequent use of positive reinforcement, low parental involvement, and low parental warmth and sensitivity) and high levels of negative parenting (i.e., poor monitoring and supervision of the child, inconsistent discipline, and use of coercive and harsh physical discipline). There is evidence that the link between problematic parenting and CD is bidirectional. That is, negative parenting can lead to increases in CD over time, and CD also evokes increasingly negative and decreasingly positive parenting over time.

Relevant to the subtypes of CD, poor monitoring and supervision are particularly important for adolescent-onset CD, possibly by allowing for greater time to affiliate and be influenced by deviant peers. Harsh and inconsistent discipline appears particularly important to the development of childhood-onset CD without elevated CU traits, by leading to harsh and coercive interactions between parent and child and by not providing the child with appropriate skills to regulate their emotions and behavior. Meanwhile, in those with elevated CU traits, parental warmth appears to be particularly important for the development of CD. Warm and responsive parenting is important to the formation of a secure parent–child attachment, which is disturbed in children with elevated CU traits and is foundational to their ability to form close bonds with others and to attend to and decipher others' emotions.

Childhood physical abuse, sexual abuse, and a history of neglect are associated with an increased risk for the development of a wide variety of mental health problems, including CD. Further, childhood maltreatment could lead to different subtypes of CD through different causal mechanisms. An adolescent who did not have behavior problems as a child may rebel in maladaptive ways to escape abuse in the home, such as dropping out of school, running away from home, and stealing to

support themselves. Also, physical abuse can lead a child to develop a hostile attributional bias in which they are hypervigilant to threat cues, making them more likely to act in a hostile, angry, and aggressive manner. Finally, chronic abuse and emotional deprivation can desensitize a child to the emotions of others and lead to a CU interpersonal style.

Sociologic Factors

NEIGHBORHOOD AND CULTURAL FACTORS. A number of extrafamilial risk factors have been associated with CD, including living in neighborhoods where the child might be exposed to high rates of community violence. Other societal factors that have been linked to CD are the easy availability of firearms and high levels of exposure to media violence. Further, poverty, low socioeconomic class, unemployment, poor housing, and overcrowded living conditions have all been linked to CD. There is some indication that the effects of socioeconomic deprivation are mediated through their effects on parenting behaviors. That is, parents living in environments with multiple chronic stressors may find it more difficult to provide consistent, warm, and responsive parenting.

PEER FACTORS. A consistent finding from the research is that children with CD are rejected by their peer group. They tend to have fewer friends, are liked less by their peers, and are more likely to be excluded from activities with peers compared to typically developing children. This rejection by peers is not surprising given that children with CD are often aggressive toward others and bully other children. While children with CD are often the instigator of aggression, they are also more likely to be the victim of aggression from others.

Children with and without elevated CU traits both appear to have problems with peers. Specifically, both groups tend to be disliked by a large number of peers. Although children with elevated CU traits are better able to make friends than other children with CD, their friendships tend to be unstable and unsatisfying, and their peers are more likely to describe them as “mean.”

CD is also related to association with deviant peers. Children with CD often have friends who also have behavior problems and engage in antisocial behavior. This association with deviant peers seems to be related to all subtypes of CD. However, while deviant peer affiliation is often considered to be a primary cause of adolescent-onset CD, it is

thought to be a consequence of rejection by prosocial peers for the childhood-onset CD subtype. Children with elevated CU traits are especially likely to commit antisocial acts with peers. They are also likely to be the leaders of their antisocial peer groups and instigators of antisocial acts.

Diagnosis and Clinical Features

The DSM-5-TR diagnostic criteria for CD are provided in Table 45–2. The assessment of CD involves 3 primary goals:

- determining the presence and severity of the primary symptoms of CD, including their pervasiveness and the degree of harm they cause others;
- determining the presence of key indicators of the distinct developmental pathways to CD (i.e., the age of onset of the first CD symptom and the presence of CU traits); and
- assessing common comorbidities and key risks and maintaining factors that should be the target of treatment.

To assess the primary symptoms of CD, information should be obtained from multiple informants, including the child, their parents, and their teacher. The child's teacher appears to be particularly important for assessing conduct problems in children prior to adolescence. In contrast, self-report becomes increasingly important as the child approaches adolescence, and parents and teachers may be less aware of the adolescent's behavior. Finally, parents are often the best source of information on the timing of symptom onset. The use of standardized rating scales is recommended; these scales are often used to document the severity and pervasiveness of CD symptoms, compare the child's behavior to a normative comparison group, and identify treatment targets. The assessment of CU traits should also be conducted by collecting information from multiple sources. Particular care should be taken to determine if the indicators of CU traits are shown by the child in most situations and with most people rather than occasionally or only in certain relationships and settings. It is important for clinicians to screen for the presence of common comorbid psychiatric conditions such as ADHD, depression, bipolar disorder, substance use disorders, and learning disabilities (e.g., reading, speech, and language delays) that frequently accompany a diagnosis of CD.

Zach is a 12-year-old boy whose parents sought a psychological evaluation as a result of his continued pattern of severe behavior problems. From a very young age, he has displayed inattention, hyperactivity, and impulsivity, but his parents are more concerned about his defiance and oppositionality, which later progressed to rule-breaking and physical aggression. For example, he once locked his mother out of the house for several hours and then ran away from home overnight. In addition, he has repeatedly destroyed the toys and property of his two siblings, lied to avoid punishment for his behavior, stolen from extended family members, and threatened violence against his mother. At school, his teachers had repeatedly complained about the danger he posed to other students due to his frequent bullying, fighting, and physical cruelty to others, including an incident in fourth grade when he choked another student. Zach's parents and teachers, along with Zach himself, report that he does not feel guilty or apologize when he does something wrong or hurts someone. Instead, he blames others for his behaviors, such as stating that the classmate whom he choked "deserved" it for making a negative remark to him on the playground. He does not appear to care about the feelings of others and does not display empathy toward others. In addition, his emotions often appear shallow or inappropriate, even in distressing situations such as his grandfather passing away. Zach rarely puts forth effort in school or extracurricular activities but manages to do well on exams and earn A and B grades. At age 7, he received a diagnosis of ADHD and was placed on stimulant medication, which improved his inattention and hyperactivity. However, his oppositionality and conduct problems have only worsened since they began around age 5, and his parents do not know how to control him, given that punishment does not appear to help.

Pathology and Laboratory Examination

No laboratory tests are useful or required for making the diagnosis of CD. All individuals meeting diagnostic criteria for CD merit a complete physical examination to rule out any associated physical trauma associated with a high-risk lifestyle. Particular attention should be paid to the possibility of drug abuse and the risk of sexually transmitted diseases. In girls with CD, early-onset sexual activity may lead to the possibility of early pregnancy.

Due to the association with learning disabilities, psychoeducational testing to assess potential academic difficulties is also necessary.

Differential Diagnosis

Isolated instances of conduct problem behaviors that do not cause substantial daily impairment need to be differentiated from a consistent pattern of rule-breaking and violations of the rights of others that may constitute a disorder. Early-onset CD needs to be differentiated from ADHD, which can be marked by hyperactivity, impulsivity, risk-taking, and problems with affect regulation. CD and ODD share symptoms in common with intermittent explosive disorder (IED) that bring the individual into conflict with adults and authority figures such as teachers and parents. However, IED does not include the nonaggressive features of CD and contains no element of premeditation in order to achieve some contingent goal such as money or social dominance. ODD behaviors do not include overt aggression toward people or animals, destruction of property, or a pattern of theft and deceit. While ODD generally precedes CD in the course of development, many children with ODD do not go on to meet the criteria for CD. When diagnostic criteria are met for both ODD and CD, both diagnoses may be assigned.

Comorbid Conditions

Children and adolescents meeting diagnostic criteria for CD often meet criteria for other psychiatric diagnoses. ADHD frequently co-occurs with CD, particularly childhood-onset CD. Many youths with CD also have internalizing disorders, such as depression and anxiety. These internalizing disorders often onset after the CD, potentially as a result of the impairments caused by the behavior problems, such as conflict with others, disciplinary problems at home and school, or legal problems. Substance use disorders and learning disorders are also common among individuals with CD.

Course and Prognosis

The development and trajectory of CD depend greatly on the different developmental subtypes, and the three common patterns of development are illustrated in Figure 45–1. As noted in the figure, childhood-onset CD is typically preceded by ODD and ADHD in early childhood. For some, CU

traits will also begin to emerge in early childhood, which can lead the child to show more severe and varied aggression, which includes both reactive and instrumental forms of aggression. Other children in the childhood-onset pathway who do not have elevated CU traits begin showing more severe behavior problems later in childhood. Their behaviors are less likely to be aggressive but, when aggression does occur, it tends to be limited to reactive forms. Research suggests that between 20% and 40% of children who show childhood-onset CD will be arrested or show ASPD as an adult. In addition, about 20% of those in the childhood-onset pathway with elevated CU traits will show significant levels of adult psychopathic traits.

In contrast, individuals who follow the adolescent-onset trajectory do not start showing significant behavior problems until they approach adolescence, at which point they start showing a range of problems involving symptoms of both ODD and CD. Their behavior problems tend not to be aggressive. However, their antisocial behavior can lead them to have problems at school, leading to school dropouts, as well as problems with the law. Their association with deviant peers can also lead to problems with substance abuse, which can continue into adulthood. In adulthood, individuals in the adolescent-onset group are less likely to have legal problems or ASPD compared to those in the childhood-onset group, but they can still have social, occupational, and mental health consequences of their adolescent behavior.

FIGURE 45–1. Three common trajectories of conduct disorder are illustrated over the course of development.

Treatment

Given that most children who develop childhood-onset CD show ADHD and ODD prior to developing CD, successful treatment of these conditions can be considered secondary prevention of CD. Thus, pharmacologic treatment to treat ADHD, such as with CNS stimulants, has also been shown to reduce conduct problems in children with comorbid diagnoses of ADHD and either ODD or CD. Further, the PMT interventions that were described previously in the treatment of ODD are also effective for young children who have begun to show CD. Children with elevated CU traits have typically not responded as well to PMT and other behavioral interventions as other children with CD. Children with CD and elevated CU traits often start and end treatment with more severe behavior problems, despite showing some improvement. These findings have led to attempts to enhance PMT interventions for children with elevated CU traits by targeting their distinct risk factors and needs. These novel treatment targets include: (a) teaching parents how to increase their warm and responsive parenting, (b) emphasizing the use of consistent rewards to encourage positive behavior, including prosocial behavior, over punishment-based parenting strategies such as time-out, and (c) parent–child emotion recognition training. To date, such interventions have shown

promising results but await randomized controlled trials to better document their effectiveness.

For older children and adolescents with CD, interventions that are multi-component and can be tailored to the unique needs of the youth appear most effective. Such interventions recognize that CD is often caused and maintained by multiple factors, and the causal processes may differ across youths with CD. Further, the subtypes of CD can help to guide these comprehensive and individualized approaches to treatment. For example, interventions that focus on enhancing identity development and increasing contact with prosocial peers, such as mentoring programs or programs that provide structured after-school activities, may be effective for youth with adolescent-onset CD. In contrast, interventions that focus on anger control or on reducing harsh and ineffective parenting may be more effective for children in the childhood-onset group who do not exhibit elevated CU traits but often show problems with emotional regulation and come from families that use dysfunctional parenting practices. Finally, interventions that teach children to pay attention to emotional cues in others, motivate them to change their behavior in ways that capitalize on their self-interest using positive reinforcement over punishment, or focus on increasing parental warmth and responsivity may be more effective for children with elevated CU traits.

Several treatment models have been developed that are designed to provide this comprehensive and individualized approach to treatment. Two of these have proven to be quite effective in treating adolescents with CD in randomized controlled trials. Functional family therapy (FFT) represents a unique integration and extension of family systems and behavioral, cognitive, and affective approaches to treatment. FFT focuses on engaging the adolescent and the family in treatment, developing individualized motivations for change, and adapting its treatment to modify structural and systemic family processes that may be maintaining the youth's problem behaviors. FFT also relies upon a number of proven behavioral principles to treat CD. For example, FFT targets enhancements in communication and mutual problem-solving skills between parents and adolescents, as well as improvements in parental contingency management. Finally, FFT focuses on the generalization of new skills to other settings, such as school or the legal system.

Another comprehensive and individualized treatment model for adolescents with CD is multisystemic therapy (MST). MST was

specifically developed as a treatment to address the multiple risk factors that can lead to severe antisocial and delinquent behavior in adolescents. As its name implies, MST tries to intervene in multiple systems, familial and extrafamilial (e.g., maladaptive parenting, deviant peer or gang affiliation, poor school achievement), that can influence the adolescent's behavior. Emphasis is placed on making changes in the adolescent's social ecology that will reduce problem behavior and support these changes after treatment ends. Treatment can range substantially across individuals, depending on an initial needs assessment.

As is the case for PMT, both FFT and MST have been proven to reduce behavior problems in youth with elevated CU traits. However, also consistent with the research on PMT, children with CD and CU traits still often leave treatment with more severe behavior problems than other children with CD. Thus, future work should focus on how to enhance these and other comprehensive approaches to treatment to be more effective for the subgroup of youths with CD and CU traits.

FUTURE DIRECTIONS

There have been a number of major advances in our understanding of the causes of ODD and CD, as well as advances in the treatment of these disorders in recent years. These advances have largely been the result of the fact that research has gone beyond simply documenting the many different risk factors that can play a role in the development or maintenance of these disorders. Instead, recent research is trying to determine the most common ways in which these risk factors can negatively impact important developmental processes, leading to behavior that brings the child into conflict with authority (ODD) or to act in a way that violates the rights of others or major age-appropriate norms (CD). This work has helped to delineate several common developmental pathways to ODD and CD that are now reflected in psychiatric diagnosis.

The importance of this approach to research on causal factors is exemplified by work showing that some children with CD show under-reactive responses to emotional stimuli (i.e., those with elevated CU traits), whereas others show hyper-reactive emotional responses (i.e., those without elevated CU traits). Failure to differentiate these subtypes likely is the reason that previous research on the emotional correlates of CD has been inconsistent. It is possible that future research in molecular

genetics and neuroimaging will result in more consistent findings on the neurocognitive correlates of CD once potential differences across subtypes are consistently tested.

This research on developmental pathways to CD has also aided the development of more effective treatments for CD. Treatments no longer focus on changing a single risk factor in the same way for all children and adolescents with CD. Instead, treatments now focus on targeting multiple risk factors and are tailored to the individual needs of the youth with CD. Interventions are beginning to use research on the developmental pathways to CD to guide these tailored approaches to treatment. A promising direction of future treatment research is adapting evidence-based treatments with enhancements specifically designed to be more effective for children with elevated CU traits, a subgroup who heretofore have not responded as well to traditional treatments.

Feeding and Eating Disorders of Infancy and Early Childhood

Irene Chatoor, M.D., and Loredana Lucarelli, Psy.D.

The term *feeding and eating disorders* describes a variety of conditions including food refusal, food selectivity, eating too little, food avoidance, fear of feeding, pica, and rumination in infancy and early childhood. Particularly, the term *feeding* is commonly used to emphasize the dyadic nature of the "feeding relationship" in infants and young children that involves complex interactions between the child and the parent. During a reciprocal feeding process, optimal parent–child interactions depend on sensitive, responsive parenting as well as the child's ability to clearly communicate hunger and satiety cues. It is estimated that in the general population, 25% to 45% of infants and young children have various feeding and eating problems and that severe disorders associated with poor weight gain occur in 1% to 5% of pediatric hospital admissions and between 4% and 14% in ambulatory care. However, an exact evaluation of the prevalence or incidence rates of feeding and eating disorders, and of particular diagnostic subtypes, has not been published up to now because of the variability of definitions used and the lack of a general diagnostic classification of feeding and disorders shared by clinicians and researchers. Overall, several studies have found that early feeding and eating problems not only cause distress to the

young child but affect the whole family and often continue into later childhood and adolescence.

DEFINITION

Criteria for Feeding Disorder of Infancy or Early Childhood in DSM-IV have been criticized for being too restrictive and not capturing many young children with feeding difficulties, and an alternative system in DC: 0–3R (2005) has often been used. This system includes six subtypes of feeding behavior disorder proposed by Chatoor. Avoidant/Restrictive Food Intake Disorder (ARFID) in DSM-5 replaced Feeding Disorder of Infancy or Early Childhood in DSM-IV, and more recently, ARFID was introduced in the 11th Revision of the World Health Organization's International Classification for Diseases (ICD-11). ARFID has expanded the earlier, more limited diagnostic criteria by introducing three main categories of feeding/eating problems based on the three subtypes of Feeding Behavior Disorder in DC: 0–3R, and the text addresses the three remaining feeding disorders from DC: 0–3R. In addition, the ARFID criteria can be applied to individuals of all ages, consistent with the recognition of the continuity of psychopathology across the age range from early childhood to adulthood. ARFID is defined as a persistent disturbance in feeding or eating that can result in severe malnutrition, significant weight loss or a failure to gain weight, growth compromise, and/or a marked interference with psychosocial functioning. ARFID provides a diagnostic label for a heterogeneous group of individuals across the age range who engage in avoidant or restrictive eating behaviors without weight or body image concerns. The new criteria of ARFID in DSM-5 and its text revision (DSM-5-TR) describe three variants of an eating or feeding disturbance that is characterized by, for example, apparent lack of interest in eating or food; avoidance based on the sensory characteristics of food; concern about aversive consequences of eating. These new DSM-5 criteria of ARFID with the accompanying text map directly on three of the DC: 0–3R subtypes. The new subtype, "apparent lack of interest in food or eating," has been described in DC: 0–3R as infantile

anorexia (IA); the second variant, “avoidance based on the sensory characteristics of food,” describes children who select or avoid food in relation to the appearance, taste, texture, smell, or temperature of food and has been defined in DC: 0–3R as Sensory Food Aversions; the third variant “concern about aversive consequences of eating” is described in DC: 0–3R as Feeding Disorder Associated with Insults to the Gastrointestinal Tract and has been described by Chatoor as Post-Traumatic Feeding Disorder (2002).

In addition, in the text, there is allowance to diagnose ARFID in infants and children with the remaining three feeding disorders described in DC: 0–3R, those who have difficulty with state regulation, those who may not engage with the caretaker during feeding, or those whose feeding problems are associated with a medical condition when the disturbance of intake is beyond what can be explained by the physical condition.

To delineate feeding disorders from less severe feeding difficulties, DSM-5-TR expanded the criteria of impairment to affect one or more of four areas of health or functioning:

- Significant weight loss (or failure to achieve expected weight gain or faltering growth in children)
- Significant nutritional deficiency
- Dependence on enteral feedings or oral nutritional supplements
- Marked interference with psychosocial functioning

HISTORY AND COMPARATIVE NOSOLOGY

Prior to the inclusion of the diagnostic category of Feeding Disorder of Infancy or Early Childhood in the DSM-IV, there were no nationally defined criteria for the diagnosis of feeding disorders. In the absence of a recognized standard, different authors have used several labels for feeding problems: picky eaters, choosy eaters, selective eaters, problem eaters, food refusal, feeding resistance, food phobia, food aversion, and dysphagia. However, none of these diagnostic labels has been operationalized. The field of feeding disorders has been further complicated by the fact that feeding disorder and failure to

thrive (FTT) have been used interchangeably. The term *failure to thrive* refers to inadequate weight gain based on standard growth charts. Historically, FTT has been dichotomized along organic and nonorganic axes. Whereas the former attributes growth failure to a medically diagnosable cause, the latter has commonly been thought to reflect maternal deprivation or neglect. A third category was later added and represents a mixture of organic and environmental etiologic factors of growth failure.

Concerns have been expressed about the usefulness of the label FTT as a “catch-all” diagnosis for all feeding disorders. First, the overlap between FTT and feeding disorders is confusing because not all infants with FTT have feeding disorders, and not all infants with feeding disorders have FTT. Second, Goldbloom pointed out that the term FTT is purely descriptive and does not address the process that caused the infant to grow inadequately. Although many authors agree that FTT should be viewed as a symptom rather than a diagnosis, FTT continues to be used as a diagnostic label, particularly in the pediatric and psychological literature.

As described above, because of the limitations of the diagnostic criteria of Feeding Disorders of Infancy or Early Childhood in DSM-IV, an alternative classification of feeding disorders has been adopted by DC: 0–3R, which served as a template for the new diagnostic category of ARFID in DSM-5 and DSM-5-TR.

The original diagnostic criteria were published by Chatoor in 2002 and were modified with the help of the 2003 Task Force for Research Diagnostic Criteria for Infants and Preschool Children. They were further developed with the help of a work group that was supported by the American Psychiatric Association, and the revised criteria were published in 2007 in *Age and Gender Considerations in Psychiatric Diagnosis.* As explained above, the diagnostic criteria for these six feeding disorder subtypes were also included in the 2005 edition of the *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood: Revised Edition* (DC: 0–3R).

The six feeding disorder subtypes are as follows: (1) feeding disorder of state regulation, (2) feeding disorder of caregiver–infant

reciprocity, (3) IA, (4) sensory food aversions, (5) feeding disorder associated with a concurrent medical condition, and (6) feeding disorder associated with insults to the gastrointestinal tract. The first four feeding disorders tend to start during specific developmental periods and are arranged accordingly, whereas post-traumatic feeding disorder and feeding disorder associated with a concurrent medical condition can occur at various stages of the child's development.

Since recently published research on feeding disorders has frequently used the classification in DC: 0–3R, the authors will discuss the various feeding disorders as listed in DSM-5-TR and will use the descriptions of the feeding disorders in DC: 0–3R as subtitles.

SPECIFIC FEEDING DISORDER SUBTYPES

Avoidant/Restrictive Food Intake Disorder

Subtype: apparent lack of interest in eating or food (DSM-5-TR)
Infantile Anorexia (DC: 0–3R)

Diagnosis and Clinical Features. IA is characterized by poor appetite, lack of interest in eating, and poor growth in an otherwise active and playful child. It was first described by Chatoor in the 80s and was adopted in DC: 0–3R (2005) as one of the subtypes of Feeding Behavior Disorder. It usually begins in the first 3 years of life, most commonly between 9 and 18 months of age, when infants learn to walk, begin to talk, and are transitioned to spoon and self-feeding. The children are active and playful and appear to be interested in everything else but food and eating. They resist going into the highchair; they refuse to open their mouth to be fed and throw the food and feeding utensils. The parents become increasingly worried because of the children's poor food intake and growth, and they often resort to distracting, coaxing, and bribing to get the children to eat. Some parents become so anxious that they try to feed the children whenever they are willing to open their

mouth, and some become so desperate that they resort to force-feeding their children. Maternal worry about the child's underweight mediates and moderates the mother–child feeding interactions and perpetuates the feeding disorder. Consequently, there is increasing conflict between the children and their parents, and mealtimes become miserable for the whole family.

Differential Diagnosis. IA needs to be differentiated from other feeding disorders that are characterized by food refusal. ARFID subtype: "concern about aversive consequences," usually has a more sudden onset of the food refusal following a traumatic event to the oropharynx or gastroesophageal tract, such as choking, severe gagging, or vomiting, or the insertion of feeding or endotracheal tubes. The infant with this feeding disorder may refuse all food, only solid food, or only the bottle, depending on what mode of feeding the infant associates with the traumatic experience(s). Infants with ARFID subtype: "avoidance based on the sensory characteristics of food" or sensory food aversions (DC: 0–3R) consistently refuse specific foods but eat well if offered preferred foods.

Etiology and Course. Toddlers with IA have been found to have a higher level of physiological arousal and more difficulty down-regulating their arousal. This may explain why they have so little awareness of hunger because they seem very excited by their play and enjoy talking, but they have difficulty turning away from these pleasurable activities. Studies from different centers have found significant correlations among difficult child temperament, irregular feeding and sleeping patterns, negative and willful behaviors by the toddlers, and mother–child conflict during feeding. At the same time, mothers' insecure attachment to their parents and mothers' drive for thinness and bulimia, anxiety, and depression also correlated significantly with mother-child conflict during feeding. Finally, mother–child conflict during feeding correlated strongly with the child's weight: the more conflict between mother and child, the lower the child's weight. However, correlations need to be used with caution to explain etiology, although the feeding histories of children

with IA suggest that the lack of appetite and food refusal by the toddlers evoke severe anxiety and feelings of helplessness in the parents, who then try to engage the children in distractions and do anything to get the children to eat. The more insecure the parents feel, the more they allow the child to control the feeding situation, and the more ineffective the parents become in setting appropriate limits to the child's demanding behaviors. Consequently, parents and children become trapped in maladaptive interactional patterns.

Research further revealed that toddlers with IA, on average, performed in the normal range of cognitive development. However, the Mental Developmental Index (MDI) score of a control group of healthy eaters was 11 points higher than that of the group of toddlers with IA. Further analyses showed that not weight but mother-toddler interactions during feeding and play seemed to contribute significantly to these differences. Mother–toddler conflict and struggle for control during feeding and maternal intrusiveness during play were associated with the lower cognitive performance of the toddlers.

A longitudinal study from Italy by Lucarelli and colleagues of 58 boys and 55 girls with IA who received only minimal intervention at the time of diagnosis revealed some interesting findings. The diagnosis of IA was made by two independent clinicians, and following the publication of DSM-5, the research team clarified that the young patients originally diagnosed with IA and enrolled in this study met the criteria for the ARFID subtype "apparent lack of interest in eating or food." The mothers of the children who were diagnosed with IA were recontacted and invited to take part in a pediatric and psychological assessment at three time points at 5, 7, and 11 years of age. Mothers received some psychoeducation about this specific eating disorder at the time of the diagnosis and during subsequent assessments but did not pursue any specific psychotherapeutic treatment for various reasons: lived or moved to another city, lived in other areas of Italy without appropriate resources, refusal by one or both parents to participate in the study, or precocious termination of treatment. However, the children were followed closely by the pediatricians at the hospital in Rome and in

their community, and they were periodically called back for subsequent appointments at the hospital in Rome. About 70% of the children with IA seen at follow-ups from 2 to 11 years of age, showed ongoing eating problems and higher scores in anxiety, moodiness, aggressive behaviors, and somatic complaints when compared to the controls. These longitudinal data also showed significant correlations between continuing maternal eating and psychopathology, especially depression and anxiety, and internalizing problems of the children. At 11 years of age, the girls' emotional/behavioral problems and their mothers' psychopathology and disturbed eating attitudes were more severe than that of the boys and their mothers. These results demonstrated a significant effect of sex–namely that at the age of 11 years, especially the girls and their mothers demonstrated increased eating pathology and associated psychopathological symptoms. Further longitudinal research is necessary to better understand how these children will negotiate adolescence. It raises the question of whether these children will develop a fear of becoming fat and transition to the full picture of anorexia nervosa or other restrictive eating disorders during the critical developmental period of adolescence, which represents a peak period for the onset of eating disorders, especially in girls. Overall, this study on the natural course of IA highlights the importance of early diagnosis and specific interventions for children diagnosed with IA.

A follow-up study of 20 children at 6 months to 2 years at the time of diagnosis, who had completed a specific treatment described later, demonstrated that 17 children had changed considerably. The conflict in the parent–child relationship over the child's food intake was resolved. The children had learned to recognize hunger and increased their food intake, which led to weight gain and improved growth. However, the parents reported that many of the children continued to lose their appetite when they were excited, if they had houseguests, if they had a birthday party, or if they traveled. Once they calmed themselves, they would regain their appetite and usually make up for the lost meals. There were three children who continued to struggle with their parents over their poor eating. In two cases,

day care seemed to be too stimulating to allow these children to relax enough for eating. In the third case, the home situation was very overcrowded and disorganized.

Clinical experience suggests that older children who have been untreated and who present for the first time with the diagnosis of IA during school age are usually thin and short for their age. However, their head size and their intellectual development appear to be normal for their chronologic age. This was confirmed in a follow-up study by Chatoor and colleagues of children who were treated as toddlers for IA. It demonstrated that two-thirds of the children had outgrown their feeding disorder whereas one-third did not. Regardless of their malnutrition at the time of diagnosis or at follow-up, there was no correlation between their weight and intellectual functioning. Indeed, one-third of the children functioned in the superior range of intelligence.

To date, few studies have followed children with feeding disorders over time with the exception of the Italian study described earlier. Other longitudinal studies which focused on the development of infants/toddlers with feeding problems have not attempted to differentiate between subtypes of feeding disorders. As a result, it is not known how specific feeding disorders in early childhood are related to eating disorders in adolescence and adulthood. This will be a challenge for future research.

Treatment. This subsection describes a treatment that is based on a transactional model for the development of IA. According to this model, the infant's difficult temperament characteristics of emotional intensity, stubbornness, lack of hunger cues, irregular feeding, and sleeping patterns evoke conflicts over issues of control, autonomy, and dependency in a vulnerable parent who is anxious and insecure in regard to limit setting. The treatment addresses the infant's temperament and the parents' anxiety in regard to limit setting to facilitate internal regulation of eating of the infant.

1. The infant's temperament is discussed with the parents to help them understand that the infant's curiosity and emotional intensity

interfere with the infant's awareness of hunger. Because the infant is very strong-willed and has learned that food refusal is a powerful tool with which to control the parents' attention, efforts by the parents to distract or entertain the infant to get them to eat may help temporarily but only perpetuate the problem by getting the infant more excited.

2. The parents' source of anxiety in regard to limit setting is explored. Some parents have been sensitized by previous losses of pregnancies, by infertility problems, or by the harshness and/or emotional unavailability of their parents. Understanding the parents' sensitivity in regard to limit setting is critical to helping them to be more effective in this area with their infant.
3. After this ground work, the parents are trained with respect to changing their behavior so as to facilitate internal regulation of eating by their infant. To boost the infant's biologic rhythms of hunger and satiety, the parents are encouraged to feed the infant only at regular 3- to 4-hour intervals and not to offer anything but water in between these regular feedings. They are helped to understand that it is important to encourage the infant's self-feeding by commenting on the infant's feeding skills ("you get the spoon in your mouth all by yourself"), but they are not to comment on how much or how little the infant eats. It is helpful to give the infant only a few bites at a time and after a while change to another food to keep the infant interested in eating and engaged with the parent without the parent becoming intrusive or distracting the infant. In addition, this helps the infant to continue eating until full and to learn to regulate their food intake by their internal signals of hunger and satiety. Eating should not be a performance for the parents. There should be no distractions during feedings, and no television or games, so that the infant is kept focused on eating. If the infant engages in inappropriate behaviors during feeding (climbing out of the high chair, throwing food, or feeding utensils), the parents need to learn to use the "time-out" procedure. The time-out is used to accomplish two goals: to help the infant to stop behaviors that interfere with eating and to learn self-calming when upset because they cannot have their way.

This three-step intervention with the parents is best accomplished in double sessions, lasting 2 hours each, with the first two sessions being held within a few weeks of each other. The intensity of this brief intervention facilitates a close therapeutic alliance between the therapist and the parents and enables many parents to make major shifts in their interactions with their infants. Many of these parents need only a few follow-up sessions to deal with some specific questions that may arise. Frequently, after the infant has changed their eating pattern, the parents ask for help concerning the sleeping problems that many of these children have as well. However, there are some families who are more deeply entrenched in maladaptive interactional patterns with their infants, and some infants are so severely malnourished that more intensive interventions or hospitalization may be required. In particular, considering the associations between the severity of IA and risk factors such as high mother-child interactional conflict, difficult child temperament, and emotional and eating dysregulation in both the children and their mothers, the therapeutic approach should have a dual focus on the child and on the parents.

Rachel was 18 months old when she was referred by her pediatrician because of food refusal and malnutrition. The mother looked exhausted as she described how Rachel had never been a big eater from birth but that she stayed on the 25th percentile for weight and height on the growth chart until she was about 10 months of age. Her refusal to be fed by spoon became so strong that her intake of solid food became less and less. She depended primarily on bottles with milk for her nutrition. In spite of all of the parents' efforts to distract Rachel during feeding, to offer different foods, and to feed her whenever she would accept anything (including at night) and their desperate efforts to force food into her mouth, Rachel's food refusal had gotten worse, and she had fallen below the 5th percentile on the growth chart for weight and height. The mother admitted that trying to feed Rachel had taken over her entire life and that she felt exhausted and envious when she watched her friends' children eating without any effort on the part of the parents.

The observation of mother and infant during feeding and play revealed that Rachel was a thin little girl who seemed "all eyes," observing everything in the room, including the pictures on the wall and her image in the mirror. However, she paid little attention to the food. She ate some finger food but refused to open her mouth and arched her back when her mother tried to feed her with spoon. After a few minutes, she appeared bored sitting in the high chair, threw the food, and indicated by grunting that she wanted to be taken out of the chair. Once she had her freedom, she ran around the room entertaining herself by exploring the furniture while her mother sat in her chair looking anxious and defeated.

The treatment addressed Rachel's special temperament characteristics, her intense curiosity and emotional intensity, her strong will, and her poor awareness of hunger, which seemed to have led to her increasing food refusal. The parents were helped to understand that they had a child with special temperament characteristics that required special parenting with special

emphasis on limit setting. Specific instructions were discussed on how to handle mealtime, how to deal with Rachel's food refusal, and how to use "time-out" with a young child.

Although the mother struggled initially with how to set limits to Rachel's inappropriate behaviors—for example, stopping her from throwing food and keeping her in the high chair—the parents supported each other in implementing the new feeding instructions and were pleased with the change in Rachel's behavior. Once Rachel realized that her screaming did not change the rules, she stayed in the high chair without protest and became interested in feeding herself with the spoon. Within a few weeks, she seemed more aware of hunger, and her food intake increased accordingly. When seen for follow-up 1 year later, there was no longer conflict over Rachel's eating. Rachel had gained weight and grown in length, which brought her back to the 10th percentile on the growth chart.

In recent years, several studies have explored the effects of cyproheptadine therapy on children with feeding difficulties and poor growth. Although most children seem to tolerate the medication quite well, their appetite and food intake improves and resulting in better weight gain. The initial positive effect often wears off after a few weeks, and the medication is then given 3 weeks on and 1 week off or in shorter intervals of 4 days on and 3 days off in order to maintain the positive effect on appetite stimulation,

Avoidant/Restrictive Food Intake Disorder

Subtype: avoidance based on the sensory characteristics of food (DSM-5-TR)

Sensory Food Aversions (DC: 0–3R)

Diagnosis and Clinical Features. Sensory food aversions are common. However, whereas some children refuse to eat only a few specific foods, others may refuse most foods and take in only a

limited diet of a few foods. The diagnosis of a feeding disorder should only be made if the food selectivity results in dietary deficiencies, and/or has led to oral motor and speech delay, and/or in older children is associated with social anxiety around eating and has led to marked interference of psychosocial functioning.

Within this disorder, food refusal is related to the taste, texture, temperature, or smell of particular foods. When the infant is fed specific foods, the infant's aversive reactions range from grimacing to spitting the food out and wiping the tongue or mouth to gagging and vomiting. After an initial aversive reaction, the infants usually refuse to continue eating that specific food. In addition, infants tend to generalize and refuse to even try foods of similar color, appearance, or smell. Occasionally, sensory food aversions become apparent in the newborn period when the infant is switched from breast milk to formula or from one formula to another. However, most commonly, infants begin to show aversive reactions when introduced to baby foods with different flavors and different textures or in the second year of life, during the introduction of different table foods. After the initial aversive reactions described earlier, some infants show such intense food refusal that they become limited to eating only a small variety of foods. They may refuse to eat whole food categories, such as vegetables, fruits, or meats. In extreme cases, they even refuse to eat a preferred food if it touched a "feared" food on the plate or if the food is not prepared by a specific restaurant or company. Children who refuse to eat vegetables and fruits usually develop vitamin deficiencies, and children who refuse to drink milk or eat meats may develop protein, zinc, and/or iron deficiencies. In addition, children who refuse to eat foods that require more chewing, such as meats, hard vegetables, or fruits, present with delay in oral motor development, which may be associated with articulation difficulties.

In addition to their sensory food aversions, many of these children experience hypersensitivities in other sensory areas as well. Parents frequently report that these children do not like to get their hands "messy," become distressed when asked to walk on grass or sand, and do not like to wear socks or shoes, certain fabrics, or labels on

clothing. Many of these children are also hypersensitive to smells, and some may have difficulty with loud sounds.

Differential Diagnosis. This feeding disorder needs to be differentiated from oppositional food refusal which is common during the toddler years. Toddlers who like to exercise control over their parents may state that they do not want to eat a certain food and demand something else to eat. However, the food choices of oppositional toddlers are inconsistent and vary according to the mood of the toddler, whereas toddlers with sensory food aversions are usually consistent in their food choices, and they become distressed when the parents insist that they eat a certain food to which they are averse. Sensory food aversions also need to be differentiated from ARFID subtype: concern about aversive consequences of eating (DSM-5-TR) or described as post-traumatic feeding disorder by Chatoor, which is characterized by the child's refusal to eat all solid food or to drink from the bottle, depending on what mode of eating the child associates with the traumatic event(s). However, some children with sensory food aversions may develop a post-traumatic feeding disorder if they have a strong aversive reaction to a food resulting in gagging or vomiting, and/or the parents continue to insist that the child eat a food to which the child is averse. These children may become fearful of eating altogether.

Etiology and Course. There are no empirical studies that have examined the etiology of sensory food aversions in infants and toddlers. However, research with preschool and older children and with adults has related taste sensitivities to the bitter substance propylthiouracil, to strong food preferences, and to the number of taste buds on the individual's tongue (those with strong taste sensitivities, the "supertasters," have significantly more taste buds than "nontasters"). A study by Cooke and colleagues that examined food neophobia (the fear to try new foods, which is one of the characteristics of sensory food aversions) in a large sample of twins aged 8 to 11 years estimated that 78% was heritable and another 22% of the variance was explained by nonshared environmental

factors. Some studies have documented that parents and their biologic children can share taste sensitivities and various models of heritability—for example, incomplete penetrance, a two-locus model, and multilocus and multiallele models—have been suggested. In 2003, Kim and colleagues reported that specific polymorphisms on the taste receptor protein gene family Tas2r on chromosome 7 differentiated supertasters from nontasters.

In addition, certain aspects of the eating environment have been linked to the development of food preferences. For example, parents with strong taste sensitivities may offer a restricted range of food to their children, and limited exposure to a variety of foods may enhance toddlers' food selectivity. On the other hand, if parents try to coax children or become forceful to get their children to try new foods, the children become oppositional and increasingly anxious and scared to try new foods. This pattern of forcing children to eat certain foods without adequate support to manage their anxiety may be a risk factor in sensory food aversions outcome. In support of this, longitudinal research by Nicholls and colleagues has shown that selective eating is associated with anxiety and obsessive-compulsive symptoms, social limitations, and school difficulties.

A longitudinal study of children's food preferences by Skinner and colleagues, who followed children from 2 to 3 years to 8 years of age, found that the number of foods liked at 8 years was predicted by the number liked at 4 years of age. Children were more likely to accept newly tasted foods between 2 and 4 years of age than during school-age years. School-age children with sensory food aversions may experience social anxiety and try to avoid social activities (parties, sleepovers, summer camp) that involve eating. Parents of children with sensory food aversions often report that they were unable to eat a variety of foods as young children and that they learned to eat new foods primarily during their adolescent or young adult years when they wanted to fit in with their peers.

Treatment. Research by Birch and colleagues indicated that repeated exposures to new foods enhance young infants' acceptance not only of that food but also of similar foods. However,

toddlers required more than 10 exposures to the same new foods until acceptance was reached. In addition, it is very difficult to get toddlers to try new foods if they are reluctant to do so. Birch and colleagues demonstrated that coercive techniques, such as threatening children to have them remain seated at the table until they finished eating everything on their plate or depriving them of certain privileges unless they tried the new food, have a significant negative effect. On the other hand, toddlers are very responsive to modeling by their parents. They are more willing to try a new food if they observe their parents eating the food but not offering it to them.

No empirical studies have systematically examined how best to treat infants and young children with sensory food aversions, but clinical experience suggests that if infants or toddlers show strong aversive reactions to a new food, such as by spitting the food out or gagging or vomiting, the parents are best advised to give up on having the child eat this food. On the other hand, if the infant just grimaces, the parents may expose the infant to the new food at another time and pair a small amount of the aversive food with a preferred food. A gradual increase of the aversive food over several meals may allow the infant to get used to the new food.

Modeling eating new foods by the parents and waiting until the toddler asks to try a new food generally is more effective than putting new foods on the toddler's plate and requesting that the toddler try them. If the parents stay neutral as to whether the toddler likes the requested food, the toddler remains neutral as well and does not appear to become afraid of trying new foods. Once children fear trying new foods, their diet becomes more and more limited, and, by 3 years of age, most young children are not swayed by what their parents eat. Occasionally, preschool children may be willing to try new foods in a preschool setting, but more often they become anxious in social situations and try to avoid eating with others. On the other hand, preschool children are rich in phantasies, and feeding the baby dolls with playfood can help to explore their fears and encourage them to first feed the baby doll and then eat themselves new foods.

John was brought for an assessment by the multidisciplinary feeding disorders team because he refused to eat vegetables, fruits, and meats. His parents had started to give him a multivitamin daily, but they were worried that he was missing other essential nutrients in his limited diet, and they were concerned that his articulation was so poor that nobody outside of the family could understand what he was saying. At the age of 2½ years, his daily diet consisted of Cheerios or pancakes in the morning and peanut butter sandwiches, some cheese (which had to be “American”), pasta, cake, crackers, ice cream, and milk during the rest of the day. His feeding problems started when he was introduced to baby food. He accepted baby food sweetened with fruit but grimaced when given baby food with vegetables and spat it out. He gagged when introduced to baby food with lumps of meat, and he refused to accept any baby food after that. At 9 months of age, John was offered soft table foods, which he ate only if he could finger-feed himself. He had another episode of gagging when introduced to green beans at 15 months of age, and consequently, he refused to touch any green vegetables and fruits. He never tried any meats, and he became very distressed when his parents put any food on his plate that he did not want. When his parents insisted that he should at least try one bite of a new food before he could leave the table, John cried throughout the whole meal and ate nothing, not even his preferred foods. The parents had strong disagreements about how to handle John’s food refusal. The father had similar food dislikes as a child and wanted to leave him alone. The mother was very concerned about John’s health because of his limited diet, and she tried everything—bribing, coaxing, distracting, and threatening—just to get John to try new foods. Both parents experienced mealtime as very stressful and felt that John was getting increasingly rigid about his food likes and dislikes.

The observation of feeding revealed intense conflict between John and his mother regarding the various foods that he refused to eat. The nutritional assessment showed that although John

was taking in adequate calories, he was not getting enough zinc and iron from his diet and, without the multivitamin, his diet was deficient in vitamins. The oral motor assessment revealed that John used an immature chewing pattern that was felt to be due to his lack of practice with chewing crunchy and chewy foods. This oral motor delay was felt to account for his articulation problems.

The parents were instructed to obtain vitamins complete with zinc and iron to compensate for the nutrients missing in John's diet. They were also offered speech therapy for John to help with his articulation problems. In addition, the parents were given a few parent training sessions to help them emotionally neutralize mealtime. After the mother's anxiety about John's health was alleviated, she was able to offer John his preferred foods without attempting to get him to eat new foods. The parents were instructed to eat their regular diet in front of John without offering him any of their food and to give him only a small piece of their food if he were to ask for it. They were not to praise him if he liked the food nor become disappointed if he no longer wanted to have it. After she had stopped offering John any new food for about 2 months, John surprised his mother by asking her to have some of her peach. He liked it and asked for more on another day. Gradually, he began to eat soft fruits without the peel, and after several months, he tried chicken nuggets. His diet increased in variety very slowly, and when he entered preschool, he tried a number of foods at school that he had not touched at home. His diet became more complete. However, John was not able to eat the variety of foods the rest of his family enjoyed.

Avoidant/Restrictive Food Intake Disorder

Subtype: concern about aversive consequences of eating (DSM-5-TR)

Feeding Disorder Associated with Insults to the Gastrointestinal Tract (DC: 0–3R)

Post-Traumatic Feeding Disorder (Chatoor et al., 1988)

Clinical Features. This feeding disorder may present with total food refusal, refusal to swallow solid food, or refusal to drink from the bottle, depending on what mode of feeding the child associates with the traumatic event. The onset of the food refusal is frequently rather sudden and follows traumatic experiences that involve the oropharynx or gastrointestinal tract, such as severe gagging, choking, vomiting, insertion of feeding or endotracheal tubes, or force-feeding. It is estimated that post-traumatic feeding disorder may affect 4% of infants with gastroesophageal reflux who do not have a history of esophageal surgery and up to 40% of children who undergo esophageal surgery. Frequently, the parents are not aware that the event was so frightening to the child that it triggered the food refusal because other children who may undergo the same experience will not necessarily develop a post-traumatic feeding disorder. It appears that children who develop a post-traumatic feeding disorder are more prone to anxiety and/or are more sensitive to pain than the average child. Older children who refused to eat solid food after an incident of gagging or choking reported that they were afraid that the food would get stuck in their throat and choke them to death. Infants and young children express this fear through their behavior by crying in anticipation of being fed or when seeing the high chair, the bottle, or the spoon. Some infants or children are brave enough to put the food in their mouths but cannot bring themselves to swallow it. They keep the food in their cheeks and/or spit it out. In severe cases, the infants refuse to feed altogether. These infants are in acute danger of dehydration because the fear of eating appears to override any awareness of hunger or thirst.

Often the food refusal of these children is so intense that the parents react with severe anxiety to their child's food refusal. They worry about their child's nutrition. Frequently, they try to coax and distract the child, they offer various types of food, and they try to feed the child day and night without success. However, some very young infants who are afraid to drink from the bottle when they are awake may drink when they are asleep and not aware of what they

are doing. However, if they wake up and see the bottle, they usually push it away and cry. In general, the food refusal of these infants poses an acute threat to their health, and they require acute intervention.

Differential Diagnosis. This feeding disorder needs to be differentiated from IA and from food refusal because of sensory food aversions. IA is characterized by an inconsistent pattern of food refusal, depending on the mood of the child. Anorectic children are not afraid to eat and can eat all types of food if they want to eat. Sensory food aversions usually involve foods with a certain taste, texture, temperature, and/or smell. Usually, the food refusal is more selective and not as global as seen in a post-traumatic feeding disorder. However, sometimes children with sensory food aversions develop a post-traumatic feeding disorder if they experience a strong aversive reaction or if they are force-fed aversive foods that trigger gagging and vomiting.

Etiology and Course. The observation of infants with a post-traumatic feeding disorder reveals that their food refusal seems to be caused by fear. However, no empirical studies have been done to explain why only some infants with distressing experiences with the oropharynx react with a post-traumatic feeding disorder. There are also no systematic longitudinal data on the course of this feeding disorder. However, individual case studies indicate that many infants and children get locked into their fears of eating. Some drink milk from the bottle and eat only pureed food until they reach school age, when the social embarrassment of their eating behavior causes the parents to seek help. In extreme cases, when the infants refuse all food, gastrostomy feedings have to be implemented. To survive, some of these children may depend on gastrostomy feedings for years.

A recent study by Lucarelli and colleagues showed that children with a post-traumatic feeding disorder scored in the clinical range of the aggressive behavior on the Child Behavior Checklist, which is mainly characterized by angry moods, temper tantrums,

stubbornness, child screams a lot, easily frustrated, and wants a lot of attention. Taking into account the history of traumatic feeding experiences, the emotional dysregulation in these children may further contribute to their ongoing feeding problems. Moreover, this study found that their mothers had significantly higher scores in anxiety symptoms, and some of them received a diagnosis of anxiety disorder. These data suggest reciprocal influences between the dysregulation in emotional functioning of these children and the anxiety symptoms of their mothers. Actually, maternal anxiety may compromise their parenting capacity to moderate the impact of the child's traumatic experience and consequent emotional dysregulation.

Treatment. Because of the complexity of many of these cases, particularly those that result from trauma inflicted by unavoidable medical procedures (e.g., intubation, suctioning), a multidisciplinary team consisting of a pediatrician or gastroenterologist, nutritionist, occupational therapist, and a psychiatrist or psychologist is best equipped to meet the needs of these infants. In cases of total food refusal, the infant is in acute medical danger of dehydration and malnutrition, and intravenous fluids need to be given. It is important to assess whether the infant might be coaxed into accepting any form of food or whether nasogastric tube feedings need to be instituted. Unfortunately, the insertion of feeding tubes can intensify the fear of feeding, and, if this is the case, the infant is better served by a gastrostomy tube. In any case, the infant's nutritional requirements need to be addressed prior to the implementation of the psychiatric treatment.

The psychiatric treatment of patients who exhibit total or partial food refusal centers on the desensitization of the infant to the fear of eating. Outpatient treatment can only be carried out if the infant accepts bottle feedings or receives adequate nutrition through a nasogastric or gastrostomy tube. It is best if the child is given the tube feedings at night and during the day there are scheduled oral feedings at 3- to 4-hour intervals with no feedings in between. If the child feeds from the bottle, the bottle feedings should follow the oral

feedings in the high chair, and there should be no bottle feedings at other times, to make the child hungry at mealtimes. Behavioral techniques of positive reinforcement, praise and social interactions of food acceptance, and preferred toys or favorite videos for distraction are instituted in the initial management to overcome the child's fear of eating. Encouragement of self-feeding is frequently helpful for these infants to gain mastery over the anticipatory anxiety of eating. When the infant begins to accept food from the spoon, it is important to proceed slowly when advancing the texture of food to avoid any incident of gagging that may set back the infant. The behavioral manipulation of the infant's eating frequently leads to external regulation of eating in response to the reinforcers. Once the infant has overcome the fear of eating, it is important to phase out the external reinforcers and to encourage eating according to internal signals of hunger and satiety. The same principles described with regard to facilitating internal regulation of eating in children with IA should also be applied in this final stage of the treatment.

Inpatient treatment becomes necessary if the child is unable to overcome the fear of eating and remains dependent on bottle or tube feedings. Inpatient treatment involves two major components: appetite manipulation and contingency management. For children who have feeding tubes, manipulating calories and ensuring hydration through water or Pedialyte are used to allow the child to become hungry. Positive and negative reinforcements for food acceptance and food refusal are the behavioral interventions most commonly used. However, these techniques need to be adjusted to the individual child and require a skilled team to help the child to overcome the resistance to feeding and to learn to eat in response to hunger and fullness. Counseling and psychological intervention for parents are necessary to help them cope with the child's traumatic and stressful experiences and support their parenting capacities during the interventions for their child.

Robert was 7 months old when he was referred by a gastroenterologist for an urgent psychiatric evaluation because of severe crying when offered the bottle and refusal to drink unless he was almost fully asleep and seemed unaware of his feeding. The mother reported that Robert was an 8-lb, full-term baby who had a vigorous suck and was feeding well from birth. However, after a few weeks he started to spit up during and after feedings, and by 3 months he developed projectile vomiting. In spite of the vomiting, he gained weight until he was about 4 months of age when he was referred to a gastroenterologist and diagnosed with gastroesophageal reflux. Several medications were tried, but the vomiting continued, and by 6 months of age Robert started to arch himself during feedings as if he were in pain. He would cry and refuse to continue with the feeding. Soon afterward, the mother noticed that he would start to cry at the sight of the bottle, and he refused to accept the bottle totally, as long as he was awake. To stave off starvation, the mother relied on feeding him during the night when he was asleep. His food intake greatly diminished, and he started to lose weight. The mother tried to introduce solid food, but Robert seemed to have difficulty moving the food back to his throat and spat most of it out. At the time Robert was referred, his mother was exhausted and frightened because of Robert's continued weight loss. A recent examination by the gastroenterologist had shown that the reflux was markedly improved and that Robert's ongoing feeding difficulties could not be explained by his medical condition.

The observation of mother and infant during feeding revealed that Robert became distressed the moment his mother positioned him for feeding, and he started to cry and arch himself as soon as he saw the bottle. His mother put the bottle away and tried to comfort him, but it took more than 10 minutes until he could settle in her arms. When the mother got the bottle and tried to feed him again, he cried even louder and would not be calmed until the bottle was out of his sight. Because it was obvious that Robert was too frightened to feed from the bottle, the mother

tried to feed him in his infant seat with the spoon, but he batted the spoon away and did not want to have anything put in his mouth.

As the first step of treatment, the parents were made aware that infants as young as Robert can make associations between pain, vomiting, or other distress and feeding and consequently become frightened of feedings. The parents were instructed to get Robert on a schedule of regular naps and to feed him from the bottle only when he appeared almost asleep to prevent any further activation of his fears while looking at the bottle. After a successful attempt at the hospital to feed Robert in the high chair with a spoon in his hand and lots of encouragement to put it in his mouth, the mother was able to use another spoon and put some food in Robert's mouth. Consequently, she was encouraged not to focus on the amount of food she was able to get into him, but to look at the feedings as practicing sessions to help Robert overcome his fear of feeding and to develop oral motor skills that would allow him to handle solid food.

In the first 2 weeks, Robert would cry and refuse to continue feeding if he woke up and saw the bottle. However, gradually he seemed to realize that it was safe to drink from the bottle. The mother reported that after 4 weeks, she could even start bottle-feeding when Robert was still awake. Robert also progressed quickly from accepting very little food from the tip of the spoon to eating several spoonfuls. After 3 weeks, Robert was finishing a whole baby jar at one meal. When Robert was 9 months old, the mother called to report that Robert was feeding better and starting to gain weight. At 10 months of age, Robert was taking the bottle when awake, and he had learned to use the spoon and feed himself.

Avoidant/Restrictive Food Intake Disorder (DSM-5-TR)

Subtype: Very young infants may present as being too sleepy, distressed, or agitated to feed

Feeding Disorder of State Regulation (DC: 0–3R)

Clinical Features. This feeding disorder begins in the postnatal period and is characterized by irregular, poor feedings and inadequate food intake by the infant. Infants with this feeding disorder exhibit difficulties in state regulation, which interfere with their ability to feed effectively. They have difficulty reaching and maintaining a state of calm alertness necessary for feeding. Some are too irritable and cry excessively and cannot calm themselves for feeding. Others are too sleepy and cannot wake up or stay awake long enough to feed adequately. The parent may be anxious or depressed or may present with more severe psychopathology. Mother-infant interactions during feeding are characterized by irritability and/or sleepiness of the infant, maternal tension, and poor engagement between mother and infant.

Feeding disorder of state regulation can be seen in infants without any organic problems, but it is frequently associated with prematurity or dysmaturity and gastrointestinal, cardiac, or pulmonary disease.

Differential Diagnosis. This feeding disorder needs to be differentiated from pure organic disorders that can interfere with the regulation of the state of the infant. As described earlier, organic problems can trigger the feeding disorder and should always be addressed first. The diagnosis of feeding disorder of state regulation should be considered if treatment of the organic problem—for example, cardiac or pulmonary disease—cannot resolve the infant's difficulty in state regulation.

Etiology and Course. There are no empirical studies that have explained why some infants have more difficulty in regulation of state than others. However, the foundation for the regulation of feedings, which is so closely linked to the regulation of state, is further developed in the first months of life. Infants with feeding problems during the early months trigger anxiety in their mothers and frequently continue to have difficulty in self-regulation of their food intake during the transition to self-feeding in the second year of life.

In a longitudinal study from Sweden, 70% of infants with feeding difficulties and food refusal in the first year of life were observed to have eating problems during childhood.

Treatment. Treatment needs to be individualized and can be directed toward the infant, toward the mother, and toward the mother-infant interaction. If the infant is too sleepy to feed and difficult to arouse, gentle infant massage to stimulate the baby may help to improve the infant's alertness and facilitate better feeding. If the infant is too irritable and fidgety to feed, reducing stimulation before and during feedings by taking the child to the quietest room in the house and swaddling the baby during feedings may help to settle the infant and facilitate better feedings. However, if the infant tires easily and is unable to take in adequate calories to grow in spite of all efforts to improve the feedings, nasogastric tube feedings may have to be considered to supplement oral feedings. On the other hand, if the mother is exhausted, overly anxious, or depressed, her difficulties have to be addressed to enable her to be more effective with her infant.

Videotaping the feedings and observing the tape together with the mother is frequently helpful to heighten the mother's awareness of the infant's cues and to explore alternative methods that she can use to facilitate the infant's regulation of state and ability to feed.

Thomas was 3 months old when he was referred for a psychiatric evaluation because of his feeding difficulties and poor weight gain since birth. His parents were college educated, and both had pursued their professional careers until Thomas was born. Although Thomas was full-term and weighed 7 lb at birth, he had difficulty drinking from the breast. When he was 4 weeks old, his mother reluctantly switched him to bottle feedings because he was losing weight. Although his intake improved somewhat on bottle feedings, he gained weight very slowly and was still less than 8 lb at 3 months of age. His mother appeared tired and described how Thomas would drink only 1, 2, or 3 oz at a time, wiggle and cry, and refuse to continue with the feeding. After a few hours, however, he might cry again as if he were hungry. However, she could not settle him to feed, and he would continue to cry inconsolably. The mother described that she would attempt to feed him on an average of 10 to 15 times in a 24-hour period, that Thomas would cry a lot during the day and at night, and that everybody in the family was getting very little sleep.

The observation of mother–infant interactions during feeding and play revealed that Thomas was a very alert and wiggly baby who had difficulty settling in his mother's arms. While drinking from the bottle he would kick his feet and move around with his arms, and soon the nipple of the bottle would slip out of his mouth. This upset him, and he started crying. His mother appeared anxious and tried to restart him by changing his position in various ways, but this only agitated him more. After repeated unsuccessful attempts to continue the feeding, mother and baby appeared exhausted, and the mother gave up.

The assessment revealed that Thomas was a very active and excitable baby who had difficulty keeping calm during feedings. After reviewing the videotape with the mother, the therapist explored ways in which the mother could better facilitate calming during feedings. Using a quiet corner in the house, swaddling Thomas in a blanket, and singing to him before starting the feeding were the most useful suggestions. Thomas stayed calm

during feedings, was able to drink larger amounts of milk, and waited longer between feedings. This, in turn, relieved the mother's anxiety and helped both to have calmer interactions.

Avoidant/Restrictive Food Intake Disorder (DSM-5-TR)

Subtype: Infants and young children may not engage with the primary caregiver during feeding.

Feeding Disorder of Caregiver–Infant Reciprocity (DC: 0–3R)

Clinical Features. This feeding disorder is characterized by a lack of engagement between mother and infant, leading to inadequate food intake and growth failure of the infant. The onset of growth failure is usually between 2 and 8 months of age. The infant shows a lack of age-appropriate social responsivity—for example, lack of smiling response, lack of vocal reciprocity, lack of anticipatory reaching out when about to be picked up, and lack of molding and cuddling when held. The mother frequently presents with acute or chronic depression, drug or alcohol abuse, and/or high psychosocial stress, which appear to interfere with her care of the infant. Mother–infant interactions are characterized by a lack of mutual engagement and a lack of pleasure in their relationship. The mother frequently appears detached and noncontingent in her responses to the infant's cues.

Differential Diagnosis. This feeding disorder needs to be differentiated from organic conditions that lead to a lack of weight gain and weakness in the infant. However, the mother and infant usually show better mutual engagement and the infant responds more readily to the examiner.

Etiology and Course. This feeding disorder has been referred to in the literature as "maternal deprivation" or "deprivation syndrome." It has been postulated that lack of emotional nurture and infrequent feedings lead to growth failure and developmental delays in these

infants. Characteristically, infants with this feeding disorder become engaged and gain weight when admitted to the hospital and are in the care of a nurturing nurse.

This feeding disorder has also been referred to as “nonorganic failure to thrive,” and in the DSM-III, this disorder was defined as “Reactive Attachment Disorder of Infancy” associated with FTT. However, in the DSM-IV, the same diagnosis was changed to encompass only problems in relatedness without growth failure. However, several studies of infants with the diagnosis of “nonorganic failure to thrive” have demonstrated very high rates of insecure attachment, ranging from 50% to 90% of the infants studied. However, not all infants with insecure attachment are failing to thrive. It appears that only a severe degree of a disturbance in the attachment process of the infant to the caretaker, or what some authors describe as “nonattachment,” results in the severe disturbances in relatedness and growth failure seen in infants with this feeding disorder.

Children with a feeding disorder of caregiver–infant reciprocity are at high risk for delayed cognitive and disturbed emotional development. When such children are followed up to school age, deficits in cognitive performance, behavioral organization, ego control, and ego resiliency and behavioral symptoms have been reported.

Treatment. Depending on the severity of the growth deficiency and the evidence of neglect, various interventions have been suggested. In cases of no evidence of deprivational behavior on the part of the mother, or if the parents have sought medical care in the past and have some support in the extended family or the community, an outpatient approach may be safe. However, if the growth deficiency is more severe, if there is serious hygiene neglect, if the mother is abusing drugs or alcohol, or if the mother lives a chaotic lifestyle, immediate hospitalization is indicated. During hospitalization, it is critical to assign a warm and nurturing nurse to engage the infant during feedings. While the nutritional, emotional, and developmental rehabilitation of the infant takes place, a more in-

depth evaluation of the mother and the mother–infant relationship needs to be addressed as well.

Many of the mothers have experienced unsatisfactory relationships with their caretakers when they were growing up, and consequently, they are distrustful and avoidant of professionals. It is important to identify any positive behavior the infant shows toward the mother to see whether the mother has any potential to engage in a mutually satisfying relationship with her infant. In addition, the mother's support system and her ability to become engaged with a therapist need to be explored prior to returning the infant to her care. In some situations of severe neglect and associated abuse, Protective Services need to be involved, and the infant has to be placed in foster care.

Discharge from the hospital is a critical time when all services need to be in place to ensure the follow-through of the treatment plan. The treatment plan should be individualized and may range from home visits by a health care professional to daycare for the infant, to mother-infant psychotherapy, and to family therapy for the parents.

Anna was 8 months old when she was admitted to the hospital through the emergency room because of a respiratory tract infection and severe “failure to thrive.” After she had recovered from the infection and a medical workup for her malnutrition was found to be negative, a psychiatric consultation was requested. After repeated unsuccessful attempts, the psychiatrist finally reached the parents and set up an appointment to obtain more history and to observe the mother and infant during feeding. The parents explained that the father had difficulty obtaining time off from his construction job and that the mother did not have any means of transportation to the hospital. The couple was not married because the father had not gotten his divorce from his first wife, but they lived together with Anna in one room in a house that they shared with nine other members of the father’s extended family.

The mother, who became pregnant with Anna during her last year in high school, described Anna as a quiet baby and denied any feeding problems. However, when the mother temporarily left the room, the father turned to the therapist and complained that the mother did not give enough attention to Anna and that she would talk on the phone or read from a magazine while feeding the baby.

The observation of the mother and infant during feeding revealed that the mother looked sad and preoccupied while she held the baby loosely on her lap. The infant lay in a “surrender position” with her arms raised beside her head, and she looked away while drinking from the bottle. However, when she looked at her mother, the mother looked away as if she could not stand to have eye contact with her infant.

Further evaluation of the mother revealed that she felt very lonely and depressed. She was unable to finish high school because of the pregnancy with Anna. Her family had abandoned her for becoming involved with a married man. She described the father’s family as hostile toward her. The baby’s father worked long hours and was hardly around. The telephone calls the

mother made to her girlfriends from high school were the only relief in her unhappy life.

During the hospitalization, Anna gained weight, became more engaged, and rewarded her favorite nurse with frequent smiles. After the social worker had arranged for transportation for the mother, she came regularly for her appointments with the social worker and spent more time with Anna. While nurturing the mother and trying to help her work on her situation with her family and the father's family, the social worker also spent time with mother and infant during play. She would point out how the baby was making progress, how she was trying to get her mother's attention, and how she had that special smile for her mother.

After 4 weeks in the hospital, Anna seemed stronger, and her mother seemed committed to continuing working with the social worker. The hospital staff felt comfortable about discharging Anna. After Anna had returned home with her mother, a visiting nurse came to the home twice a week to check on the mother and infant, and the mother visited weekly with Anna at the hospital to see the social worker. After 6 months, the visiting nurse came less frequently, but the mother and Anna stayed in treatment with the social worker for another year, when both seemed engaged and comfortable with each other.

Avoidant/Restrictive Food Intake Disorder

ARFID can be diagnosed if the feeding disturbance may persist after being triggered by a medical condition and following resolution of the medical condition.

Feeding Disorder Associated with Concurrent Medical Condition (DC: 0–3R)

Clinical Features. Although respiratory problems or cardiac diseases that may tire out the infant during feeding are easily recognized, some medical conditions are not readily diagnosed, and

food refusal may be the leading symptom. For example, food allergies can be difficult to diagnose in infants, and “silent” gastroesophageal reflux without vomiting can be overlooked because vomiting is usually the leading symptom that alerts pediatricians to this condition. Typically, infants with reflux can drink 1 to 2 oz until the reflux becomes activated. However, once reflux occurs, the infants experience distress and may arch, cry, and refuse to continue feeding. Some infants can be calmed and resume feeding, but others may become increasingly agitated while their caretakers continue to offer the bottle or food. Infants with respiratory distress may feed for a while and take a few ounces until they tire and stop feeding. In general, the feeding difficulties of these infants lead to inadequate food intake, failure to gain weight, or loss of weight.

Differential Diagnosis. This feeding disorder needs to be differentiated from other feeding disorders characterized by food refusal, such as IA, sensory food aversions, and post-traumatic feeding disorder. What helps in understanding this feeding disorder is the observation of feeding, which reveals that the infant usually initiates feeding without difficulty and that mother and child engage in pleasant reciprocal interactions until the infant experiences distress and stops feeding.

Etiology and Course. FTT of infants and young children was initially believed to be caused by either organic or nonorganic causes (e.g., maternal deprivation). In 1981, Homer and Ludwig described a third category of FTT, which is caused by a combination of various organic and nonorganic problems. Since then, it has been accepted that organic conditions can be complicated by psychological difficulties and lead to severe feeding problems and growth failure. However, although many young infants suffer from gastroesophageal reflux, only less than one-third of them are reported to present with feeding difficulties and growth failure. Clinically, these infants appear particularly alert and sensitive. However, no empirical studies have

been done to explore why some infants develop severe reactions to their reflux, whereas others hardly seem bothered by it.

Only a few studies have been reported on the follow-up of these infants. Fortunately, with therapy, up to 80% of children with gastroesophageal reflux improve within 12 months. For those with more serious feeding difficulties and the inability to take in adequate amounts of food for growth, modern technology allows for gastric tube feedings over a long time to safeguard their survival. However, the regulation of oral feedings is often very difficult, and even after the medical condition has been successfully treated, it may take time until the child learns to eat independently.

Treatment. Because of the interaction of organic and psychological factors contributing to the severe feeding difficulties of these children, a collaboration between the pediatrician or pediatric specialist and the psychiatrist is critical. Optimal medical treatment of the child's illness is necessary before psychological interventions can be successful. Direct observation of infants with their primary caregiver during feeding is most helpful in monitoring how well the medical condition is responding to the treatment. In addition, the observations during feeding can guide the therapist in helping the parents to develop more appropriate strategies that allow infants to calm down instead of escalating their distress during feeding. However, in situations in which the medical illness cannot be adequately treated, and the infant continues to experience distress during feedings, supplemental nutrition through nasogastric or gastrostomy tubes must be considered. Then the therapist must work with the parents to maintain the infant's oral feeding skills while most of the nutrition is given via tube feedings. The parents need to learn to feed the infant to the point of discomfort but not beyond it. Reviewing the videotape of the infant's feeding and discussing the infant's cues with the parents is usually helpful in sorting out how to best feed the infant. In general, these are very difficult cases that require individualized attention by an experienced multidisciplinary team.

Sarah was 6 months old when she was referred by her pediatrician to the Multidisciplinary Feeding Disorders Team because of severe food refusal and poor growth. The mother reported that since birth Sarah occasionally “spat up” a little during and after feedings, but during the last 6 weeks, she had become increasingly difficult to feed. Usually, she took 1 or 2 oz of her formula and then started to arch and push the nipple out from her mouth. If her mother tried to continue feeding Sarah, she cried and became increasingly agitated until her mother picked her up and comforted her by holding her on her mother’s shoulder and walking her. Sometimes after 10 to 20 minutes, her mother could resume feeding Sarah, but often, Sarah started to cry again after suckling from the bottle for a few minutes only. In spite of her mother’s efforts to feed Sarah every 2 hours, Sarah drank only half of the formula that she was supposed to take in for her age, and in recent weeks, she had started to lose weight.

The observation of feeding revealed pleasant mother-infant interactions at the beginning of the feeding, but after a few minutes of suckling, Sarah pushed the nipple of the bottle out of her mouth, arched her back, and started to cry when her mother tried to get her back to feeding. The harder her mother tried, the more agitated Sarah became, and mother and baby looked very distressed and gave up feeding. These feeding interactions raised concerns that Sarah experienced gastroesophageal reflux that caused her pain and interfered with her feeding. Further medical testing confirmed the diagnosis of moderate gastroesophageal reflux, which was somewhat surprising to the pediatrician and the gastroenterologist because Sarah had not shown any vomiting, the most common symptom of reflux.

Sarah was treated with medications for reflux, and her food intake doubled quickly. However, if she drank more than 3 or 4 oz at a time, the symptoms recurred. However, once the mother understood the reason for Sarah’s food refusal, she learned to ease Sarah’s feeding difficulties by thickening the formula and feeding her smaller amounts at more frequent intervals.

Gradually, Sarah tolerated larger amounts of formula at each feeding, and at 15 months of age, she was found to have outgrown the gastroesophageal reflux.

Rumination Disorder

Clinical Features. Rumination has been defined as repetitive regurgitation of gastric contents that are subsequently rechewed and then reswallowed or spit out. The regurgitation occurs very soon after a meal and tends to persist for 1 to 2 hours. The sequence of events leading to regurgitation has been documented by using combined multichannel intraluminal impedance and manometry. These events include an increase in intra-abdominal pressure identified in the stomach, which initiates the reflux, followed by peristaltic fore contractions, which clear the intraesophageal content. Rumination has been described in infants, individuals with developmental disabilities, and in children, adolescents, and adults with psychiatric or neurologic disorders. The major change for rumination disorder in the *Diagnostic and Statistical Manual for Mental Disorders,* Fifth Edition, was its relocation from the section titled “Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence” to the new section, “Feeding and Eating Disorders.” This change emphasizes that this disorder occurs across the age range, including adulthood. Minor changes have been introduced to the DSM-5 and DSM-5-TR phrasing of diagnostic criteria for rumination disorder to improve clinical utility by ensuring applicability across the age range and removing some ambiguity inherent in the DSM-IV phrasing.

Some infants can be observed to put the thumb or the whole hand in the mouth, suck the tongue rhythmically, or arch the back to initiate regurgitation. However, some infants ruminate when left alone after they have been placed in the crib to sleep. They are frequently found in a puddle of vomitus, which is then falsely attributed to some organic problem. The latter type of rumination is most commonly observed in infants who have received little

emotional stimulation and who have learned to stimulate and soothe themselves through rumination. Although initially most of the regurgitated food is vomited, some infants gradually learn to hold more of the food in their mouth, to rechew, and to reswallow it. “Experienced” ruminators are able to bring up the food through tongue movements and reswallow it without losing any of it. Their rumination can only be discovered by observing the movements of their cheeks and the foul oral odor. Social functioning may be significantly impaired due to the recognized social undesirability of this behavior.

Differential Diagnosis. The term *regurgitation* implies that the behavior is volitional, distinguishing it from vomiting or gastroesophageal reflux. The regurgitation is not associated with nausea and is not explained by an illness or medical condition. Individuals may cough, engage in the tongue or abdominal muscle contractions or movements, or place fingers in the mouth to facilitate food being brought back up. Because, in young children, reflux and rumination frequently coexist, it is important to observe the infant in different situations to see the initiation and the rhythmic oral movements of the ruminatory activity. As in pica, the diagnosis of rumination disorder should be given in the context of another mental disorder only if the symptoms require additional clinical attention.

Epidemiology. Rumination is believed to be a rare disorder. It appears to occur more often in males than in females and also in individuals with mental retardation. There are a few reports of children, adolescents, and adults who were diagnosed with rumination disorder, and some had associated eating disorders.

Etiology and Course. Various mechanisms of etiology have been proposed. Several authors have attributed rumination to separations or a disturbed mother-infant relationship—for example, lack of responsiveness or neglect by the mother secondary to stressful family relations or life events. Others have considered rumination as a symptom of gastroesophageal reflux. Several authors have

postulated that rumination is a learned behavior that is maintained with special attention to the regurgitation. In more recent years, opiate receptor insensitivity or reduced endorphinergic transmission has been implicated in rumination.

A biopsychosocial model has been proposed by which rumination is seen along a continuum in which an infant may have gastrointestinal pathology and little psychopathology at one end of the spectrum, or the opposite, in which an infant may have no organic pathology and severe psychopathology in the mother-infant relationship at the other end of the spectrum. Frequently, vomiting secondary to gastroesophageal reflux or vomiting associated with an acute illness precedes the beginning of rumination. It appears that at some point the infant learns to initiate vomiting and to rechew the food to achieve relief of tension, to self-soothe, and/or to self-stimulate. It seems that in situations in which the infant fails to elicit or loses either caring attention or tension-relieving responses from the mother, rumination becomes a means of self-regulation. Once the infant has experienced rumination as a means of self-soothing or self-stimulation, the rumination develops into a habit that is difficult to break.

The onset of rumination is frequently in infancy, most commonly in the first year of life. However, rumination may start at any point in life. It is believed that in some individuals the disorder remits spontaneously. However, some infants suffer serious complications, such as electrolyte imbalance, dehydration, and weight loss, and in earlier reports mortality rates as high as 25% have been described.

Treatment. Depending on the theories of the etiology of rumination, different treatments have been suggested. These range from mechanical restraints as described in the early literature and surgical interventions (Nissen fundoplication) to prevent reflux, to behavioral and psychodynamic treatments.

Based on the assumption that rumination is a learned habit that is reinforced by the increased attention that is given to the regurgitation, unlearning by behavioral techniques has been suggested. These treatments include the use of aversive taste

stimuli (lemon juice or hot sauce), oral hygiene, differential reinforcement of incompatible behaviors, and electric shock. Proponents of the assumption that rumination is based on an unsatisfactory mother-infant relationship have suggested a psychodynamic approach. A mother substitute who feeds the infant while the mother is helped through psychotherapy has been proposed.

After a thorough evaluation that should include the assessment of the infant and the mother, the therapist needs to individualize the treatment. In severe situations, if the infant is malnourished and continues to lose most of the food through rumination, a jejunal tube may have to be inserted before any psychosocial treatment can begin. Frequently, a combination of psychodynamic and behavioral interventions to enhance the mother–infant relationship in general and to treat the symptom of rumination, in particular, is most effective.

Justin was 9 months old when he was referred by a gastroenterologist for a psychiatric evaluation because of concerns that he continued to vomit because of rumination. Justin was born full-term and had developed nicely until he was about 6 weeks old when he began to vomit increasing amounts of milk during and after feedings. He was diagnosed with gastroesophageal reflux, which was treated with thickened feedings and medication. Justin responded well to the treatment; he stopped vomiting almost completely and gained weight adequately. Because Justin was doing so well, his mother decided to go back to work when Justin was 8 months old. She transitioned his care to a young woman who would come to the house during the mother's working hours. Justin started to vomit soon after his mother left the house. The vomiting seemed to increase from day to day in frequency and in intensity, and after 2 weeks of the mother's return to work, Justin vomited several times daily and was losing weight. He was seen by a gastroenterologist, and during the barium swallow, it was noticed that Justin put his hand in his mouth, which seemed to trigger vomiting. Justin was put back on medication for gastroesophageal reflux, but he continued to vomit with increasing frequency, which led to a psychiatric consultation.

Observation of mother and infant during feeding revealed that as soon as Justin finished feeding, he put his hand in his mouth and vomited. When his mother restricted his hand, Justin moved his tongue back and forth in a rhythmic manner until he vomited again. This happened repeatedly, and Justin continued the rhythmic tongue movements even when he could not bring up any more milk.

Because of his poor nutritional state and moderate dehydration, Justin was admitted to the hospital, and a nasojejunal tube was inserted for feedings. When Justin was awake, a special nurse or the parents played with him and tried to distract him whenever he attempted to put his hand in his mouth or thrust his tongue rhythmically. Justin became

increasingly engaged, and his ruminatory activity decreased accordingly. After 1 week in the hospital, small feedings were started, but Justin tried to ruminate again, and the oral feedings had to be stopped. At this point, the mother decided to stop working and take Justin home to continue the treatment there. The mother started small feedings, played with Justin after feedings, and was able to keep him from ruminating. After 4 weeks of slow increments in his feedings, Justin was able to take all of his feedings by mouth without ruminating, and the nasojejunal tube could be removed.

Pica

Clinical Features. Young children with this disorder typically eat plaster, paper, paint, cloth, hair, insects, animal droppings, sand, pebbles, and dirt. Many of the children engage in other oral activities, such as thumb sucking or nail biting, which they seem to use for relief of tension and for self-soothing. In some younger patients, as well as those with neurodevelopmental or learning disorders, some clinicians regard pica as a form of self-soothing behavior. The pica may lead to anemia, diarrhea/constipation, worm infestation, toxoplasmosis, lead poisoning, and malnutrition. In some cases, it may lead to intestinal obstruction as the result of hairball tumors. In addition to the heterogeneity of substances consumed, pica's associated behavioral features can differ considerably among individuals (e.g., its compulsive nature and relationship to emotional arousal or need for oral stimulation).

The major change for pica disorder in the *Diagnostic and Statistical Manual for Mental Disorders*, Fifth Edition, was its relocation from the section titled "Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence" to the new section "Feeding and Eating Disorders." This change emphasizes that this disorder occurs across the age range, including adulthood. In particular, changes to the phrasing of diagnostic criteria in DSM-5 are intended to guide clinicians in distinguishing eating behaviors that warrant a

diagnosis of pica from behaviors that are developmentally normal, culturally supported, or socially normative or that support a diagnosis of a different mental disorder.

Differential Diagnosis. Before the age of 18 to 24 months, mouthing and sometimes eating non-nutritive substances can be relatively common and should only be diagnosed as pica if it is persistent and inappropriate for the developmental level of the child. In DSM-5-TR, 2 years is suggested as the minimum age for a diagnosis of pica; at younger ages, mouthing different kinds of objects is considered developmentally normal. Consumption of substances consistent with local cultural practices or social norms would not warrant a pica diagnosis. Pica may be comorbid with a number of mental disorders, which are more likely to come to clinical attention than pica itself, (e.g., intellectual development disorder, autism spectrum disorder, schizophrenia, and obsessive-compulsive disorder). In addition, pica can co-occur with hair-pulling disorder and skin-picking disorder when hair or skin is ingested. When non-nutritive substances are ingested as a means to suppress appetite in anorexia nervosa, a pica diagnosis is not warranted. Some individuals with ARFID, particularly those whose selective or restricted intake is based on sensory aspects of food, may also present with comorbid pica.

Epidemiology. A survey of a large clinic population with a wide range of ethnic backgrounds revealed that 75% of 12-month-old infants and 15% of 2- to 3-year-old toddlers were reported by their parents to put non-nutritive substances in their mouths. However, the true incidence of pica is not known. Available data suggest that in the United States pica is rare in healthy children older than 2 years. However, a study reported that 33.9% of children in Detroit who were in treatment for sickle cell anemia had pica eating. Pica has also been reported as prevalent in children elsewhere, including in some school-age populations in Africa (as high as 77%). Among individuals with mental retardation, the prevalence of the disorder appears to increase with the severity of the retardation. The

prevalence of pica among institutionalized individuals with mental retardation has been estimated to range from 10% to 33%.

Etiology and Course. Organic, psychodynamic, socioeconomic, and cultural factors have been implicated in the etiology of pica. Inadequate intake of iron and calcium has been shown in rats to induce pica and has been considered to lead to abnormal cravings and pica in humans. Low plasma levels of iron and zinc have been found to be associated with pica, and it has been suggested that hypozincemia with low iron levels may be a possible cause rather than a consequence of pica. Psychosocial factors—for example, poverty, maternal neglect and abuse, and disorganized family situations with inadequate nurturing and supervision of the children—have been implicated in the etiology of pica. The cultural acceptance of pica in certain population groups has also been considered to play a role in its etiology. Some authors have proposed a multifactorial model of etiology by which organic, familial, socioeconomic, and cultural factors interact with each other.

In most instances, the disorder is believed to last for several months and then remit. However, it may occasionally continue into adolescence or, less frequently, into adulthood. Several authors have pointed to the seriousness of the developmental effect of the disorder. The younger children showed delays in their speech and psychosocial development. Half of the adolescents were observed to suffer from depression and/or personality disorders, engaged in other forms of disturbed oral activities, such as thumb sucking and nail-biting, and abused tobacco, alcohol, or drugs. More recently, some authors pointed to a strong relationship between pica during early childhood and bulimia nervosa during the adolescent years.

Treatment. A variety of treatments have been proposed. These include physical restraints, aversive and nonaversive behavior therapy, the teaching of children to exchange inedible items for edibles, environmental enrichment, and individual and group therapy for the children and their mothers. It is important to conduct a comprehensive evaluation of the child, the caretakers, and the

child’s environment to develop an individualized treatment plan. This should include helping the adults to become aware of the short- and long-term dangers of pica, providing a lead-free and childproof environment, facilitating a more satisfying parent–child relationship, and applying behavioral techniques to extinguish the maladaptive behavior of pica.

Susan was 3 years old when her mother took her to the pediatrician because of abdominal pain and lack of appetite. The mother complained that Susan put everything in her mouth but did not want to eat regular food. The pediatrician observed that Susan looked pale, thin, and withdrawn. She sucked her thumb and quietly looked down while her mother reported that Susan liked to chew on newspapers and put plaster in her mouth.

The medical examination revealed that Susan was anemic and suffered from lead poisoning. She was admitted to the hospital for treatment, and a psychiatric consultation was obtained.

Further exploration of the history and the observation of mother and child during feeding and play revealed that the mother was overwhelmed with having to care for three young children and had little affection for Susan. The mother was unmarried and lived with her three children and five other family members in a three-bedroom apartment in an old housing project. Her 4-year-old son was hyperactive and demanded almost constant supervision. Her 18-month-old infant was an engaging and active little girl, whereas Susan would sit quietly, rock herself, suck her thumb, or chew on newspaper.

The treatment plan included the involvement of social services and protective services to remove any lead paint from the walls in the apartment and to look for better living arrangements for the family. The mother was helped to enroll Susan and her brother in a preschool program that provided them with more structure and stimulation and gave the mother a few hours of relief every day. In addition, Susan was seen with her mother and her younger sister in play therapy to help the mother understand the different temperaments of the two children and to make her more responsive to Susan's weak attempts to engage her. Once the mother felt more supported and less overwhelmed by her situation, she became more empathic and understanding of Susan. When Susan put something in her mouth, the mother was able to engage her in a play activity rather than scream at her and scold her for whatever she was doing. Over the period of 1

year, the relationship between Susan and her mother gradually improved, and Susan seemed less in need of putting her thumb or inedible things in her mouth.

To conclude our chapter, it is pivotal to underline that a problem arises when the children exhibit symptoms that appear to fit the diagnoses of more than one feeding disorders subtype (i.e., IA and post-traumatic feeding disorder, IA, and sensory food aversions). We recommend that the symptoms should be differentiated as much as possible to understand what the underlying diagnoses may be, because, as pointed out earlier in the treatment targeted to specific diagnostic subtypes, each feeding disorder requires a specific therapeutic approach, and the treatment needs to combine these individual approaches for each disorder to be successful.

Tic Disorders

Rahil R. Jummani, M.D., Elizabeth A. Deckler, M.D., and Barbara J. Coffey, M.D., M.S.

The best known of the tic disorders is Tourette disorder (TD), also known as Tourette syndrome, named after the French neurologist Georges Gilles de la Tourette, who in 1885, was among the first to recognize and describe the disorder and its comorbid conditions. Since the descriptions of Gilles de la Tourette, a spectrum of tic disorders has come to be recognized and codified in psychiatric nomenclature. No longer is TD viewed as a rare, bizarre psychological entity with primarily disturbing manifestations, such as the shouting of obscenities, screeching, or barking. The comorbid psychiatric disorders that frequently occur in individuals with TD have become more widely recognized in recent years; it is these disorders that may often warrant treatment more than the tics themselves. Although the underlying etiologies of these disorders continue to be elusive, substantial progress has been made in the last few decades using innovative neuroimaging techniques, genomics studies, and clinical science. Tic disorders have emerged as complex, heterogeneous neurodevelopmental disorders that are the manifestation of an intricate interplay of genes and environment. Understanding of the etiology, genetics, neuroanatomy, and epidemiology of tic disorders has been significantly enhanced. Novel treatment approaches have also emerged, providing alternatives to

the established pharmacologic management of tics. Specific behavioral interventions have been established as first-line treatments for tic disorders. Deep brain stimulation (DBS), botulinum toxin injection, targeted surgery, and stem cell transplantation are examples of promising new treatments. The future holds tremendous possibilities as new insights into the etiology, pathophysiology, and treatment of tic disorders are rapidly developing. This chapter provides a review and update of the history, comparative nosology, epidemiology, etiology, diagnosis and clinical features, pathology, differential diagnosis, course and prognosis, and clinical treatment of tic disorders, including TD.

DEFINITIONS

Tics are rapid, recurring motor movements (motor tics) or vocalizations (phonic or vocal tics) that are nonrhythmic, involuntary or semivoluntary, and sudden in onset. Tics typically involve one muscle or a group of muscles and are characterized by their anatomical location, number, frequency, duration, and complexity (Table 47–1). They can be classified as *simple* (involving one muscle, muscle group, or sound) or *complex* (slower, more purposeful movements involving coordinated muscle groups or multiple sounds). Simple motor tics cause a brief, jerking movement (*clonic tic*); a briefly sustained abnormal posture (*dystonic tic*); or an isometric contraction (*tonic tic*). Examples of simple motor clonic tics are eye blinking, shoulder shrugging, and head-turning. Dystonic tics include sustained eye closure (blepharospasm), ocular deviations, teeth grinding (bruxism), mouth opening, twisting and tilting of the neck (torticollis), and shoulder rotation. Tonic tics are typically manifested by tensing of abdominal or limb muscles. Complex motor tics may include touching objects, jumping, rotating, or imitating others' gestures (*echopraxia*). Examples of simple vocal tics are throat clearing, coughing, and sniffing. Repeating syllables, words, or one's own phrases (*palilalia*) or repeating others' words or phrases (*echolalia*) are examples of complex vocal tics. Less commonly occurring tics include the involuntary vocalization of obscenities

(*coprolalia*) and the involuntary production of obscene gestures (*copropraxia*).

Tics are often emitted in bouts of one or several tics separated by variable periods of no tic activity. Tics change in frequency, anatomical location, number, complexity, and severity over minutes, hours, and days, as well as over longer periods of time. Tics may persist during sleep. Simple motor tics are the most common initial presentation of a tic disorder, and eye blinking is the most common initial tic.

Tics are experienced as irresistible but can be suppressed for varying periods of time. Some patients describe suppressing tics for several hours, for example, while at work or school, and then experiencing a bout of tics. There is usually a reduction in the frequency and severity of tics during concentration on mental or physical tasks such as reading. Stress, excitement, boredom, fatigue, and exposure to heat can exacerbate tics. Tic frequency may also increase during relaxation following a period of stress or sometimes when an individual is actively attempting to suppress tics. Some children, and occasionally adults, are unaware of their tics.

Many individuals with TD characterize their tics as a voluntary response to an uncomfortable feeling that precedes them. These feelings, or premonitory sensations, have been described by many individuals with TD; they can be localized or general, and physical or mental, in nature. These premonitory sensations distinguish tic disorders from other movement disorders. An example is a burning feeling in the eye before an eye blink. However, there are often nonlocalizable and more generalized premonitory phenomena, such as urges, sensations, or anxiety. Many individuals report a “just right phenomenon,” that to relieve the uncomfortable urge they must repeat a particular movement or sound or pattern of movements or sounds, until “it feels good” or “it feels just right.”

Table 47–1.
Examples of Tics

Motor		Vocal	
Simple	**Complex**	**Simple**	**Complex**
Eye blinking	Touching objects or self	Throat clearing	Syllables or words
Nose twitching	Hitting or kicking	Coughing	Phrases
Shoulder shrugging	Hand gestures	Sniffing	Swearing
Sustained eye closure	Throwing	Blowing	Repeating one's or others' words
Tensing of abdominal or limb muscles	Squatting or jumping	Barking	Changes in the rate, rhythm, and volume of speech

Complex tics may be difficult to distinguish from compulsive behaviors. This is further complicated by the frequent presentation of obsessive-compulsive disorder (OCD) symptoms with tics. The difference between some complex tics and compulsions is subtle. It is important to determine whether the behavior is being pursued as a strategy to prevent or relieve anxiety rather than simply to satisfy an urge. If anxiety relief or prevention is the case, a compulsion rather than a tic is likely. Studies by Miguel and coworkers demonstrated that more cognitions and autonomic anxiety, and fewer sensory phenomena are reported with repetitive behaviors in individuals with OCD without concomitant tics, whereas more sensory phenomena, such as the "just right phenomenon," and fewer cognitions are associated with repetitive behaviors in individuals with TD.

The fifth edition of the Diagnostic and Statistical Manual of Mental Disorders text revision (DSM-5-TR) and the eleventh revision of the International Statistical Classification of Diseases and Related Health

Problems (ICD-11) provide diagnostic criteria in common use for tic disorders. According to the DSM-5-TR (with the equivalent ICD-11 diagnoses in parentheses), tic disorders include provisional tic disorder (transient motor tics in ICD-11), persistent motor or vocal tic disorder (chronic motor or vocal tic disorder in ICD-11), TD (Tourette syndrome in ICD-11), and other specified tic disorder and unspecified tic disorder (other specified primary tics or tic disorders, primary tics or tic disorders, unspecified, other specified tic disorders, and tic disorders, unspecified in ICD-11).

By DSM-5-TR criteria, a provisional tic disorder is characterized by the presence of single or multiple motor and/or vocal tics for less than 1 year. A persistent motor or vocal tic disorder is diagnosed when either motor or vocal tics, but not both, are present for more than 1 year. For this category of tic disorders, DSM-5-TR provides specifiers to indicate whether motor or vocal tics are present: *With motor tics only* and *With vocal tics only.* TD (Tourette syndrome in ICD-11) is defined by the presence of both multiple motor and one or more vocal tics for more than 1 year.

According to the DSM-5-TR, other specified tic disorder is a tic disorder that does not meet the criteria for any of the other tic disorders, and the clinician specifies the reason criteria are not met. An unspecified tic disorder, on the other hand, is a condition that also does not meet criteria for any of the other tic disorders, but for which the clinician does not elaborate a specific reason. Included are presentations for which information to make a more specific diagnosis is lacking.

In addition to the foregoing criteria that the DSM-5-TR and ICD-11 share for the diagnosis of a specific tic disorder, the DSM-5-TR specifies a few common criteria that must be met to diagnose provisional tic disorder, persistent motor or vocal tic disorder, or TD. The onset of tics must be before the age of 18 years, and a substance or medical condition must not be causally implicated. The DSM-5-TR notes that tics wax and wane in frequency.

HISTORY

In 1825, the French physician Jean-Marc Gaspard Itard provided the first clinical description of Tourette syndrome in a French noblewoman, the Marquise de Dampierre, who displayed body tics, barking sounds, and uncontrollable utterances of obscenities. In his description, Itard also noted the presence of comorbid obsessive thoughts. In 1885, Georges Edouard Albert Brutus Gilles de la Tourette, a French neurologist, described eight patients, in addition to the patient originally reported by Itard, with childhood-onset tics and coexisting emotional symptoms and behavioral problems, such as inattention, hyperactivity, impulsivity, obsessions, and compulsions. Gilles de la Tourette coined the term *coprolalia* for vocal tics that manifested as uncontrollable utterance of obscenities. Furthermore, he and his mentor, Jean-Martin Charcot, viewed the disease as progressive and believed they had identified a hereditary degenerative disorder.

Psychoanalytic views of TD, introduced in the 1920s and 1930s, thrived in the early twentieth century and interpreted tics as expressions of repressed childhood sexual conflict. In the 1940s, Margaret Mahler attributed tic symptoms to infantilization, parental overindulgence, and overprotection, as well as sexual conflict. Serge Lebovici, the leading French child psychoanalyst during the 1950s and 1960s, asserted that neurotic mothers were the cause of tics in their children.

As more biologically based theories of the etiology and pathophysiology of tic disorders emerged, sedatives, stimulants, carbon dioxide inhalants, and other agents came to be used in the treatment of tics, in conjunction with, or as alternatives to, psychoanalytic psychotherapy. In the 1960s and 1970s, as the scientific era of the understanding of Tourette syndrome began with the work of Arthur and Elaine Shapiro, the first randomized clinical trials using neuroleptic medications were published. The perception of Tourette and tic disorders as rare, bizarre, psychological conditions slowly began to change. Advances in the last 50 years have led to the use of the α-adrenergic agonists and second-generation neuroleptics as the primary psychopharmacologic agents for the treatment of tics. Comorbid psychiatric disorders have come to be

more widely recognized and treated. Over the last several decades, the Tourette Association of America (TAA) (https://tourette.org) has effectively promoted clinical awareness of the condition and supported research into its causes and treatment. Behavioral interventions have come to the forefront. The quest for a more comprehensive understanding of the underlying etiology and pathophysiology of tic disorders continues.

COMPARATIVE NOSOLOGY

The nosology of the tic disorders has depended, since their recognition, on the presence and classification of their primary symptom—tics. The two predominant current classification systems of tic disorders, the DSM-5-TR and the ICD-11 criteria, are based primarily, as described earlier, on the type of tics present (motor, vocal, or both) and the duration of symptoms (greater or less than 1 year). ICD-11 also distinguishes between primary tics and tic disorders and secondary tics in its categorization. As new information about the etiology and pathogenesis of tic disorders emerges, a new nosology based on an etiologic or pathogenic understanding may replace the current symptom-based taxonomy. Over the years, with newer iterations of the DSM, individual criteria have changed slightly as advances in the understanding of the prevalence and course of tic disorders have emerged. For example, the age of onset of TD has varied from before age 15 years to before age 21 years. The most recent version, DSM-5-TR, has instituted changes to the criteria that reflect the current understanding of the neurodevelopmental and temporal nature of tics, as tic disorders are now contained in the section on Neurodevelopmental Disorders. Tics are now recognized to wax and wane, and restrictions on the time frame of tic-free periods have been removed.

EPIDEMIOLOGY

Provisional tic disorder, which can encompass both motor and vocal symptoms, is the most common of the tic disorders; the prevalence is

estimated at up to 20% of school-aged children. A methodologically rigorous study of more than 800 schoolchildren ages 4 through 16 years in the Basque region, however, indicated a prevalence of approximately 6.5% for all tic disorders. The vast majority of tics were mild in severity and duration. The prevalence of persistent tic disorders is between 2% and 4%. Prevalence estimates for TD also vary. As in all population-based studies, results may be influenced by a variety of factors, including criteria used for diagnosis, methods of sampling and inquiry, gender and age distributions in the study population, and size of the sample. Once considered an extremely rare disorder, current lifetime rate estimates vary from 1 to 10 per 1,000 children in European and Asian populations, and a common prevalence figure for individuals meeting criteria for TD is 1 per 200 for the full spectrum of chronic tic disorders. A population-based, epidemiologic study of lifetime prevalence of TD in Israel estimated a point prevalence of 3.1 to 5.5 per 10,000 in 16- and 17-year-olds. Prevalence rates have been estimated to be as high as 4% in one community-based study, and 3% in a survey of middle school youth in the United Kingdom. In a school-based community survey, Kurlan and colleagues reported prevalence rates of tic disorders of 23% in special education classes and as high as 8% for TD, as compared to 19% for tic disorders and about 3% for TD in regular classrooms. The 2007 U.S. National Survey of Children's Health (NSCH) surveyed parents of children and adolescents aged 6 to 17 years. The estimated prevalence of a lifetime diagnosis of TD by parent report was 3 per 1,000. In a meta-analysis of 13 studies of children, Knight and colleagues reported a prevalence of TD at 0.77% (95% confidence interval, 0.39% to 1.51%).

The average age of onset for TD is age 6 years with peak tic severity between 10 and 12 years of age. Limited and somewhat contradictory information exists on the longitudinal course of the disorder. Recent studies suggest that whereas tics may often persist into adulthood, tic severity often declines significantly in adolescence. Only 20% or fewer of those with TD continue to experience significant functional impairment by age 20 years. In most cases, tics in adults represent the persistence or recurrence of childhood-onset tics, but in

extremely rare instances, patients may have their first occurrence of tics during adulthood. Studies in both children and adults suggest that males are at least three to four times more likely than females to manifest TD.

Comorbidity with psychiatric disorders, especially attention-deficit/hyperactivity disorder (ADHD) and OCD, is common in both clinically referred individuals and community samples. In addition, mood disorders and anxiety disorders, such as separation anxiety disorder and generalized anxiety disorder, often co-occur. In the 2007 U.S. National Survey of Children's Health (NSCH), 79% of those with TD had at least one comorbid mental health or neurodevelopmental condition. ADHD was the most frequent co-occurring condition, and the prevalence of comorbid ADHD with TD was reported to be as high as 60% to 70%. In addition, approximately 50% of patients with TD have prominent obsessive-compulsive symptoms. A more recent estimate of psychiatric comorbidity in those with TD at about 86% is the result of the work of Hirschtritt and collaborators.

Jeffrey was a 5-year-old boy whose parents sought evaluation for recent onset of tics. Jeffrey developed onset of eye-blinking tics at age 4 years and subsequently began to repeatedly push out his hands and legs in front of him, kicking and stomping his feet. These symptoms persisted for about 3 months and remitted. The movements returned about 1 year later, somewhat abruptly, according to his parents. At that time, Jeffrey developed eye blinking and nose twitching. Sometimes, he hopped while walking. He also developed vocal tics around that time, including clicking, throat clearing, sniffing, and coughing. Approximately 1 month prior to the evaluation, Jeffrey developed truncal tics that occasionally began to disrupt his gait.

Jeffrey's parents were also concerned about his problems paying attention in school in the last year. Hyperactive since preschool, he had a very short attention span and was often distracted. He could be impulsive, often unaware that he was doing things that could be dangerous. He often interrupted his parents when they were speaking. He was restless and fidgety in school, and his teachers were concerned that he might disrupt his classmates.

Jeffrey was the product of a pregnancy complicated by intrauterine growth retardation. When the amniotic fluid was found to be at low volume at 36 weeks, delivery was induced. The delivery was uncomplicated, and the birth weight was 5 pounds, 10 ounces. Except for a minor delay in the acquisition of speech, developmental milestones were within normal limits.

Currently in kindergarten, Jeffrey has attended a well-regarded public school since he was 2 years of age. He lived with his parents and 2-year-old sister, had many friends, and enjoyed play dates.

Jeffrey had frequent upper respiratory infections. There were no known allergies and no major medical problems. There was no known family history of TD, tics, or OCD.

MENTAL STATUS EXAMINATION

Jeffrey was a healthy-looking 5-year-old boy, well-groomed and dressed. He was initially very shy, clinging to his mother. He appeared to be quite active and restless. Multiple tics were noted, including nose twitches, finger-snapping, and a cough. Jeffrey was somewhat oppositional when asked to do a drawing.

IMPRESSION

In summary, Jeffrey was a 5-year-old boy with multiple motor and vocal tics for short episodes, including a bout lasting 3 months at age 4 years, and just over 2 months currently, consistent with provisional tic disorder. TD could not be entirely ruled out, but there was no diathesis based on family history. Jeffrey also appeared to meet criteria for ADHD, combined presentation, which may have predisposed him to the development of tics. The ADHD symptoms were causing impairment in his academic functioning.

TREATMENT PLAN

Parent and teacher ratings of ADHD symptoms were recommended at initial evaluation, and at follow-up after treatment was initiated. Treatment of ADHD was recommended, starting with a cautious trial of a methylphenidate-based stimulant. The plan was to add a low dose of an α-adrenergic agonist such as guanfacine or clonidine if tics increased significantly. Consultation and psychoeducation were recommended for Jeffrey's teacher.

ETIOLOGY AND PATHOPHYSIOLOGY

The etiology and pathophysiology of TD and other tic disorders remain unknown. Considerable data accumulated during the last few decades from neuroanatomical and neurochemical studies of TD point to a diffuse process in the brain involving cortico–striato–thalamic–cortical (CSTC) pathways in the frontal lobes and basal ganglia, including the striatum (caudate nucleus and putamen). Several neurotransmitters and neuromodulators have been

implicated, including dopamine, serotonin, glutamate, GABA, and endogenous opioids. Although a specific animal model has not been identified, some parallels may exist with horses with crib biting, which display spontaneous motor tics accompanied by vocalizations, dogs with acral lick syndrome, and mouse models with repetitive movements and stereotypies.

A host of biochemical, imaging, neurophysiologic, and genetic studies support the concept that TD is an inherited neurodevelopmental disorder. Twin studies have reported 89% to 94% concordance for TD. However, environmental factors have also been implicated. In one study of 16 pairs of monozygotic twins, low–birth-weight was a strong predictor of more severe tics. Several gestational and perinatal insults, including hypoxia–ischemia, exposure to androgens, heat, and infectious agents, have been implicated in the pathophysiology of tic disorders. The effect of prenatal ischemic events may be to alter dopamine signaling, heralding the development of tics. Delivery complications, especially forceps deliveries, and fetal exposure to high levels of coffee, cigarettes, or alcohol were associated with male gender and OCD in a sample of TD probands.

Androgen exposure is speculated to play a role in the development of tics, given the higher prevalence of TD in males. Studies in both children and adults suggest that males are at least three to four times more likely than females to manifest TD. X-linked genomic transmission has also been considered, but this appears less likely in the context of frequent male-to-male transmission within families. The role of stress, given the strong association of tics with anxiety, is also compelling. TD patients have been found to have significantly higher levels of cerebrospinal fluid (CSF) corticotrophin-releasing factor (CRF) than normal controls or patients with OCD who do not have a tic disorder, demonstrating a heightened reactivity of the hypothalamic–pituitary–adrenal axis. Increased reactivity of the noradrenergic sympathetic system has also been shown in patients with TD. A dopamine-mediated pathway in the hypothalamus that modulates sweating in response to changes in temperature has also been linked with tic activity. Increases in ambient and core body

temperatures have been shown to transiently increase tics in some individuals. A stress diathesis model modulated by the hypothalamic–pituitary–adrenal axis, the associated stress-related neurotransmitters and hormones, and their targets may represent the final common pathway that may explain the variable expression of the tic disorders.

Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infection

A postinfectious mechanism for the development of tics and OCD has been postulated since the late 1800s. A poststreptococcal infection autoimmune etiology has long been well established for Sydenham chorea, the movement disorder that was the model for the development of pediatric autoimmune neuropsychiatric disorders associated with streptococcus (PANDAS) hypothesis. In addition to chorea, some Sydenham's patients display motor and phonic tics, as well as obsessions, compulsions, hyperactivity, impulsivity, and inattention. In 1998, Swedo and colleagues first described a putative subgroup of 50 children with PANDAS with OCD and/or tic disorders with acute symptom onset and/or exacerbation precipitated by infection with group A β-hemolytic Streptococcus (GABHS). Although GABHS is considered the initial autoimmune response-inciting event in children with PANDAS, viruses, other bacteria, and even noninfectious immunologic responses are thought to be capable of precipitating later symptom exacerbations. Case reports have also implicated Lyme disease and Mycoplasma pneumonia in the development of infection-triggered tics. By molecular mimicry—the postulated autoimmune mechanism—antibodies are formed against the inciting agent and subsequently attack neurons because of some structural similarity.

Specific diagnostic criteria for PANDAS have been described, including the presence of OCD and/or tic symptoms, prepubertal onset, episodic course with sudden, explosive onset and/or exacerbations and remissions, and a temporal relationship of GABHS infection and neuropsychiatric symptoms. A case-control study of 144 children with OCD, TD, or another tic disorder conducted by Mell and colleagues provided the strongest evidence for the involvement of

GABHS in the onset of tic disorders and OCD. Patients with OCD, TD, or another tic disorder were found to be more likely than controls to have had a streptococcal infection in the 3 months prior to the onset of symptoms. Risk was greatest among those with multiple streptococcal infections in the preceding 12 months. Others have found no more than a chance association between GABHS infections and tic symptom exacerbations. A case-control study by Perrin and colleagues found little evidence of increased tics, obsessions, or compulsions after well-documented and treated GABHS infections.

Several groups have reported increased antistreptococcal antibody titers in individuals with OCD and tic disorders, but several other groups have not found this association. A double-blind, placebo-controlled, crossover study of prophylactic oral penicillin to attempt to reduce PANDAS recurrences failed to show differences between drug and placebo. More recently, in two prospective case-control studies of children with PANDAS, Kurlan and colleagues reported that Group A B-hemolytic streptococcus infection was not the only antecedent associated with exacerbations of tics and OCD symptoms in the cases; similarly, Leckman and colleagues found there was no evidence for a temporal association between GABHS infections and tic/OC symptom exacerbations in children who met published PANDAS diagnostic criteria.

Treatments based on a postulated autoimmune mechanism have been nonspecific, and the results have been inconsistent. Immune therapies such as intravenous immunoglobulin (IVIG), plasmapheresis, corticosteroids, and plasma exchange have been explored with inconsistent results. Immunomodulatory treatments remain experimental, and current recommendations are for use only in research protocols.

The link between an infectious etiology and tic disorders/OCD remains a work in progress. Building on previous work, the most recent investigation has shifted its focus on acute, explosive onset OCD symptoms, which Swedo and colleagues have described as pediatric acute onset neuropsychiatric syndrome (PANS). Anxiety, emotional lability, developmental and behavioral regression,

deterioration in schoolwork and handwriting, and excessive urination are among the secondary characteristics.

Other new areas of research include the investigation of proinflammatory cytokine elevation, as well as decreased numbers of regulatory T-cells in some TD patients. Clinical implications suggest vigilance in the evaluation of tic or OCD patients with pharyngitis or streptococcus exposure, a low threshold for obtaining streptococcus throat culture, antistreptolysin O (ASO) and anti-DNAse B titers, and vigorous treatment with antibiotics when a streptococcal infection is confirmed. Antibiotic treatment has been shown to be remarkably effective in some unambiguous cases of sudden onset or exacerbation of tics with associated laboratory-documented streptococcal infection.

Neuroimaging Studies

Structural MRI studies in TD demonstrate volume changes in brain regions associated with CSTC circuits. Some studies have shown a loss of the normal basal ganglia asymmetry, as well as decreased basal ganglia volume in TD patients. In ten pairs of monozygotic twins, the right caudate was smaller in the more severely afflicted individuals, supporting evidence for the role of epigenetic mechanisms. A large study of basal ganglia volume in 154 patients with TD and 130 controls, conducted by Peterson and colleagues, found a significant decrease in the volume of the caudate nucleus in both children and adults. Larger dorsal prefrontal regions in children, but significantly smaller volumes in adults, were also reported by this group. Dorsal prefrontal volume was inversely related to tic severity, such that patients with greater prefrontal volumes exhibited decreased tic severity. Larger prefrontal volumes in children with TD may be a manifestation of synaptic plasticity associated with the constant need to suppress tics in social contexts. Adults with persistent tics may represent a subsection of the overall TD population who do not generate a neuroplastic, compensatory response in the prefrontal cortex, leading to increased severity of the tic disorder and its continuity into adulthood.

Larger parieto-occipital region volumes and smaller inferior occipital volumes have also been observed in individuals with TD when compared with controls. Bloch and colleagues found an inverse correlation between caudate volume in childhood and tic severity in late adolescence and early adulthood. Smaller caudate volumes were associated with more significant later tic activity, as well as with OCD symptoms. Another more recent study reported increased volume of the putamen bilaterally in boys with TD.

Decrease in corpus callosum size in children and an increase in corpus callosum size in adults with TD have also been reported. Corpus callosum size correlates inversely with prefrontal volume and is positively related to tic severity. These findings may indicate age-dependent changes in the white matter tracts in the disorder. Alternatively, decreased corpus callosum size, like increased dorsolateral prefrontal volume, may represent a compensatory mechanism children with TD develop to facilitate suppression of tics. Adults with TD tend to show the opposite pattern, exhibiting relatively decreased dorsal prefrontal and increased corpus callosum volumes that may be associated with the persistence of symptoms into adulthood.

Several studies consistently implicate primary cortical dysfunction in TD. Cortical thinning has been documented in frontal and parietal lobes, especially the sensorimotor cortex; the degree of thinning may correlate with tic severity. Increased sensorimotor cortical volume has been correlated with strength of premonitory sensations in a study of adults with TD. Evaluation of subgroups of TD patients has shown a relationship between symptoms and location of cortical thinning. While most have found thinner cortex or decreased volume in several different cortical areas, a few studies have reported overall brain volume decreases in TD subjects.

Larger left thalamic volumes were found in 18 patients with TD compared to 16 control subjects in one study. Increased gray-matter volumes bilaterally in the ventral putamen and decrease in gray matter in the left hippocampal gyrus have also been shown. Peterson and team demonstrated significantly increased overall hippocampus and amygdala volumes in TD patients, with a decline in volume with

age in the TD group, but not in healthy controls. In children and adults with TD, these volumes were inversely correlated with the severity of tics, OCD symptoms, and ADHD symptoms. An explanation for these findings is that the subregion plays a compensatory and neuromodulatory role in tic, OCD, and ADHD symptoms. In addition, cerebral hyperintensities—bright patches in brain parenchyma on T_2-weighted MRI that are indicative of neuroinflammatory or neurodegenerative processes—have been detected at increased rates in children and adolescents with TD, OCD, or ADHD in subcortical regions (primarily the basal ganglia and thalamus). Taken together, volumetric studies suggest that cortical and subcortical impairment, including striatal anomalies, and disruption of the temporolimbic pathways of the CSTC circuits are implicated in the pathophysiology of TD.

Functional neuroimaging studies using state-dependent cerebral blood flow, oxygenation, and energy (glucose) metabolism parameters as a measure of brain activity (e.g., functional MRI [fMRI], positron emission tomography [PET], and single photon emission tomography [SPECT]) suggest altered activity (increased or decreased) in various areas of the brain (e.g., frontal and orbital cortex, striatum, putamen) in TD patients compared to controls, or across brain regions within TD patients. An fMRI study by Bohlhalter and colleagues that analyzed activity two seconds before and after tic onset indicated that paralimbic and sensory association areas are critical to tic generation. Other fMRI studies in individuals with TD indicate that greater ability of basal ganglia structures to suppress cortical activity may be related to decreased tic severity, supporting findings from PET and SPECT studies of the role of the basal ganglia in TD. Functional neuroimaging studies suggest that voluntary tic suppression involves deactivation of the putamen and globus pallidus, coupled with partial activation of regions of the prefrontal cortex and caudate nucleus.

Event-related PET scanning has connected increased or decreased activity in many brain areas with the presence of tics, including the prefrontal cortex, premotor and primary motor cortex, anterior cingulate cortex, putamen, and caudate. fMRI scanning has

demonstrated increased neural activity in individuals with TD compared to controls throughout various motor areas, including the sensorimotor cortex, putamen, pallidum, and substantia nigra; this increased activity correlates with symptom severity. On the other hand, weaker activity has been demonstrated in the TD patients' motor control pathways, including the caudate and anterior cingulate cortex. More severe tics have been observed in those with progressively less activity in these regions, suggesting a disruption in these areas results in failure to control tics or premonitory urges. Other fMRI studies have also shown age-related abnormalities in frontostriatal and frontoparietal connections, implicating abnormal maturational changes in TD patients, strengthening the understanding that tics are the result of neurodevelopmental deficits.

Abnormal dopamine neurotransmission that contributes to the pathophysiology of TD is supported by increased levels of dopaminergic innervation of the striatum of TD patients in SPECT studies. A study in monozygotic twins concordant for TD but discordant for severity demonstrated abnormalities in D_2 receptors in the caudate area in the more severely afflicted twin. These neuroimaging findings are consistent with results of well-established tic suppression treatments with neuroleptic drugs that block dopamine receptors. Furthermore, TD patients have been shown to release more dopamine in response to amphetamine at dopaminergic synapses than healthy controls and dopamine-releasing drugs may precipitate or exacerbate tics. Midbrain dopaminergic neurons play a central role in motor control and attentional processes through direct connections to the striatum and cortex, respectively. Glutamatergic, GABAergic, serotonergic, cholinergic, noradrenergic, and opioid systems may also be implicated, given that they are present in CSTC circuits and interact with the dopaminergic system.

Taken together, structural and functional neuroanatomical findings support the understanding that TD results from abnormal activity in diverse cortical and subcortical brain regions. Active suppression of tics may require activation of dorsolateral prefrontal circuits that increase overall activity in the caudate nucleus, thereby inhibiting activity in the putamen.

Genetic Findings

Genetic data have been derived historically from family pedigree and twin studies. TD, persistent tic disorders, and OCD cluster in families. Twin studies have shown a high concordance rate for tic disorders among monozygotic (MZ) pairs (ranging from about 50% to 90%), in contrast to a relatively low rate among dizygotic twins (often around 20%). Other studies have shown that first-degree relatives of TD patients have a higher risk of TD, persistent tics, and OCD than normal controls. One large population cohort, multigenerational family study with 4,826 individuals diagnosed with TD or chronic tic disorders in the Swedish National Patient Register, estimated the heritability of tic disorders to be 0.77.

Historically, genetic analyses were thought to be consistent with an autosomal dominant mode (with incomplete penetrance) of inheritance; some investigators argued that a semidominant, semirecessive pattern could also exist. However, older studies were confounded by relatively high rates of bilineal transmission with apparent genetic contributions from both paternal and maternal lines.

More recently, investigators have proposed multiple gene loci in combination with environmental factors. The precise type or severity of tic disorder may be different from one generation to another and may be modified by nongenetic factors. A systematic genome scan of 76 affected sibling pair families with 110 sib pairs conducted by the Tourette Syndrome Association International Consortium for Genetics (TSAICG) demonstrated that 4q, 8p, and four other regions on chromosomes 1, 10, 13, and 19 were regions of interest. Efforts to confirm and extend these findings, however, have led to the identification of new regions and a failure to replicate the original findings.

Specific TD populations have been studied in South Africa, Costa Rica, and French-speaking Canada. Regions near the centromere of chromosome 2, as well as on 6p, 8q, 11q, 14q, 20q, 21q, and X, have been implicated. A linkage analysis study of a large pedigree of multigenerational TD patients in the United Kingdom is suggestive of linkage at loci on chromosomes 5, 10, and 13 in at least one of the

families. The largest genetic linkage study, undertaken by the TSAICG, consisting of more than 2,000 individuals, using a whole-genome scan with 390 microsatellite markers, demonstrated strong evidence of linkage for a region on chromosome 2p.

Cytogenetic abnormalities in TD families have also been studied. A TSAICG study reported disruption of the contactin-associated protein 2 gene (CNTNAP2) on chromosome 7, coding for a membrane protein important for signal conduction along myelinated neurons at the nodes of Ranvier, in TD patients. Affected individuals were found to have alterations in chromosomes 2 and 7. Other TD patients have been described with *de novo* duplication of the long arm of chromosome 7, a balanced translocation between chromosomes 6 and 8 with a translocation breakpoint on chromosome 8q, and an 18q21.1–q22.2 inversion. Abelson and colleagues identified a candidate gene, SLITRK1, on chromosome 13q31.1 in some individuals with TD, with expression of the gene product in the basal ganglia and deep layers of cortex, brain regions implicated in the pathophysiology of TD. Ercan-Sencicek and colleagues reported a rare functional mutation in the *HDC* gene encoding l-histidine decarboxylase, the rate-limiting enzyme in histamine biosynthesis, in linkage analysis in a two-generation TD pedigree.

Overall, the current understanding of TD and tic disorders implicates multiple vulnerability genes that likely determine the form and severity of tics in the wide variety of afflicted individuals and their families. Candidate genes have been identified in individuals with TD, including the dopamine receptor genes, the dopamine transporter genes, several noradrenergic genes, and some serotonergic genes. The TSAICG genome-wide association study (GWAS) reported that no genes reached threshold significance. A more recent analysis by Huang and colleagues of a European ancestry sample of 2,434 TD cases and 4,093 ancestry-matched controls for rare copy number variants has led to the identification of two genome-wide significant loci, *NRXN1* deletions, and *CNTN6* duplications, each contributing a significant increase in TD risk.

Willsey and peers have used whole-exome sequencing and *de novo* variant detection techniques to identify four likely risk genes with

multiple *de novo* damaging variants in unrelated individuals: *WWC1*, *CELSR3*, *NIPBL*, and *FN1*. They estimate that *de novo* damaging variants in about 400 genes contribute risk in 12% of clinical cases.

DIAGNOSIS AND CLINICAL FEATURES

A comprehensive, detailed history with observations derived from multiple sources is the cornerstone of clinical evaluation of tics and comorbid neurodevelopmental and psychiatric disorders. Neurologic, laboratory, and imaging examinations in patients with tic disorders are usually normal. Since tic disorders are diagnosed based on history, reliable sources of information are essential. This is particularly important because in many patients tics may be suppressed during the initial examination. It is critical to determine the degree to which tics interfere with emotional, social, family, and academic functioning, as treatment strategies are most effective when the severity and impact of tics are taken into consideration. Diagnostic evaluation is closely connected with the first steps of treatment.

Historical inquiry should include detailed medical and developmental information, medication history (including substances of abuse or recreation), educational and occupational data, social and interpersonal history, and a thorough family pedigree covering at least three generations. A careful, descriptive, longitudinal assessment of the tic disorder is important, including onset, course, current severity, presence of premonitory sensations and the capacity for tic suppression, overall burden, and treatments to date. The physical examination should include height, weight, presence or absence of dysmorphic features, posture, gait, reflexes, and a systematic rating of current abnormal movements. The Abnormal Involuntary Movement Scale (AIMS) is a systematic assessment procedure (and rating form) that can be adapted for use with children. Videotaped standardized interviews and evaluation procedures are used in some research studies; these could also be used in the clinical setting. However, the absence of observed tics on initial examination does not preclude the diagnosis of a tic disorder. Unusual histories, co-

occurring mental status changes, or the presence of seizures always warrant referrals for thorough neurologic evaluation.

Psychiatric evaluation should include a formal assessment of the behavioral and emotional problems known clinically to co-occur with tic disorders, including ADHD, OCD, anxiety disorders, mood disorders, and manifestations of impaired or dysregulated affect (e.g., aggression). The use of structured or semistructured interviews, such as the Diagnostic Interview Schedule for Children (DISC) or the Children's Schedule for Affective Disorders and Schizophrenia (K-SADS), can improve classification and evaluation of psychiatric comorbidity. Standardized rating scales developed specifically for the tic disorder population have improved diagnostic reliability in research studies and can also be helpful in clinical care. The Yale Global Tic Severity Scale (Y-GTSS) and the Tourette Syndrome Symptom List (TSSL) rate tics, compulsions, and other associated features. Specific rating scales for OCD (the Children's Yale-Brown Obsessive-Compulsive Scale [C-YBOCS]) and ADHD (the IOWA Conners parent and teacher rating scales, or the Swanson, Nolan, and Pelham [SNAP] scale) can also be used. Because rating instruments can provide quantifiable baseline data, such as frequency and intensity of tics, these data can also be used to measure treatment response (Table 47–2).

Table 47–2.
Rating Scales

Domain	Type	Reliability and Validity	Sensitive to Change
Tics			
Yale Global Tic Severity Scale (YGTSS)	Clinician	Excellent	Yes
Abnormal Involuntary Movement Scale (AIMS)	Clinician	Excellent	Yes
Tic Symptom Self-Report (TSSR)	Parent/self	Good	Yes
ADHD			
Swanson, Nolan, and Pelham-IV (SNAP-IV)	Parent/teacher	Excellent	Yes
Abbreviated Conners Questionnaire	Parent/teacher	Excellent	Yes
OCD			
Yale-Brown Obsessive-Compulsive Scale (YBOCS) and Children's Yale-Brown Obsessive-Compulsive Scale (CYBOCS)	Clinician	Excellent	Yes
National Institute of Mental Health Global Obsessive-Compulsive Scale (NIMH-GOCS)	Clinician	Excellent	Yes
Mood and Anxiety Disorders			
Children's Depression Inventory (CDI)	Clinician	Good	Yes
Children's Depression Rating Scale (CDRS)	Self	Good	Yes
Multidimensional Anxiety	Self	Good	Yes

Scale for Children (MASC)			
General			
Achenbach Child Behavior Checklist (CBCL)	Parent/teacher	Excellent	No
Clinical Global Impressions Scale (CGI)	Clinician	Excellent	Yes

Auxiliary data from outside sources are essential. Pediatric and medical records may document developmental and medical history, adequacy of medication trials, hospitalizations, and laboratory findings. Review of educational records is advised for children because many TD patients manifest tics or associated problems in school settings. Report cards document academic performance. Direct phone contact with teachers may provide data about attentional functioning, learning challenges, social and emotional competencies, and any behavioral difficulties. Neuropsychological or speech and language testing may be indicated for patients with impairments in school or occupational functioning. Identified areas of strength and weakness are subsequently conveyed to appropriate personnel for inclusion in educational or vocational planning.

PATHOLOGY AND LABORATORY EXAMINATION

In general, laboratory tests are indicated only to rule out other disorders when such conditions are highly implicated in the differential diagnosis of a given patient. For example, specific tests are available for the definitive diagnosis of Huntington disease, Wilson disease, and neuroacanthocytosis.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of tic disorders can be challenging (Table 47–3). Medical and family histories, physical and neurologic examinations, and baseline laboratory testing enable clinicians to rule out potential causes of *de novo* tics such as infection, trauma, substance use, or

toxin ingestion. Diagnostic hallmarks of tic disorders include the waxing-and-waning natural history, onset in childhood or adolescence, repetitive, rapid, nonrhythmic phenomenology, and involuntary features. In the absence of at least some history of simple tics, the diagnosis of a tic disorder may be questioned. Furthermore, the presence of vocal tics is helpful in ruling out other disorders because phonic manifestations are rare in other neurologic conditions. Tics must be distinguished from other types of abnormal movements: myoclonus, tremors, chorea, athetosis, dystonias, akathisia, and compulsive rituals.

Diagnostic considerations among the movement disorders include Sydenham chorea, poststreptococcal neurologic complications such as choreiform, writhing, and truncal movements; Huntington disease, an autosomal dominant disorder presenting with chorea and dementia and with an onset typically in the fourth or fifth decade; Parkinson disease, typically a late-life disorder, characterized by flattened facies, bradykinesia, rigidity, cogwheeling, and “pill-rolling” resting tremor; Wilson disease, an autosomal recessive disorder of copper metabolism that presents with liver abnormalities and neurologic symptoms: early dementia, mood disorders or psychosis, asterixis (a flapping tremor of the hands); Parkinsonism; structural diseases such as hemiballismus associated with subthalamic nucleus impairment; and neuroacanthocytosis, a rare movement disorder marked by progressive muscle weakness and atrophy, progressive cognitive loss, chorea, acanthocytosis (spiked red blood cells), and, sometimes, facial tics. In psychiatric settings, patients who have been exposed to neuroleptics are at risk for neuroleptic-related dyskinesias, including tardive and withdrawal dyskinesias. It is important to remember that dyskinesias may also be observed in tic disorder patients secondary to neuroleptic therapy but may be easily overlooked.

Table 47–3.
Differential Diagnosis of Abnormal Movements

Descriptive Terms	Observable Movement Pattern(s)
Akathisia	Motor restlessness (unpleasant need to move), usually in the lower extremities
Athetosis	Slow, irregular, writhing movements, usually in the hands and fingers but often involving the neck
Ballismus	Intermittent, coarse, large amplitude, jerking, shaking, flinging movements
Chorea	Irregular, spasmodic movements, usually affecting the limbs or face
Compulsion	Repetitive behavior that is more goal-directed and may be undertaken to prevent or reduce anxiety or distress
Dyskinesia	Choreiform or dystonic movement that is involuntary, stereotyped, and not suppressible
Dystonia	Sustained, tonic contraction that progresses to abnormal postures
Myoclonus	Sudden, brief, clonic, shock-like jerks, usually involving the limbs
Periodic movements of sleep	Periodic dorsiflexion of the foot and flexion of the knee, occurring during sleep
Spasm	Stereotypic, prolonged movement involving the same group of muscles
Stereotypy	Repetitive, usually meaningless, gestures, habits, or automatisms
Tic	Stereotyped, rapid, recurring motor movement (motor tic) or vocalization (phonic or vocal tic) that is nonrhythmic, involuntary or semivoluntary, and sudden in onset

Tremor	Unintentional, somewhat rhythmic muscle movement involving oscillations of one or more parts of the body

COURSE AND PROGNOSIS

The typical course of TD is characterized by onset of simple motor tics of the eyes, face, head, or neck by about age 6 or 7 years, followed by a rostral-caudal progression of motor tics over several years to involve the shoulders, trunk, and extremities. Eye blinking is the most common initial tic. Vocal tics typically start at ages 8 to 9 years; more-complex tics often begin later, as do obsessive-compulsive symptoms, at about ages 11 to 12 years. As many as half of clinically referred TD patients may show signs of ADHD, such as hyperactivity, impulsivity, and distractibility, prior to the onset of tics. Tics range from mild to severe and tend to stabilize over time; most children evaluated even in specialty clinics have mild to moderate tics. Some patients have lengthy periods during which most or all manifestations attenuate or remit. Recent studies indicate that tic severity improves significantly in most patients by early to mid adolescence.

Social functioning may be impaired because of bullying or rejection by peers or anxiety about having tics in social situations. Tics may impair academic functioning by their disruptive impact in class or interference with homework completion. Academic underachievement across educational levels is seen in many seeking treatment for TD or chronic tic disorders. Occupational functioning may be impaired by inability to use a computer or complete work tasks. By early adulthood, tics are greatly diminished in most individuals, and some are tic-free. Persistent tic symptoms may cause considerable distress and can lead to social isolation and personality changes. In severe cases, tics may directly interfere with daily activities. For example, violent head and neck tics may cause physical complications, such as compressive cervical myelopathy.

Fernández de la Cruz and peers report that there is a fourfold increase in the risk of suicide in individuals with tic disorders. The

strongest predictor of risk is the presence of tics beyond the second decade of life. Psychiatric comorbidity and a history of suicide attempts increase risk as well.

Comorbid Psychiatric Disorders

Hirschtritt and colleagues conducted a large cross-sectional study of TD patients and unaffected family members, estimating a lifetime prevalence of psychiatric comorbidity in those with TD at 85.7%. 57.7% had two or more psychiatric comorbidities. The relationship between TD and frequently observed comorbid psychiatric disorders has not yet been disentangled. Obsessive-compulsive symptoms, developmentally inappropriate motoric hyperactivity and inattention, anxiety, and aggressive dyscontrol have often been described in patients with TD. Motor, vocal, behavioral, cognitive, and emotional dysfunction may represent manifestations of an underlying central core disinhibition.

A majority of clinically referred individuals with TD meet full or subthreshold diagnostic criteria for ADHD, OCD, or both at some time during the course of their illness. Interestingly, these findings are also reported in community samples. ADHD and OCD are more likely to interfere with overall functioning and academic and work performance than the tics. Investigation of functional impairment in youth with TD conducted by Storch and colleagues found that non–tic-related problems caused more dysfunction than the tics per se, most often either ADHD or OCD symptoms.

ADHD is diagnosed by history of an enduring pattern of developmentally inappropriate inattention and/or hyperactivity and impulsive behavior; there is a bidirectional relationship between tics and ADHD. Some investigators have reported that 50% to 75% of TD patients also meet criteria for ADHD, whereas about 10% to 30% of ADHD patients also meet criteria for a tic disorder. Co-occurring TD and ADHD are often associated with academic difficulties, peer rejection, family conflict, and disruptive behaviors such as explosive outbursts, overt aggression, low frustration tolerance, and poor treatment adherence. The nature of the relationship between ADHD and TD is not firmly established, but it has been clearly demonstrated

that ADHD predicts greater disability than that associated with tic disorders alone, including an earlier diagnosis of TD, and a much higher rate of anger control problems and oppositional defiant disorder, sleep difficulties, learning disability, mood disorders, social skills deficits, sexually inappropriate behavior, and self-injurious behavior.

There also appears to be a bidirectional relationship between TD and OCD in most patient cohorts. OCD is characterized by obsessions—recurrent, intense, intrusive ideas, thoughts, impulses, or images that cause anxiety or distress, or compulsions—repetitive behaviors or mental acts sought to prevent or ward off anxiety or distress caused by an obsession. 20% to 40% of TD patients meet full criteria for OCD, and up to 90% have been reported to have subthreshold symptoms such as repetitive counting, touching, ordering, arranging, or symmetry needs.

Family studies provide the most compelling evidence for the association of tic disorders with OCD. First-degree relatives of TD probands have higher frequencies of TD, as well as OCD, and first-degree relatives of OCD probands have higher frequencies of OCD and tic disorders than relatives of control subjects. Studies of OCD probands indicate that the earlier the onset of obsessions or compulsions in the proband, the higher the genetic loading in family members for both OCD and tics.

In addition to ADHD and OCD, mood and anxiety disorders have been described in clinically referred and community samples of TD patients, including major depression, bipolar disorder, generalized anxiety disorder, separation anxiety disorder, panic disorder, and simple and social phobias. Some estimates suggest that up to 60% of children with TD will experience major depression at some point, and about 40% will have a non-OCD anxiety disorder. Vermilion and team compared anxiety symptoms in anxious youth with and without tic disorders. The anxiety profile in youth with tics appears to be different from those without tics. Those with tics are more likely to experience separation anxiety and physical symptoms of anxiety than anxious youth without tics.

Coffey and colleagues reported that comorbid mood disorders were the most robust predictors of psychiatric hospitalization and illness severity in a cohort of TD patients. Tic severity was only marginally significant as a predictor of psychiatric hospitalization. In a controlled study of older adolescents with TD, Gorman and colleagues found that, independent of comorbidity with ADHD, TD patients had significantly higher rates of depression and poorer overall outcome than healthy controls.

More recently, the work of Rizzo and peers demonstrated that depression in those with TD is associated with tic severity, the presence of comorbid ADHD, co-occurring anxiety, disruptive behavior, and a family history of depression. Whether mood symptoms are primary (i.e., related to the underlying pathophysiology of TD) or secondary to the demoralization and/or impairment related to having a chronic illness remains to be further clarified.

A substantial minority of youth with TD evaluated in clinical settings may meet criteria for intermittent explosive disorder manifested by rage attacks or oppositional defiant disorder. Budman and colleagues reported that children with TD as well as ADHD and OCD are more likely to experience explosive outbursts, and the number of outbursts is positively correlated with the number of comorbid conditions. Tic type and severity are not linked to the presence of explosive outbursts.

Learning and academic problems are common in children with TD; in a database of 5,450 patients with TD, 1,235 (22.7%) had learning disabilities. Young patients with TD may experience problems with executive functions, such as planning, persistence, organizational skills, and social problem-solving. Patients with TD have been consistently shown to have difficulties with procedural learning, fine motor control, motor inhibition, nonverbal memory, and visual motor integration. In addition, handwriting may be poor. Comorbid ADHD confers a greater risk of learning and academic problems in those with tic disorders.

Many clinically referred children with TD are reported to have difficulty with sensory-perceptual functioning, such as extreme sensitivity to touch or sound. Investigators have hypothesized that

dysregulation of central sensory integration and/or sensory gating problems may result in these sensitivities, but more research is needed. Some of these children may have comorbid autism spectrum disorder (ASD), which occurs at higher rates in children with TD than in the general population. Estimates range from 6% to 16%. Emerging research examining other conditions that may frequently co-occur with tic disorders includes stuttering, sleep disturbances, migraine headaches, asthma, and metabolic and cardiovascular disorders.

Mark was a 13-year-old boy referred by his pediatrician for consultation for tics and anxiety. Mark developed the onset of collar chewing at around age 4 or 5 years. Between ages 5 and 6 years, he began to make sniffing and snorting sounds, and at age 6 or 7 years, he developed eye blinking and head and neck movements. Mark was subsequently referred at age 8 years to a pediatric neurologist who diagnosed TD. No treatment was initiated at that time because Mark's tics were not causing any distress or impairment. His parents reported that since age 10 years, the severity of Mark's tics had diminished. He was currently repeating words and making guttural sounds and bird noises at times.

His parents reported that Mark had a long history of anxiety. As a very young child, he was anxious about separation for preschool. He was described as a child who was slow to warm, with a cautious temperament, waiting until he was familiar with a situation to enter a group. Over the years, teachers commented that they would like to see more class participation from him. His parents reported that Mark often preferred to stay at home rather than go out to see friends on play dates.

Mark reported that he did not like to speak in public because he was afraid that what he would say would "not be perfect." Mark described ruminating on "things he should have said or done differently." Mark always worried about performance, about his mother dying, and about bad things happening. Mark had slept with his parents until the age of 10 years because of a history of nightmares.

Mark had concerns about contamination, and he used Purell and washed his hands frequently. Mark hoarded objects and preferred to do things a certain number of times; in his backpack, he kept 20 books, 20 blue pencils, and 20 black pencils. In the past, he used to sharpen pencils excessively to get them to a "just right" point.

Mark was the product of a full-term, uncomplicated pregnancy; developmental milestones were described as entirely within

normal limits. Currently in eighth grade, he had attended private school since kindergarten and was an A student. Mark enjoyed sports and spending time with friends.

There was no family history of TD or OCD. Mark's father had been treated for anxiety. A paternal uncle had a long-standing history of eye blinking. Mark had no history of hospitalization, head injury, seizures, allergies, or other major medical problems.

MENTAL STATUS EXAMINATION

Mark was a slender, peripubertal boy in age-appropriate casual clothing. He was very restless. There were multiple motor and vocal tics, including eye blinking, shoulder shrugging, facial grimacing, mouth opening, coughing, and grunting. Mark showed a range of affect and was pleasant and cooperative. Mark reported that his tics did not really cause him any problems, but he worried a lot.

IMPRESSION

In summary, Mark was a 13-year-old peripubertal boy with a long history of multiple motor and vocal tics consistent with TD. Given the contamination concerns, obsessional worries and ruminations, and the tendency to count and arrange, Mark also met the criteria for OCD. In addition, there were symptoms suggestive of social anxiety disorder, given his reluctance to speak up in class, his slow-to-warm-up behavior, and his history of shyness. The excessive worry about performance was suggestive of a generalized anxiety disorder.

TREATMENT PLAN

Treatment of Mark's anxiety was indicated because it appeared to be pervasive and was causing distress. The recommendation was to start cognitive-behavioral therapy to address both his social anxiety and obsessive-compulsive behaviors. Given that Mark was neither in distress nor impaired by his tics, and was probably past his lifetime peak severity, simple monitoring of the tics was recommended. It was likely the tics would decrease once the anxiety was treated.

TREATMENT

Individuals with mild and even some moderate tics may not need treatment if the tics are not causing significant distress or impairment. Simple, active monitoring may be all that is necessary for some individuals with mild tics. Indications for treatment of tics include physical pain or discomfort, interference with social interactions, and impairment in any aspect of educational or occupational functioning. The first step in treatment is proper education of the patient, family members, teachers, and others who interact with the patient. Parents, educators, and physicians must work as partners to advocate for the optimal school environment for children with tic disorders. National and local support groups, such as the Tourette Association of America (https://www.tourette.org), can provide additional information and can serve as a valuable resource for patients and their families.

Nonpharmacologic treatments have been developed that are as successful as pharmacotherapy. In fact, the first-line treatment for mild to moderate tics is cognitive-behavioral intervention. Medications are usually considered only when symptoms are unable to be addressed by psychotherapeutic interventions and/or interfere with academic or occupational performance, peer relationships, social interactions, or activities of daily living. Pharmacotherapy for tic disorders is individualized and tailored specifically to the needs of the patient; the most distressing and/or impairing symptoms are targeted first. The goal of treatment is not to eliminate tics but to relieve tic-related discomfort or distress and to achieve a degree of control of tics that allows the patient to function as normally as possible.

General Guidelines

Behavioral intervention is the cornerstone of effective treatment for tic disorders. Treatment goals should be to reduce symptoms, support adaptive functioning and strengths, and enhance developmental progress. Self-esteem should always be supported, given that most patients with tic disorders will have at least some sense of personal and emotional vulnerability. Early in the diagnostic process, education in phenomenology and the natural history of tic disorders is essential.

Clarification that the patient's symptoms are not voluntary in most situations eases psychological burdens for both patients and families. This is especially important because families observe that tics, at times, can be suppressed. Struggles over whether the symptoms are tics or "negative behavior" are pointless and should be curtailed; a more practical goal involves personal management of, and responsibility for, symptoms and behavior, regardless of their origin.

Containment is another cornerstone of treatment. Even with the use of effective medications, it is rare for tics to remit completely. The use of a "tic room" or a "time out" area provides an opportunity to contain problematic tics or compulsions and to "de-stimulate." Because emotional conflicts and stress frequently increase symptom intensity and frequency, time-limited withdrawal from stressful situations can be beneficial. A balanced, healthy diet and exercise regimen may contribute to stress reduction and overall well-being. Caffeine and excess amounts of sugar should be minimized because they might exacerbate tics in some patients.

Psychoeducational Approaches

Educating patients and their families is essential. Patients and their parents frequently experience relief at the time of diagnosis. There should be ongoing opportunities for discussion of patients' and families' questions and concerns. Referral to the Tourette Association of America and to its local chapters is recommended for all newly diagnosed patients and their families to maintain continuing education and support.

Behavioral Therapies

Behavioral treatment is a primary intervention for many tic disorder patients. Simple behavioral approaches can be used with the majority of TD patients to "de-stimulate" and contain the symptoms. Specific paradigms are indicated for obsessions, compulsions, and tics. Relaxation techniques, such as deep breathing, guided imagery, mindfulness, and the use of relaxation tapes, can be useful for the anxious TD patient.

Habit-reversal therapy or training (HRT) forms the essence of therapeutic intervention in a cognitive behavioral treatment known as comprehensive behavioral intervention for tics (CBIT) in youth and adults. The superiority of CBIT over psychoeducation and supportive therapy alone is well established; CBIT is considered the first-line treatment for mild to moderate tics when intervention is warranted. The primary components of CBIT include awareness training, competing response training, relaxation training, contingency management, social support, and relapse prevention. Awareness training teaches patients to identify the premonitory urges or sensations that typically precede tics, as well as to recognize the situations in which tics are likely to occur. The second component of CBIT, teaching the patient a competing response to the targeted tic, has been developed to prevent the emergence of the tic. Parents are taught to provide appropriate support and encouragement to the child in practicing the technique at home. Tic substitution (substituting a more socially tolerable tic for a less socially tolerable one) can be useful.

Due to barriers to accessibility of behavioral interventions for tics, Singer and co-workers examined home-based parent-administered HRT. Their study found the home-based intervention to produce tic reduction comparable to in-person behavior intervention with a therapist. However, there were more dropouts from the parent-administered therapy group. Various interactive online treatment programs based on CBIT are now available for youth with tic disorders.

Behavioral interventions are also critical for the management of oppositional, defiant, or explosive outbursts, which are not uncommon in clinically referred youth with tic disorders. Scahill and colleagues demonstrated that parent management training is helpful in improving disruptive and explosive behavior problems in children with tic disorders, and Sukhodolsky and team have developed anger control training (ACT) for adolescents with TD and disruptive behavior. In children and adolescents, cognitive-behavioral paradigms are also the cornerstone of the treatment of mood and

anxiety disorders, which often co-occur in clinically referred individuals with TD.

Psychotherapy

Individual, group, and family therapies are supportive adjuncts to behavioral interventions and pharmacotherapy. Individual supportive therapy is indicated for patients having difficulty adjusting to the disorder, to their peers or family, or with school or occupational functioning. It is particularly useful when there is evidence of moderate stress or anxiety or another comorbid psychiatric disorder responsive to this form of psychotherapy (e.g., mild depression). It can help to restore or maintain self-esteem and promote mastery and coping. Furthermore, supportive psychotherapeutic interventions may facilitate the normal developmental tasks of friendship development, school adjustment, and day-to-day stress management.

Family therapy is extremely useful in dealing with the many complex interpersonal and family issues that arise for children with TD. At a minimum, both parents should be involved in the initial evaluation. Ideally, family members can be sources of support and nurturance. Ongoing family therapy is indicated when family development (i.e., growth and maturation) has slowed or halted because of the focus on the patient with the tic disorder. It may also help with maladaptive reactions from or to siblings or with specific symptoms that are affecting the entire family.

Group therapy is another important adjunct treatment. Support and education for parents and family members of patients with TD can be found through the Tourette Association of America, which has created a well-organized network of state and community support groups. Informal, unstructured activities can be arranged through local chapters of the Tourette Association of America. Formal, structured support is also possible through social skills groups.

School and Occupational Interventions

Learning problems and classroom difficulties occur commonly in tic disorder patients. Specific developmental disorders and ADHD- or

OCD-related symptoms may interfere with academic performance.

Clinicians should be available to provide consultation, guidance, and education to teachers or employers of patients with tic disorders. Useful special educational interventions include creating a moderate, task-oriented structure in the classroom, preferential seating, one-to-one support, and individualized educational or work plans. Flexibility is a key element in educational and occupational intervention. To promote tic control, there may be a need for optional “time outs” from class or work settings. Time limits may have to be extended or eliminated for exams. Some patients may also benefit from writing aids, such as laptops. Laptop and tablet computers may allow patients with handwriting difficulties to take notes in class without disturbing others. Adaptive, as contrasted to regular physical education, can be particularly helpful for children with TD. This form of physical education can be arranged through special education departments in local schools. Programs can be tailored to each child’s needs, strengths, and challenges.

Specific workplace interventions include structured tasks, organization of tasks into smaller units, flexible time limits, and ample physical space.

Pharmacotherapy

The decision to treat tics and/or comorbid symptoms with medication should be based on a comprehensive evaluation. Patients with symptoms that significantly interfere with adaptation to family, school or work life, peer relationships, or developmental progress should be treated, especially if psychotherapeutic options are either unavailable or not optimally beneficial. Patients who suffer significant emotional distress or inadvertently cause distress to significant others in their lives may also be candidates for treatment, even when symptoms are relatively mild. Most patients with very mild symptoms need only monitoring, education, guidance, and support. Moderate to severe symptoms should usually be treated aggressively.

The clinical workup before initiating pharmacologic treatment should include a complete physical examination and neurologic screening, psychiatric evaluation, vital signs including height, weight,

and body mass index (BMI), an Abnormal Involuntary Movement Scale (AIMS) screening, basic laboratory screening (including a complete blood count with differential, urinalysis, and a comprehensive metabolic panel including liver and thyroid function tests, fasting blood glucose, and metabolic screen including cholesterol and triglycerides), and an electrocardiogram (ECG).

Medication should be initiated at the lowest possible dose, and dose titration should be gradual in general. Most maximum doses will be low (compared to doses needed for other indications for these same medications) in TD patients. When possible, a single medication (monotherapy) should be used initially. At times more than one agent will need to be prescribed simultaneously (targeted combined pharmacotherapy) when monotherapy has not been effective or has resulted in limiting adverse effects or when target symptoms include more than one disorder.

Determining an adequate duration for a medication trial for patients with tics can be quite challenging because the natural history of TD is characterized by the waxing and waning of symptoms over time. A 1-month baseline observation period before treatment is initiated is recommended, if feasible. In general, it is best to wait at least several weeks after changing a dose before making any conclusions about a therapeutic response. External stressors must always be considered as potential determinants of increased symptomatology during medication trials. Comorbid conditions, such as ADHD and OCD, which significantly affect the individual, should be targeted aggressively because it is well established that these conditions are often more impairing than tics, and they respond to treatment.

α-Adrenergic Agonists. The α-adrenergic agents are recommended as a first-line pharmacologic treatment for most patients with mild to moderate TD, especially in those with comorbid ADHD, in whom they are more effective. Clonidine (Catapres), an α_2-adrenergic (presynaptic) agonist, has been used for over three decades for the treatment of TD. When given in low doses, it is postulated that presynaptic noradrenergic effects mediate the observed clinical improvement in motor and vocal tics. Clonidine

activates presynaptic autoreceptors in the locus coeruleus to reduce norepinephrine release and turnover in the cerebral cortex. In addition, clonidine also reduces the disinhibition, impulsivity, inattention, and hyperactivity often present in young TD patients. Data supporting its use have been mixed, but there have been well-designed studies that demonstrate clinical effectiveness.

Clonidine should generally be started at 0.025 mg daily to twice daily for prepubertal children and increased by 0.025 mg every 5 to 14 days. Prepubertal patients will generally need dosing three or four times daily. Adolescents or adults can be started on 0.05 mg daily and increased by 0.05-mg increments to twice-daily dosing. The total daily dose typically is 0.05 mg to 0.45 mg (i.e., up to 8.0 μg/kg). Common side effects include sedation, bradycardia, orthostatic hypotension, headache, dry mouth, stomachache, midsleep awakening, and irritability. Sedation, the most common and sometimes limiting side effect, usually abates over several weeks; when it does not, dose reduction may be helpful. Hypotensive effects are minimal in this dose range, but blood pressure, pulse, and ECG should be monitored at baseline and follow-up visits. More concerning is the risk of rebound increases in blood pressure, anxiety, and tics if abrupt discontinuation of clonidine occurs. A transdermal form (Catapres TTS-1, TTS-2) is available and may be an alternative when patients require very frequent dosing and/or cannot tolerate the sedative effects. A long-acting oral formulation is also available (Kapvay) and designed to be administered twice daily.

Guanfacine (Tenex), an alternative α_2-adrenergic agonist, may also be efficacious for hyperactivity, impulsivity, and tics. Guanfacine activates postsynaptic prefrontal α-adrenergic cortical receptors. Prepubertal patients are typically started on 0.25 mg daily and increased by 0.25-mg increments every 5 to 14 days given twice daily; older patients and adults are typically started on 0.5 mg daily and increased by 0.5-mg increments to about 3.0 mg daily. Adverse effects, generally less significant and more tolerable than with clonidine, include sedation, fatigue, midsleep awakening/insomnia, irritability, stomach upset, constipation, and hypotension/lightheadedness. A long-acting, once-daily extended-

release form (Intuniv) is also available. While previous uncontrolled studies and randomized control trials have supported the clinical use of guanfacine, a recent small, randomized, double-blind, placebo-controlled pilot study conducted by Murphy and colleagues found that there was no difference in efficacy between extended-release guanfacine and placebo.

Neuroleptic Agents. Since the late 1960s, when haloperidol was first introduced as a treatment for TD patients, haloperidol (Haldol) and pimozide (Orap) have been the only Food and Drug Administration (FDA)–labeled, formally approved agents for the treatment of TD. These typical neuroleptic medications block postsynaptic D_2 (dopamine) receptors in the basal ganglia, decreasing dopaminergic input from the substantia nigra and ventral tegmentum and thus reducing tics. These medications are generally effective in tic reduction; however, considerable variation exists in clinicians' and patients' thresholds for neuroleptic use. The decision to use a neuroleptic may be guided by both symptom severity and quality-of-life concerns. Significant adverse effects, including acute dystonic reactions, oculogyric crises, torticollis, Parkinsonism, akathisia, tardive dyskinesia, weight gain, sedation, dry mouth, blurred vision, galactorrhea, gynecomastia, constipation, urinary retention, social phobia, loss of drive/energy/personality, and electrocardiographic changes including tachycardia and QTc prolongation, limit their use to second- or third-line treatments. In general, neuroleptic agents are not recommended for mild tics. Of the typical neuroleptics, haloperidol and pimozide have been the most investigated, with double-blind, placebo-controlled studies supporting their use.

The newer, atypical neuroleptics, or second-generation antipsychotic agents, are recommended as a first-line treatment when a neuroleptic is indicated for moderate to severe tics. These agents, which block both D_2 dopamine and 5-HT_2 serotonin receptors, have the potential advantage of fewer extrapyramidal adverse effects (EPSs) (acute dystonic reactions, oculogyric crises, torticollis, Parkinsonism, akathisia, tardive dyskinesia). Their dual

pharmacologic activity appears to protect against the neurologic adverse effects associated with typical neuroleptic agents. Among them, risperidone (Risperdal) has been found to be efficacious for tics. Risperidone is a 5-HT2 receptor antagonist at low doses and a D2 antagonist at high doses. It acts at the α-2, D3, D4, and H1 receptors with moderate to high affinity as well. Multiple trials, including randomized, controlled trials, support risperidone's efficacy. It has been shown to be superior to placebo and equally effective as pimozide and clonidine for tic reduction. Doses are typically in the 1 to 4 mg range. Common adverse effects include appetite increase, weight gain, lipid and glucose metabolism abnormalities, and sedation. Sleep disturbance, social phobia, galactorrhea, gynecomastia, menstrual irregularities, and erectile dysfunction have also been reported.

Aripiprazole (Abilify) is a novel atypical neuroleptic with partial agonist-antagonist effects on the dopamine and serotonin system. It is a partial D2, D3, and D4 receptor agonist as well as a partial 5-HT1A and 5-HT2C receptor agonist. Several published placebo-controlled studies and open-label trials have reported effectiveness and tolerability in TD. A meta-analysis of ten studies with a total of 302 patients conducted by Liu and peers confirms that aripiprazole is safe and effective for the treatment of tics in children and adolescents. The most common adverse effects include weight gain, akathisia, and sedation. Aripiprazole became the most recent and only the third agent to be FDA-approved for the treatment of tics in 2014.

Additional atypical options with some evidence base for efficacy in TD include ziprasidone (Geodon), olanzapine (Zyprexa), and quetiapine (Seroquel). Results of one placebo-controlled trial of ziprasidone indicated that it was as efficacious as risperidone for tic reduction. Weight gain is typically less likely than that with other neuroleptic agents. Ziprasidone carries the added risk of altered cardiac conduction, especially QTc prolongation. An ECG is recommended before initiating treatment, during dose adjustments, on reaching the maintenance dose, and annually thereafter. Other adverse effects include somnolence, sedation, and akathisia.

Evidence for the effectiveness of olanzapine is supported by open-label and case-report studies, but its significant association with weight gain, the highest among the atypical neuroleptics, limits its use. Only two open-label studies demonstrate quetiapine's effectiveness for treating tics. Sedation and weight gain are the most common adverse effects.

Fasting glucose and a lipid panel are recommended before initiating treatment with a second-generation antipsychotic, as well as at the maintenance dose and at regular intervals thereafter. Weight, waist circumference, and BMI should also be monitored. An ECG may be helpful, especially when there is a known individual or family cardiac history.

Neuroleptics should be initiated at the lowest possible dose and increased very gradually. The starting dose for aripiprazole is between 1 to 2 mg per day with maximum doses of 10 to 20 mg daily. Risperidone is typically started at 0.125 to 0.25 mg daily to twice daily and titrated upward over weeks to about 1 to 2 mg daily in prepubertal children; adolescents are typically started on 0.25 mg daily to twice daily. For haloperidol, children are typically started at 0.125 to 0.25 mg daily to twice daily and increased by 0.125- to 0.25-mg increments weekly or biweekly. Adults are usually started on 0.5 mg with weekly or biweekly increases of 0.5 mg. Pimozide is an alternative D_2-blocking agent, which may cause fewer side effects than haloperidol. However, because pimozide also has calcium-channel–blocking properties, normal cardiac function (ascertained from cardiac assessment and an ECG) is a prerequisite to its use. Pimozide has been shown to prolong QTc intervals, and the risk for cardiac conduction abnormalities may increase when pimozide is combined with drugs that inhibit the cytochrome P450 3A4 isozyme. An ECG is also recommended during dose adjustments, on reaching the maintenance dose, and annually thereafter. Approximately half as potent as haloperidol, pimozide should be started at 0.5 mg to 1.0 mg for children and at about 1.0 mg for adolescents or adults. Most patients require less than 10 mg daily.

Common adverse effects of neuroleptics include weight gain, sedation, muscle cramps, and stiffness. Dose reduction or switching

to an alternative drug is the best way to address these adverse effects. Fortunately, EPSs do not appear to be common sequelae from neuroleptic use at usual doses in tic disorder patients; nevertheless, clinicians should be alert to the possibility of these reactions and consider appropriate interventions (e.g., dose reduction, anti-Parkinson agents) on a case-by-case basis. EPSs may be less common with the atypical agents than with the typicals. Tardive dyskinesia, although probably not common, has been described in patients with TD and may be difficult to differentiate from tics.

Weight gain is likely with both typical and atypical neuroleptics, but the risk appears to be greater with the use of atypical agents such as olanzapine and risperidone. The possibility of weight gain should be addressed proactively in all youth who are candidates for neuroleptics. Education at the outset of treatment regarding the need for a healthy diet and regular exercise is helpful; at times nutritional consultation may be indicated.

Tiapride, sulpiride, and amisulpride are D_2-receptor–blocking neuroleptics used in tic treatment in Europe but not available in the United States. Tetrabenazine and deutetrabenazine, nonneuroleptic dopamine antagonists that act by inhibiting central vesicular monoamine transporter type 2 (VMAT2), may be useful for the treatment of tics but are currently FDA-approved only for the treatment of chorea in Huntington disease and tardive dyskinesia. There are two open-label studies of tetrabenazine for tics with limited demonstrated effectiveness, and more study is needed. A recent randomized, double-blind, placebo-controlled study of deutetrabenazine in children and adolescents with TD did not demonstrate efficacy for the management of tics. Although results indicated active drug did not separate from placebo, it was well tolerated and was not associated with depressive symptoms (unlike tetrabenazine).

Selective Serotonin Reuptake Inhibitors. Serotonergic agents such as fluoxetine (Prozac), paroxetine (Paxil), fluvoxamine (Luvox), citalopram (Celexa), escitalopram (Lexapro), and sertraline (Zoloft)

are first-line agents for pharmacologic treatment of significant OCD, anxiety disorders, and mood symptoms. All the selective serotonin reuptake inhibitors (SSRIs) except citalopram and escitalopram have been studied in placebo-controlled investigations in children with OCD. Although there is no evidence to support the use of SSRIs for tics, their use may be warranted. Since many TD patients have obsessions, compulsions, anxiety, and depression, and neuroleptics and α_2-agonists do not effectively alter these specific symptoms, the SSRIs may be beneficial in some patients. In addition, complex motor tics such as repetitive squatting and touching may be very similar to compulsive rituals. Furthermore, stress and anxiety are known to exacerbate tics, and the use of SSRIs to reduce anxiety may indirectly serve to reduce tics.

Fluoxetine has received the most study in TD, but efficacy is likely relatively comparable among serotonergic agents. The choice typically rests with consideration of the adverse-effect profiles of the agents. Often, higher doses of SSRIs are required for the treatment of OCD symptoms than for anxiety disorders or depression, and many patients with co-occurring OCD and a tic disorder respond less well to SSRIs. The addition of small doses of a neuroleptic or an atypical neuroleptic, which increases the response to the SSRIs, may be required.

Mild OCD symptoms often respond to cognitive behavioral therapy alone, which is equally effective for OCD symptoms with or without comorbid tics. When obsessions or compulsions are of moderate to severe intensity or impair adaptive functioning, SSRIs are potentially indicated in addition to therapy. Fluoxetine is typically started at 2.5 to 5.0 mg daily for children and at 5.0 to 10 mg for adolescents or adults. Dose ranges are not well established for children and adolescents with TD. It appears that most children will respond to 10 to 20 mg daily; adults may require 20 to 80 mg daily. Fluoxetine, in combination with a neuroleptic, can be useful for both tics and obsessive-compulsive symptoms; neuroleptic doses may require reduction or adjustment because of the cytochrome P450 enzyme–inhibiting properties of fluoxetine. Common adverse effects include activation, insomnia, headaches, anorexia, and weight loss.

Sertraline, fluvoxamine, citalopram, and escitalopram are also options. There is also considerable data available on the use of clomipramine (Anafranil), a tricyclic antidepressant, in OCD, but adverse effects may be more problematic. These medications may represent alternatives for patients who experience limiting side effects on fluoxetine. Current recommendations for the treatment of comorbid tics and OCD are to use the appropriate agent indicated for each symptom. For example, an α-agonist or atypical neuroleptic can be combined with an SSRI to target significant tics and OCD symptoms.

Table 47–4.
Pharmacotherapies for Tourette and Tic Disorders

Class/Medication	Typical Range (mg)	Starting Dose (mg)	Maximum Dose[a] (mg)	Common Side Effects
Neuroleptics				
Haloperidol	0.25–5.0	0.25–0.5	10–20	Sedation, weight gain, dysphoria, extrapyramidal effects, dry mouth, blurred vision, constipation, urinary retention, tardive dyskinesia
Pimozide	1.0–10	0.5–1.0	15–20	Sedation, weight gain, dysphoria, extrapyramidal effects, dry mouth, blurred vision, constipation, urinary retention, ECG changes (QTc prolongation and cardiac arrhythmias)
Risperidone	1.0–3.0	0.25–0.5	4–6	Weight gain, sedation, lipid and glucose metabolism abnormalities, extrapyramidal effects, gynecomastia, galactorrhea, menstrual abnormalities, sexual dysfunction
Aripiprazole	2–15	1–2	20	Akathisia, sedation, agitation, weight gain, lipid, and glucose metabolism abnormalities, extrapyramidal effects
Ziprasidone	20–80	5–10	120–160	Weight gain, sedation, lipid and glucose metabolism abnormalities, extrapyramidal effects, ECG changes (QTc prolongation)
Partial α_2-Adrenergic Agonists				
Clonidine	0.05–0.45	0.025–0.05	0.45	Sedation, headaches, insomnia, stomachaches, hypotension, dry mouth, midsleep awakening, irritability
Guanfacine	1.0–3.0	0.25–0.5	3–4	Sedation, headaches, hypotension, midsleep awakening, constipation
Tricyclic Antidepressants				
Desipramine	25–300	10–25	250–300	Sedation, dry mouth, weight gain, tachycardia, constipation, blurred vision, ECG changes

ECG, electrocardiogram.
[a]These are usual maximum doses for adults.

Tricyclic Antidepressants. Some studies of desipramine (Norpramin) have suggested potential efficacy for the treatment of tics as well as ADHD symptoms in patients with comorbid ADHD. Doses are not established but may parallel doses used in ADHD without tics. Careful cardiovascular monitoring must take place, including blood pressure, pulse, and baseline and follow-up ECGs (Table 47–4).

Clomipramine is used for the treatment of OCD when the patient has failed to respond or cannot tolerate two trials of an SSRI. It can be started at 10 to 25 mg daily in children and 25 to 50 mg in adolescents or adults. Total dose ranges are typically 100 to 200 mg

daily; blood levels may be obtained, but no therapeutic range has been established. Common adverse effects are those seen typically with other tricyclic antidepressants, including sedation, dry mouth, constipation, blurring of vision, weight gain, tachycardia, and ECG changes.

Benzodiazepines. Benzodiazepines have not been well investigated in tic treatment but may hold some promise (e.g., clonazepam [Klonopin]). Some studies suggest a reduction in tics independent of anxiolytic effects. This effect may also result from a reduction in anxiety that, in turn, could reduce tic frequency. In addition, benzodiazepines can be used to treat comorbid anxiety symptomatology or panic attacks that can also occur in TD patients. Doses are not established but are often quite low (e.g., 0.125 mg daily to twice daily for clonazepam). Adverse effects of particular concern in the juvenile population are sedation, disinhibition, cognitive impairment, and dependence.

Stimulants. Stimulants are first-line agents for the treatment of ADHD. There has been controversy over the role of stimulants in TD and whether their use causes or exacerbates tics; however, recent studies have demonstrated that TD patients with clinically significant ADHD symptoms may be candidates for stimulants. In the first systematic investigation of methylphenidate use by Gadow and colleagues, behavior improved, and tics did not worsen at moderate doses of 0.1 to 0.5 mg/kg methylphenidate. When group data are analyzed, there is no significant increase in tics when stimulants are used in patients with tic disorders; however, individual patients may experience at least a transient increase in tics. Interestingly, in some studies, stimulant use is associated with a decrease in tics.

Stimulants are equally effective in improving ADHD symptoms with or without comorbid tics. A randomized, controlled study of clonidine and methylphenidate in ADHD and chronic tics conducted by the Tourette Syndrome Study Group reported that the combination and each drug alone was more effective than placebo in reducing both tics and ADHD symptoms. An increase in tics did not occur in the

methylphenidate group to any extent more significantly than in the placebo group. Additionally, a meta-analysis examining pharmacotherapy for youth with comorbid ADHD and tics demonstrated methylphenidate, α_2 agonists, desipramine, and atomoxetine (Strattera) were effective for ADHD symptoms. Supra-therapeutic doses of dextroamphetamine appeared to worsen tics. There was no short-term evidence that methylphenidate exacerbated tics.

A more recent meta-analysis of 22 randomized, double-blind, placebo-controlled trials involving 2,385 children with diagnosed ADHD conducted by Cohen and colleagues demonstrated that the risk of new-onset or worsening of tics associated with stimulant use (5.7%) was similar to that observed with placebo (6.5%). Age, type or dose of stimulant used, and duration of treatment did not affect risk.

A judicious approach to the treatment of ADHD in the context of a tic disorder is to evaluate whether tics or ADHD symptoms are causing the most distress or impairment. If ADHD is more problematic, it is reasonable to start with a methylphenidate-based stimulant. Stimulants should be initiated in low doses and gradually increased, monitoring for any exacerbation of tics. If tics are more problematic, an alpha agonist is recommended first. Both medications can be safely combined if necessary. Common adverse effects of stimulants include insomnia, appetite suppression, and weight loss.

Nonstimulant ADHD Treatment: Atomoxetine. Atomoxetine, a selective norepinephrine reuptake inhibitor, is approved for treatment of ADHD in children, adolescents, and adults. It has also been studied in youth with ADHD and chronic tics. One study reported that atomoxetine improved both ADHD symptoms and tics in children and adolescents with comorbid ADHD and TD. It is dosed based on body weight and titrated from a daily starting dose of 0.5 mg/kg to 1 to 1.5 mg/kg. Therapeutic response, unlike stimulants, takes a few weeks. Common adverse effects include headache, nausea, fatigue, and stomachaches.

Other Alternatives. Many other medical treatments have been used in TD patients. Immune therapies such as IVIG, plasmapheresis, and corticosteroids have been explored in patients with PANDAS/PANS. These remain experimental treatments under investigation. Opioid antagonists (e.g., naltrexone) may be an alternative for patients with self-injurious behaviors. The dose range for naltrexone may be approximately 25 to 75 mg per day. Nicotine, both in gum and in the transdermal form, has also been studied in TD. Results have been equivocal. In a double-blind, placebo-controlled trial of 61 patients with TD at doses up to 7.5 mg daily, mecamylamine (Inversine), a nicotine antagonist, was found to be no more effective than a placebo. In addition, a randomized, controlled trial of pramipexole, a mixed dopamine agonist with presynaptic autoreceptor effects, failed to show efficacy.

Baclofen, a GABAergic muscle relaxant used to treat spasticity, has been studied in one large open-label and one controlled trial. In the controlled trial, there was no difference between drug and placebo in Yale Global Tic Severity Scale Total Tic score, but baclofen was superior to placebo with regard to tic-related impairment. A placebo-controlled study of omega-3 fatty acids derived from fish oil revealed no improvement in tic measures, but clinically meaningful improvement in tic-related impairment compared to placebo was reported.

The use of botulinum toxin to suppress tics by injection into discrete muscles involved in tic generation has been examined in several studies. Botulinum toxin blocks acetylcholine release at the neuromuscular junction and produces a temporary, reversible diminution of muscle activity, which may last weeks to months for dystonic tics. Placebo-controlled and open-label trials have demonstrated efficacy for isolated tics. Botulinum toxin may be the most useful agent for the treatment of solitary, focal dystonias. There are reports of suppression of ear-wiggling tics and laryngeal tics. Adverse effects include soreness at the injection site and muscle weakness.

Targeted combined pharmacotherapy—the specific combination of two or more medications at one time—has evolved as a treatment

option. Ideally, this approach should be used only after adequate trials of monotherapy have failed. However, many patients with TD also have comorbid ADHD or OCD, and often both, and frequently monotherapy addresses one problem but not the other. Judicious use of SSRIs and neuroleptics for TD and comorbid OCD is one example of this approach; in some patients with OCD and tics, this approach may be more effective than monotherapy. Another example is the combination of methylphenidate and clonidine to target tics and ADHD symptoms. In general, for comorbid tic disorders and OCD or ADHD, each condition should be treated with its respective first-line option.

Surgical Treatment. Initial reports on surgical interventions for TD appeared in the 1960s. Stereotaxic neurosurgical techniques have since been used in a few cases of severely impaired adults. Bilateral capsulotomy was associated with at least 50% improvement in both motor and vocal tics in 12 patients who had TD, with no severe adverse effects. In 1999, deep brain stimulation (DBS) was introduced for the treatment of intractable tics. Several patients have since undergone bilateral thalamic stimulation with promising results. However, given the significant medical risks of these procedures, there has been limited experience with use of these techniques in youth, and they have generally been reserved for severe and refractory tics that significantly interfere with function and persist into adulthood.

Transcranial magnetic stimulation involves generating a brief, powerful magnetic field by a small coil positioned over the skull, inducing an electrical current in the brain. This noninvasive approach has been demonstrated to effect long-term changes in cortical excitability, which may be abnormal in tic disorders. It is an exciting potential future treatment for tics. Neural stem cell transplantation is another proposed treatment for tics, and studies are underway.

Jack was a 14-year-old boy referred by his mother for management of his TD. Jack developed the onset of skipping and clapping episodes when he was approximately age 7 years. This was followed by stretching movements of his mouth and nose accompanied by facial grimaces. His mother reported that Jack's tics remitted entirely until just before his 12th birthday when he began to "give the finger" for no apparent reason and began to curse using the "F" word. Children often teased him, and he was in significant distress about this.

Jack was the product of a full-term, uncomplicated pregnancy; developmental milestones were described as within normal limits. Jack's parents divorced when he was 2 years of age. Jack attended private school from prekindergarten through, at the time of referral, the ninth grade. He had difficulty with mathematics. He had a group of friends, including a best friend, and enjoyed music and video games.

Jack's maternal grandmother had OCD, and maternal great-uncles had eye-blinking tics. Jack had no history of head injury or seizures. Electroencephalographic and computed tomography scans were within normal limits. Past medication included adequate trials of clonidine, guanfacine, risperidone, and ziprasidone. Medications at the time of referral included haloperidol 4 mg, which led to excessive sedation, including somnolence in school.

MENTAL STATUS EXAMINATION

Jack was a moderately overweight adolescent boy. Of note were multiple motor tics, including pelvic thrusting, hand movements, outward leg twisting, head and neck thrusting, eye blinking, abnormal inhalation, chin hitting, shoulder licking, and genital scratching. In addition, there was copropraxia in the form of "giving the finger." There was also a change in his vocal inflection intermittently and a tendency to yawn on occasion.

IMPRESSION

In summary, Jack was a 14-year-old adolescent referred for management of his TD. His clinical picture was consistent with moderately severe TD. He had been treated with a variety of tic medications that were ineffective or intolerable.

TREATMENT PLAN

The recommendation was for a trial of aripiprazole. In addition, a trial of Comprehensive Behavioral Intervention for Tics (CBIT) was recommended. Jack and his parents were also counseled that at age 14, it was possible he was currently seeking treatment at his lifetime peak tic severity, and tic symptoms might begin to attenuate over the next few years.

SUMMARY AND FUTURE DIRECTIONS

The French neurologist Georges Gilles de la Tourette in 1885 was among the first to recognize and describe the neurodevelopmental disorder that now bears his name, as well as its psychiatric comorbid conditions. Since the first case descriptions of Gilles de la Tourette, a spectrum of tic disorders has come to be recognized and codified in psychiatric nomenclature. Tic disorders are complex neurodevelopmental disorders with heterogeneous phenotypes characterized by core disinhibition mediated by the CSTC tracts. Tic disorders are genetically determined in most cases. There is a growing appreciation and understanding of the role of psychiatric comorbidity in the diverse clinical presentation, and it is often the neurobehavioral, occupational, and psychosocial problems that co-occur in clinically referred individuals that warrant treatment rather than the tics per se. Treatment strategies should be multimodal in nature and include cognitive-behavioral, individual and family intervention, social and educational monitoring and support, and, where indicated, pharmacotherapy. Future investigation is needed to better understand the phenomenology, developmental psychopathology, and novel approaches to the treatment of tics. Tremendous progress has been made in the last few decades using innovative neuroimaging techniques, genetic studies, and clinical

interventions. Understanding of the etiology, genetics, neuroanatomy, and epidemiology of tic disorders has been significantly enhanced. Novel treatment approaches have also emerged, providing alternatives to the pharmacologic management of tics. Targeted behavioral intervention has been proven to be as effective as medication and is now first-line treatment. DBS, botulinum toxin, targeted surgery, and stem cell transplantation are examples of promising new treatments. Complementary and integrative treatments such as music, exercise, and herbal remedies are also being investigated. The future holds tremendous promise as new insights into the etiology, pathophysiology, and treatment of tic disorders are rapidly developing.

Elimination Disorders

Edwin Jens Mikkelsen, M.D.

ENURESIS

The disorder of enuresis has been recognized for centuries. However, substantial progress in the understanding of the disorder did not begin to occur until there were effective treatments. The first effective treatment was the application of the bell-and-pad method of conditioning, which was subsequently followed by pharmacologic treatment in the form of imipramine (Tofranil) and, more recently, desmopressin acetate (DDAVP). Each of these advances has led to etiologic research that might explain the efficacy of the particular intervention. This chapter reviews the accumulated clinical knowledge concerning enuresis, as well as the emerging research that may lead to a greater understanding of the disorder.

Definition

Enuresis is defined as the involuntary or intentional voiding of urine. The severity is determined by the frequency of urination; quantity is not a diagnostic consideration per se. Quantity can become a factor in treatment decisions if a child emits only small quantities of urine; in actual practice, quantity usually does not figure heavily into the treatment plan. Frequency, however, can be important in planning a hierarchy of treatment approaches. The major diagnostic qualifier

relates to the age of onset. Finally, the definition precludes a physical cause for the disorder.

The length of time before continence is considered established varies in the literature between 6 months and 1 year. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and its text revision (DSM-5-TR) require a chronologic age of 5 years or, alternately, a developmental level equivalent to that age. In practical clinical terms, children who have never maintained continence for more than 1 year are referred to as having *primary enuresis*, whereas children who have achieved continence for 1 year or longer and then resume wetting are referred to as having *secondary enuresis.* The DSM-5-TR requires a frequency of at least two episodes a week for 3 consecutive months. However, it allows an exception for distress or impairment in functions. This means that an individual can receive the diagnosis if they are deemed to experience significant distress and do not meet the frequency criteria.

The disorder is also further defined according to the timing of the episodes throughout the day. Episodes occurring only at night are referred to as *nocturnal*; daytime wetting is labeled *diurnal.* The term "nocturnal and diurnal" refers to a combination of these two subtypes. Most children display only nocturnal enuresis, but some manifest diurnal or nocturnal and diurnal patterns.

History

A scholarly review of the history of enuresis found references dating back about 3,550 years to the Papyrus Ebers. The term derives from the Greek word *enourein*, which means "to void urine." In retrospect, many of the treatment approaches that were used in the past now appear almost sadistic in nature. Although some of these interventions may have been misguided but well-intentioned therapies (as in the use of leeching for other disorders), they may also reflect the commonly held view that the disorder is somehow under the (direct or indirect) control of the child and that punishment would lead to its cessation.

A confluence of somewhat disparate observations contributed to the evolution of the current understanding of enuresis. Although each of these is discussed in more detail in the following sections, a brief reference to them here will provide an overview of the various lines of research and their relative contributions to the present understanding of the disorder. The long-standing observation that enuresis tends to run in families evolved into the observation that a positive family history was a positive prognostic indicator for response to pharmacologic interventions and, ultimately, to sophisticated research with large pedigrees pointing toward specific genetic loci and modes of transmission. The observation that imipramine was an effective treatment for enuresis ushered in the modern era of research because the efficacy of imipramine suggested biologic contributions to the etiology of the disorder. Imipramine has now been largely supplanted by DDAVP as a pharmacologic treatment modality, and related research into its mechanism of action has contributed interesting insights into the pathophysiology of the disorder. Juxtaposed with the research into pharmacologic treatment and organic contributions to the disorder has been the impressive literature, which now dates back several decades, indicating that behavioral treatment in the form of the bell-and-pad method of conditioning is equally effective as the two leading pharmacologic interventions for the disorder. The observation that the wetting episodes usually occur at night also led to decades of research investigating the relation between sleep architecture and the occurrence of enuretic events. Although none of these lines of research has provided a parsimonious explanation, each has provided important contributions to the evolving understanding of the disorder. The accumulating literature with regard to enuresis increasingly suggests that a single unified theory of enuresis that applies to all children will not be identified.

Comparative Nosology

The variety of differing nosologic and diagnostic schemas seen with many disorders does not exist for enuresis. The behavior is concrete

and definite: The child wets or does not. That criterion makes it possible to integrate research data from different countries, cultures, and treatment centers with greater reliability than is possible for many other disorders. The efficacy of a given treatment is reported in terms of its effect on the frequency of enuretic events. The primary differences with regard to diagnosis concern the frequency required to make a diagnosis of enuresis as a pathologic state and the period of continence necessary to separate primary from secondary enuresis, with a duration of 6 months occasionally being used instead of 1 year. Only slight differences exist between the eleventh revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-11) and the DSM-5-TR (Tables 48–1 and 48–2).

Table 48–1.
DSM-5-TR Diagnostic Criteria for Enuresis

A. Repeated voiding of urine into bed or clothes, whether involuntary or intentional.
B. The behavior is clinically significant as manifested by either a frequency of at least twice a week for at least 3 consecutive months or the presence of clinically significant distress or impairment in social, academic (occupational), or other important areas of functioning.
C. Chronological age is at least 5 years (or equivalent developmental level).
D. The behavior is not attributable to the physiological effects of a substance (e.g., a diuretic, an antipsychotic medication) or another medical condition (e.g., diabetes, spina bifida, a seizure disorder).

Specify whether:
Nocturnal only: Passage of urine only during nighttime sleep.
Diurnal only: Passage of urine during waking hours.
Nocturnal and diurnal: A combination of the two subtypes above.

Epidemiology

The first comprehensive data concerning the incidence of enuresis came from the Isle of Wight Study. They found that 15.2% of boys (7 years of age) were enuretic less than once a week, whereas 6.7% were wetting at least once a week or more. In 7-year-old girls, the frequency was 12.2% for those wetting less than once a week and 3.3% with a frequency of once a week or more. By 9 and 10 years of age, 6.1% of the boys were wetting less often than once a week, and 2.9% were wetting once a week or more. The corresponding figures for 9- and 10-year-old girls were 3.5 % wetting less than once a week and 2.9% wetting once a week or more. The frequency for

boys decreased considerably by 14 years of age, at which time 1.9% were wetting less than once a week, and 1.1% were wetting at a frequency of once a week or more. The rates also decreased for girls by 14 years of age, with 1.2% wetting less than once a week and only 0.5% wetting once a week or more.

Table 48–2.
ICD-11 Diagnostic Criteria for Enuresis

- Repeated and persistent voiding of urine into bed or clothes (e.g., several times per week over several months), which may occur during the day or at night.
- The individual has reached a developmental age when urinary continence is ordinarily expected (approximately equivalent to a chronologic age of 5 years).
- The symptoms are not better accounted for by the physiologic effects of a substance or medication or by another medical condition (e.g., a Disease of the Nervous System, a Disease of the Musculoskeletal System or Connective Tissue, or congenital or acquired abnormalities of the urinary tract).

Specifiers:

Nocturnal Enuresis:

Inappropriate voiding of urine occurs only during the night. This is the most common form of enuresis and typically occurs during the first part of the night soon after the individual has gone to sleep.

Diurnal Enuresis:

Inappropriate voiding of urine occurs only during waking hours. This form of enuresis is also referred to as urinary incontinence.

Nocturnal and Diurnal Enuresis:

Inappropriate voiding of urine occurs both during the night and during waking hours.

A New Zealand study involving 8-year-old children found the prevalence of nocturnal enuresis to be 7.4%, with 3.3% primary, and 4.1% labeled secondary. A similar large Scandinavian study involving 7-year-old children reported a prevalence of 9.8%, with the highest prevalence (6.4%) involving children with nocturnal enuresis, 1.8% with diurnal enuresis, and 1.6% with mixed nocturnal and diurnal enuresis. A report from Australia described an incidence of 5.1% for children in the range from 5 to 12 years of age. A review of the published epidemiologic literature concerning enuresis indicates remarkably consistent findings from different countries and cultures, even though the research methods are somewhat variable. A standard consensus format that defines uniform reporting parameters would greatly enhance the epidemiologic literature base.

The epidemiologic literature is consistent in confirming that enuresis is a self-limiting disorder that will eventually spontaneously resolve. Common point prevalence figures are in the range of 7% of boys and 3% of girls at 5 years of age, dropping to 3% of boys and 2% of girls by 10 years of age. Only 1% of boys still wet at age 18 years of age, and still fewer girls wet at this age. A spontaneous remission rate of between 5% and 10% per year after 5 years of age is usually cited. Secondary enuresis may occur at any time, but most commonly, it begins between 5 and 8 years of age.

Etiology

Inclusion in the DSM-5-TR (as well as previous editions) definition of enuresis of children who wet intentionally with those whose enuresis is involuntary can be problematic. The vast majority of enuretic children do not wet intentionally or even on a subconsciously motivated basis. Increasingly, the research is pointing toward causal factors that may involve irregularities in physiologic processes. Clearly, children who wet intentionally are in a different phenomenologic grouping than those who do so on an involuntary basis, even if they do meet the other diagnostic requirements. The most likely explanations for voluntary intentional wetting are an oppositional defiant disorder (ODD) or a psychotic disorder. There

are also a small number of children who originally have enuretic events involuntarily and subsequently manifest the behavior on a voluntary learned basis as well.

There is a correlation between enuresis and psychological disturbance that increases with age. This association is even more significant for enuresis, which persists into adolescence. Children living in socially disadvantaged situations and experiencing psychosocial stress have a greater frequency of enuresis than those who are not. The type and range of behavioral disturbance seen in children with enuresis are broad, and no marker can reliably differentiate between behaviorally disturbed and nondisturbed enuretic children. Thus, the associated behavioral disturbances are nonspecific and may represent a coincidental or secondary relationship rather than a causal correlation. Further supporting a secondary correlation are the repeated findings that children with enuresis have significantly more developmental delays and minor neurologic dysfunction than nonenuretic children compared to controls and other children attending a psychiatric clinic. Reports of delayed bone development in children with enuresis have also been linked to a possible general delay of maturation as a common underlying factor. However, new studies refute this finding, and no clear conclusion can be drawn at this time. The most recent research into a general developmental delay contributing to enuresis has used evoked potentials and electromyographic recording of startle eye-blink performance. Separate investigations using these methods have pointed to delayed maturation of brainstem functions.

Another approach to this etiologic question is represented by a large, longitudinal, population-based study in the United Kingdom, which compared the intelligence (as assessed by the Wechsler Intelligence Scale for Children–Third Edition [WISC-III]) of controls with children who still exhibited bedwetting in the age range of 7 years and 6 months to 9 years and 3 months. The authors reported that the bedwetting was associated with lower intelligence quotient (IQ) even after children with an IQ of less than 70 were excluded. However, this finding was primarily related to lower scores on the Performance section of the WISC-III. This observation led the

authors to conclude that enuresis may be related to deficits in the maturation of the central nervous system.

One comprehensive effort reviewed the psychodynamic literature concerning enuresis and encopresis to define the concepts conveyed in that literature and then to determine empirically how often those concepts were verified and supported by the analysis of clinical material. The literature review yielded 24 generalizations that were consistently applied to enuretic and encopretic children. In subsequent statistical analysis of the clinical material, only 2 of the 24 generalizations reached statistical significance. Another recent study in this regard used a standardized behavioral rating scale, the Eyberg Child Behavior Inventory (ECBI), which was applied to children with primary nocturnal enuresis (PNE) (N = 92), a nonclinical control sample (N = 92), and a clinical sample (N = 92). The results indicated that the children with PNE had higher scores than the nonclinical control sample but significantly lower scores than the clinical sample. However, the mean score for the children with PNE was actually lower than the clinical cutoff score that had been determined for the ECBI.

Related to the association between behavioral disturbance and PNE are studies that address the frequency of diagnostic comorbidity. The most commonly reported comorbid diagnosis is attention-deficit/hyperactivity disorder (ADHD). In general, studies have reported that the co-occurrence of ADHD and PNE is approximately 30% greater than the frequency that would be expected from chance alone. A large contemporary study found that 32% of children diagnosed with ADHD also met diagnostic criteria for enuresis, whereas only 14% of a control group met the criteria. This finding was statistically significant at the $P < .001$ level. The rates of primary and secondary enuresis were not significantly different in the two groups. This study then investigated the degree of psychopathology and impairment in ADHD children (with and without comorbid enuresis) and found no significant differences. Similar findings were reported for the rates of psychopathology when the control children with enuresis were compared to those without the condition. Thus, the diagnosis of enuresis did not appear to increase

the risk of psychopathology for the controls or the degree of impairment in the children who also had a diagnosis of ADHD. However, there was a higher incidence of learning disabilities and impaired academic performance in the control children with enuresis when compared to the control children without enuresis. This difference in the incidence of learning disabilities was not found when the ADHD children with enuresis were compared to those without the comorbid disorder. Thus, the co-occurrence of enuresis did not appear to increase the risk of learning disabilities in children with ADHD.

Another investigation used a family pedigree methodology to study the transmission of enuresis in the relatives of index family members who were diagnosed with PNE and in control probands who were diagnosed with ADHD as compared to those without this diagnosis. The results indicated that the two disorders were transmitted independently of one another.

Enuresis has been noted to occur statistically more frequently in the premorbid histories of children who develop early adolescent bipolar I disorder as compared to controls. An increased incidence of enuresis and other childhood psychiatric disorders has also been found in the history of adults with bipolar disorder and is associated with earlier onset of the disorder.

The association between behavioral disturbance and enuresis is stronger with secondary enuresis. This has been demonstrated by controlled studies and anecdotal reports of an association between the onset of enuresis and the loss of a parent through divorce or death. However, it should be noted that a large study from the Netherlands reported similar rates of psychopathology in children with primary enuresis as compared to those with secondary enuresis. The prevalence of psychodynamic factors in children with secondary enuresis would intuitively make sense because they have, by definition, demonstrated the physiologic competence to maintain continence for a prolonged period of time before losing that ability. The most specific study of this association indicated that exposure to four or more stressful life events in a year and delayed acquisition of nocturnal continence were risk factors for the

development of secondary enuresis. An association between the occurrence of traumatic events and the development of secondary enuresis has also been demonstrated.

There has been one innovative attempt to explore the possible relationship between physiologic and psychological factors. Specifically, it was postulated that children with enuresis who did not present with a concomitant behavioral disturbance would be those with dysfunctional or abnormal bladders, whereas those with a behavioral disturbance would be more apt to have normal bladders. The study found the converse to be true: The group with behavioral disturbance had more dysfunctional bladders with lower volumes. The behaviorally disturbed group also had a greater number of developmental delays. A subsequent investigation reported no difference in bladder size among controls, children with PNE, and those who had been diagnosed with PNE but who were now continent. It also was demonstrated by two independent investigations that fluid loading can precipitate enuresis in children who have no prior history of enuretic events. The most recent investigations into this issue have used ultrasound techniques, which investigate both the volume capacity of the bladder and the thickness of the bladder wall in both controls and children with enuresis. This research suggested three subtypes: large-capacity bladder with a thick wall, normal-capacity bladder with normal wall thickness, and low-capacity bladder with a thick wall. The children with enuresis were then assessed with regard to their response to treatment with DDAVP. The results indicated that the children with the two abnormal bladder subtypes were less responsive to treatment than those with normal bladder physiologic characteristics.

The observation that enuresis tends to occur in family members has been known for decades. A large Scandinavian study involving more than 3,000 children found that a child's risk for developing enuresis was 5.2 times greater if the mother also had the disorder and 7.1 times greater if the father had the disorder, lending further support to a genetic influence. Within the last few years, there have been tremendous advances in the study of the genetic transmission of enuresis, which suggests that genetic contributions are likely to be

significant in families with multigenerational histories of enuresis. A Scandinavian group identified 11 families that manifested PNE over three generations in a pattern that was suggestive of an autosomal-dominant inheritance, with a penetrance greater than 90%. Genetic linkage studies with these families indicated markers on chromosome 13q. Similarly designed studies have also implicated chromosomes 4p, 8, 12q, and 22, suggesting genetic heterogeneity. A large multigenerational study that specifically investigated chromosome 22 found that only 39.3% of families had linkage to genetic markers on this chromosome. The genetic modes of transmission that have been discussed include sporadic, autosomal recessive, and autosomal dominant. Linkage studies have also suggested the possibility of mutation in the aquaporin-2 (AQP2) water channel locus in families with a dominant mode of transmission of primary enuresis, in that AQP2 appears to be essential for concentrating urine. Although genetic linkage studies continue to provide important information with regard to the etiology of enuresis, it increasingly appears that the genetic contributions are heterogeneous in nature and vary substantially among pedigrees that contain multiple generations of individuals with enuresis. Thus, it is likely that there is more than one mode of genetic transmission that contributes to the disorder; and different mechanisms may be operating in different family pedigrees.

One particularly important etiologic hypothesis was that urinary tract obstruction frequently caused enuresis. The significance of that belief revolves around the related implications for surgery to correct the obstruction. An extensive review of the relevant literature found no basis for concluding that bladder neck repair or urethral dilation was a reasonable or effective treatment for enuresis. That generalization does not apply to patients with specific anatomical or pathophysiologic findings.

Research into the association between sleep physiology and enuretic events has evolved steadily since the 1970s. The research can be seen as evolving through the following four stages. During the first phase of the research, it was postulated that enuretic events were dream equivalents that occurred in a deep sleep. The second

major theory grew out of the observation that enuretic events originated in delta sleep and followed arousal signals. Thus, enuresis was seen as a disorder of arousal, which led to the hypothesis that enuretic children who were not psychologically disturbed did not produce arousal signals, whereas behaviorally disordered children did but failed to respond to them. The third phase of sleep research is represented by the two largest controlled studies, both of which found that when the time of night is also considered, enuretic events occur in all sleep stages in proportion to the amount of time spent sleeping in each stage. A fourth phase of investigation has attempted to couple cystometry with sleep studies in an attempt to identify subtypes. These investigations have yet to produce any definitive results that can be replicated.

A long-debated issue has been whether children with nocturnal enuresis are more difficult to awaken from sleep than other children. Earlier literature had suggested that anecdotal reports from the parents of children with enuresis that they were difficult to arouse stemmed from their lack of experience in attempting to arouse their other children, who did not have enuresis, from a deep sleep. However, studies have suggested that children with enuresis may, in fact, be more difficult to arouse than control children. Recent reports have also found that obstructive sleep apnea may play a role in the development of PNE in some children.

The efficacy of DDAVP as a treatment for enuresis has led to the theory that some children lack the ability to concentrate urine produced during the night and thus cannot reduce urine volume, and manifest enuretic episodes as a result. That hypothesis has led to studies investigating the circadian variation of plasma atrial natriuretic peptide (ANP). Children with enuresis have not consistently been found to differ from controls with regard to ANP. In one study, 14 of 55 children with enuresis had lower ANP concentrations than controls, and 9 of the 14 children had an excellent response to treatment with DDAVP. An investigation into the concentration of vasopressin in plasma and urine in 18 children with PNE and 20 matched controls found the concentration of

vasopressin in plasma at 8:00 AM was significantly lower in the enuretic group. Total 24-hour urinary vasopressin excretion was also lower in the enuretic group but not significantly so.

Another hypothesis that has been investigated is that endogenous arginine vasopressin (AVP) levels would be different in children with enuresis who respond to DDAVP as opposed to those who do not. This would suggest the existence of a specific subgroup of children with enuresis based on their endogenous AVP levels and their positive response to DDAVP. A study involving a small number of subjects supported this hypothesis by indicating that AVP levels in the morning differentiated between controls and children with enuresis, as well as between DDAVP responders and nonresponders. However, a large study that also controlled for water intake over 72 hours and that sampled AVP more frequently found that only 14 of the 55 children with enuresis had a significant decrease in AVP when compared to controls. Of these, 9 had a significant positive response to DDAVP. Further complicating this line of research is the finding that AVP is not secreted in a continuous manner over 24 hours but rather is secreted in a pulsatile pattern, suggesting that definitive studies of this variable require frequent sampling. Investigations that have adopted this methodology have yielded conflicting results, in that one reported no differences between DDAVP responders and nonresponders, whereas another study with a small number of subjects that used hourly measurements found that in the 11:00 PM to 4:00 AM time period, children with enuresis ($N = 9$) had significantly lower AVP levels than did controls ($N = 8$).

There have also been related studies into the role of urine osmolality. One hypothesis is that a decreased ability to concentrate urine could contribute to an increase in the volume of urine. In general, these studies indicated that children with enuresis do have lower urinary specific gravities (as compared to controls) but not to a level that reaches statistical significance. It has also been reported that the levels of AVP can be increased in controls and children with enuresis by fluid restriction and, furthermore, that plasma osmolality

can affect AVP secretion. In this regard, a comparison of controls, DDAVP nonresponders, and DDAVP responders indicated that fluid deprivation produced an increase in AVP levels in all groups, but the response was less robust in the DDAVP responders than in the other groups.

Another variation on this line of research is that refractory enuresis persisting into adolescence and adulthood may be secondary to a relative insensitivity to AVP, which can be positively affected by DDAVP. These observations contribute to the hypothesis that the primary pathophysiology of enuresis may occur at the receptor level, and this may also explain why some children do not respond to DDAVP.

Further complicating the research into the mechanism of action of DDAVP are two independent investigations that suggested that there is a central nervous system mechanism that may account for its efficacy in some children with enuresis.

Thus, as the foregoing review suggests, what initially appeared to be an intuitive explanation for the mechanism of action of DDAVP has not been supported by a number of studies and a precise mechanism that applies to all children who respond to DDAVP has not been identified.

There have also been investigations that have implicated tubular mechanisms with regard to the urinary excretion of potassium and sodium by children with enuresis. Although this research has primarily focused on the possible mechanism of action of DDAVP, it has also led to a reanalysis of imipramine's mechanism of action. Imipramine can produce a decrease in the excretion of sodium and potassium, which then produces a reduction in osmolal clearance and a decrease in urinary output. It has also been reported that imipramine can affect the secretion of nocturnal urinary antidiuretic hormone (ADH) and that this may account for its efficacy.

Diagnosis and Clinical Features

The concreteness and simplicity of enuresis make the diagnosis relatively easy. The DSM-5-TR continues the same age criteria that

were used in the DSM-IV and DSM-IV-TR by specifying that the diagnosis is not made in a child whose chronologic or mental age is younger than 5 years of age. The stated rationale is that, by this age, continence can be expected to have occurred. As noted by the reference to a mental age of 5 years, children with developmental disabilities may have a greater chronologic age. The wetting must occur at least twice per week for at least 3 consecutive months, or, if less frequent, it must produce significant distress or functional impairment. Physical causes, such as a bladder infection, must be excluded. Qualifiers to the diagnosis indicate whether it is primary or secondary enuresis. As previously noted, *primary enuresis* refers to those children who have never maintained continence for any length of time, whereas *secondary enuresis* refers to those who had achieved continence for at least 6 to 12 months and then resumed wetting. The other qualifiers refer to the timing of the enuretic event during the day. Although most children exhibit only nocturnal enuresis, some have daytime (diurnal) patterns or a combined nocturnal and diurnal pattern.

The inclusion of children who wet intentionally with those who wet involuntarily under the same diagnostic heading can be problematic because that distinction has significant clinical implications. Children who are wetting intentionally almost certainly are doing so as a manifestation of a psychological disturbance. Although there is an association between behavioral disturbance and involuntary enuresis, the nature of the correlation is relatively nonspecific. Thus, although the coexistence of other behavioral problems is not a diagnostic issue per se, it is of clinical importance.

John was a 10-year-old boy who had consistently wet the bed throughout his life. He averaged three to four nocturnal episodes per week, and his longest period of continence was a few weeks. Thus, John warranted a diagnosis of primary enuresis. John's father had been enuretic until 12 years of age, as were his father and a paternal uncle. Accordingly, the family had always assumed that this was a hereditary genetic disorder that John could not control. In keeping with this perception, John's parents had never adopted a punitive approach to the bedwetting. The wetting was handled in a matter-of-fact manner, with John washing his sheets every morning and showering before going to school.

The family sought consultation at this time because John was increasingly being asked to sleep overnight at the homes of friends and also wanted to attend an overnight Boy Scout camp. These concerns led the family to meet with their pediatrician, who suggested a trial of the bell-and-pad method of conditioning. This approach was not effective, in part because the family lived in cramped quarters and the alarm that was meant to awaken John also woke his two brothers who shared the bedroom with him.

At this point, the family's pediatrician suggested that they meet with a child psychiatrist with whom she worked. The child psychiatrist described the clinical literature on DDAVP. However, when John's father indicated that his health insurance did not cover prescriptions and that the family was having difficulty covering their household expenses on his income, which was only moderately above minimum wage, the psychiatrist felt compelled to discuss the relative costs of DDAVP and imipramine, which was less expensive than DDAVP. However, the psychiatrist also indicated that John would require a baseline electrocardiogram (ECG) (which his insurance could cover).

Ultimately, the family decided that John would need medication only for brief, discrete periods (overnights at friends and 1 to 2 weeks of summer camp) because they had worked out an

acceptable plan for responding to the wetting on a day-to-day basis. Furthermore, they reasoned that, within approximately 2 years, John would experience a spontaneous remission of his enuresis, given that this was the family pattern. Thus, they decided that, because DDAVP has a rapid onset of action, they would pay out of pocket for the relatively small amounts of DDAVP that would be needed for these discrete periods over the next 2 years. The pediatrician advised the family of the Federal Drug Administration (FDA) alert regarding the risk of hyponatremia and seizures. They decided to use the oral form of DDAVP because the FDA identified the nasal spray as being more likely to produce hyponatremia and indicated that this form of DDAVP was no longer indicated for childhood enuresis. They were also advised to (1) limit John's fluid intake on the nights when DDAVP was administered, (2) discontinue its use if John developed the flu or another illness that could affect his fluid balance, and (3) discontinue the medication and notify their physician if symptoms of nausea, vomiting, or headache developed.

Pathology and Laboratory Examination

Because urinary tract infections can produce enuresis, a urinalysis should be part of every evaluation. Using radiographic procedures with contrast media to detect an anatomical or physiologic cause for the enuresis is more problematic because the procedures are invasive and painful and the diagnostic yield is low. A large study carried out in a pediatric primary care setting found a 3.7% incidence of obstructive lesions in children with enuresis. Others have reported similar findings. The literature cited earlier in the section on etiology concerning the use of noninvasive ultrasound techniques to establish bladder capacity and wall thickness have not been replicated to a degree that would warrant their use on a routine basis. However, they may be of use for children who are refractory to standard treatment.

Differential Diagnosis

As suggested previously, the primary differential diagnosis is a urinary tract infection. This is especially true for girls, who are more prone than boys to develop urinary tract infections. A urinary tract infection should be the first consideration for a girl who has been continent for a considerable period of time and has recently begun wetting. Although the diagnostic yield is smaller with boys, a urinalysis should still be carried out.

Enuresis can result from anatomical malformations or obstructive lesions, but the percentages are relatively low. If the history and interviews with the child suggest that the enuresis is intentional, then it is almost certainly related to an underlying psychological disturbance. The relation between psychological disturbance and involuntary enuresis is less clear. The coexistence of another behavioral disturbance should be noted and attended to clinically. The most common comorbid psychiatric disorder is ADHD.

It has also been documented that enuresis has a negative effect on self-image and that enuretic children have more negative feelings about their disorder as compared to children who have other chronic illnesses.

There have also been case reports linking the onset of enuresis in children to the administration of both the selective serotonin reuptake inhibitor (SSRI) antidepressants and the atypical antipsychotic agent risperidone (Risperdal). Thus, the possibility of enuresis as a side effect of these medications should be considered if a chronologic correlation exists.

Secondary enuresis has also been identified as an important symptom of the abrupt onset of Type 1 Diabetes in children and is related to the polydipsia and polyuria that accompany that disorder.

Course and Prognosis

The natural history of enuresis is significant because it is a self-limited disorder that can spontaneously remit. The fact that the diagnosis is not made until 5 years of age takes into account children who have delays in toilet training that are not outside the accepted

range (between 2 and 5 years of age). The prevalence of enuresis is relatively high, between 5 and 7 years of age, and then drops off substantially. The vast majority of enuretic children experience a spontaneous resolution of the problem at some time, and only a few remain enuretic into adulthood. By 14 years of age, only 1.1% of boys wet once a week or more. The peak age for secondary enuresis is between 5 and 8 years of age.

Treatment

The methods for the treatment of enuresis that have been empirically proven to be effective are primarily behavioral and pharmacologic. Psychotherapy may be useful for ameliorating some of the associated behavioral problems that can be seen with enuresis, especially secondary enuresis. A particularly common clinical scenario for secondary enuresis is the development of wetting after the loss of a parent through death or divorce. In these patients, psychotherapy is the primary treatment modality. A review of the efficacy of psychotherapy for primary enuresis found a 20% success rate, which is probably not significantly greater than would be expected by the rate of spontaneous remissions and random chance.

Behavior Therapy. A comprehensive review of several studies determined the success rate for behavioral interventions as 75%. Recent studies have yielded comparable response rates. The primary behavioral intervention is the bell-and-pad method of conditioning. A pad is placed on the bed, with a wire running to a bell. When the child wets, the moisture completes a circuit in the pad, ringing the bell and waking the child. With repeated use, the child learns to awaken before wetting occurs. Several studies have indicated that concomitant behavioral disturbance reduces the likelihood of success of behavioral interventions.

Recent behavioral studies have focused on embellishment of the standard method and comparisons with different methods. For example, no difference was found between an audio alarm and a

vibratory alarm. A study that compared the basic bell-and-pad method with methods in which the bell and pad were coupled with more response contingencies for wetting versus not wetting found no statistical difference other than a slightly lower relapse rate with the adjunctive use of reward contingencies. One innovative strategy involved replacing the bell and pad with an alarm clock timed to go off after 2 to 3 hours of sleep when maximum bladder capacity would be expected. The authors reported responses that were equal to results with the standard bell-and-pad method.

The relationship between bladder capacity and response to behavioral treatment has also been investigated. One study found that bladder capacity did not affect outcome with the bell-and-pad method of conditioning, whereas another found that children with smaller bladder capacities tended to do slightly better when retention-control training was linked to the bell-and-pad method. A meticulous investigation into which treatment variables might relate to the efficacy of the bell-and-pad method found that the inability to be awoken by the alarm correlated significantly with failure, as did low functional bladder capacity.

There is some evidence to support the use of biofeedback for children who have small bladder capacities and unstable detrusors and who have been refractory to prior treatment. The newest advance in this behavioral methodology has been the use of an external ultrasonic monitor that is attached to a waistband. The monitor then signals the alarm when the bladder reaches maximal capacity. Clinical research with this device has yielded success rates similar to those with the basic bell and pad and has also reported increases in bladder capacity. The bell-and-pad approach has also been coupled with the use of DDAVP for children who have been refractory to prior treatment owing to family dysfunction or a concomitant behavioral disorder, or both. Although the bell and pad is the most intensively studied method of behavioral intervention, it is not the only type of behavioral treatment. A recent comprehensive review of this subject also noted other behavioral methods, such as evening fluid restriction, night-time toileting, rewards, overlearning, and retention-control training.

Pharmacotherapy. The initial description of imipramine's efficacy for enuresis was followed by more than 40 double-blind studies that confirmed its therapeutic value. This marked the advent of the pharmacologic era of the treatment of enuresis, with imipramine being the dominant pharmacologic entity used for more than two decades. Although imipramine has now been largely replaced by DDAVP, there are still reasons to include a discussion of its use in a comprehensive review of enuresis. Imipramine is still a consideration for children who are refractory to other forms of treatment. There is also a significant cost differential between imipramine and DDAVP, so that imipramine may well be the first pharmacologic choice for those families who do not have any form of insurance and who have limited financial resources.

Later studies with imipramine focused on the relation between response and concentration of imipramine in the blood. Although one study found no connection between positive response and imipramine concentration alone or in combination with its metabolite desipramine (Norpramin), three studies found a significant correlation between positive response and total concentration of imipramine and desipramine. More specifically, optimal response was found at combined concentrations (imipramine plus desipramine) of greater than 60 ng/mL in one study and of greater than 80 ng/mL in another. The most recent study also found that efficacy was related to increasing doses but noted tremendous variation in serum concentrations among individual children receiving the same dose. The adverse effect of dry mouth also correlated with concentration in blood, providing clinicians with a crude index of blood concentration in children who are extremely reluctant to have their blood drawn.

Clinically, when one encounters a history of a lack of response to imipramine, one must ascertain the specific dose used because nonresponse is frequently related to dose: primary care physicians often prescribe only 25 to 50 mg per day. However, low-dose responders do exist, and it is reasonable to start treatment at a daily dose of 25 mg, titrating up by 25 mg every 4 to 7 days. This enables identification of the low-dose responders because the response to

imipramine usually occurs within 1 to 2 days. The majority of children exhibit a positive response in the range from 75 to 125 mg. The standard maximal limit for dose is 5 mg/kg body weight, and ECG monitoring is recommended at doses greater than 3.5 mg/kg. A pretreatment baseline ECG is also recommended. Blood concentration values may also be clinically useful if higher doses fail to elicit a response.

There is also a possible risk of overdose by the child with enuresis. Children can engage in magical thinking, and there have been reports of children who believed that, if taking a few pills would stop the wetting for a night, then consuming the whole bottle would make it disappear forever. Thus, parents should be advised to control the medication carefully and to store it in a secure place. Severe overdoses may require treatment with physostigmine (Antilirium), whereas more moderate overdoses may be treated by the symptomatic management of arrhythmias and seizures.

Because almost all children at some point experience spontaneous remission of the enuresis, it does not make sense to prescribe medication for years without checking for a spontaneous remission. One solution to that problem is to taper the imipramine dose at 3-month intervals. Should enuresis reappear as imipramine dose is tapered, it can simply be returned to the optimal level for another 3-month period. Clinically, one often finds that more children remain dry after 3 to 6 months of treatment than can be expected from spontaneous remission alone. In general, treatment with imipramine should be viewed as necessary until spontaneous remission occurs.

Three clinical subtypes of enuretic response to imipramine exist: true nonresponders, true responders who maintain a response over time, and transient responders who respond for a few weeks and then resume wetting. Increasing the dose for transient responders usually recaptures the response but only for another few weeks, and ultimately one reaches a point at which the dose cannot be increased further. However, the initial transient response can be replicated after a medication-free interval; thus, one can use the

medication for especially important, time-limited social events, such as summer camp.

As indicated previously, DDAVP has now surpassed imipramine as the first-line pharmacologic approach for enuresis. A thorough review done as early as 1993 revealed 18 randomized, controlled trials, including a total of 689 subjects. Many subjects had been refractory to previous treatment for enuresis. DDAVP reduced enuretic frequency by 10% to 91% in these studies. Positive prognostic factors were age (older than 9 years of age) and lower pretreatment frequency of enuretic events. In most studies, wetting resumed after the medication was discontinued. Follow-up studies indicated that 5.7% of children remained dry after cessation of medication, but many of those cases could have been due to spontaneous remission. The most commonly reported adverse effects were mild abdominal pain, epistaxis, headache, and nasal stuffiness. Several subsequent studies attempted to find factors that might predict or relate to an increased likelihood of a positive response to DDAVP. No one factor appears to predict a positive response, but larger functional bladder capacity and a positive family history of enuresis appear to be positively correlated with treatment success. Factors that are not reliably related to treatment outcome are urine osmolality, plasma osmolality, ADH secretion, urine production, and nocturnal AVP concentration. However, individual studies can be found that link these factors with a positive outcome.

A large multicenter follow-up treatment study of DDAVP from Sweden (N = 399) used a 4-week baseline observation phase, a 6-week dose titration period (range from 20 to 40 μg), and a 1-year follow-up period. The study design also included an assessment for the rate of spontaneous remission by means of a 1-week medication-free period every 3 months. Sixty-one percent (N = 245) of the children met the requirement of at least a 50% reduction in frequency during the dose titration period that was required to enter the 1-year follow-up phase of the study. The average frequency of enuretic events in the baseline observation period was 5.3 events per week, and this declined to 0.8 nights by the end of the year-long follow-up period. As with other studies, older age was a positive

prognostic sign. Of interest was the observation that 77 children experienced a complete remission of their enuresis within the first 6 months of the active treatment phase. There has been one report of an attempt to increase the rate of spontaneous remission by aggressively titrating the dose until cessation of wetting is obtained and then maintaining this dose for 4 to 6 weeks before beginning to decrease the dose by 10 μg per month until it is discontinued. The authors reported that, by using this strategy, complete remission was achieved for 71% of the children. The median length of follow-up was 18 months, and the mean dose of DDAVP was 20 μg.

Studies have also specifically investigated the efficacy of DDAVP for children who were refractory to a conditioning treatment and imipramine. One of these involving 52 children (dose range from 20 to 40 μg intranasally) found complete cessation of wetting in 53%, a partial response in 19%, and minimal or no response in 28%. A long-term follow-up study (mean length of follow-up of 13 months) of children treated with DDAVP found no hematologic or hormonal adverse effects.

Treatment with DDAVP has been compared to the bell-and-pad method of conditioning. The difference in response rate was not statistically significant; 86% improved with the bell and pad, and 70% improved with DDAVP. Another investigation comparing the combined use of the bell-and-pad method and DDAVP with placebo indicated that the combination achieved significantly more dry nights. Similar results were found in a study comparing alarm monotherapy to alarm treatment coupled with DDAVP. The combination proved superior, especially for children with severe, almost nightly, wetting.

The development of oral tablets greatly simplified the administration of DDAVP. The nasal spray was difficult for some children to use, and this could (in some cases) contribute to variable administration. A controlled multicenter study found no difference in response between oral DDAVP and the traditional nasal spray. A dose of 400 μg produced more dry nights than did a 200-μg dose.

A significant dose-effect correlation was found in a placebo-controlled study that used 200-, 400-, and 600-μg oral doses. In a separate follow-up study (7 years), the rate of spontaneous

remission at 2 and 7 years was reported as greater than would be expected solely on the natural history of the disorder. As with other treatment modalities, consistent findings in the clinical literature concerning positive responses to DDAVP are older age, larger bladder capacity, and lower pretreatment frequency of enuresis. The newest innovation in the use of DDAVP has been the development of a sublingual desmopressin oral lyophilisate (MELT). A randomized, controlled study that compared this formulation to oral tablets found it to be equally effective. The children also expressed a greater preference for the MELT. This increase in preference was especially pronounced in the younger age group (5 to 11 years of age).

As the use of the DDAVP nasal preparation became more common, there were an increasing number of case reports of hyponatremic seizures with prolonged use. A review of 14 articles that reported data on serum sodium concentration in DDAVP-treated patients and 11 articles that reported individuals who developed altered consciousness or a seizure while taking DDAVP for enuresis concluded that hyponatremia is a potential adverse effect of DDAVP treatment. The authors also noted that excess fluid intake was a contributing factor in 6 of the 11 case reports. They concluded that patients receiving DDAVP for nocturnal enuresis should be advised not to consume more than 8 oz of fluid on nights when DDAVP is administered. The data on hyponatremia also suggest that periodic monitoring of serum sodium concentration would be prudent. The number of reported cases of hyponatremia and seizures, including two deaths, prompted the FDA to issue an alert concerning DDAVP in December 2007. The alert identified 61 postmarketing incidents of hyponatremia-related seizures that were related to the use of DDAVP. Sodium levels obtained at the time of the seizure ranged from 104 to 130 mEq/L. A particular concern was that two of the individuals who experienced seizures with hyponatremia died. The intranasal formulation of DDAVP was implicated in 36 of the cases, and 25 of these were individuals younger than the age of 17 years, most of whom were receiving DDAVP for treatment of nocturnal enuresis. The FDA alert concluded that the intranasal formulation of

DDAVP was no longer indicated for the treatment of PNE. The alert also suggested that treatment with the tablet form should be halted during illnesses that could produce disturbances in fluid dynamics and/or produce electrolyte imbalance. The alert also recommended that fluids should be restricted from 1 hour before to 8 hours after the administration of the tablets. The latter recommendation is consistent with earlier published reports that linked the amount of fluid intake to the risk of acute hyponatremia.

Although imipramine and DDAVP have been the dominant pharmacologic treatment modalities over the last several years, there continue to be reports of success with anticholinergic agents. The majority of these reports relate to oxybutynin, both as a first-line intervention and for individuals who are refractory to other interventions.

General Treatment Considerations. The results of the studies reviewed, in conjunction with the natural history of enuresis, can help the clinician to develop a decision tree tailored to a given child. The first decision, naturally, is whether to treat at all. That decision is affected by the frequency of the wetting, the age of the child, and the amount of psychological distress that the wetting causes the child. Enuresis has a negative effect on the self-esteem of these children, and self-esteem improves after successful treatment. One may choose not to treat a child who is infrequently wetting and who is at an age at which spontaneous remission may be expected.

If one does elect to treat, it makes sense first to try the bell-and-pad method of conditioning because its efficacy has been repeatedly demonstrated, and behavioral intervention is considered less invasive than pharmacologic approaches. A large follow-up study that compared observation only with imipramine, DDAVP, and the bell and pad indicated that, although all of the active treatments were significantly superior to observation alone, the positive response was much more likely to be sustained after treatment cessation with the bell and pad than with either pharmacologic treatment. Despite these apparent advantages, one large population-based investigation revealed that only a relatively small number of enuretic children

(38%) saw a physician, and, of that number, only 3% were treated with the bell-and-pad method of conditioning, whereas more than one-third received pharmacologic treatment. A more geographically restricted survey of primary care physicians yielded significantly different responses, in that 80% of physicians indicated that they recommended the bell-and-pad method of conditioning. The most recent comparative study of the long-term efficacy of DDAVP versus the enuretic alarm involved 142 children who were randomized to either form of treatment for 6 months, with the determination of success rates at 6 and 12 months. Interestingly, only 5.2% of the DDAVP group withdrew after randomization, as compared to 30.7% of those assigned to the enuretic alarm group. The results for those who completed 6 months of treatment (defined as at least 90% in wet nights) indicated that 76.8% of the DDAVP group was deemed to be successful, as compared to 61.8% of the alarm group. The success rates at 12 months were comparable, with 77.8% of the DDAVP group meeting success criteria, as compared to 75% of the alarm group. However, when the large drop-out rate after the assignment to the alarm group was taken into account, the success rates were adjusted to 68.8% for the DDAVP group and 46.2% for the alarm group. Thus, this study essentially confirmed the results of numerous prior studies in that the two treatment modalities were found to be equally effective, but the ability to implement the bell-and-pad alarm system was too difficult for many families to implement successfully.

When the bell-and-pad method of treatment is unsuccessful or not feasible, it makes sense to proceed to pharmacologic treatment, assuming that the enuresis is severe enough to warrant pharmacologic intervention. For decades, imipramine was the first choice for pharmacologic treatment. Although precise figures are not available for its relative use in the treatment of PNE, DDAVP has surpassed imipramine as the most popular pharmacologic treatment.

ENCOPRESIS

Definition

The DSM-5-TR criteria are virtually unchanged from those of the DSM-IV and DSM-IV-TR and define *encopresis* with four related criteria: (1) the repeated inappropriate passage of feces, usually involuntary, (2) occurrence at least once a month for at least 3 months, (3) a chronologic or mental age of 4 years of age, and (4) exclusion of a substance or medical condition as a cause.

For several years, the clinical and research literature concerning encopresis has distinguished between retentive and nonretentive encopresis. The DSM-5-TR recognizes this distinction and lists two subtypes: With constipation and overflow incontinence and without constipation and overflow incontinence. The subtype with constipation and overflow incontinence corresponds to retentive encopresis. The subtype without constipation and overflow incontinence corresponds to nonretentive encopresis.

Some clinicians refer to a *primary type* in which the person has never established fecal continence and a *secondary type* in which the disturbance develops after a period of established fecal continence.

History

The history of encopresis is not as richly detailed as that of enuresis, possibly because encopresis affects fewer children, and the events are less frequent. Unless the feces are particularly fluid, it may also be easier for children to hide the symptoms. A high frequency of encopresis and enuresis was found in children who were separated from their parents in World War II, thus documenting the effect of environmental factors.

The more contemporary history of encopresis is noteworthy for the establishment of a treatment methodology that involves cathartics to re-establish bowel dynamics (coupled with education), which has proven to be quite successful. The innovative use of biofeedback technology showed much initial promise after its introduction in the 1980s, but it now appears that it is not more effective than the older method. Constipation is a common precursor to encopresis, and

recent research has also focused on effective treatment for this disorder.

Table 48–3.
DSM-5-TR Diagnostic Criteria for Encopresis

A. Repeated passage of feces into inappropriate places (e.g., clothing, floor), whether involuntary or intentional.
B. At least one such event occurs each month for at least 3 months.
C. Chronological age is at least 4 years (or equivalent developmental level).
D. The behavior is not attributable to the physiological effects of a substance (e.g., laxatives) or another medical condition except through a mechanism involving constipation.

Specify whether:

With constipation and overflow incontinence: There is evidence of constipation on physical examination or by history.

Without constipation and overflow incontinence: There is no evidence of constipation on physical examination or by history.

Comparative Nosology

As noted above, the DSM-5-TR has adopted the widely held clinical distinction between retentive and nonretentive encopresis, although the terminology differs slightly. The current DSM-5-TR definition includes voluntary and intentional encopresis, which is obviously a distinction of major clinical importance. This statement appears to minimize the importance of a rather substantial subgroup of children with nonretentive encopresis who are encopretic because they cannot adequately control the anal sphincter or do not recognize the need to defecate in time (Table 48–3).

The ICD-11 diagnostic classification for encopresis essentially follows the DSM-5-TR approach (Table 48–4).

The most comprehensive categorization of encopresis distinguishes three types of patients: (1) intentional—children who do have bowel control but intentionally deposit feces in inappropriate places for psychological reasons; (2) involuntary—those who cannot adequately control the sphincter or lack an awareness of the process, or both; and (3) involuntary—those whose soiling is related to excessive fluid from retentive overflow (75% of this category), diarrhea, or anxiety. Thus, this classification schema incorporates the retentive and nonretentive dichotomy and the distinction between voluntary and involuntary incontinence.

Table 48–4.
ICD-11 Diagnostic Criteria for Encopresis

- Repeated and persistent passage of feces in inappropriate places (e.g., at least once per month over a period of several months).
- The individual who has reached the developmental age when fecal continence is ordinarily expected (approximately equivalent to a chronological age of 4 years).
- Fecal soiling is not better accounted for by the physiological effects of a substance (e.g., excessive use of laxatives) or another medical condition (e.g., aganglionic megacolon, spina bifida, anal stenosis, chronic diarrhea, congenital or acquired abnormalities of the bowel, or gastrointestinal infection).

Specifiers

Encopresis with constipation and overflow incontinence:

- Encopresis with constipation and overflow incontinence is the most common form of fecal soiling, and is characterized by retention and impaction of feces. Stools are typically—but not always—poorly formed (loose or liquid) and leakage may range from occasional to continuous.
- There is often a history of toilet avoidance leading to constipation.

Encopresis without constipation and overflow incontinence:

- Encopresis without constipation and overflow incontinence is not associated with retention and impaction of feces, but rather is characterized by reluctance, resistance, or failure to conform to social norms in defecating in acceptable places in the context of normal physiologic control over defecation.
- Stools are typically of normal consistency and inappropriate defecation is likely to be intermittent.

Epidemiology

Two large epidemiologic studies have yielded consistent results. The Isle of Wight Study reported a prevalence of 1.3% for boys and 0.3% for girls (10 to 12 years of age) soiling at least once a month. A large study involving 8,863 children found a 1.5% prevalence rate for boys (7 and 8 years of age). In that study, the ratio of boys to girls was more than 3:1. A significant correlation between encopresis and enuresis has also been found.

Etiology

The dramatic nature of fecal soiling has contributed to psychodynamic speculation. The term *chronic neurotic encopresis* has been used to describe the small number of children whose encopresis is predominantly psychological. The clinical characteristics described in these children are (1) a distant father and neurotic mother, (2) early and often harsh bowel training, and (3) a history of neurologic delay. The one systematic study that attempted to verify the clinical features usually attributed to enuretic and encopretic children in the literature by analyzing actual case material could not substantiate the existence of 20 of the 22 factors developed through the literature review. As with enuresis, the distinction between primary and secondary encopresis relates to the issue of associated psychopathology. A study involving 63 boys with encopresis found that boys with primary encopresis were more likely to have developmental delays and associated enuresis, whereas those with secondary encopresis were more likely to have experienced higher levels of psychosocial stressors and to be diagnosed with conduct disorder. Another large study examined several psychological and physiologic variables in children with chronic constipation as compared to children with encopresis unrelated to constipation. The group with constipation had significantly longer colonic transit times (CTTs), whereas both groups had relatively high frequencies of abnormal defecation dynamics. A subsequent independent investigation of CTT in children with chronic constipation found that a CTT greater than 100 hours was related to a poor outcome at 1-year follow-up.

A large population-based study in the United Kingdom involving 8,242 children (7 to 8 years of age) investigated the association of soiling with a variety of psychological disturbances. The children with encopresis were divided into those who frequently soiled (at least once a week) or occasionally (defined as less than once a week). There was also a large control group. Both of the symptomatic groups had significantly higher rates of behavioral and psychological disturbance than the controls. The rates of disturbance were also higher in the group that frequently soiled than in the occasional-soiling group. However, there was no particular behavioral profile that correlated with encopresis. The authors noted higher rates of attentional, obsessive-compulsive, and oppositional presentations in the symptomatic children than in the controls.

A premorbid history of encopresis has been found to occur more frequently in individuals with prepubertal and early adolescent bipolar disorder phenotype (PEA-BP) than in controls. A recent large, retrospective study (in a military health-system database) involved 32,773 children who were identified as having ADHD. The results indicated that 4.1% of those children had constipation, as opposed to 1.5% of control children without ADHD. The corresponding rates for fecal incontinence were 0.9% in the children with ADHD, as compared to 0.15% of the controls. Both of these results were statistically significant with high levels of confidence, leading the authors to conclude that ADHD was a risk factor for fecal incontinence.

A recent large birth cohort study involving 358 children also found higher rates of both enuresis and encopresis among children with ADHD.

No correlation between encopresis and social class was reported in two independent studies. The issue of neurologic competence as a contribution to encopresis has been investigated. One study found no abnormalities of anal–rectal motor or sensory function but did find that a significant number of encopretic boys had abnormal anal–rectal expulsion dynamics. A sophisticated physiologic study using a triple-lumen catheter attached to a hydraulic manometry infusion system found that age of onset, frequency, and duration of

encopresis were all highly correlated with the amount of anal sphincter spasm that occurred when defecation was attempted. The amount of pain reported with bowel movements correlated positively with the frequency of encopresis and inversely with maximum squeeze pressure. An investigation involving the concentrations of gastrointestinal (GI) hormones in controls and children with retentive encopresis indicated that the latter had higher concentrations of pancreatic polypeptide after a meal and less of a motilin response. However, the authors noted that these abnormalities could be the result of, or the cause of, chronic constipation.

An extensive series of studies concerning physiologic factors and the interplay of physiologic and psychological factors has been carried out. The principal physiologic findings were (1) 56% of children with retentive encopresis could not defecate rectal balloons (research technique used to assess sphincter competency), and most had abnormal anal sphincter contractions; (2) only 14% of those who could not defecate the balloons were found to have responded to treatment at 1-year follow-up, compared to a 64% success rate for those who could; (3) at 1-year follow-up, 70% of children who could relax the anal sphincter at the time of initial evaluation were improved, as opposed to 13% of those who could not; and (4) none of the children who initially presented with an abdominal fecal mass was improved at 1-year follow-up, regardless of other factors.

One subset of these studies physiologically compared constipated children to controls during the act of bearing down. All of the control children displayed decreased anal sphincter activity when bearing down, compared to 58% of the constipated children who could defecate a balloon and 7% of constipated children who could not defecate the balloon. The constipated children who could not defecate the balloon were also significantly less likely to respond to laxative treatment. Nonrelaxation of the anal sphincter was found in 75% of encopretic children, as opposed to 13% of a control group in a study that used anal electromyography. This study also reported lower pressures for the encopretic children at rest and on squeezing; this observation has also been described by other investigators.

An attempt was also made to assess the relative effect of physiologic and psychological factors. Specifically, anal–rectal manometric and electromyographic assessments were correlated with behavioral and social competence profiles as related to treatment outcome. Psychological variables were not found to be predictive of outcome, but physiologic variables were.

Diagnosis and Clinical Features

The objective and concrete nature of the encopretic event makes diagnosis relatively easy and uncomplicated from a phenomenologic perspective if the child meets the frequency, duration, and age requirements set forth in the DSM-5-TR. The involuntary versus intentional dichotomy is not a requirement or reason for subclassification according to the DSM-5-TR, but it has important clinical implications. Similarly, the retentive versus nonretentive schema has clinical usefulness. Differentiating between primary and secondary encopresis is important, given that one might expect medical or psychological factors to play a greater role in secondary encopresis.

Henry was an 11-year-old boy with almost-daily encopresis and a number of associated behaviors, including hiding the feces around the house. He resided in a specialized foster care setting, having been removed from his biologic parents at 7 years of age because of physical and sexual abuse. Both parents were involved with substance abuse, and his early history was not well documented. However, the parents did indicate that he had never exhibited sustained bowel continence for several months. Henry had also been enuretic until 6 years of age, but this had resolved to an occasional nocturnal episode every 4 to 6 months.

Henry also qualified for a diagnosis of ODD. Although he had experienced physical and sexual abuse, he did not have flashbacks or other symptoms that would meet the criteria for post-traumatic stress disorder (PTSD). Henry also had ADHD and was being effectively treated with 10 mg of methylphenidate (Ritalin) twice a day.

The foster family resided in an urban area that had access to a nationally recognized children's hospital. The ambulatory care department had a specialized behavioral encopresis program that coupled the bowel training method with a psychoeducational component and psychotherapy. The psychiatric consultant to the specialized foster care program doubted that this program would be successful for Henry because he had so much associated psychopathology, and the feces were often deposited around the house in a symbolic manner. In addition, the encopresis was not of the retentive-overflow type, and the feces were always well-formed. However, because no apparent harm could come from the referral, the consulting child psychiatrist agreed to it. Much to the surprise of the consultant, the several-week outpatient bowel training course, coupled with the psychoeducational component and psychotherapy, resulted in a complete cessation of the encopresis. On one of her visits to the home, Henry proudly showed his case manager a diagram of the functioning of the digestive system that was part of the psychoeducational program. In retrospect, it appeared that, although there were

symbolic aspects to Henry's encopretic behavior, the soiling was ego-dystonic, and he was highly motivated to change the behavior, although this motivation could not be prospectively detected by the treatment team because of his oppositional defiant manner of responding to adults.

Pathology and Laboratory Examination

The extensive, detailed physiologic studies cited previously suggest that physiologic factors are important in many children with encopresis, given that they correlate with treatment outcomes at 6-month and 1-year follow-up. However, that does not imply that a physiologic workup that is this thorough is required for every child who presents clinically. The clinician needs to rule out definite physiologic illnesses, such as Hirschsprung disease. Beyond that, clinicians might consider more detailed physiologic investigations, such as those used in the experiments described previously, for children who prove refractory to conventional treatment. That type of specialized testing could also be difficult to obtain outside of an academic research center. A simple plain abdominal roentgenogram may aid in the diagnosis and confirmation of retentive encopresis. In one study, 78% of children who met the diagnostic criteria for encopresis also met roentgenographic criteria, whereas 22% did not.

Children with a condition referred to as *slow transit constipation* may present with intractable encopresis. Although the etiology of this disorder is not fully understood, some of these children appear to have abnormal innervation of the colon. Clinical signs of this disorder include severe constipation within the first year of life and refractory encopresis at an early age. Colonic transit studies are necessary to confirm the diagnosis.

Psychological testing can be useful for those children who exhibit concomitant behavioral problems or for those who are intentionally encopretic. Finally, clinicians should not overlook the importance of a detailed history obtained from the parents and the child that documents the time course, frequency, and circumstances surrounding the encopresis.

Differential Diagnosis

Encopresis can be a symptom of other processes or can be a syndrome in itself, as described previously. The medical illnesses that need to be ruled out include stenosis of the rectum or anus, endocrine abnormalities, smooth muscle disease, and Hirschsprung disease.

The child's psychological profile should be considered because children with intellectual deficits or pervasive developmental delay may have episodes of soiling related to those processes. Children with impulse-control disorders or attention-deficit disorder may, at times, have episodes of soiling related to lack of attention. Encopresis has been reported as one of a number of symptoms that can be seen following sexual abuse. A large retrospective study investigated the hypothesis that the association between encopresis and sexual abuse was of sufficient significance and that encopresis could be classified as an indicator of sexual abuse. The three study groups (4 to 12 years of age) included 466 children with documented sexual abuse, 429 children with externalizing psychiatric disorders, and 641 controls. A history of sexual abuse had been ruled out in the latter two groups. The rates of fecal soiling were similar in both the abuse (10.3%) and psychiatric groups (10.5%). The soiling rate in the control group was much lower (2%). Thus, the authors concluded that the symptom of fecal soiling could not, in and of itself, be used as a predictive indicator of sexual abuse. A thorough history and psychiatric assessment should make it possible to identify those children, as well as those children who soil on an intentional-oppositional basis. Extreme stress may also provoke encopretic episodes in children who are otherwise functioning well.

Course and Prognosis

As with enuresis, continued maturation provides increasing numbers of spontaneous remissions over time. However, the rate of spontaneous remission is not as clearly defined as that for enuresis. That trend should be factored into the assessment of the efficacy of any long-term intervention. The results from relatively simple

behavioral interventions involving educational, behavioral, and physiologic components are striking (78%), suggesting that the disorder responds to treatment in most cases.

Treatment

The first clinical approach to encopresis is primarily behavioral, with educational and physiologic components. That method entails initial educational interventions with the child and family around bowel function. The process is meant to correct misconceptions that the family may have and to dissipate anxiety that may develop around the soiling. The physiologic component is instituted next with an initial bowel catharsis, followed by daily doses of laxatives or mineral oil. The behavioral element of the program entails daily timed intervals on the toilet, with success being rewarded. Follow-up studies have reported a 78% success rate for this method. The physiologic research findings concerning abnormal defecation dynamics in children with encopresis led to an interest in biofeedback training as an adjunctive treatment. Although this treatment received positive reports from uncontrolled studies, a review of controlled studies indicated that biofeedback training did not provide additional benefit over conventional treatment. A large, long-term, controlled outcome study that compared conventional treatment with biofeedback training plus conventional treatment indicated that the positive results for both groups were high and quite similar. Specifically, the conventional method yielded an 86% improvement rate, as compared to 87% for the combined group. This suggests that the combination treatment was no better than the conventional treatment alone. However, it was also found that length of time at follow-up was a powerful factor because it significantly correlated with improvement for the group as a whole at the $P < .01$ level. This indicates that the passage of time is an important variable to consider in any investigation of treatment approaches.

A recent systematic meta-analysis of the literature with regard to behavioral and/or cognitive treatments for fecal incontinence

concluded that treatment with biofeedback did not improve the results obtained from the traditional treatment.

One element of the aforementioned physiologic studies, namely, the ability to defecate a rectal balloon, has been shown to correlate with treatment outcome. A study involving 139 children with constipation and encopresis and 20 controls found that all of the controls were able to defecate the balloon, as compared to 47% of the encopretic group.

One year after beginning treatment, 51% of the children who could defecate the balloon at baseline were considered to be recovered, but only 34% of those who could not defecate the balloon were improved. Although the group comparisons were considered significant, the balloon test alone could not predict response to treatment on an individual basis.

Psychotherapy may be of use for children who have concomitant behavioral problems and those with psychodynamic factors that appear to be especially strong and are contributing to the disorder. This would also be true for those who began soiling after a stressful or traumatic event. Naturally, psychotherapeutic approaches are of primary importance for children who are intentionally soiling or depositing feces in inappropriate places.

Pharmacologic treatment for encopresis has not been extensively studied or reported. There are six case reports (encompassing 15 individual patients) that have described imipramine as effective for encopresis. Twelve of the 15 patients were boys. The therapeutic effect had relatively rapid onset (as it does with enuresis), occurring within a few days to 2 weeks, usually at doses of 25 to 75 mg. Although the subtype of encopresis is not clearly delineated in all of the case reports, one would anticipate that, if imipramine were to be helpful, it would be in those with nonretentive encopresis. There is one well-controlled study that substantiated the efficacy of the prokinetic-propulsive agent cisapride (Propulsid). This agent is no longer commercially available in the United States, having been removed from the market owing to concerns about side effects.

The relatively high success rate of the combined educational, physiologic, and psychological approach described makes it a

reasonable first approach once other diagnoses have been ruled out. Psychotherapeutic and pharmacologic approaches could be considered for children who prove refractory to that form of treatment.

Other Disorders of Infancy, Childhood, and Adolescence

49.1 Reactive Attachment Disorder and Disinhibited Social Engagement Disorder

Karin M. Best, Ph.D., Mary Margaret Gleason, M.D., and Charles H. Zeanah, M.D.

As early as the 13th century, astute observers and lay researchers documented a range of atypical reactions among some children who experience social neglect or physical and social neglect. Observational data and research findings coalesced in the 1970s with the inclusion of reactive attachment disorder (RAD) in infancy and early childhood in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III, 1980). The description of RAD was framed in the observational and theoretical work of John Bowlby.

The DSM-III's revision (DSM-IIIR, 1987) and the next *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV, 1994; DSM-IV-TR, 2000) delineated two subtypes of RAD—an emotionally

withdrawn/inhibited pattern and an indiscriminately social/disinhibited pattern. The differentiation was grounded in emerging research that provided evidence suggesting that the subtypes differed in presentation, neurobiology, and developmental course. Research continued to demonstrate that both subtypes emerged only after an infant or very young child experienced significantly inadequate caregiving.

Informed by the seminal research of the English-Romanian Adoption (ERA) study and the Bucharest Early Intervention Project (BEIP), the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) and its text revision (DSM-5-TR) defined the subtypes as two distinct disorders: RAD, which describes children who display the emotionally withdrawn/inhibited pattern of behavior; and disinhibited social engagement disorder (DSED), which describes children who demonstrate the indiscriminately social/disinhibited pattern. These disorders often continue to be categorized as “disorders of attachment,” and the criteria for each reference are early-rearing conditions that limit the development of attachments. However, whether DSED should be considered an attachment disorder remains controversial. DSM-5 classified both Trauma and Stress-Related Disorders, and DSM-5-TR took the same approach. RAD and DSED in DSM-5-TR are also defined in the *International Classification of Disease, eleventh edition* (ICD-11), with similar criteria.

The ERA study and BEIP have contributed to the behavioral delineation of RAD and DSED and the development of “gold standard” methodology and measures for the diagnosis of young and early school-age children. In the past 10 years, research has broadened to include efforts to characterize them in adolescence and in the adult years, with the goal of better understanding their respective sequelae. This research includes a detailed follow-up of the ERA and BEIP samples as well as a retrospective application of childhood diagnostic criteria to high-risk adolescent samples, some of which have extensive childhood health registry data available. The diagnostic precision of studies that apply diagnostic criteria retrospectively is limited, and findings must be interpreted with due

caution as exploratory. The efforts include attention to delineating the adolescent behavioral equivalents of RAD and DSED, which both the DSM-5-TR and ICD-11 define with criteria specific to younger children. Additional research also focuses on identifying familial and life experience risk factors for the development of RAD and DSED, exploring child characteristics and skills that may mediate and moderate the long-term sequelae, and identifying alterations in brain structure and activity associated with each diagnosis. This work is central to the development and refinement of evidence-based intervention techniques and programs.

Clinically, the diagnoses of RAD and DSED have been embraced, and there is evidence that both are *overdiagnosed in community settings*. In 2016, the American Academy of Child and Adolescent Psychiatry published practice parameters to guide accurate diagnosis and to discredit dangerous and unproven interventions, such as various holding/restraints, that have resulted in the death of children.

In what follows, we highlight contexts and details relevant to the diagnosis of RAD and DSED. Our goals are to support accurate assessment and diagnosis, provide an update on emerging information about the long-term sequelae of RAD and DSED symptomatology, and provide information regarding care and evidence-informed treatment.

ATTACHMENT THEORY

The normal development of the infant and young child's attachment system, first described by John Bowlby, is the trajectory to which behavior indicating disordered attachment is compared (Table 49.1–1).

Attachment, as described by Bowlby's influential theory, refers to a biobehavioral system that coordinates the balance between the very young child's need, on the one hand, to seek safety by proximity to a caregiver or set of caregivers and, on the other, to explore surroundings, to seek novelty, and to develop mastery. Bowlby argued that human infants are motivated by an attachment behavior control system to seek proximity to a small number of identified

caregivers. He inferred that the reason for seeking proximity was to attain an internal feeling of security. This internal sense of security is reinforced by repeated experiences of the caregiver's emotional and physical availability in times of need.

Table 49.1–1. Developmental Features of Attachment in Early Childhood

	Birth–2 Months	2–7 Months	7–12 Months	12–18 Months	Older than 18 Months
Phase of attachment	Limited discrimination	Discrimination with limited preference	Preferred attachment	Secure base	Goal-oriented partnership
Characteristics	Physical attributes of babyishness attract caregivers, but infant expressions of preference are limited to olfactory and auditory realms and require experimental conditions to be demonstrated.	Infant differentiates among different interactive partners; infant may seem more comfortable with primary caregiver but is willing to interact readily with other social partners.	Clearly expressed preference for a small number of caregiving adults; separation protest and stranger wariness are normative.	Use of the attachment figures as a secure base from which to venture out confidently and to explore the world and a safe haven to return to in times of danger; proximity to caregiver promotes feeling of security in infant.	Co-operation with caregiver despite frequent conflicts; goal is to balance autonomous functioning with reliance on caregiver for help when needed; verbal relatedness is important, including attention to emotional integration and fluency of discourse.

Beginning between 7 and 9 months of age, infants are thought to develop internal representations of their relationships with important caregivers. These representations, or internal working models, form the basis for the intense emotional bond between infants and their primary caregivers and their behavior in later relationships. The normal developmental progression of attachment, captured in attachment-related behaviors, is summarized in Table 49.1–1. The commonly accepted method for classifying patterns of attachment is the strange situation procedure, which includes interaction with an attachment figure and an unfamiliar adult in various combinations. Differences in the balance between attachment and exploratory behavior and how those are expressed are used to classify the infant's attachment to this caregiver into one of four types of attachment: *secure*, in which children express distress directly, seek comfort actively, and obtain soothing readily from attachment figures; *avoidant*, in which children minimize signs of distress and show no comfort seeking efforts despite physiologic arousal; *resistant*, in

which children show significant distress to separation but fail to obtain comfort from their attachment figure and cannot be soothed; or *disorganized*, in which children show some mixture of the secure, avoidant or resistant, or anomalous behaviors that preclude classification as another pattern. These patterns of attachment represent risk or protective factors rather than diagnoses.

IMPACT OF EARLY ENVIRONMENT

The importance of an infant's early experience was recognized as far back as the 13th century when the Holy Roman Emperor Frederick II reportedly initiated an experiment to see what language children would develop independently. He ordered that a group of infants be provided simple physical care but not spoken to by their caregivers. According to the Franciscan monk whose chronicle recounted the events, the experiment ended with the premature death of the children, who "could not live without clapping of the hands, and gestures, and gladness of countenance, and blandishments."

The relatively common practice of institutionalizing infants in the United States in the first half of the 18th century unwittingly provided more evidence of the detrimental effects of what has been called "maternal deprivation." Although pediatricians had long argued against the practice of institutionalization, particularly because of the high mortality rates related to failure to thrive, other healthcare providers did not take notice of the effects of institutionalization on social and emotional development until René Spitz (in the 1940s) and James and Joyce Robertson (in the 1950s) conducted more rigorous studies (including control groups). Spitz subsequently proposed a diagnostic entity that he called *anaclitic depression*, which foreshadowed the DSM-III criteria for RAD. Anaclitic depression, which included mood and social symptoms as well as immunologic and growth problems, seemed to follow the prolonged separation of infants from their caregivers. It was most severe when the infants were old enough to have developed a preference for the caregiver from whom they were separated.

In the 1970s, research by Barbara Tizard identified the two sets of behaviors that inform the current DSM-5-TR and ICD-11 classifications of attachment disorders. The children she studied resided in institutions with relatively low caregiver-to-child ratios, mixed age groups, and toys and books to enrich the environment. Their caregivers, however, were explicitly instructed not to form attachments to the children. Eight of the 26 children managed to form secure attachments, 8 were emotionally withdrawn and socially unresponsive (similar to children with RAD), and 10 were indiscriminately social with unfamiliar adults (as seen in children with DSED and DAD).

Recognition of the detrimental clinical consequences of institutional rearing eventually led to a marked decrease in state-run orphanages in the United States and the United Kingdom. Nevertheless, institutional care remains widely used for orphaned, abandoned, and maltreated young children in Asia, Central and South America, and Europe, particularly Eastern Europe.

Since the early 1960s, spurred by C. Henry Kempe's classic 1962 article on the *battered child syndrome*, recognition of and research on the developmental effects of maltreatment on children have grown. The research documents substantial consequences of abuse and serious neglect, including associations between abuse and serious disturbances of attachment.

Thus, descriptions of the phenotypes associated with attachment disorders emerged in early case reports and descriptive studies, but systematic research appeared only in the past four decades. Studies of institutionalized and maltreated infants and young children provided broad support for the phenotypic patterns of disordered attachment, now referred to as RAD and DSED.

EVOLVING NOSOLOGY

The criteria for RAD have evolved markedly since the diagnosis was introduced. The DSM-III description included as central features growth failure and lack of social responsivity. The diagnosis had to start by 8 months of age (the age at which preferred attachment to a

restricted set of caregivers is usually just beginning to be evident) and could not result from a diagnosable medical condition. Gross neglect of the infant's physical and emotional needs had to be evident, and the presence of autism or mental retardation precluded the diagnosis. Pertinent behaviors cited in the criteria included poor tone, weak cry, excessive sleep, lack of interest in the environment, and weak rooting and grasping when feeding.

Although failure to thrive is an important problem in infant mental health, it is not equivalent to an attachment disorder. The DSM-III's restrictive age range criterion and the requirement for growth failure significantly restricted the application of the diagnosis. Furthermore, it is rarely possible to rule out an autistic disorder or mental retardation in severely malnourished infants younger than 1 year of age. DSM-III-R dropped the failure to thrive criterion and broadened the age of onset to within the first 5 years of life. DSM-III-R also introduced two subtypes of RAD—inhibited and disinhibited—and these were retained through the DSM-IV versions. DSM-IV criteria continued to highlight the etiologic link between RAD and "pathogenic care" at the hands of the young child's primary caregivers and excluded children whose symptoms might be due to cognitive delay or one of the pervasive developmental disorders.

With the publication of the DSM-5, the subtypes of RAD were defined as separate disorders: RAD and DSED. This separation more closely aligned DSM and ICD nosology. The ICD-10 included Reactive Attachment Disorder of Childhood (RAD), which is similar to RAD in the DSM-5, and Disinhibited Attachment Disorder of Childhood (DAD), which is similar to DSED in the DSM-5. ICD-11 instead mirrored the DSM-5 approach with the diagnoses of RAD and DSED, using similar criteria to the DSM.

A significant body of research examining RAD and DSED criteria has affirmed that they can be reliably identified in high-risk children, and the diagnoses are rare in clinical samples, absent histories of severe neglect. Research also indicates that children with RAD respond to improvements in the caregiving environment. For example, in a prospective randomized controlled trial of foster care as an alternative to institutional care in Romania (BEIP), children with

RAD randomized to foster families demonstrated a reduction in symptomatology within months of placement, with symptom levels decreasing to levels in a community sample of never-institutionalized children. In contrast, children with DSED randomized to foster care continued to exhibit behaviors consistent with the diagnosis after family placement, typically exhibiting a reduction but not an elimination of their signs of DSED. Consistent with this, postplacement studies of Romanian children adopted from institutions by English families (ERA) show that these children do not continue to manifest RAD but do demonstrate persistent signs of DSED. That signs of RAD, which reflects a lack of attachment, diminished when children had the opportunity to form an attachment to foster or adoptive parents, and that signs of DSED may persist in a minority of children even after they form attachments to foster or adoptive parents suggests that the core deficit in DSED may not be the lack of an attachment relationship.

ETIOLOGY

Although research has established that the risk of RAD and DSED increases in the context of grossly neglectful care, the degree of neglect that is necessary for the disorders to emerge is not clear. In fact, even in environments characterized by severe deprivation, most children do not develop signs of RAD or DSED. Of note, however, relatively few children who experience extended institutional care emerge without symptoms of psychopathology. (Only 15% of children who were adopted after at least 6 months of institutional care in Romania did not meet the diagnostic threshold for any disorder at any point through their mid-20s.) More research on vulnerability factors and the critical elements of neglectful care responsible for RAD, DSED, and other disorders is needed.

The longer children live in conditions of deprivation, the more likely they are to develop an attachment disorder. Additionally, for children removed from institutional care, the number of caregiving disruptions or changes is associated with the persistence of RAD up to age 12. A critical age of vulnerability to the disorder may exist, as research has

found attachment disorders to be very rare in children adopted before 6 months of age, and signs of DSED have not been reported in children whose deprivation began only after age 2. Children with lower IQs and stunted growth may also have attachment disorders because deprivation compromises both IQ and growth; hence, it is difficult to know whether these problems precede, co-occur, or are merely additional consequences of deprivation. Studies are beginning to identify possible genetic polymorphisms as risk factors for attachment disorders.

Preliminary research suggests that children who have experienced serious deprivation may show differences in brain structure and functioning compared to nondeprived children, and many of these children may show signs of attachment disorders. For example, researchers have found reductions in gray and white matter volumes and reduced electrical activity in higher frequencies, and increased electrical activities in lower frequencies in children who have experienced institutional deprivation. Importantly, reduced white matter volume mediated the effect of institutional rearing on electroencephalogram (EEG) alpha power, meaning that reductions in myelinated circuitry likely account for the reduced EEG power. If children were placed with families before 24 months of age, the differences in electrical activity between deprived and nondeprived children were no longer seen at 8 years of age. These findings have been demonstrated in children with histories of institutional deprivation and are not specific to those with attachment disorders, however. At age 16, the institutionalized children not randomized to foster care had higher relative theta and lower relative alpha power on EEG, a pattern characterized as immature, compared to those who experienced foster care. The brain activity of the fostered children did not differ from that of a community comparison group. Of note, however, the number of placement disruptions (but not the age of placement) among the fostered group was associated with adverse changes in brain activity.

Difficulties with inhibitory control also have been shown in children with indiscriminate social behaviors, implicating ventral frontostriatal circuitry, though findings are not consistent across studies. Children

adopted from institutions also showed reduced amygdala discrimination between mothers and strangers on functional magnetic resonance imaging (fMRI), and these reductions were moderately associated with the children showing indiscriminate behaviors. Thus, preliminary research is demonstrating that early deprivation has an impact on brain development, although this relationship has been shown primarily in children with behaviors consistent with a diagnosis of DSED and requires replication.

Studies employing a variety of magnetic resonance imaging (MRI) techniques have variously associated RAD with decreased volume in the left visual cortex and differences in the corpus callosum and projections in thalamic pathways. These studies, however, have been conducted with children diagnosed in the community as early adolescents and may be compromised by diagnostic imprecision.

Recent research suggests that institutional rearing increases the risk of lower executive functioning, externalizing, and “p” (a latent measure of risk for general pathology) at age 12; each measure is further associated with the risk of general pathology at age 16, suggesting that lower executive functioning contributes to challenges over time.

Although research on what causes caregivers to be neglectful is limited, caregiver characteristics, from severe personality disturbance to psychopathology, appear to be important. Research using registry data exploring risk factors for the development of RAD among children who did not experience early institutional placement suggests that prenatal maternal smoking, advanced paternal age, maternal or paternal psychiatric disorder, and single motherhood all increase the risk of the RAD diagnosis. Parental intellectual disability and difficulty meeting a baby’s basic needs, particularly in the context of limited social support, may also increase the risk of neglect, though neglect sufficiently severe to contribute to RAD and DSED is rare, even in families with these challenges. Infants who are cared for by multiple caregivers in succession, as sometimes happens in the foster care system in the United States, are also at increased risk of attachment disorders. The traumatic experience of prolonged separation from a caregiver in early childhood, as documented by

Spitz, the Robertsons, and Bowlby, is enough to cause attachment disturbance (as distinct from RAD and DSED). Repeated, prolonged separations typically cause more severe symptoms, and when these separations are accompanied by neglect, DSED and RAD appear to be more likely.

EPIDEMIOLOGY

Very little data exist on the prevalence of either RAD or DSED in the general population. RAD is rarely diagnosed in children with adequate caregiving environments and requires but does not necessarily follow a history of severe deprivation. DSED appears to be more prevalent, though it also is diagnosed only in a small minority of children who experienced inadequate caregiving.

Among high-risk groups diagnosed retrospectively, such as adolescents in tertiary therapeutic treatment settings, prevalence estimates for RAD and DSED each approach 10%.

DIAGNOSIS AND CLINICAL FEATURES

The diagnosis of RAD or DSED requires that a child have a developmental age of at least 9 months (the cognitive level at which attachment formation is possible) and have experienced a high level of insufficient care, which is presumed causative of each disorder.

RAD is characterized by both inhibition of positive emotional and social engagement *and* the lack of selective or discriminating attachment behaviors directed at an adult caregiver. At times when young children should be motivated to seek closeness or comfort for distress or protection from danger, children with RAD do not seek or readily respond to adults' efforts to comfort, reassure or protect them. Instead, the children may appear withdrawn and unresponsive or may show distress with no anticipation of comfort. Emotion regulation abnormalities include reduced or absent expression of positive emotions and unexplained displays of irritability, sadness, or anxiety. Among children with the requisite history of severe neglect, operationalized as social neglect/deprivation, repeated changes of

primary caregivers that limit opportunities to form stable attachments (e.g., frequent changes in foster care), and/or rearing in group settings that severely limit opportunities to form selective attachments (e.g., institutions with high child-to-caregiver ratios), signs of RAD typically recede within weeks of placement in an adequate caregiving environment. Occasionally, symptoms of RAD persist following placement. Symptom persistence often marks continuing de facto neglect. The de facto neglect occurs because the child's withdrawn and negative behavior is off-putting to adult caregivers. The caregivers fail to override their natural responses to the child's behavior, which obscures the child's needs and avoids interactions.

For diagnosis of RAD, a child must first exhibit symptoms before age 5 and not meet the criteria for autism spectrum disorder (ASD).

DSED is characterized by a lack of stranger wariness, which ordinarily becomes apparent between 7 and 9 months of age. The disinhibition in DSED is social, leading to behaviors in which a child actively approaches and interacts with unfamiliar adults. Although sometimes referred to as indiscriminate friendliness, the behavior is often experienced as intrusive and may include overly familiar verbal or physical behavior that goes beyond culturally sanctioned and age-appropriate social boundaries. Children with DSED often fail to track their caregiver's whereabouts, even in unfamiliar settings, and may even be willing to go off with an unfamiliar adult without hesitation. DSED criteria stipulate that the disordered behaviors include socially disinhibited behaviors beyond the behavioral impulsivity that occurs in attention-deficit/hyperactivity disorder (ADHD; ADHD may co-occur).

Diagnosis of RAD or DSED requires a multisession evaluation, particularly when the child's history does not include multiple placements and the caregiver's behavior has not previously been identified as abusive or neglectful. Ascertaining whether the child's behavior is less atypical in the presence of the clinician or another trusted adult is important to differential diagnosis and may take time. This comparison may be especially helpful in distinguishing highly social children, for example, from those with DSED or somewhat behaviorally inhibited children from those with RAD. The child's relationship with the primary caregiver can be adequately assessed

with a combination of a careful history and observations of interactions during free play, structured tasks (that stress the dyad), and a brief separation and reunion. Videotaping the assessment is a useful way to document social responses, and the introduction of a clinically trained person whom neither partner has met is often informative. Children who meet the criteria for this disorder may look quite different, depending on their developmental stage.

An 11-month-old girl was recently placed in foster care. Foster care placement occurred after police, who were called to the home during an episode of violence, found squalid conditions, including narcotic pain pills strewn on the floor. Her parents both had chronic and serious histories of substance use disorders, violence in their relationship, and grossly inadequate care of the child and her older siblings. The girl, with her biologic and foster families, was referred for clinical services by state child protective services to assist with long-term case management.

The foster mother reported that the child looked frightened much of the time, cried sporadically and was not soothed by her, and did not respond to social overture when she first arrived in the foster home. For the initial 2 weeks of placement, the child exhibited little interest in exploring and mostly rocked quietly by herself. The girl's appetite increased over the first few days, and she began to stuff herself to the point that the foster mother, at the direction of the child's pediatrician, limited the food offered at meals and snacks. The foster mother reported it was weeks before the girl smiled. This behavioral pattern was suggestive of RAD.

The clinicians encouraged the foster mother to interact with the child despite the girl's lack of interest and to respond to the girl's distress as if the girl had requested it in order to teach her that she could be comforted when distressed. Gradually, the girl seemed to relax more and began to smile—at first fleetingly but then more frequently, to accept comfort for distress and then to seek comfort for her distress. By one month following placement, the foster mother reported the child seemed to be showing attachment behaviors toward her. The foster mother also described feeling closer to the girl, whom the foster mother had found hard to connect with initially. After this point, the ravenous behavior slowly dissipated. The girl became somewhat clingy with her foster mother and was quick to show distress to even minor changes in routine. Her affect brightened, and she came to demonstrate better emotion regulation.

A 45-month-old boy was referred for services by his adoptive parents because of hyperactivity and disruptive behavior at school. He had joined his parents at 30 months, after living most of his life in a Romanian orphanage, where a rotating staff of caregivers provided his care. When he arrived at his new home, he was below the fifth percentile for height and weight; his growth accelerated, and he quickly approached the 10th percentile. Both his adoptive parents were frustrated by their inability to “reach him.” They had initially worried he might have a hearing impairment, but testing and his capacity to engage many adults and children verbally suggested otherwise. He approached and engaged socially with complete strangers and, more than once, had followed strangers willingly. Teachers liked him; they also found him attention-seeking and sometimes disruptive. At times, teachers experienced him as appealing, even charming, but at other times, they characterized his feelings as shallow. He was injured frequently due to seemingly reckless behavior and had an extremely high pain tolerance. He was diagnosed with DSED. The intensive intervention focused on decreasing his self-endangering behavior, enhancing his ability to read emotional expressions and describe social situations, and rewarding him for culturally appropriate social hesitance. With several months of treatment, his reckless behaviors decreased, and his ability to read and describe social situations improved. His tendency to engage with unfamiliar adults persisted at a reduced and more manageable level.

DIFFERENTIAL DIAGNOSIS

Since RAD and DSED differ in clinical presentation, various diagnoses must be evaluated in the differential diagnosis of each. For RAD: ASD, and depressive disorders require evaluation; for DSED: ADHD. Additionally, a child’s intellectual ability must be considered; classifying some behaviors as atypical occurs in relation to a child’s developmental level.

Depressive Disorders

Children with RAD, and those with depression, both show reduced or absent positive affect and social withdrawal. In a longitudinal study of current or previously institutionalized young children, there was a moderate-to-high association between RAD and signs of depression, but the majority of children who were diagnosed with a depressive disorder did not meet the criteria for RAD. In general, children with depression turn to caregivers for comfort and show behaviors that are indicative of an attachment. The neurovegetative signs of depression and the excessive guilt associated with depression are not characteristic of RAD. Only if a child with depression has a history of significant social neglect and does not seek comfort should the diagnosis of RAD be considered.

Autism Spectrum Disorder

The differential diagnosis of RAD and ASD may be challenging in some cases because quasi-autistic behaviors have been noted in formerly institutionalized, adopted children. Of note, however, the course of quasi-autism varies from that of ASD in that at least partial remission may occur after several years of familial placement.

Children with both ASD and RAD show impaired social behaviors, especially social withdrawal, and minimal reciprocity. However, children with ASD typically also show atypical language development; the language skills of children with RAD may be delayed but are not stereotyped or otherwise deviant. Additionally, children with ASD exhibit restricted and repetitive behaviors; these are not found in children with RAD. Finally, children with ASD demonstrate attachment behaviors with caregivers some of the time and very rarely have the history of social neglect or maltreatment required for the diagnosis of RAD.

Attention-Deficit/Hyperactivity Disorder

Deprivation is known to increase the risk both of inattentive and hyperactive behaviors and of DSED. Children with DSED can also meet the criteria for ADHD, requiring careful assessment of ADHD as

an alternative diagnosis as well as a potential comorbid condition. Young children who are hyperactive and impulsive may appear socially disinhibited. The social disinhibition of DSED, however, is not necessarily accompanied by inattention or hyperactivity.

Intellectual Disability (Intellectual Developmental Disorder)

The adverse caregiving environment necessary for the manifestation of RAD or DSED may include environmental deprivation associated with developmental delays. However, in longitudinal studies of children from institutions, RAD and DSED were only moderately associated with cognitive delays. In terms of differential diagnosis, children with intellectual disability typically demonstrate social and emotional development that is relatively consistent with their cognitive functioning. Further, it is well established that children with intellectual disability are capable of forming stable attachments as long as their developmental ages are greater than 9 months.

COURSE AND PROGNOSIS

Research addressing the natural course of RAD and DSED diagnoses and symptomatology is limited but increasing.

Among children in institutions, RAD appears relatively stable; young children who met the criteria for RAD at one point in time continued to show the behaviors at other times. Children who are placed into families typically do not show significant signs of RAD over time, which suggests that a stable caregiving environment ameliorates symptoms of the disorder. In the Bucharest study, symptoms of RAD at age 12 were associated with poorer social functioning. Data from the same study, utilizing variable and person center models, identified four patterns of RAD symptomatology through age 12: children who never evidence symptoms, children who evidence an early and swift decrease in symptoms, children who demonstrate persistent and low-level symptoms, and children who, although demonstrating an initial drop in symptoms, maintain a relatively higher level across time. As one might expect, the persistently high group was primarily populated with children who

were not placed with foster families; they also spent significantly more time in institutions and experienced a greater number of placement disruptions. Diagnosis of RAD was associated with internalizing and externalizing symptoms and symptoms of ADHD.

Studies of young children diagnosed with DSED suggest that the diagnosis is moderately stable from year to year. Studies that have followed children into later childhood find that those with over-friendly and attention-seeking behaviors at the age of 4 tend to continue to show these behaviors at the age of eight. At age 12, symptoms of DSED were associated with lower social competence and with the caregiver's viewing the child as a victim (e.g., of bullying, relational victimization, rejection). At the age of 16, these children demonstrated superficial and conflicted relationships with peers. In adulthood, DSED symptoms may persist, with an indication that the level of these symptoms does not interfere with overall adaptation.

As only a fraction of institutionalized children are diagnosed with RAD or DESD, and most symptoms decrease, studies of long-term outcomes frequently characterize outcomes by comparing groups based on length of institutionalization before adoption and/or type of placement following initial institutionalization. Children with shorter-term institutionalized care or foster care placement resemble comparison groups (in-county adoptees or never placed children) on most measures at most ages. In the ERA study, young adults (ages 22 to 25) with longer institutional care prior to adoption had lower educational achievement, higher unemployment, and greater mental health service use in early adulthood. Group differences include increasing levels of self-reported emotional symptoms from the cusp of adolescence through adulthood; the difference in self-reported psychopathology emerged 20 years postplacement. Additionally, longer institutional care is associated with high rates of ADHD (as well as ASD and callous-unemotional traits).

Studies of adolescents in residential placement, diagnosed retrospectively with RAD or DSED, suggest those diagnosed with DSED may differ from the general population, from other adolescents in placement, and from those with RAD in aspects of self-esteem;

however, the findings require follow-up and may be compromised by diagnostic imprecision.

In sum, the expanding research corpus highlights the many persistent risks associated with all but very short-term institutionalized care to the children who experience it. Only a fifth of the Romanian adoptees who spent 6 months or more in institutions scored in the typical range across assessments of psychopathy over a 20 period. Simultaneously, research also clearly documents the potent effect of devoted care and raises hope that appropriate intervention can ameliorate symptoms, mitigate long-term risk and improve adult functioning.

TREATMENT

The first step in the diagnostic evaluation of and treatment planning for children exposed to grossly inadequate care is assessing and securing the child's safety. Child maltreatment is associated with significant morbidity, and mortality is not uncommon, particularly in children younger than 48 months of age. Children may not have had appropriate medical care, and medical referral is usually indicated. Child protective services involvement may be warranted, and assessment of parental fitness may be a necessary part of the child's evaluation. In some cases, the placement of the child may be necessary. Unfortunately, the foster care system and the family court system sometimes lead to multiple placements in the first years of life, thus further increasing the risk of RAD, DSED. The clinician may play a crucial role in staying involved with the child who is placed in foster care, providing expert testimony in court and individual or family treatment.

Once the child's safety is established, full attention can be paid to the diagnosis and psychosocial intervention, which must be tailored to the child and living situation. For children who exhibit RAD and DSED, providing and supporting a primary attachment figure is the goal. Caregivers who foster secure attachments in infants and young children are those who are sensitively responsive, value the child as an individual, and place the needs of the child ahead of their own.

Caregivers with such characteristics are well-suited to assist children who have experienced severe early social deprivation.

In general, research following children with RAD suggests that the symptoms of the disorder resolve with placement in a family that can provide a positive caregiving environment. This research additionally finds that these children may continue to show insecure or disorganized attachments in the Strange Situation Paradigm, suggesting that treatment to improve attachments with foster or adoptive caregivers is important.

For children who exhibit the high levels of indiscriminate behavior seen in DSED, the clinical consensus is to advise adoptive or foster parents who are establishing attachment with the child to limit the child's unnecessary contact with adults outside the family for several months, if possible. The rationale is that children need time to consolidate attachment relationships within their family before they experience other relationships. Although this approach has face validity, it has not been evaluated formally. Research finds that some children diagnosed with DSED continue to show indiscriminate behavior, even after being placed in enhanced caregiving environments and forming secure attachments, an indication that more than enhanced caregiving may be necessary to reduce the signs of DSED significantly. It is important to note that the quality of caregiving for children with DSED is associated with the rate of decline of symptoms, even when they do not fully resolve. It has been suggested that intervention to target social cognitive abnormalities that may underlie the indiscriminate social behaviors shown in DSED would be a possible way to improve these behaviors, but research is needed in this area.

Additional interventions should be formulated to reduce child or adult (caregiver) barriers to attachment. Child barriers include behaviors that provide miscues about their needs, including aggressive and oppositional behavior, emotional dysregulation, and withdrawn behavior. Adult barriers include distractions from the newly developing relationship, such as here-and-now crises, their own problematic relationship histories—including unresolved losses and trauma—and lack of psychological commitment to the child.

Attachment-specific treatments often focus on the adult–child dyad and include the Circle of Security, which weaves together psychoeducation with psychotherapy, and Attachment and Biobehavioral Catch-Up, which is manualized and more prescriptive about which behaviors are coached. Both treatments rely heavily on a review of videotaped parent–child interactions. Other interventions that involve caregiver–child dyadic therapy include child–parent psychotherapy. These approaches typically combine developmental training and guidance with an active attempt to address pressing instrumental issues (e.g., poor housing and inadequate medical care). The complexity of these treatment approaches reflects the complexity of the clinical problem. Long-term interventions are often necessary; family and individual treatment are bolstered by other early intervention programs and ongoing medical care.

CONCLUDING THOUGHTS

In the 40 years since the addition of attachment disorders (as they were originally labeled) to the diagnostic canon, a great deal has been learned about the sequelae of profound deprivation in some children. The diagnoses RAD and DSED have been delineated, instruments and methods of assessment developed and validated, and evidence-informed treatments created. Longitudinal research, including a randomized controlled trial, indicates that placement with caring adults after deprivation effectively lessens or dissipates children's symptoms of RAD and, to a lesser degree, of DSED. Emerging longitudinal data suggest that patterns and sequelae of these disorders may persist into young adulthood. Additionally, emerging work suggests RAD and DSED may be associated with structural and functional differences in the brain. Much remains to be learned.

Forty years of research continue to indicate that RAD and DSED are rare disorders and that they may be overdiagnosed in community settings when established diagnostic assessment instruments and procedures are not embraced and employed. The challenge in future research is to bridge, differentiate, generalize, and/or extend, as

appropriate, findings from rigorous research on RAD and DSED to work on the broader topic of child abuse and neglect, as clinicians are eager for guidance.

49.2 Stereotypic Movement Disorders in Children

ROBERT LLOYD DOYLE, M.A., D.D.S., M.D.

Stereotypic movements are defined as repetitive, sometimes rhythmic, seemingly volitional, but purposeless movements. They encompass a wide range of behaviors, including the tapping of hands or feet and nail biting, and may occur in typically developing children or those with developmental disorders such as spinning behaviors often seen in children with autism spectrum disorders. A stereotype can be as benign as eye blinking or can be quite dangerous, as in the case of intense head banging resulting in traumatic brain injury. However, the term “stereotypy” may be applied to many types of behaviors, including normal repetitive behaviors of infancy, abnormal repetitive behaviors in autistic individuals, dyskinesias caused by psychotropic medications, and symbolic gestures associated with schizophrenia, to name a few, this section focuses on stereotypic movement disorders of childhood as described in the text revision of the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5-TR) and the eleventh edition of the *International Classification of Diseases and Related Health Problems* (ICD-11).

HISTORY

The first mention of purposeless, repetitive behaviors in the clinical literature dates back 300 years to Nehemiah Grew, who wrote, “We see also Mad people … run upon some one action … without variation.” Possibly the first description of a dopamine-driven stereotypy should be attributed to Samuel Gee, who conducted an experiment in which he injected a large dose of apomorphine into a dog. A few minutes after the animal vomited, it began to pace around the room in a “curiously persistent methodical manner.” In the early 1900s, Emil Kraepelin linked stereotypic behaviors to dementia praecox. Of note, Kraepelin’s careful observations of stereotypic behaviors were made before the development of antipsychotic medications, and so the behaviors were likely related to a pathologic brain state rather than to medication-induced dyskinesia. Several seminal papers published in the 1940s set the stage for the following 50 years of research on the subject.

Landmark research on stereotypic behaviors began with Lauretta Bender and Paul Schilder in the early 1940s. Their contribution differentiated impulsions from obsessions and compulsions based on the premise that impulsions were associated with positive affect, whereas obsessions were notably negative. They also speculated that impulsions could have connections to the primitive motor stereotypic behaviors of infancy and that impulsions might become obsessions and compulsions in adolescence. In 1949, Reginald S. Lourie theorized that the feedback from infantile rhythmic behaviors fostered normal motor development. For instance, infants will assume the four-point crawling position on hands and knees, then rock front to back as if rehearsing the more complex coordinated movement in which only the arm and leg on one side of the body moves forward to provide locomotion. This simple repetitive rocking in place could serve as the basis for a repertoire of more-coordinated movements needed to crawl. Thus, according to this theory, repetitive behaviors occur in a normally developing child, but these recede as the child masters more complex, functional behaviors. These behaviors become stereotyped if they persist beyond the developmental purpose they serve, as seen in persons who are blind or have autism or intellectual disabilities,

ETIOLOGY

Several theories have been proposed to explain the emergence and maintenance of stereotypic behaviors. As just described, stereotypic movements may be the precursor to mastery of more sophisticated motor tasks. This path toward more complex motor behaviors may veer in a pathologic direction based on the interplay among abnormal development, behavioral reinforcement, and psychological conflict. In Down syndrome, for instance, stereotypic behaviors are similar to those seen in children without a diagnosis of mental retardation but differ in that in Down syndrome, they appear at a later-than-expected chronologic age and do not disappear. Therefore, developmental factors could contribute to the manifestation of stereotypic behaviors.

Behavioral factors might maintain the stereotypic behavior through positive or negative reinforcement. Careful behavioral analysis can identify social reinforcers and then aim to eliminate them. From a psychodynamic standpoint, stereotypies are considered instinctual, autoerotic, and self-soothing or gratifying behaviors. The psychodynamic factor implies that a stereotypic behavior, such as nail biting, might be a reaction to intense feelings about one or more conflicts. Biologically based theories have replaced most psychodynamic formulations explaining stereotypic behaviors.

Early observations in animals and humans indicated that environmental factors might modify the expression of stereotypic behaviors. For example, R. J. Gallagher and Gershon Berkson showed that even short periods of normal social interaction reduced the expression of stereotypic behaviors in institutionalized infants with profound intellectual disabilities. Most studies show that substituting alternative activities for stereotypic behaviors effectively reduces their expression.

Even though enriched environments usually diminish stereotypic behaviors they do not eliminate them. The predictable persistence of stereotyped behaviors in childhood autism and other conditions, despite environmental enhancement, indicates that organic factors might play a role. One organic theory proposes that endogenous opioid compounds are released in persons with autism as they

engage in stereotypic behaviors. The pleasurable *effect* of the endorphin *release* could reinforce the repetitive maladaptive behaviors. Although studies using the opioid antagonists naloxone (Narcan) and naltrexone (Trexan) resulted in modest improvements in stereotypic behaviors, these have not been a definitive cure for stereotypic behaviors in individuals with autism. Therefore, an organic-based explanation is not entirely satisfactory either. Perhaps an interplay between experiential effects on the brain and physiologic processes within the brain might best account for stereotypic behaviors. Bender and Schilder theorized that a common connection must tie all sorts of stereotypy together; however, studies fail to support the existence of an encompassing stereotypic factor.

Nevertheless, research has pointed to several factors that might act independently or in concert to bring about the expression of a stereotypic movement. These include genetic factors, as seen in nail biting and Lesch–Nyhan syndrome, and neurobiologic factors, as evidenced by the many compounds that can precipitate stereotypic or self-injurious behaviors (SIBs). For example, dopamine supersensitivity due to chronically low levels of dopamine has been described in animal models of SIBs. Of interest, postmortem tissue from patients with Lesch–Nyhan syndrome appears to be dopamine deficient as well. Furthermore, dopamine antagonists have successfully treated nonsyndromal SIBs and at least one case of Lesch–Nyhan syndrome. Dopamine has also been implicated in the emergence or exacerbation of certain repetitive behaviors related to stimulant use. Psychostimulants work by blocking the reuptake of dopamine, thereby causing a relative increase in the availability of dopamine in the synaptic cleft. Stimulant-induced repetitive behaviors include bruxism, skin picking, lip biting, compulsions, nail biting, perseveration, tics, and various other stereotypes. Other neurotransmitters, such as serotonin, opioids, and γ-aminobutyric acid, may be involved as well.

EPIDEMIOLOGY

Many stereotypic behaviors emerge in early childhood and are considered part of normal development. These rhythmic, repetitive behaviors appear and progress in a cephalocaudal direction and can be correlated with chronologic age. An estimated 80% of normal children display rhythmic activities that disappear by the age of 4 years. Although determining the prevalence rate in the general population is difficult, studies estimate that some 3% to 15% of children without disabilities engage in head banging. About 20% of children exhibit repetitive body rocking. If these behaviors continue beyond the normal developmental age range for such behaviors, they might evolve into a stereotypic movement disorder. Consider thumb sucking. Endearing in infants, thumb sucking easily becomes a reason for teasing in the school-age child. In an extreme case, an adolescent boy with profound developmental and intellectual disabilities sucked his thumb until a large portion of soft tissue eroded away and exposed the underlying bone. Although rarely to such a degree, finger, and thumb sucking occurs more often in girls than boys and more in whites than in African Americans.

Bruxism—the habitual grinding of teeth—occurs in approximately 56% of normally developing infants. Even if chrome bruxism wears down enamel, this rarely results in long-term problems in young children because deciduous teeth will be replaced by the permanent dentition. Bruxism in adolescents and adults can cause major dental pathology ranging from periodontal disease to temporomandibular joint dysfunction.

Sean was a burly but affable dental student with severe bruxism. He had no personal or family history of psychiatric illness. He was the eldest child of a large, upper–socioeconomic status family. Sean had always maintained a respectable grade point average, and he continued to do so in dental school. By age 23 years, Sean had worn the cusps of his posterior teeth completely away due to his chronic bruxism, which began in childhood. Although bruxism is often caused by malocclusion between maxillary and mandibular dentitions, this could not explain his persistent problem. Sean's posterior teeth had been worn down to flat occlusal surfaces without any cusps to cause interferences in his bite. His case was so impressive that his professors requested permission to take photographs and make models of his teeth to teach future generations of dental students. Ironically, his bruxism worsened as the stress of dental school caused him to chronically clench his teeth together. His dental health was compromised by broad areas of exposed dentin in places once covered by enamel. Sean was at risk of losing his molar teeth, as well as developing painful temporomandibular joint dysfunction.

The treatment took a multimodal approach. Sean was advised to monitor himself for clenching and grinding during the day. Whenever he became aware of these behaviors, he was instructed to simply separate his upper and lower teeth. To prevent neuromuscular programming, his dentist recommended that he stop chewing gum. These interventions helped during the day; however, nocturnal bruxing continued. Sean was not aware of grinding his teeth in his sleep, but he did notice tenderness around his jaw in the morning. On exam, his dentist noted crepitus—the sound of bone rubbing against bone—with mandibular movement. Because crepitus is a sentinel sign of temporomandibular joint dysfunction, the dentist fitted Sean with a custom night guard that served two purposes: it prevented further eroding of enamel, and it curtailed the chronic temporomandibular joint inflammation. Sean also took ibuprofen to relieve inflammation and pain. His dentist offered a prescription for

clonazepam (Klonopin) to help hint deal with the pressures of his professional education. Sean, however, did not want to become addicted to a benzodiazepine, so he chose to try other measures first. Buspirone (BuSpar) was also offered as an option because of its reduced abuse potential. Fortunately, his dental condition stabilized fairly quickly, and he set his sights on having his left tooth structure restored with ceramic crowns.

Nail biting occurs quite commonly in childhood and frequently continues into adulthood. Occasionally, nail biting progresses to the point of causing dermatologic or even dental problems. It does not seem to be associated with the child's age, level of intelligence, or socioeconomic status, but nail biting seems to have a familial basis. Toenail biting, however, does appear to be much more prevalent in girls. An estimated 50% of children exhibit nail biting. It can be seen as early as 4 years of age, with peak prevalence between ages 10 and 18 years. According to one study, 4.5% of adults continue to bite their nails. Adults with onychophagia may not have comorbid psychiatric illness, and children with nail biting do not appear to be more anxious than peers who do not bite their nails. In most adult cases, nail biting seems to cause distress rather than result from stress.

As mentioned earlier, genetics seems to play a factor in the expression of some stereotypic behaviors. In twin studies, children born to parents who were nail biters were nearly three times as likely to be nail biters as control subjects. The concordance rate for monozygotic twins was 66% versus 34% in dizygotic twins. Onychophagia is the most severe type of nail biting. Monozygotic twins with onychophagia had a 75% concordance rate, whereas dizygotic twins only had an 18% concordance.

Of interest, stereotyped behaviors often occur in blind children. Elise Fazzi and others studied a group of congenitally blind children. In their group of 11 boys and 15 girls with and without developmental disabilities, 73% showed stereotypic behaviors. The most frequently encountered stereotypic behaviors were body rocking (30.7%),

repetitive handling of objects (30.7%), and eye pressing along with eye poking (30.7%). These researchers also found that the stereotypic behaviors could be decreased by encouraging appropriate adaptive behaviors and increased by restricting the environment, reducing sensory stimulation, and limiting mobility.

Stereotypic behaviors are more common among children with a history of parental neglect, but they may be present in children who do not have emotional problems. An estimated 20% of individuals with severe intellectual disabilities exhibit stereotypic behaviors. Alfred A. Baumeister and Rex L. Forehand found that two-thirds of a population institutionalized with intellectual disabilities exhibited stereotyped behaviors, and J. R. Dura and colleagues later reported that 34% of nonambulatory individuals with profound retardation who were institutionalized exhibited at least one stereotypic behavior. Despite the need for longitudinal studies, evidence from cross-sectional studies suggests that developmental age and experiential history, rather than chronologic age, are the relevant mediating variables for stereotypic movements. Stereotypic movements frequently peak in adolescence and then diminish thereafter.

The prevalence of SIBs varies from between 2% and 3% for children and adolescents in the community to about 10% to 15% for adults with severe or profound intellectual delays living in residential facilities. In individuals with severe intellectual disabilities living in institutions, stereotyped movements increase with chronologic age; however, the opposite is true of children without disabilities. In individuals with intellectual disabilities, the most common stereotypic movements are body rocking, head rolling, repetitive hand movements, self-hitting, head banging, and self-biting. The prevalence of head banging ranges between 3% and 15% in normally developing children. Approximately three times as many boys as girls exhibit the behavior. Head banging usually emerges between 5 and 11 months of age, but only 5% of these cases persist beyond 3 years of age.

Per the DSM-5, stereotypic movements may occur with or without SIBs. A study by Gal and colleagues monitored SIB and stereotypy in typically developing children as well as those who were intellectually

impaired, visually impaired, hearing-impaired, or autistic. In this sample of 90 subjects with at least one SIB, only 3 did not exhibit a co-occurring stereotypy. Interestingly, the rank order of prevalence of SIB and stereotypy was same across all five groups.

Given that the strongest predictor for the presence antiseverity of SIB was other repetitive behavior, an earlier model proposed by Guess and Carr in which SIB was thought to evolve from stereotyped movements makes some sense. SIBS, such as head banging, and stereotypy occur in typically developing children, but the SIB emerges later in development than stereotypy. In individuals with intellectual disabilities, SIB and repetitive behaviors appear temporally related; however, stereotypic behaviors still precede SIB.

Of note, Cornelia de Lange syndrome (mutations including the NIPBL gene in region 5p13, SMC1L1 in the Xp11.2 region, SMC3 gene in region 10q125), Fragile X syndrome (mutation at Xq127.3), Smith–Magenis (3.7 Mb interstitial deletion in chromosome 17p11.2), Cri-du-Chat syndrome (deletion in chromosome 5p15), and Rett syndrome (mutation in the methyl CpG—binding protein 2) are genetic disorders that present with various forms of stereotypic movements and SIB. Since these genetic defects are quite diverse, yet each gives rise to stereotypies with and without self-injury in the same individual, finding treatments for stereotypic behaviors remains a challenge.

Nevertheless, theories for stereotypic movements abound, and research continues to reveal new information regarding the etiology of these behaviors. An array of new research techniques will allow genetic information to be linked with neuroimaging results and facilitate understanding of the phenotypic expression of stereotypic behaviors.

NOSOLOGY

In many cases, the origin of stereotypic movements seems contextual to certain psychiatric illnesses or medical conditions in which they occur. The evolution of the DSM has tried to reflect such insights in its various iterations. Recent versions of the DSM had reserved the

diagnosis of stereotypic movement disorder for cases in which the stereotypic behavior is not a core symptom of another psychiatric disorder or the expected manifestation of a medical condition. Therefore, the repetitive facial movements due to either prolonged neuroleptic use or rapid discontinuation of this class of medication would be described as stereotypic movements, but these would not have met DSM-IV-TR criteria for stereotypic movement disorder. Although this continues to be the case in DSM-5, the current criteria require the clinician to specify whether stereotypic movement is associated with a known medical or genetic condition, neurodevelopmental disorder, or environmental factor. For instance, a person with Down syndrome and stereotypic movements would be coded as (307.3) stereotypic movement disorder associated with Down syndrome. In the case of autism spectrum disorder, a comorbid diagnosis of stereotypic movement disorder should be made whenever the stereotypic behaviors cause injury or appear sufficiently severe to become a focus of treatment.

Also, the DSM-5 has placed more emphasis on culture-related issues. Although stereotypic movements, with or without self-injury, manifest in all races and cultures, the attitudes of a particular culture may delay diagnosis. Clinicians need to be aware of cultural context and remain sensitive as they explain the diagnosis to patients and their families who come from a different country or culture. This will help patients accept and maintain appropriate treatment for the condition.

At first, the DSM criteria were somewhat broad. The DSM-III provided criteria for a diagnosis of atypical stereotypic movement disorder for conditions such as rocking, head banging, and repetitive hand movements characterized by quick, rhythmic hand rotations or tentative voluntary movements that usually involved the arms or fingers. The DSM-11 stipulated that such movements differed from tics in that they were voluntary but not spasmodic or distressing. In the DSM-III, atypical stereotypic behaviors were considered often to occur in patients with extreme psychosocial deprivation, intellectual disabilities, and pervasive developmental disorders; however, another mental disorder did not have to be present.

In the revised version of the DSM-III (DSM-III-R), atypical stereotypic movement disorder was renamed stereotypy/habit disorder. The criteria for stereotypy/habit disorder became broader so that intentional, repetitive, nonfunctional behaviors such as nail biting, nose picking, skin picking, and object mouthing were included. The DSM-III-R also specified a severity criterion, which required the behavior to cause injury or markedly interfere with normal activities to be considered a clinically significant “disorder.” The severity criterion allowed clinicians to determine whether the stereotypic movement was part of normal development, as is often seen with transient nose picking or a more pathologic picture, in which chronic nose picking causes significant tissue trauma or social stigmatization. A stereotypy or habit described by DSM-III-R criteria could include more intense forms of normal motor patterns seen in childhood, or they might be associated with some type of psychiatric or organic pathology. An additional criterion, however, excluded the diagnosis if the patient met the criteria for pervasive developmental disorder or tic disorder. This exclusion criterion recognized and eliminated the redundancy of making the diagnosis of stereotypy/habit disorder in these disorders, which have repetitive behaviors as core symptoms.

Another name change occurred with the publication of the DSM-IV. In an effort to be compatible with the ICD-10, the DSM-IV renamed the disorder stereotypic movement disorder. Because the intentional nature of a stereotypic movement might be impossible to determine in certain cases—for example, individuals with severe intellectual disabilities with limited ability to communicate, the clinician is no longer obligated to prove that the movement was intentional. The DSM-IV also drew boundaries between stereotypic movement disorders and several other disorders, including pervasive developmental disorder, tic disorder, obsessive-compulsive disorder (OCD), trichotillomania, and intellectual disabilities. As in the DSM-III-R, the diagnosis is not made if the stereotypic behavior is attributable to pervasive developmental disorder or tic disorder. Given the similarity between tics and compulsions, the DSM-IV excluded stereotypic behaviors that were compulsions related to OCD. The DSM-IV also stipulated that the stereotypic behavior could not be due

to the physiologic effects of a substance or a general medical condition. A diagnosis of stereotypic movement disorder would not be made for repetitive hair pulling if DSM-IV criteria for trichotillomania were met. In addition, a diagnosis of stereotypic movement disorder with SIB could be made in persons with intellectual disabilities if the SIB was significant enough to become a focus of therapy. Subsequent versions of the DSM—the DSM-IV-R and the DSM-IV-TR—used those criteria established by the DSM-IV.

In general, the DSM-IV-TR and DSM-5 as well as ICD-10 criteria for stereotypic movement disorder describe the diverse and unrelated stereotyped movements that are not part of any other recognized neurologic or psychiatric condition. According to the DSM-5, a stereotypic movement disorder is a repetitive, seemingly driven, and nonfunctional motor behavior. It lists hand shaking or waving, body rocking, head banging, mouthing of objects, self-biting, picking at skin or body orifices, and hitting one's body as examples. The DSM-5 definitions exclude behaviors with a clear purpose or adaptive function, but, as acknowledged in the DSM-IV-TR, the driving force behind a stereotyped movement may be difficult to determine in cases in which the person has limited ability to communicate internal states. What is more, a stereotypic behavior may provide a signal that an undiagnosed neurodevelopmental disorder exists, especially in children younger than 3 years of age.

The DSM-5 specifies that for a repetitive motor behavior to be considered a stereotypic movement disorder, it must interfere with social, academic, or other activities and may result in self-injury. In severe cases, the behavior can cause death, but even less severe cases might result in disabling or disfiguring impairments.

Consider the case of Ruth, a middle-aged woman, who was admitted to the inpatient unit at a university-based teaching hospital due to unrelenting head scratching. Her outpatient psychiatrist had tried the full array of pharmacologic interventions, including combinations of anxiolytic, antidepressant, and antipsychotic medications, but the stereotypic scratching progressed to the point that she required surgical intervention. Ruth had scratched through her scalp and penetrated the skull, exposing the dura mater.

In Ruth's case, a complete DSM-5 diagnosis would be stereotypic movement disorder with self-injurious behavior, severe. Per the DSM-5, the diagnosis is specified as with or without SIB. Note, however, that the disorder should be specified as "with self-injurious behaviors," if injury would occur in cases where protective measures were not present to prevent injury. Ruth obviously displayed severe symptoms, given that continuous monitoring and protective measures were required to prevent serious injury. Moderate symptoms require protective measures and behavioral modification; whereas, mild symptoms can be easily suppressed with sensory stimulus or distraction. Clinicians should also specify whether the stereotypic movement is associated with a known medical or genetic condition, neurodevelopmental disorder, or environmental factor. An additional code identifying the associated medical/genetic condition or neurodevelopmental disorder aids in billing and communicating with third-party payers.

The ICD-10 diagnostic criteria for stereotypic movement disorders appear more succinct. Per the ICD-10, the stereotyped movements must either cause physical injury or markedly interfere with normal activities. The duration of symptoms lasts at least 1 month. In contrast to DSM-5, no other mental or behavioral disorder can be present, except for intellectual disabilities.

DIFFERENTIAL DIAGNOSIS

The outward appearance of a complex tic or a compulsion may closely resemble stereotypic movements, and this may lead to diagnostic difficulties. James W. Bodfish, T. W. Crawford, and colleagues found high rates of stereotyped behavior in adults with comorbid mental retardation and compulsion disorder. Compared with a noncompulsive matched control group, their sample showed an increased prevalence of stereotypy (32%), an increased prevalence of self-injury (40%), and an increased prevalence of stereotypy plus self-injury (37%) in those with compulsive disorder. A review by J. L. Rappoport reported that 20% of patients with OCD also exhibit motor tics, which complicates the diagnosis further. Nevertheless, some simple caveats can help to sort out stereotypic movements from other repetitive movements:

Generally speaking, a stereotypic movement is a rhythmic, repetitive motor behavior. It usually is simpler than other forms of repetitive behaviors. Although a stereotypic behavior appears purposeless, it can also serve to alleviate anxiety or another aversive state. Tics ordinarily have an involuntary quality even though tics may be suppressed for limited periods of time and they are not rhythmic. Compulsions appear more complex and ritualized. A stereotypic movement differs from a complex tic and a repeating compulsion in that it is not performed as a preventative measure, nor is it motivated by a sense of incompletion. In addition, complex tics and compulsive behaviors typically are not rhythmic.

With regard to autism, a study by Fiona Zandt and colleagues suggested that compulsions coexist with stereotypic behaviors in children with autism spectrum disorder. They found that children with OCD had more obsessions and compulsions than children with autism spectrum disorder; however, both the OCD group and the group with autistic stereotyped behaviors exhibited more obsessions and compulsions than a comparison group with a typical developmental trajectory. Similarly, J. M. Ringman and J. Jankovic reported on a series of 12 patients with autism spectrum disorders and stereotypic movements. These patients were referred to a specialized movement disorder clinic for the evaluation of tics. Tics were clearly present in seven of the patients, and six of these patients

met the criteria for both Asperger syndrome and Tourette syndrome. Even though the diagnosis of stereotypic movement disorder excludes repetitive movements that may be core symptoms of other DSM-5 disorders, the literature suggests, and this author observes, that stereo behaviors in autistic spectrum disorders may be comorbid with OCD or tic disorder.

The DSM-IV-TR specifies that the stereotypic behavior is not due to the direct physiologic effects of a substance or a general medical condition. This criterion would exclude tardive dyskinesias, as in chronic neuroleptic exposure or skin picking secondary to stimulant use. Although tremors associated with Parkinson syndrome and Parkinson disease are abnormal and stereotypic, neither would fit the current criteria for stereotypic movement disorder because they are due to the physiologic effects of neuroleptic medication in Parkinson syndrome and a medical condition in the case of Parkinson disease.

Intellectual disability is a common feature of numerous genetic disorders. If the stereotypic or SIB occurs in the context of intellectual disability, the behavior no longer must be severe enough to become a focus of the treatment to meet the diagnostic criteria for DSM-5. Repetitive motor behaviors noted in a person with intellectual disabilities would be correctly recorded per the DSM-5 as stereotypic movement disorder associated with intellectual developmental disability. In Lesch–Nyhan syndrome, the degree of intellectual disability does not seem to predict the magnitude of self-mutilation. Some patients with mild mental intellectual disability may display extreme forms of self-injury. Notably, stereotypic movements occur in approximately two-thirds of individuals with intellectual disabilities living in residential facilities.

In addition, the DSM-5 criteria no longer require that the repetitive movement must be present for 4 weeks or more. Typically, stereotypic movements peak in adolescence, but they have no typical age of onset. Stereotypic movements in persons with severe or profound intellectual disabilities may last for years; however, an abrupt onset of stereotypic behaviors may signal the presence of an underlying acute medical condition in nonverbal individuals with severe mental retardation. Clinicians should be mindful of clues that

such individuals may be experiencing pain, distress, anxiety, or mood shifts and then promptly treat any identified problems. Stressful events also may precipitate stereotypic behaviors. However, stereotypic movements may emerge and become a focus of treatment in individuals with mental retardation who are institutionalized in nonstimulating environments.

ICD-10 AND 11

The ICD-10 and ICD-11 define stereotypic movements in childhood in a fashion similar to the DSM-5 since one of the goals of DSM-5 aimed to provide compatibility between the two diagnostic systems. As in the DSM, physical injury or marked impairment in normal activities must be present for the diagnosis. This criterion attempts to sort out stereotypic movement disorder from stereotypic movements that are benign or typical of normal development. The duration criterion provides another dimension to the impairment and ensures that the stereotypic movement is more than a passing novelty. In addition, a history of another psychiatric or behavioral disorder should not be present and account for the stereotypic movement.

DIAGNOSIS

No clinical tests are available to make the diagnosis of stereotypic movement disorder. Nevertheless, the history and physical exam may be revealing. Dental and physical exams may provide evidence of tissue trauma that would raise suspicions for stereotypic behaviors, especially the self-injurious type. Anemia may be a sign of self-induced rectal bleeding. The delicate architecture of the eye is particularly vulnerable to repetitive trauma from behaviors such as head banging and eye poking. Sometimes a subtle physical sign clues the clinician to stereotypic behaviors and movements that go unobserved by others.

Rating scales assist in diagnosing and tracking responses to treatment in many psychiatric conditions; however, rating scales for stereotypic behaviors have not been so helpful. Several rating scales

have been developed, but none provides optimal psychometric properties across the spectrum of stereotypic behaviors. Even commonly used instruments for tracking drug-induced stereotypic behaviors, such as the Angus Involuntary Movement Scale (AIMS) and the Barnes Scale, focus on involuntary movements rather than the wide range seen with stereotypic movements. Berkson and Davenport developed a stereotypy checklist to track stereotyped behaviors mainly due to social deprivation. Unfortunately, experiments intended to test the reliability and validity of the Berkson and Davenport Stereotypy Checklist have shown variable results.

Recently, video- and computer-assisted technologies have been used to study tardive dyskinesia. These technologies may elucidate the characteristics of other stereotypic behaviors, such as that developed for use in monitoring attention-deficit/hyperactivity disorder (ADHD). These motion-detecting devices connected to sophisticated computer programs can give detailed descriptions of the randomness, as well as the range of movements on a second-by-second basis. This type of technology might prove valuable in research or for clinical applications related to stereotypic behaviors.

Eventually, research may lead to feasible diagnostic tests using genetic and/or neuroimaging techniques to assist in the diagnosis and treatment of stereotypic behaviors. In the meantime, a comprehensive clinical exam remains the standard for making an accurate diagnosis.

INJURIOUS BEHAVIORS

Stereotypic movements can manifest in a variety of injurious behaviors that put patients and caregivers at risk. The ramifications of head banging range from hematomas and head injuries to retinal detachment and blindness. However, even seemingly benign stereotypic behaviors could cause cumulative damage over time. For example, hair loss could be a consequence of chronic head rolling. In addition, parents and caregivers are at risk of accidental bites and bruises as they attempt to protect children and many adults who engage in stereotyped self-injury. Even children who typically do not

exhibit self-injury can be hazardous to others. A child being held may surprise a parent or caregiver with spontaneous swift lead bobbing that results in a broken nose or blackened eye. Stereotypic movements, with or without the potential for self-injury, may cause major management problems, which hamper habilitation and stifle social adaptation.

Onychotillomania refers to compulsive picking or tearing at the nails. It can produce ridges and a central depression on the nail from chronic rubbing by the nail or another finger. Most commonly, the thumbnail of the dominant hand produces trauma to the nail plate of the second or third finger. Onycholysis refers to the separation of the nail from the nail bed. Onychotillomania and onycholysis may be manifestations of rare conditions involving self-mutilation like Lesch–Nyhan syndrome and congenital insensitivity to pain.

Appropriate attention to the patient's history will help to sort out other stereotypic or SIBs. For example, a stereotypic behavior may have been present in a patient with schizophrenia prior to any neuroleptic medication exposure. A careful history of symptom onset can prevent a misdiagnosis of medication-induced stereotypy. Secondary gain in fictitious disorders might be the driving force in some instances. In other cases, the inability to control anger or anxiety may lead to repetitive cutting, as seen with patients with borderline personality disorder.

TREATMENT

A variety of treatment options, from psychotherapy to pharmacotherapy, have been used to treat stereotypic and SIBs. Even surgery and electroconvulsive treatments have been used in refractory cases. Behavioral treatments have been used with some success, and these include positive reward techniques such as differential reinforcement of behaviors other than the targeted maladaptive behavior (Differential Reinforcement of Other Behavior [DRO]) and differential reinforcement of behavior incompatible with the targeted maladaptive behavior (Differential Reinforcement of Incompatible Behavior [DRI]). Rewards may be immediate or

delayed, as in token economies, but they must be individualized so that they produce the maximum motivation. Rewards also may lose their novelty over time; therefore, changing rewards may provide a fresh incentive for motivation. Punishment can range from misting water into the face to applying mild electric shocks to the patient. Although these techniques might seem mean-spirited, they should be employed if self-injurious or stereotypic behaviors have a high potential for severe harm. Of course, the clinician should document a thoughtful risk versus benefits analysis and discuss this with the guardian or family before using such methods. Other forms of punishment include positive practice, removal of reinforcement, and restitution. A study by Jonathan M. Miller and others used behavioral modification techniques of habit reversal and differential reinforcement of other behaviors in an attempt to suppress stereotypic behaviors in 12 nonautistic children between the ages of 6 and 14 years. After a mean follow-up time of 12.1 months, motor stereotypies were significantly reduced on the Stereotypy Linear Analog Scale and the Stereotypy Severity Scale. These results correlated with the subject's motivation and the number of sessions attended. The Child Global Assessment Scale also improved, but no correlations were seen with the level of motivation or number of sessions.

Pharmacologic approaches have been a mainstay treatment of stereotypic behaviors. An estimated 50% of persons with intellectual disabilities living in residential or institutional settings are prescribed high doses of antipsychotic medication, but this statistic does not give an accurate account of the percentage of these patients who have a known psychotic illness. About 75% of patients receiving psychotropic medications develop some form of motor dysfunction. In the early days of treatment, movement disorders occurred at even higher rates due to the misconception that motor dysfunction was the definitive sign that a patient had achieved an adequate dose of medication to treat psychosis. Even though antipsychotic agents are used to treat stereotypic movements, they also can cause repetitive, purposeless movements. For instance, akathisia secondary to neuroleptic medication may appear clinically as shifting from foot to

foot, crossing, and uncrossing of legs, pacing, hand wringing, or rocking, among other manifestations.

The newer generation of atypical antipsychotic medications does not pose the typical risk for motor dysfunction seen in older drugs. To date, risperidone (Risperdal) and aripiprazole (Abilify) have been approved by the U.S. Food and Drug Administration (FDA) for self-injurious and disruptive behaviors in children with autism. For the double-blinded, placebo-controlled clinical trial of risperidone, the dose ranged from 0.5 to 3.5 mg per day in the 101 children studied. In a placebo-controlled study of chlorpromazine (Thorazine) used in doses ranging from 2 to 3 mg/kg per day, four adolescents and young adults with profound intellectual disabilities exhibited a 35% reduction in stereotypic behaviors. Unfortunately, the improvement in stereotypic behaviors was offset by a cognitive decline. Several double-blinded placebo-controlled studies used haloperidol (Haldol) in daily doses of between 0.5 and 4 mg to treat stereotypic behaviors in youth with autism. In these studies, haloperidol significantly reduced stereotypic behaviors without causing notable cognitive impairment.

With FDA approval of risperidone and aripiprazole for the treatment of disruptive behaviors, including stereotypic SIBs, these medications have been used more frequently in individuals with autism. This increase in these and other neuroleptic medications in the autism population may lead to other types of repetitive movement disorders, such as Parkinson syndrome with a “pill-rolling” tremor or tardive dyskinesia. Anticholinergic agents such as benztropine (Cogentin), diphenhydramine (Benadryl), and others effectively counteract extrapyramidal movements associated with neuroleptic use. Until recently, the only way to address tardive dyskinesia was to immediately stop or taper off the neuroleptic and hope that it would resolve over the course of weeks to months. In many cases, tardive dyskinesia would decrease to a degree but not fully resolve. Although not life-threatening, the prospect of social stigma from permanent tardive dyskinesia had been one of the main limiting factors in the use of this class of medications. In 2017 however, the FDA approved valbenazine and deutetrabenazine for the treatment of tardive

dyskinesia. These vesicular monoamine transporter type 2 (VMAT 2) inhibitors are not approved in Canada, but tetrabenazine is. Tetrabenazine was approved by the U. S. FDA in 2008 for chorea movements in Huntington disease. In the randomized 6-week trials of valbenazine, Abnormal Involuntary Movement Scale (AIMS) mean scores were reduced (−3.2) on 80 mg/day, (−1.9) on 40 mg/day, and (−0.1) on placebo at week six compared to baseline. For the 12-week trials of deutetrabenazine, AIMS score reductions with a mean daily dose of 39 mg/day was (−3.0) compared to (−1.6) with placebo in the smaller study of 117 subjects. In a larger trial of this drug, AIMS scores were reduced (−3.3) on 36 mg/day and (−3.2) on 24 mg/day compared to (−1.4) on placebo. The 12 mg/day dose did not show improvement compared to the placebo. Although FDA-approved, these medications can reduce yet not necessarily eliminate symptoms of tardive dyskinesia. Thus, judicious use of antipsychotic medications continues to be the best approach for individuals with autism and stereotypic self-injurious, disruptive behaviors. Otherwise, attempts to eliminate stereotypic movements could lead to the emergence of other types of movement disorders.

A variety of other agents have been tried, but these have fallen short due to limitations of study size or design. Although lithium carbonate (Eskalith) has been studied for SIBs in patients with intellectual disabilities, the results of the few studies are inconsistent. Fenfluramine (Ponderax, Pondimin) reduced stereotypic behaviors and other problem behaviors in individuals with autism; however, the results also varied across studies. In addition, fenfluramine has been associated with cardiovascular and pulmonary problems. Several other serotonergic agents have been tried, including fluoxetine (Prozac), sertraline (Zoloft), citalopram (Celexa), trazodone (Desyrel), and buspirone (Buspar), but methodologic issues related to the size or design of each study limited their usefulness.

Clomipramine (Anafranil) and desipramine (Norpramin) have been studied for their effect on stereotypic behaviors in autism and onychophagia. Gordon and coworkers showed that clomipramine was superior to desipramine, but both were better than placebo in reducing stereotypic behaviors associated with autism. Clomipramine

was better than desipramine in treating severe onychophagia, but the dropout rate was greater than that seen in other studies of its use in OCD and trichotillomania. Henrietta L. Leonard and colleagues concluded that clomipramine was not the optimal treatment for severe onychophagia.

An endogenous opioid theory for SIBs has prompted the use of opioid antagonists. The original study of naloxone (Narcan) successfully reduced SIBs in two young adults with profound intellectual disabilities. SIBs with low frequency of occurrence responded best to the intervention at low doses. Subsequently, several other studies showed that individuals responded variably to naloxone or naltrexone. However, these two agents may decrease stereotypic, self-injurious, and hyperactive behaviors in some patients.

Clearly, more controlled studies are needed to evaluate these and other therapies based on behavioral and pharmacologic interventions. Recent technologic advances in genetic analysis, neuroimaging, and movement monitoring will promote this goal.

Although stereotypic behaviors manifest in many ways, diagnostic criteria for a stereotypic movement disorder in the DSM-5-TR and the ICD-11 describe repetitive, rhythmic movements that are not due to another psychiatric disorder, medical condition, or medication effect. Criteria for impairment help to clarify whether a stereotypic movement is an inconsequential habit or part of normal development. The careful clinician should use a thorough history and exam to identify the presence and possible causes of stereotypic behaviors. Once the clinician accurately characterizes the stereotypic movement, behavioral therapy with or without medication intervention may be applied. Although the literature on the treatment of stereotypic behaviors is limited, it does provide a starting point for developing treatment plans that will likely be subject to change as warranted.

Mood Disorders in Children and Adolescents

50.1 Depressive Disorders and Suicide

Karen Dineen Wagner, M.D., Ph.D., Tami Benton, M.D., and Catharyn A. Turner, II, M.D., M.Ed.

Depressive disorders in children and adolescents have a significant adverse effect on a youth's emotional, social, and cognitive development. Early onset of major depression is associated with more lifetime depressive episodes and suicide attempts, greater psychiatric and medical comorbidity, and poorer quality of life than later age onset of depression. Disruptive mood dysregulation disorder leads to impairments in school functioning and relationships with family and peers. Recognition of these disorders is essential so that children and adolescents may receive effective evidence-based treatments.

DEFINITION

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5-TR) includes in the category of depressive disorders the following: disruptive mood dysregulation disorder, major depressive disorder, persistent depressive disorder, premenstrual dysphoric disorder,

substance/medication-induced depressive disorder, depressive disorder due to another medical condition, other specified depressive disorder, and unspecified depressive disorder. To be in the category of depressive disorders, there cannot be a history of ever having had a manic or hypomanic episode. There are coded specifiers for the depressive episode for severity (mild, moderate, severe, with psychotic features) and course (in partial remission, in full remission). The uncoded specifiers for the current episode include with anxious distress, with mixed features, with melancholic features, with atypical features, with mood-incongruent psychotic features, with catatonia, with peripartum onset, and with seasonal pattern.

Disruptive mood dysregulation disorder in children is characterized by recurrent verbal or behavioral temper outbursts (>3 or more times per week) that are excessive and age inappropriate. In between these episodes, mood is irritable or angry most of the day, nearly every day. These symptoms occur in at least two settings (school, home, or with peers). The duration of symptoms must be more than 12 months, without a 3-month symptom-free period in this time frame. The age of onset of the symptoms must be before 10 years old, and the diagnosis should not be made before age 6 years or after age 18 years.

Criteria for major depressive disorder in children and adolescents are at least one major depressive episode in which there has been at least a 2-week period of either depressed or irritable mood or a loss of interest or pleasure. In addition, at least four of the following symptoms are required: weight loss, weight gain, failure to make expected weight gain, or an increase or decrease in appetite; insomnia or hypersomnia; psychomotor agitation or retardation; fatigue or loss of energy; feelings of worthlessness or excessive or inappropriate guilt; diminished ability to think or concentrate or indecisiveness; and recurrent thoughts of death, recurrent suicidal ideation, suicide attempt, or suicide plan. The symptoms must cause impairment in functioning or cause clinically significant distress.

Persistent depressive disorder in children and adolescents is a chronically depressed or irritable mood for at least 1 year. In addition, there must be at least two of the following symptoms: poor appetite or overeating; insomnia or hypersomnia; low energy or fatigue; low self-esteem; poor concentration or difficulty making decisions; and feelings of

hopelessness. During the 1-year period, the youth also has not been without depressive symptoms for more than 2 months at a time.

Premenstrual dysphoric disorder requires at least five symptoms in the final week before the onset of menses which start to improve a few days after the onset of menses and are either minimal or absent in the week following menses. One or more of the following symptoms must be present: affective lability, irritability/anger/interpersonal conflict, depressed mood/hopelessness/self-deprecating thoughts, or anxiety/tension/keyed up or on edge. In addition, at least one of the following symptoms must be present: decreased interest, concentration difficulties, fatigue/low energy, appetite changes, hypersomnia/insomnia, feeling overwhelmed/out of control, and physical symptoms. The symptoms must be severe enough to interfere with functioning or cause clinically significant distress.

A diagnosis of other specified depressive disorder is used when full criteria for a depressive disorder are not met, but the symptoms cause significant distress or impairment. The specific reason for not meeting the full criteria is identified. The diagnosis of unspecified depressive disorder is used when the reasons for not meeting the full criteria are not identified.

HISTORY

Although depression in children and adolescents is now recognized as a common and serious illness, it was not until the 1980s that studies demonstrated that children do develop depressive disorders that can be diagnosed in a standardized manner. It was originally thought that children and adolescents developed a “masked” form of depression with predominantly behavioral symptoms, but subsequent studies have shown that children and adolescents have symptoms similar to those of adults with depression.

Disruptive mood dysregulation disorder is a new diagnosis in DSM-5 depressive disorders to address issues related to the potential overdiagnosis of bipolar disorder in children and adolescents. Children with severe nonepisodic irritability were increasingly diagnosed with bipolar disorder but did not have distinct episodes of mania or hypomania. Disruptive mood dysregulation disorder had its origins in the construct of severe mood dysregulation developed by researchers (Leibenluft and colleagues) at the National Institute of Mental Health.

EPIDEMIOLOGY

The prevalence of major depressive disorder in children is approximately 2%. In adolescence, there is a substantial increase in the prevalence of major depression, with lifetime prevalence rates of 12%. In children, the sex ratio is 1:1, whereas, with puberty, adolescent females are two to three times more likely to have an episode of major depression than adolescent males. Children with a family history of affective disorders are about three times more likely to develop a major depressive disorder than children with a first-degree relative without a lifetime affective disorder. The prevalence rate for persistent depressive disorder in children ranges from 0.6% to 4.6%, and in adolescents, it ranges from 1.6% to 8.0%.

Estimates of the prevalence rate of disruptive mood dysregulation disorder are about 3%. The prevalence is higher in young children (3% to 8%) than in adolescents (0.8%). This disorder is more commonly diagnosed in males compared to females.

ETIOLOGY

Genetic

The most predictive factor for a child or adolescent to develop major depressive disorder is a high family loading for major depressive disorder. There is an increased risk of depression in relatives of depressed children (odds ratio = 3.98 compared to healthy controls) and among offspring of depressed adults (odds ratio = 2.12 compared with healthy controls). Younger age of onset of depression in parents increases the risk of depression in children. Parental major depression is associated with greater severity of illness, longer episode duration, more impairment, and more recurrences in depressed offspring. Twin studies have demonstrated that depression is moderately heritable, with rates of about 31% to 42%.

Heritability of disruptive mood dysregulation disorder has not been specifically determined, although there may be a heritable component to the phasic irritability.

Neurobiology

Neuroendocrine studies have evaluated the hypothalamic–pituitary–adrenal (HPA), hypothalamic growth hormone (HGH), hypothalamic–pituitary–thyroid (HPT), and hypothalamic–pituitary–gonadal (HPG) axes

in youth to determine whether there are abnormalities related to depression. HPA-axis abnormalities have been detected in depressed children and adolescents with some evidence of nonsuppression in stimulation studies and higher baseline cortisol values. Growth hormone–axis abnormalities have been found in prepubertal depressed children who have a blunted growth hormone response to stimulation with growth hormone–releasing hormone. There have been inconsistent findings regarding abnormalities in the HPT axis in children and adolescents with depression. The majority of studies of corticotropin-releasing hormone have found no abnormalities in depressed youth.

Abnormalities in the serotonergic system have been examined in depressed youth. Serotonin challenge agents that cause the release of prolactin have shown greater prolactin release in depressed children compared to controls.

Neuroimaging studies of depressed youth have found smaller left subgenual prefrontal cortex in adolescent girls, smaller frontal white matter volumes, larger frontal gray matter volumes, and larger lateral ventricular volumes. Amygdala functioning has been shown to be disrupted in depressed children. Disconnectivity in frontolimbic circuitry has been associated with depression in adolescents. Larger pituitary- and amygdala-to-hippocampal volume ratios have been found in depressed youth compared to healthy controls. Depressed children and adolescents have been found to have smaller left and right amygdala volume than healthy controls. Increased pituitary gland volume has been found in treatment-naive youth with major depressive disorder, particularly in males with nonfamilial major depressive disorder. Magnetic resonance spectroscopic imaging has found an increase in choline in the left dorsolateral prefrontal cortex and orbitofrontal cortex and increased choline/creatinine and choline/*N*-acetylaspartate ratios in the left anterior medial frontal lobe in depressed youth. A functional magnetic resonance imaging (fMRI) monetary task showed disruption in reward system neural circuitry in adolescent depression. Highly irritable youth with disruptive mood dysregulation disorder showed increased frontal striatal activation on fMRI following a frustrating task.

A meta-analysis of depression and inflammation among children and adolescents showed significant associations between depression and c-reactive protein (CPR) and interleukin-6 (IL-6). Sleep abnormalities have been examined in depressed youth, and the findings from

polysomnography have been mixed. Some studies found no differences between children with major depressive disorder and controls, whereas other studies have found shorter rapid eye movement (REM) latencies, longer sleep latency, a higher number of REM periods, and increased REM time for depressed children. In studies of depressed adolescents, shorter REM latency, more REM sleep, more REM density, and longer sleep latency have been reported. Subjective reports by youths of sleep disturbance (sleep quality, waking in the middle of the night, morning tiredness) were not confirmed by an electroencephalogram (EEG). Of interest, the depressed children who rated their sleep most poorly had a better sleep by EEG measures than those who rated their sleep more positively. In a study using polysomnography as a measure of the recurrence of depression in youth, those youth who had a later recurrence had decreased sleep efficiency and delayed sleep onset at baseline sleep polysomnography. No clinically significant associations have been shown between disruptive mood dysregulation disorder and findings on polysomnography.

Environmental

Adoption studies have supported the role of environment more than genetic factors in the development of pediatric depression. Family factors, including parental substance abuse, poor marital adjustment, parent–child conflict, and lack of family cohesion, are risk factors for depression in children and adolescents. Life stressors, such as abuse, neglect, death of a parent, bullying, and psychosocial adversities, may contribute to depression in youth. Cigarette smoking, physical illness, and functional impairment have been associated with youth depression. Recurrence of major depression may also be affected by environmental stressors.

There may be gene–environment interactions with regard to pediatric depression. Twin studies of life events have shown that the effect of life events on depression is greater in youth with higher genetic liability. Family conflict and family adversity have also been demonstrated to interact with genetic liability and contribute to depression in youth.

Preliminary findings suggest that environmental factors such as parenting, peer victimization, and adverse life events may have a role in development of irritability and disruptive mood dysregulation disorder.

DIAGNOSIS AND CLINICAL FEATURES

It is important for the clinician to conduct a comprehensive evaluation of a child to ensure the accuracy of the primary diagnosis, as well as of comorbid diagnoses. The clinician should interview the child and parent separately so that each can express their concerns. Teenagers are often reluctant to disclose their feelings or issues related to peers in the presence of their parents. Similarly, parents may be reticent to discuss sensitive topics with their children present. Other sources of information may be obtained from discussion with school personnel, from school records, or from medical records.

Children with a diagnosis of disruptive mood dysregulation disorder are persistently irritable or angry most of the day nearly every day and have severe recurrent (>3 times per week) temper outbursts, either verbal or behavioral. These temper outbursts are developmentally inappropriate and are out of proportion to the situation. To make this diagnosis, the symptoms must be present for at least 12 months (no period >3 months without symptoms in this time frame) and be present in at least two settings (school, home, or with peers). The diagnosis cannot be given to children under the age of 6 years, and the onset of symptoms must be before age 10 years.

The irritability/angry mood state for children with disruptive mood dysregulation is chronic (tonic irritability). Particularly when faced with frustration, these children have marked difficulty regulating their emotions and respond with verbal or behavioral outbursts (phasic irritability). For example, a child may throw a chair in school during one of these outbursts. This persistent irritability and severe temper outbursts lead to significant impairment in school, at home, and in social settings. Children and adolescents with major depression have depressed or irritable mood and/or loss of interest or pleasure, along with at least four of the following symptoms: Weight or appetite change, sleep disturbance, psychomotor retardation or agitation, fatigue or loss of energy, feelings of worthlessness or guilt, diminished concentration, and suicidal ideation, intent, or plan. The symptoms must cause impairment in the child's functioning with regard to, for example, social or school performance or peer relationships, which is critical to the diagnosis in youth. Impairment helps to distinguish these symptoms from a passing phase of childhood or adolescence.

Youth with major depressive disorder often display irritable mood rather than dysphoria. Typically, they are not aware of the extent of their

irritability or its effects on their interaction with other people. Teenagers who have some insight into their irritability might say that everything makes them angry whether it is important or not. Loss of pleasure or interest may be noted by the youth's withdrawal from school or sports activities and from friends. Sleep disturbance is common in depressed youth, particularly difficulty falling asleep. Weight loss or failure to gain weight is more common than significant weight gain. Youth with depression are often fatigued and may nap after school. Diminished concentration may be manifested by declining school grades. A child often describes a feeling of worthlessness as no one liking them, including peers, teachers, and family members. Suicide attempts and psychotic features are more common in depressed adolescents than in depressed children.

Depressed youth may not view themselves as having depression if their mood is irritable rather than depressed. Parents often do not recognize individual symptoms of an adolescent's depression, but they recognize the burden on the family in dealing with an extremely irritable adolescent. Children and adolescents with depression are more likely to be brought for evaluation because of declining school grades, substance abuse, suicide attempt, or a change in behavior.

For a diagnosis of persistent depressive disorder, a child or adolescent must have depressed or irritable mood for at least 1 year. In addition, the youth must have two of the following symptoms: poor appetite or overeating, insomnia or hypersomnia, low energy or fatigue, low self-esteem, poor concentration or difficulty making decisions, and feeling of hopelessness. Youth with persistent depressive disorder have fewer melancholic and neurovegetative symptoms than youth with major depressive disorder. Although the depressive symptoms are milder in persistent depressive disorder than in major depressive disorder, the chronicity of persistent depressive disorder results in significant psychosocial impairment (e.g., relationships with friends and family).

Depressive disorders in youth are often comorbid with other psychiatric conditions. Rates of comorbidity range from 40% to 90% of children and adolescents with a depressive disorder, with up to 50% of depressed youths having two or more comorbid disorders. Anxiety disorders often precede the onset of depression and are a very common comorbid disorder. Major depression and persistent depressive disorder also frequently co-occur in youth. Other common comorbidities especially with

disruptive mood dysregulation disorder are attention deficit hyperactivity disorder (ADHD), oppositional defiant disorder (ODD), conduct disorder, and substance use disorder. It is important for clinicians to identify comorbid disorders that are associated with depressive disorders in youth, since these comorbidities may adversely affect the course and treatment outcomes of depressive disorders.

LABORATORY EXAMINATIONS/ASSESSMENT INSTRUMENT

No laboratory findings are diagnostic of depressive disorders in youth. If a child presents with symptoms of depression and hypothyroidism (e.g., dry skin, feeling cold, and memory difficulties), then thyroid function tests should be obtained. If hypothyroidism was found, the diagnosis would be depressive disorder due to another medical condition.

The Patient Health Questionnaire-9 modified for adolescents (PHQ-A) is a widely used self-report screening instrument for depression in youth aged 11 to 17 years. The scale has nine depression symptom items rated on a 4-point scale from 0 (not at all) to 3 (nearly every day). Scores range from 0 to 27. PHQ-A score ≥10 is typically the cut-off threshold for further evaluation to determine a diagnosis of major depression. This scale may also be useful for monitoring treatment outcomes.

The Children's Depression Rating Scale-Revised (CDRS-R) is a 17-item, clinician-administered instrument that assesses symptoms of depression in children and adolescents. The scale assesses cognitive, somatic, affective, and psychomotor symptoms. The items are rated for severity on a scale of 1 to 7 for some items and 1 to 5 for other items for a total score of 113. Typically, a score of 45 or greater is considered a marker of clinically significant depression. The CDRS-R is useful for obtaining baseline symptomatology prior to treatment and for monitoring treatment outcome.

Given that youth with bipolar disorder may present with a depressive episode, it is important to ask about symptoms of mania or hypomania. Some diagnostic checklists for mania have been shown to discriminate bipolar from nonbipolar disorder in youth of ages 5 to 18 years, including the Mood Disorder Questionnaire-Adolescent (MDQ-A), the Parent General Behavior Inventory 10-item short form (PGBI-SF10), and the Parent Young Mania Rating Scale (P-YMRS). These checklists are

completed by the parents about their child's behavior. Adolescent self-report measures about symptoms of mania have demonstrated low validity in identifying bipolar disorder.

DIFFERENTIAL DIAGNOSIS

Depressive symptoms may be related to stressors and fulfill criteria for an adjustment disorder with depressed mood. A child may have experienced the death of a significant person in their life, and the depressive symptoms may be related to bereavement. Depression or irritability may be attributable to substance use or withdrawal, which would be considered a substance-induced depressive disorder.

When a child presents with depressive symptoms, it is important for the clinician to consider bipolar disorder within the differential diagnosis. The clinician should ask about a past or present history of manic or hypomanic symptoms.

There is substantial symptom overlap among various psychiatric disorders, which might complicate the differential diagnosis. Irritability may be found in disruptive mood dysregulation disorder, major depression, persistent depressive disorder, bipolar disorder, post-traumatic stress disorder, and generalized anxiety disorder. Children with ADHD who are failing in school and having difficulty with peer relationships may exhibit symptoms such as depressed mood, low self-esteem, irritability, and behavioral outbursts. Anxiety disorders and ODD may have some symptom features of depression and disruptive mood dysregulation disorder. Children with pervasive developmental disorder may present with depressive symptoms but not fulfill diagnostic criteria for a depressive disorder.

Medical conditions may manifest with symptoms of a depressive episode and should be diagnosed as depressive disorder due to a general medical condition if the mood disorder is attributable to the consequences of the medical condition. Neurologic disorders (e.g., seizure disorder and multiple sclerosis), endocrinologic abnormalities (hypothyroidism, hypopituitarism, Cushing disease), infections (e.g., pneumonia, AIDS, and mononucleosis), autoimmune diseases, and cancer are some medical conditions to consider within the differential diagnosis. Medications such as anti-inflammatory agents, antibiotics, steroids, stimulants, and oral contraceptives may lead to depressive symptoms.

COURSE AND PROGNOSIS

Disruptive mood dysregulation disorder has its onset after the age of 6 years. It has been found that disruptive mood dysregulation disorder at age 6 predicted disruptive mood dysregulation disorder, depressive disorders, and ADHD at age 9 years. Academic difficulties, use of education support services, school suspensions, peer relationship problems, and impaired relationships with parents and siblings are frequent outcomes of this disorder. The symptoms are predominantly limited to childhood. Of children who were diagnosed with disruptive mood dysregulation disorder, only 19% continued to meet criteria for the disorder at 12- and 24-month follow-up. Children with disruptive mood dysregulation disorder are at risk to develop depression and anxiety disorders in adulthood.

The mean length of an episode of major depression in children and adolescents is 8 months. Recovery rates from an index episode of depression are high in youth, even independent of treatment. More than 90% of depressed children and adolescents typically recover from an episode of major depression within 1 to 2 years.

Depression relapse rates, with relapse being defined as a return of symptoms in the index episode, are between 34% and 50%, with the greatest likelihood of relapse in the first 6 months to 1 year after treatment discontinuation. Recurrence rates (onset of a new episode of depression) are high, with rates ranging from 20% to 60% after 2 years of remission and up to 70% at 5-year follow-up.

Risk factors for relapse or recurrence include severity of illness, suicidality, comorbid disorders, residual symptoms, psychosocial stressors, family conflict, family history of recurrent depression, negative cognitive style, low socioeconomic status, early onset of parental mood disorder, baseline social difficulties, and history of sexual abuse.

Youth who present with an episode of major depression are at risk of developing bipolar disorder. Overall estimates are that 20% to 40% of youth with a major depressive episode are at risk of subsequent development of bipolar disorder. In a longitudinal study of prepubertal children diagnosed with major depression, the rate of bipolar I disorder was 33% and that of bipolar spectrum disorders (I, II, not otherwise specified [NOS]) was 48% by young adulthood. Risk factors for switch to bipolar disorder are prepubertal onset of major depression, loaded or

multigenerational family history for mood disorders, psychotic features, and hypomania when treated with antidepressant medications.

There is increased recognition of the continuity between depression in youth and depression in adulthood. In a follow-up study of depressed school-aged children in community and clinic samples, 18% continued to have major depression into adulthood. In a clinical sample, adolescent-onset major depressive disorder increased the risk twofold of major depressive disorder in adulthood. In a community sample, 53% of adolescents with a history of major depressive disorder developed a new major depressive disorder in young adulthood.

Early age of onset of depression increases the risk of anxiety disorders, substance abuse, psychiatric comorbidity, suicide attempts, psychiatric and medical hospitalization, impairment in relationships with parents, siblings, and friends, more lifetime depressive episodes, nicotine dependence, increased adulthood body mass index, educational underachievement, unemployment, early parenthood, and worse overall quality of life.

The duration of persistent depressive disorder ranges from 2 to 3 years in clinically referred and community-based youth. After recovery after an episode of persistent depressive disorder, the estimated relapse rate is 45%. Youth with persistent depressive disorder are at increased risk of psychosocial difficulties, substance use disorder, episodes of major depression, and suicidality. The risk of suicide attempts in youths with persistent depressive disorder increases with comorbid conduct disorder or substance use disorder.

Children and adolescents with both major depressive disorder and persistent depressive disorder have a worse course of illness than those with either disorder alone. These youth have more-severe depression, longer depressive episodes, more comorbid disorders, more suicidality, and greater psychosocial impairment.

PHARMACOLOGIC TREATMENT

There are no U.S. Food and Drug Administration (FDA)-approved medications to treat disruptive mood dysregulation disorder. There are limited data on pharmacologic treatment specifically for disruptive mood dysregulation disorder in youth. Medications aimed to treat emotional dysregulation, irritability, and aggression include stimulants, selective

serotonin reuptake inhibitors (SSRIs), mood stabilizers, and second-generation antipsychotics.

Citalopram adjunctive to stimulant medication has recently been studied in a double-blind placebo-controlled trial of youth aged 7 to 17 years with severe mood dysregulation disorder (98% met criteria for disruptive mood dysregulation disorder). After 5 weeks of open treatment with methylphenidate to optimize control of ADHD symptoms, youth who continued to meet criteria for severe mood dysregulation disorder were randomized to citalopram plus methylphenidate (n = 25) or placebo plus methylphenidate (n = 28) for 8 weeks. A significantly higher proportion of response (improvement of irritability) was found for the citalopram plus methylphenidate group (35%) versus the placebo plus methylphenidate group (6%). There was no difference between the groups in measure of functional impairment.

Lithium for treatment of severe mood dysregulation disorder has been evaluated in a 6-week double-blind placebo-controlled trial for youth aged 7 to 17 years. After a 2-week single-blinded placebo run-in, those youth who continued to meet criteria for severe mood dysregulation disorder were randomized to lithium (n = 14) or placebo (n = 11). There were no significant differences in clinical improvement between the youth randomized to lithium or placebo.

Risperidone was evaluated for treatment of 21 youths aged 7 to 17 years with severe mood dysregulation in an open-label trial. A significant reduction in irritability scores was reported from baseline to endpoint.

There are two SSRIs that have FDA approval for acute and maintenance treatment of major depression in children and adolescents: fluoxetine (≥8 years old) and escitalopram (≥12 years old).

Other SSRIs that have also demonstrated efficacy in controlled studies of depressed children and adolescents are citalopram and sertraline. Some studies of SSRIs did not demonstrate superiority of medication to placebo on the primary outcome measure, including citalopram, paroxetine, and escitalopram. A meta-analysis of SSRI trials in youth showed superiority of SSRIs to placebo, with an average response rate of 60% for antidepressants and 49% for placebo.

Other classes of antidepressants have not shown statistically significant improvement with antidepressant medication compared to placebo, including venlafaxine, nefazodone, desvenlafaxine, vilazodone, mirtazapine, and selegiline transdermal system. In failed studies,

duloxetine and fluoxetine were not superior to placebo and desvenlafaxine and fluoxetine were not superior to placebo on primary outcome measures. Tricyclic antidepressants have not been shown to be effective in the treatment of depressed children and adolescents. There is some speculation that the early maturation of the serotonergic system compared to the noradrenergic system may account for the lack of efficacy in noradrenergic antidepressants compared to serotonergic agents in youth. There are no controlled trials of bupropion in the treatment of major depression in children and adolescents.

There has been much discussion about why controlled studies of antidepressants in children and adolescents with major depression have not shown efficacy, that is, statistically significant separation from placebo. One explanation is the high rate of placebo response in these studies—up to 59%. Other explanations are methodologic issues in the antidepressant trials, including number of sites, experience of site personnel, patient recruitment source, inclusion and exclusion criteria, duration of treatment trial, dosing, and outcome measures.

Adverse Events

Common side effects of SSRIs are nausea, abdominal pain, headaches, dry mouth, insomnia, somnolence, and sexual dysfunction. Impulsivity, agitation, irritability, and behavioral activation may occur, particularly with young children. Potential serious side effects include serotonin syndrome, increased bleeding, and amotivational syndrome. Common side effects of venlafaxine are anorexia, abdominal pain, insomnia, somnolence, dizziness, and elevated blood pressure. Common side effects of mirtazapine are increased appetite, weight gain, and somnolence. Common side effects of duloxetine are nausea, headache, abdominal pain, and somnolence. Common side effects of desvenlafaxine are headache, abdominal pain, nausea, and dizziness. Common side effects of vilazodone are nausea, abdominal pain, vomiting, diarrhea, nasopharyngitis, headache, and dizziness.

FDA Warning and Suicidality

In a combined analysis conducted by the FDA of 24 short-term, placebo-controlled trials of antidepressant medications in children and adolescents with major depressive disorder, obsessive-compulsive disorder, or other psychiatric disorders, the risk of suicidality (suicidal thinking and behavior)

was 4%—twice the placebo rate of 2%. There were no suicides in any of the clinical trials. The FDA directed manufacturers to add a black box warning to the health professional label of antidepressant medications to describe the increased risk of suicidal thoughts and behavior in children and adolescents being treated with antidepressants, as well as to recommend the need for close monitoring of patients on antidepressant medications.

In a later meta-analysis of 27 trials of pediatric major depression, the risk of suicidality (suicidal ideation and attempts) was 3% in the antidepressant group and 2% in youth who received placebo. The pooled absolute rate of antidepressant response was 61%, and the placebo response was 50%. The number needed to treat (NNT) (number needed to treat to get one positive response to medication) was 10, and the number needed to harm (NNH) (number needed to get one event of suicidality) was 112. Based on this finding, the investigators concluded that the benefits of antidepressants in youths outweigh the potential risk of suicidal ideation or attempts.

There have been recent reports of an increase in suicide rate in youth following the black box warning on antidepressants and a significant decrease in the rates of diagnosis and treatment of pediatric depression.

A medication guide that addresses antidepressant medications, depression, and suicidality has been approved by the FDA. The guide states that depression and other serious mental illnesses are the most important causes of suicidal thoughts and actions and that antidepressant medication may increase suicidal thoughts or actions in some children and teenagers when medication is first started. The patient or family member is encouraged to contact the healthcare provider if there is a change in mood or thoughts.

Informed Consent

Prior to prescribing antidepressant medication to a child or adolescent, an informed consent process should occur with the youth and the parent. Elements of informed consent are the purpose of treatment, description of the treatment process, benefits and risks of the proposed treatment, and alternative treatments. Because there is minimal information about the long-term effects of antidepressant medication in children, parents should be informed that there may be unknown risks of these medications.

Medication Treatment Algorithm

An evidence-based consensus algorithm for the treatment of major depression in children and adolescents was reported in which four stages of medication treatment were identified. It was recommended that if a child failed to respond to treatment in one stage, then the clinician should move to treatment in the next stage. The first stage of treatment is with an SSRI. The second stage of treatment is with an alternative SSRI. The third stage of treatment is selection of a different class of antidepressant medication. If a child fails to respond to these agents, then it was recommended that there be reassessment of the diagnosis and treatment consultation.

In the Treatment of SSRI-Resistant Depression in Adolescents (TORDIA) study, it was found that there was no difference in response rates for those adolescents switched to venlafaxine or another SSRI (48% vs. 47%) after treatment failure with an SSRI. Therefore, if an adolescent does not respond to the initial antidepressant, there is approximately a 50% chance of responding to the second antidepressant.

Lower initial starting doses of antidepressants are typically used in children and adolescents than in adults. However, the dose range tends to be similar to that used with adults. Doses are usually increased by 3 weeks if there is no symptom improvement. If there is no improvement with additional dose adjustment after 8 to 10 weeks, then switching to another treatment is recommended. Antidepressants should be continued for 6 to 12 months after symptom remission. At the time of discontinuation of an antidepressant, the dose should be tapered slowly, usually over a 2- to 3-month period.

PSYCHOTHERAPY

There are limited evidence-based psychosocial treatments for disruptive mood dysregulation in youth.

The feasibility and preliminary efficacy of dialectical behavior therapy for preadolescent children (DBT-C) was assessed in a randomized clinical trial for 43 children aged 7 to 12 years with disruptive mood dysregulation disorder. DBT-C consisted of 32 weekly 90-minute sessions and included a parent-training component. The primary outcome measure was the positive response on the Clinical Global Impression Improvement Scale (improvements in behavior outbursts and angry/irritable mood). The rate

of positive response was higher in the DBT-C group compared to the treatment as usual (90.4% vs. 45.5% respectively).

Other psychosocial treatments for symptoms of disruptive mood dysregulation disorder include behavioral therapy, cognitive behavioral therapy (CBT), exposure-based CBT, integrative group therapy (parent–child sessions), and parent management training.

The two most studied psychotherapy modalities for depression in adolescents are CBT and interpersonal psychotherapy (IPT).

Cognitive Behavioral Therapy

CBT focuses on cognitive distortions and behavioral deficits associated with depression in youth. Components of CBT for children and adolescents include psychoeducation and mood monitoring, pleasant activity scheduling and behavioral activation, and cognitive restructuring. Relaxation training and improvement in social and problem-solving skills may be included.

The efficacy of CBT was assessed in adolescents with major depression or dysthymia. The youth were randomly assigned to adolescent group CBT, adolescent group CBT with a separate parent group, or wait-list control. The CBT groups showed higher depression recovery rates (67%) than the wait-list group (48%) and greater reduction in self-reported depression. The addition of a parent group did not affect outcome.

CBT (12 to 16 sessions) was compared to nondirective supportive psychotherapy and systemic behavior therapy in a randomized trial. CBT was significantly superior to the other treatments, with greater reduction in depression, more rapid symptom relief, and a higher remission rate—65%, compared to 39% for nondirective supportive therapy and 38% for systemic behavior family therapy. However, in a 2-year follow-up study, there were no significant differences in outcome among the psychotherapies. Eighty percent of the adolescents had recovered from depression, but 30% had a recurrence of depression.

Computerized CBT in the form of an interactive fantasy game (SPARX) has been developed for adolescent depression. A study comparing SPARX to treatment as usual for adolescents with depressive symptoms showed similar treatment response rates.

Interpersonal Psychotherapy

IPT focuses on the relationship between depressed symptoms and interpersonal relationships. Four areas of focus are loss, interpersonal disputes, role transition, and interpersonal deficits. IPT has been modified for depressed adolescents (IPT-A) and has added a focus on developmental issues such as separation from parents, authority figures, peer pressures, and dyadic relationships. The adolescent and parents are educated about the association between depressive symptoms and events in interpersonal relationships. The adolescent learns skills to improve interpersonal relationships that may help to relieve depression.

The efficacy of IPT-A was assessed in a 12-week study of 48 adolescents with major depression who were randomly assigned to IPT-A or clinical monitoring. IPT-A led to greater decrease in depressive symptoms, improvement in social functioning, and improved problem solving compared to clinical monitoring.

The effectiveness of IPT-A in school-based health clinics was evaluated in depressed adolescents who were randomly assigned to IPT-A or treatment as usual for 16 weeks. The IPT-A training was done with existing staff at the health care clinics in high school. The adolescents who received IPT-A had greater symptom reduction and improvement in overall functioning. The greatest treatment effects occurred in older and more severely depressed adolescents.

There is also a group format (IPT-AG) that allows for peer support for depressed adolescents who have similar interpersonal problems. Adolescents can receive feedback from their peers about their interpersonal interactions and strategies to improve them. The efficacy of IPT-AG was compared to individual IPT-A, and there was similar improvement in depression for both formats of IPT.

In a recent systematic review and meta-analysis of psychotherapy for depression, across age groups, effect sizes in children were 0.35 and in adolescents 0.55.

A meta-analysis of 50 controlled psychotherapy trials for treatment of depression in youth found an overall modest effect size of 0.36 at posttreatment and 0.21 at follow-up (mean 42 weeks after treatment).

Combination Treatment

The Treatment for Adolescents with Depression Study (TADS) was the largest randomized, controlled trial to compare the efficacy of CBT, fluoxetine, CBT plus fluoxetine, and placebo in adolescent outpatients

with a diagnosis of major depression. Response rates (much or very much improved) for CBT (43%) were not statistically significant compared to those for placebo (35%). Response rates to fluoxetine plus CBT (71%) and fluoxetine alone (61%) were significantly superior to those to CBT alone and to placebo. Fluoxetine with CBT showed the greatest reduction in suicidal thinking. Although remission rates at the end of 12 weeks of treatment were highest in the combination group (37%) compared to the other treatment groups (fluoxetine, 23%; CBT, 16%; placebo, 17%), these overall remission rates were low. The long-term effectiveness of these treatments was assessed over 36 weeks. It was found that for adolescents with moderate to severe depression, treatment with fluoxetine alone or the combination of fluoxetine with CBT accelerated the improvement of depression compared to CBT alone. The addition of CBT to fluoxetine decreased persistent suicidal ideation and treatment-emergent suicidal events.

A recent systematic review and network meta-analysis was conducted to compare the efficacy of antidepressants, psychotherapies, and their combination for treatment of children and adolescents with major depression. Fluoxetine alone or in combination with CBT was superior to CBT alone and psychotherapy for moderate to severe depression in children and adolescents.

TREATMENT-RESISTANT DEPRESSION

Forty percent of youth with major depression do not respond to treatment with antidepressant medication or psychotherapy.

Ketamine has recently been investigated for treatment-resistant depression in adolescents. In an open-label study, 13 adolescents received intravenous ketamine infusion and 38% met criteria for clinical response. In a double-blind crossover trial that included 17 adolescents with treatment-resistant depression, single-dose intravenous ketamine was shown to be significantly superior to midazolam on depression rating scores. Response rates were 76% for ketamine versus 35% for midazolam. Ketamine was associated with transient dissociative symptoms.

Transcranial magnetic stimulation (TMS) has been investigated in uncontrolled studies which have reported some effectiveness for treatment-resistant depression in adolescents. However, a recent double-

blind randomized sham-controlled trial did not demonstrate superiority of 10-Hz TMS compared to sham TMS for adolescents with treatment-resistant depression. Response rates were 41.7% for active TMS and 36.4% for sham treatment.

OTHER TREATMENT COMPONENTS

Treatment of depressive disorders in children and adolescents should also include psychosocial factors, psychoeducation, supportive management, family involvement, and school involvement.

Psychosocial factors such as abuse, family conflict, parental psychopathology, peer difficulties, bullying, and family discord might be exacerbating the symptoms of depression and mood dysregulation and should be addressed as part of the treatment plan.

Psychoeducation involves educating the patient and parents about depression, including causes, symptoms, course, and treatment options, including benefits and risks of treatment. Depression should be explained as an illness, not a character flaw of the child or parent. The parent and child should be informed about the importance of adhering to treatment to ensure an optimal outcome.

Supportive management includes assisting the child with problem solving, improving coping skills, and fostering involvement in treatment.

It is important to involve parents in the treatment process. Parents can provide needed information about the child's symptoms over the course of treatment. Parents may also benefit from guidance in managing their depressed child at home.

Regarding school involvement, children with depression may have academic difficulties that require school remediation or accommodation in the child's school schedule or program.

SUICIDAL BEHAVIOR IN CHILDREN AND ADOLESCENTS

Although suicide is not a psychiatric diagnosis, suicidal behaviors are a significant public health problem and a focus of attention. Suicidal behavior is often present in individuals with depression, and the presence of a psychiatric diagnosis of depression is one of the most potent risk factors for suicide. However, not all individuals with depression exhibit

suicidal behaviors or die by suicide. Furthermore, treatments targeting depression alone have been insufficient for reducing suicide risk.

Definitions

Suicidal behavior is complex and there is no single etiology, it exists on a continuum from wishing to be dead, to thoughts or plans to die by suicide, to death by suicide. Suicidal thoughts or suicidal ideation can vary from passive thoughts of death (e.g., maybe I would be better off dead, I wish I wouldn't wake up in the morning), to active suicidal ideation (e.g., I would like to kill myself, I wonder if I would die if I jumped off the roof.), to suicidal ideation with a plan and intent (e.g., I plan to kill myself with my hunting rifle when my parents go out tonight. I am going to take a bottle of pills after my parents go to sleep). Suicidal threats are the verbalization or a written account of suicidal ideation. A suicide attempt can be defined as "self-destructive behavior with inferred or explicit intent to die." This definition differentiates suicidal behavior from "nonsuicidal self-injurious behavior (NSSI)," which can be defined as a "direct and deliberate destruction of one's own bodily tissue (e.g. cutting, burning, scratching, self-hitting) in the absence of lethal intent and for reasons not socially sanctioned, and without the intent to die. NSSI is most commonly a maladaptive behavior to address affect. Though NSSI is not suicidal behavior, recent literature suggests that for some adolescents, particularly girls in early to midadolescence, NSSI is an independent risk factor for death by suicide. Suicide is an intentional self-destructive act that results in death. Suicide contagion is the exposure to suicide or suicidal behaviors within a person's family, social group, or through media reporting on high-profile deaths by suicide, which can result in an increase in suicidal behaviors and death by suicide among children and adolescents at risk for death by suicide.

Intentional asphyxiation can resemble suicide by hanging. In intentional asphyxiation, there can be a sexual component—often termed autoerotic asphyxiation, or there can be no sexual component. This has been seen more recently in the rise of children and adolescents playing "the choking game." In both forms of intentional asphyxiation, an individual intentionally restricts carotid circulation to the brain using a neck ligature in order to experience euphoria. In autoerotic asphyxiation, there is also simultaneous masturbation or other sexual play to heighten the intensity of sexual climax. The presence of a ligature, sexual paraphernalia, and

evidence of sexual activity support the autoerotic asphyxiation as an accidental death versus suicide. In intentional asphyxiation not related to sexual behavior (e.g., child or adolescent playing the choking game after being introduced to it at school or through online videos), there may be no suicide note and no sexual paraphernalia present. Although intentional asphyxiation may not be intentional suicide, this does not exclude suicidal intent as a child or adolescent who is engaging in intentional asphyxia may know the risk that they might die by engaging in this behavior, and thus this may still be suicide.

Epidemiology

Suicide in children and adolescents is a significant public health concern. Suicide is the second leading cause of death among children and adolescents aged 10 to 19 years. The Youth Risk Behavior Survey (YRBSS) includes national, state, territorial, and freely associated state, tribal government, and local school-based surveys of representative samples of 9th- to 12th-grade students. The YRBSS for 2019, which gathered data on risk behaviors using self-report, found that, in 2019, about 37% of high school students had experienced periods of persistent feelings of sadness or hopelessness, 16% of youth had a suicidal plan, 9% made a suicide attempt, and 3% made an attempt requiring medical attention.

FIGURE 50.1–1. U.S. rates of suicide (per 100,000) in youth aged 10 to 19 years: overall by sex. (Centers for Disease Control and Prevention. Accessed Injury Prevention Control: Data & Statistics [WISQARS]. Updated July 16, 2021. http://www.cdc.gov/injury/wisqars/index.html)

Lifetime rates of suicidal behavior using interview data as opposed to self-report yield lower estimates of lifetime suicidal ideation with plan and attempts, both around 4%. However, these rates may also be skewed as certain populations may not be included in such interviews, and secondary to stigma, not all children or adolescents would volunteer information regarding suicidal behavior.

Although deaths by suicide are much rarer than suicidal behavior, occurring in 10.5/100,000 of adolescents aged 15 to 19 years in 2019, and 2.57/100,000 of adolescents aged 10 to 14 years. Suicide remains the second leading cause of death for children and youth aged 10 to 24 years (see Fig. 50.1–1). There is an unstable death by suicide variable of 0.04/100,000 in children aged 5 to 9 years. This may be in part because suicide deaths in this age range are often not listed by coroners or medical examiners as suicide. Governmental agencies tend to believe that children younger than 10 years old may not appreciate the seriousness of suicide, despite the evidence that children as young as 5 years old do die by suicide. Further, even in older children and adolescents, the cause of death by suicide is often misclassified as unintentional accident. The reasons for this misclassification are myriad: they may include reasons related to social stigma, the age of the child, social or cultural norms, or a coroner's unwillingness and/or inability to

accept suicide death in a young person. It is likely that the true rate of death by suicide among children and adolescents is higher than what is reported.

The rates of suicidal ideation, attempts, and deaths by suicide increase with age across childhood and adolescence, peaking in late adolescence. This increase in ideation may be explained by an increased incidence of depression that occurs during adolescence. The increased rate of attempts and suicide deaths in adolescence relative to childhood may also be explained by higher rates of depression, ongoing emotional dysregulation, any substance use, more sophisticated ability to plan and execute a potentially lethal suicide attempt, and easier access to lethal methods. There is limited evidence suggesting that overuse of social media and internet access may lead to increased exposure to suicidal themes, and to an increased risk of suicide secondary to suicide contagion.

Suicidal ideation has previously been thought to occur more frequently in female than male adolescents, though recent literature indicates there is not a true gender disparity in suicidal ideation or thinking about suicide. Suicide attempts do have a gender disparity with adolescent girls attempting suicide with greater frequency than adolescent boys, particularly after puberty. This is a pattern that is also observed with incidence of depression in adolescents post puberty. However, suicide deaths are 1 to 1.5 times as common in males than females aged 10 to 14 years, (with the exception of indigenous people where the rate is 2:1 males to females) and as much as 3 times as common in males than females aged 15 to 19 years. The higher rate of suicide in late adolescent males relative to females may be due to higher rates of substance abuse and conduct disorder and a tendency to use more lethal means of suicide.

The rate of suicide is particularly high in the United States among the indigenous people (Native Americans/Pacific Islanders) with indigenous males dying by suicide at a rate that is three times higher than the overall death-by-suicide rate for children and adolescents (Fig. 50.1–2). There is an elevated risk of suicide among indigenous peoples worldwide and may be related to erosion of traditional cultural values secondary to colonization and attempted genocide, and resulting social ills most notably poverty, unemployment, substance use, and disruption of traditional family structure.

White youth have a higher rate of death by suicide than African American youth, although the rate of suicide among African American boys has climbed over the years to around 75% of the rate in white males. There has been an alarming increase in rates of suicide deaths in younger African American boys (aged 5 to 11 years), while rates in White boys in the same age range have decreased. Suicide rates have been increasing for Black boys aged 10 to 19 years for some time, increasing by 114% between 1980 to 1995. There continues to be an upward trend for Black youth, simultaneously with downward trends for Caucasian youth through 2019. This alarming increase in Black youth suicide prompted Congress to convene an emergency task force to address suicidality and mental health for Black youth in 2019.

FIGURE 50.1–2. U.S. suicide rate in 10 to 19 year olds (per 100,000) by sex and race (2019). (Centers for Disease Control and Prevention. Accessed Injury Prevention & Control: Data & Statistics [WISQARS]. Updated July 16, 2021. http://www.cdc.gov/injury/wisqars/index)

After initially peaking in the 1990s, the reported suicide rate in adolescents began to decline until 2004, when it increased for the first time in a decade. Since 2007, there has been a gradual increase in the suicide rate both in males and females, with 2018 showing the highest rate of death by suicide in the past 30 years. The decline in the rate during

the 1990s had been attributed to several factors, including more restrictive gun control laws and increased prescription of SSRIs though it is difficult to identify causal factors. The use of SSRIs among adolescents has declined since 2004, which is when the FDA initiated a black box warning on antidepressants. Some pharmacoepidemiologic studies have shown a relationship between the decline in use of antidepressants and an increase in the rate of suicide and suicide attempts, but none of these studies are definitive. There are likely other confounders that arose during this period including increased reliance on technology, the use of social media (and media in general), and fewer in-person social interactions as children and adolescents connect with friends through various gaming and online platforms.

The most common method for adolescent suicide attempts is overdose, with the second-most common method being wrist cutting. Although suicide attempts in adolescents are frequently of relatively low intent, ingestion of acetaminophen is associated with a significant risk of liver toxicity and fatality without prompt medical attempt. Much more rarely, adolescents engage in highly lethal suicide attempts, using methods more commonly found in suicide deaths. The most common method in the United States for suicide fatality (in the past 5 years) is by firearm, followed in frequency by hanging (suffocation), drug poisoning, nondrug poisoning, falling or jumping, cutting, and drowning.

Risk Factors, Assessment, and Etiology

Suicide risk is moderated by the interactions between a variety of factors. Most conceptual models of suicide posit that suicide risks result from interactions between predisposing factors (distal, familial/genetic), precipitating factors (proximal, triggering), and developmental factors. The biopsychosocial model for suicide and suicide risks conceptualizes the interplay between genetic, psychological, sociologic, clinical, experiential, and environmental states as causative factors for suicide. While this framework is helpful in understanding the relationships between risk factors, their immediate relevance to suicide risk is imprecise. Any one or all of these factors might be involved at any point in time, and their impacts are moderated by individual traits.

Other relevant risk factors that can help to identify suicide risk are clinical factors that influence the transition from suicidal ideation to attempt, such as prior self-harm events, exposure to suicide by others,

depressive disorders, substance use, impulse control disorders, anxiety disorders, eating disorders, and traumatic stress-related disorders. Essentially, any disorder that may decrease restraint, such as impulse control disorders, or increase distress, such as panic, may increase the likelihood of moving from suicidal ideation to suicide attempt, especially if a mood disorder is also present.

Other important risk factors and antecedents to suicide include psychiatric disorders, psychological and biologic factors, familial and environmental factors, chronic physical illnesses, risky health behaviors, and personal, community, or public exposure to suicidal behavior that occurs in media reports.

Psychiatric Disorders. Estimates of the proportion of individuals with a mental illness at the time of their death by suicide or suicide death approximates 90%. These disorders, gathered through retrospective chart reviews, family interviews, and psychological autopsy, may have been undiagnosed prior to their deaths. Mood disorders are strongly associated with suicidal ideation, attempts, and completed suicides. Of adolescents who die by suicide, approximately 60% had a mood disorder at the time of their deaths. Most youths with psychiatric disorders never engage in suicidal behavior or die by suicide, suggesting that the treatment of psychiatric disorders may be a modifiable risk factor for suicidal individuals though not sufficient in itself. The presence of a psychiatric disorder does not in itself predict suicide. However, there are specific features of certain disorders that increase suicide risk, such as bipolar disorder, when an individual is experiencing mixed or rapid cycling states or irritable dysphoric states, or when a depressive disorder is accompanied by suicidal ideation, insomnia, agitation, and irritability. Disorders characterized by greater chronicity, severity, or complicated by comorbidity are more likely to be present in psychiatrically ill adolescents with suicidal ideation, attempts, or completion. Recent data suggests high rates of suicidality among clinically referred mood-disordered youths, with approximately one-third of those with bipolar disorder endorsing one suicide attempt. One study found a 10-year rate of suicide of 7.7% when compared with no suicides among a control group.

Anxiety disorders have also been reported to be associated with suicidal ideation and attempts. Social anxiety, panic disorder, and post-traumatic stress disorder have been most commonly associated and

contribute most strongly to suicide risk in the context of an anxiety disorder.

Studies have shown that alcohol misuse increases the risks of suicide attempts and suicide deaths in clinical and nonclinical samples by decreasing restraint from suicidal behaviors for individuals who are contemplating suicide. The presence of a mood disorder further increases the risk for suicidal behaviors. Alcohol misuse may trigger suicidal ideation even in the absence of high levels of depressive symptoms. Although alcohol has been the most studied substance of abuse in suicide, cannabis, and sedative–hypnotic use are more closely associated with suicidal behaviors than other substances. Schizophrenia and eating disorders are also associated with suicide attempts in adolescence, but increased mortality is more likely to occur in adulthood. There is growing evidence describing increasing rates of suicide among youth with autism spectrum disorders.

Medical Conditions. Studies of adolescents with chronic illnesses have found that the overall risk for suicidal ideation and behaviors is greater when compared to adolescents without chronic illnesses. However, the risk for suicidality is dependent upon the specific medical illness, the required treatments, and pre-existing psychiatric conditions. Some disorders, such as those involving the central nervous system, including migraine and epilepsy, inflammatory disorders, such as inflammatory bowel disorders, respiratory disorders such as asthma, endocrine disorders such as diabetes, and chronic pain may have an increased risk of suicidal behavior. Some disorders, such as cancer, may have increased suicide risks at differing times during treatment as a result of remission or relapse status and/or the treatment itself. Factors that appear to contribute to increased risk for depression and suicidal behavior in chronic illness are related to the general experience of illness, including pain and discomfort, disability, disruption of enjoyable activities and achievement, the pathophysiology of the disease itself, for example, inflammation, and effects of treatments used to treat the disorder, for example, steroids.

Biologic Factors. Understanding the neurobiology of suicidal behavior is complicated by the myriad biologic changes in the brain affecting many different neural pathways. However, parsing out the effects of these changes to determine which are specific to suicide and suicidal behaviors

or shared with mood disorders and other conditions is not easily achievable. The best-described pathway in suicidal ideation, suicidal behavior, and suicide are the stress response pathway mediated by the hypothalamic-pituitary-adrenal axis (HPA) axis. Disruption of the HPA axis with altered glucocorticoid activity may increase the risk for suicidal behavior. Postmortem brain studies of individuals who died by suicide have shown significant alterations in the prefrontal cortex and hippocampus, areas associated with emotion regulation and executive functioning. These studies also revealed alterations in 5-HT2A binding, decreased activity of brain-derived neurotrophic factor (BDNF) both neuroprotective factors, and dysregulated glutaminergic signaling and gamma-aminobutyric acid (GABA) dysfunction. Several studies have shown an association between inflammation, depression, and suicide generating increasing focus on the microbiome. Neuroimaging studies of depressed people who attempted suicide found alterations of attention and salience networks in that cohort compared with depressed people who did not attempt suicide. In addition, cognitive bias toward suicidal preoccupation, risky decision making, and findings consistent with the characteristics of impulsive aggression, risk taking, and emotion dysregulation have been observed with adolescents who attempted suicide. Neurocognitive testing has demonstrated that adolescents who attempt suicide make impulsive decisions and show a failure to learn from consequences.

Psychological Factors. Personality traits that have been strongly associated with suicidality in adolescents are aggressive–impulsive traits, which are worsened in the presence of depression. Anxiety is weakly linked to suicidality, likely contributing by interacting with individual factors in vulnerable individuals. The aggressive–impulsive behavioral profile has also been found to distinguish those who attempt suicide from psychiatric controls and is more likely to be associated with familial transmission. Also, in studies examining the transmission of suicidal behavior, the transmission of aggressive–impulsive behaviors partially explained the familial aggregation of suicidal behavior. Most adolescent suicide attempts are impulsive, so it is not surprising that impulsivity correlates strongly with suicidality. Other psychological factors include impairments in problem solving, memory bias, and ruminations.

Disordered emotion regulation, characterized as having a lower threshold for dysregulation (prolonged, severe responses to provocation), has been shown to be associated with suicidal behaviors.

Hopelessness is an important factor that has been associated with suicidal behavior, and among depressed youth signals an increased risk for suicide. A negative cognitive style has been associated with suicide attempts independent of depression. There is also evidence that those who attempt suicide are more likely to show a self-identification with death and suicidal behavior and that this self-identification is a robust predictor of future suicidal behaviors.

Familial and Environmental Factors. Although suicide and suicidal behaviors have been known to cluster in families for some time, recent data have begun to clarify these relationships. Parents of suicidal adolescents have higher rates of psychiatric disorders, including depression, substance use, and impulsive aggression. Suicide and attempted suicide have been found to be increased in families in which a parent has attempted or died by suicide even after controlling for parental psychopathology, suggesting that suicidal behaviors may be transmitted independently. Adoption, twin, and national registry studies suggest a heritability of 30% to 50%, while other studies suggest lower rates after controlling for psychopathology. The children of people who attempt suicide show a fivefold greater risk of suicide attempts than population averages, with suicide risk being doubled for individuals who lost a parent to suicide compared with those who lost a parent abruptly to other causes. It is important to note, however, that fewer than 5% of those who die by suicide have a parental history.

While genetic etiologies for suicide and suicidal behaviors have been sought for many years, no single gene or group of genes has been identified as responsible for suicide. Because suicide deaths are rare, genome-wide association studies (GWAS) have been used to investigate suicide attempts, with few studies including suicide as a primary phenotype. While some studies have found associations between genes identified in GWAS and suicidality, these studies have not met reproducibility and significance testing and have produced inconsistent results. Other proposed mechanisms for genetic transmission suggest familial transmission of impulsive aggression and mental disorders that do not include suicidal behaviors. Higher levels of 5-HT receptors have been

found in postmortem studies of adults and youth who have died by suicide, suggesting that this may be a marker for suicide death.

The familial transmission of suicide and suicidal behavior is likely explained by familial environmental factors as well as genetic transmission. Environmental factors known to be associated with suicidal behavior are exposure to suicidal behavior within the family. Parent–child conflict increases risk for suicide, especially among younger youth and historically marginalized youth populations. Parental loss, in youth who lose their parent prior to the age of 12, is associated with an increased risk of suicide in offspring.

The most clinically significant familial–environmental risk factor for suicide and suicidal behavior is maltreatment. Physical and sexual abuse and emotional and physical neglect have been strongly associated with suicidal behaviors, even after controlling for parental psychiatric disorders. The strongest associations with suicidality have been reported for sexual abuse. The population-attributable risk of sexual abuse for suicidal behavior has been estimated as slightly less than 20%, suggesting that one in five suicide attempts could be eliminated with the elimination of sexual abuse. In reality, the relationship between abuse and suicidal behavior is more complicated because abuse occurs within the social context of socioeconomic strain, family disruption, parental history of abuse, parental psychopathology—including depression, substance abuse, and suicidal behavior—and low parental monitoring and supervision. The likelihood of suicidal behavior is greater with greater severity of abuse. Studies also show that lesbian, gay, bisexual, transgender, queer (or questioning sexual orientation), and othesr (LGBTQ+) youth are more likely to have experienced sexual abuse than youth who identify as heterosexual.

Youth who are engaged in bullying as victims or perpetrators are at increased risk for suicidal ideation and behaviors. Longitudinal studies suggest that students who were most likely to experience negative outcomes such as suicidal ideation or behaviors showed signs of depression at the time of victimization, suggesting that the impact of bullying may be mediated by the presence of depression. Students at risk of dropping out of school, as characterized by poor academic performance and attendance, are also at high suicidal risk. Youth who live in impoverished communities characterized by violence, trauma, underresourced schools, and lack of community support are at greater

risk for depression and suicidal behavior. Youth who have a strong connection to school, even in the face of other risk factors, experience some protection from suicidal risk. A deviant peer group is associated with an increased risk of suicidal behaviors, and the presence of a prosocial peer group is protective for youth, including those who are at high risk.

Youth who experience legal problems are at increased risk for death by suicide. While legal problems commonly overlap with other problem behaviors, there is clear evidence that youth who have contact with the juvenile justice system are at high risk for suicidal behavior and death by suicide. Several studies have demonstrated high rates of suicidal ideation and suicide death in juvenile detention facilities. Studies also show high rates of mental illnesses with some studies finding that 75% of youth who died by suicide while in detention had a history of mental illness, 71% had had a history of prior suicidal ideation, and 45% had prior suicide attempts.

Emerging data for Black and Latina/o/x youth found that perceived racial discrimination is associated with increased suicidal ideation and that positive racial identity is protective against suicidal behaviors in Black and Latina/o/x youth.

Youth who identify as gender nonbinary, as well as LGBTQ+ have consistently been at a higher risk for suicide compared to their non-LGBTQ+ peers. LGBTQ+ identity has been identified as a risk factor for suicidal behavior in youth. This association is especially true for those sexual minority youth who are also racial and ethnic minorities. Suicide risks for these youth are in part mediated by family and peer rejection. LGBTQ+ youth who experience significant family rejection has been found to be nine times more likely to make a suicide attempt compared to those with no rejection. This same population of youth appears to be significantly more likely than other youth to experience harassment and bully victimization, and being bullied due to perceived sexual orientation has been found to have a greater impact on the quality of life for youth than bullying victimization for other reasons. Youth who identify as LGBTQ+ at early ages or with cross-gender appearance or behaviors are more likely to experience bullying. Nonetheless, depression and hopelessness remain stronger predictors of suicidal behavior for sexual minority youth than bullying.

Exposure to Suicidal Behavior. Adolescents are vulnerable to the impacts of suicide contagion that occurs when there has been media coverage of suicide. Studies of media publicity of suicide consistently find that rates of suicide and suicidal behaviors increase, especially among younger adolescents. Research further finds that the increased rates of suicide are proportional to the amount of publicity, the notoriety of the individual who died, details regarding the manner of death, and the extent to which the death was romanticized when compared to presenting the information regarding the death highlighting the relationship between psychiatric illness and the outcome of death by suicide.

Contagion effects can also occur with suicides that occur within the family, community, or among friends. Several studies show increased suicidal thoughts or behaviors following the suicide of a friend or acquaintance. They also found that youth with mental health problems have a greater risk for suicidal behaviors following exposure.

Suicide Risk Assessment

The assessment of suicide risk must consider the spectrum of risky behaviors that impair an adolescent's health. Suicidal behavior most commonly occurs within the context of risky behaviors such as NSSI, binge drinking, substance use, disordered eating, carrying a weapon, and unprotected intercourse. A plethora of studies have shown that common risk factors for these behaviors include impulsivity and poor problem-solving skills, a weak connection between parent and child and/or a conflictual parent–child relationship, low degree of parental supervision and monitoring, poor connection between child and school, and association with deviant peers.

The assessment must also consider protective factors that are present in the adolescent and the family including family connectedness and support, school connectedness and school safety, intelligence and good social–behavioral and communication skills, and reduced access to lethal means.

Suicide is a rare event, and studies of suicide generally investigate nonfatal suicidal behavior including suicidal ideation and attempts. Research has identified factors that are precipitating and strongly associated with future suicidal behavior. The strongest predictor of future suicidal behavior and suicide death is current and recent past suicidal behaviors. The greater the severity of the previous suicidal ideation (e.g.,

with plan) and suicidal behavior (e.g., lethality of attempt), the greater the likelihood of another suicide attempt. In one study examining individuals who died by suicide, 40% had previously attempted suicide.

The risk for suicide, suicidal behavior, and suicidal ideation are assessed across five domains: intensity, lethality, precipitants, motivation, and availability of lethal agents.

Intensity and intent: Suicidal ideation is assessed both with respect to intensity (how frequent and how compelling) and severity from passive ideation to active planning. Suicidal intensity refers to the degree to which the individual with suicidal ideation intends to carry out a suicidal act; when the individual has made an attempt, intent refers to the degree to which the individual wished to die. The worst-ever level of suicidal ideation is also predictive of future suicidal attempts and suicide deaths. Suicidal ideation is a strong predictor of future suicidal behavior.

Suicidal intent is assessed using the patient's self-report and assessment of the actions occurring during the suicidal behaviors including the degree of preparatory behavior, the timing of the event to minimize discovery, and other factors that convey intent. A recent study found NSSI to be a predictor of suicidal behavior associating more strongly with suicide risk than prior suicide attempts. For adolescents who express regret for having survived a suicide attempt, they remain at risk of recurrent and fatal suicidal behavior.

Motivation: Motivation refers to the reason why the individual engaged in suicidal behavior. An understanding of motivation is essential to developing an effective treatment plan. Approximately a third of adolescents who attempt suicide report that they want to escape their intolerable psychological pain and distress, express hostility, or to get the attention and support that was needed.

Precipitant: Parent–child conflict, difficulties in peer and romantic relationships, and disciplinary problems are the most common precipitants for suicidal behavior. In younger children and adolescents, precipitants are most often parent–child conflict, in comparison to older youth who are more likely to report romantic or peer difficulties.

Availability of Lethal Agents. In the United States, approximately 45% of youth suicides involve firearms, although suicide deaths involving firearms are declining, those involving hanging or strangulation are increasing. Studies show an association between the availability of guns,

especially handguns, and risk for suicide. Handguns are 2 to 10 times more likely to be found in the homes of suicide victims than in those of psychiatrically matched controls. The only risk factor that differentiated youth who died by suicide and living control youth, all of whom had no clear evidence of psychiatric disorder, is the availability of a loaded gun in the homes of those who died by suicide. Restriction of access to guns has been associated with regional and national declines in firearm-related and overall suicide rates. Restricting the availability of prescription medications and dispensing a limited number of pills/tablets/capsules wrapped in blister packs to prevent easy ingestion of large quantities have been shown to favorably affect rates of fatality by ingestion of prescription drugs. Other prevention methods include placing barriers on bridges to prevent jumping. In countries where poisoning is common with pesticides, using a lock box to contain the poisons has been effective in reducing pesticide ingestions.

Assessment of Imminent Suicidal Risk. Clinicians are frequently asked to assess patients to determine their level of suicide risk in the emergency setting.

Often, the clinician is called upon to assess a patient for imminent risk for suicide, in the emergency or urgent setting—does this person really want to kill themself in the next 24 to 48 hours? When assessing acute risk for suicide, factors that must be assessed urgently are those that increase distress and decrease restraint to determine levels of risk, and availability of lethal means. High levels of distress are found with anxiety and panic, hopelessness, mixed and irritable bipolar states, agitation, psychosis, emotion dysregulation, and insomnia. Insomnia is especially potent as it increases distress and decreases restraint. Factors that decrease restraint include impulsivity, substance use or misuse, a belief that no one cares about the person, or that they are a burden. The most effective interventions target increased restraint and decreased distress, and a plan for safety that will provide resources for recognizing when distress is building and a plan for intervening when risks are increasing, for example, The Safety Planning Intervention.

Treatment

When a child or adolescent is suicidal secondary to an underlying depression, treatment of the depressive episode is important; however,

this treatment takes time and a more immediate brief intervention can be used in the interim. In the emergency room setting, targeted safety planning such as the Safety Planning Intervention, which can help patients address suicidal thoughts and feelings and reduce the risk of death by suicide. Safety planning intervention is not the same as a no-suicide contract or a safety contract, rather it is a therapeutic-based approach to helping the suicidal adolescent or child engage in crisis management skills prior to engaging in any sort of self-harm. The Safety Planning Intervention involves identifying antecedents to a suicide attempt, stressors or warning signs that a patient is feeling more dysregulated, coping skills or activities for distraction or avoidance of the negative suicidal thoughts, and creating a list of family friends and trusted adults including providers to whom a child or adolescent can turn before acting on any thoughts of suicide. This type of planning is done in conjunction with the patient, the parent, and a clinician. This particular type of planning works well because it's not just a relying on a safety contract, which has not proven to be a deterrent to suicide or suicide attempts, rather it is an attempt to help the child or adolescent build skills on which they may rely when they are feeling suicidal, or more importantly when they are feeling negative affect that may lead to suicidal thinking. This is also a plan that is adjustable based on the needs, mindset, and skills that a child or adolescent has developed. Thus, the safety plan can be modified as needed over time. Other brief interventions have included attachment-based family therapy (AFBT) multisystemic therapy (MST), cognitive behavioral therapy for suicide prevention (CBT-SP) especially when paired with parent interaction, and dialectical behavioral therapy (DBT). Both CBT-SP and DBT show evidence for the prevention of future suicide attempts and self-harm in children and adolescents. Several studies suggest that parent involvement or treatment that also addresses substance use can be efficacious in reducing the risk of death by suicide. Although hospitalization often occurs when patients have had a suicide attempt or are at risk for suicide and unable to engage in safety planning, hospitalization in and of itself is not necessarily treatment. It can be the beginning of treatment especially if specific evidence-based therapies to treat depression, underlying anxiety, ADHD, substance use disorders, or other disruptive behavior disorders are incorporated in hospital treatment plans.

While there are no medications specifically targeted to treat suicidality, SSRIs used in the treatment of depression may help prevent suicidal behavior. In children and adolescents with schizophrenia disorders, clozapine has been shown to be protective against death by suicide; however, clozapine is rarely used first line in treating psychotic disorders. In children and adolescents with bipolar disorder, there is evidence that lithium may also have a protective effect; however, with its limited therapeutic range and risk of serious adverse outcomes, including death in overdose, this medication must be administered and monitored closely. In the adult literature, there is evidence for ketamine, or its enantiomer esketamine for treatment-resistant depression, although there are no randomized controlled trials (RCTs) involving children, the literature does suggest in small case-controlled studies and case reports involving children and adolescents that IV ketamine has been used to alleviate depression and suicidal thoughts in selected individuals.

In addition to the brief interventions used in emergency or crisis situations, there are several school-based interventions involving social and emotional learning which show some evidence for suicide prevention. Social and emotional learning with an emphasis on cooperation with others, self-regulation, and maintaining self-control while working toward goals valued by school-aged children, have shown some efficacy in decreasing risk of suicide in youth. Social–emotional learning that focuses on the expression, understanding, and regulation of emotional expression has also shown efficacy in school-aged children and beyond. Examples of these programs include “The Good Behavior Game” and “Promoting Alternative Thinking Strategies program (PATHS).”

For adolescents, there is new research using electronic application (app-based) programs to target suicidal thoughts and behaviors. While these programs or apps are still in the early stages, it may be that targeting adolescents, who spend a significant portion of their day interacting with media through the use of apps, can help reduce suicidal behavior as well as nonsuicidal self-injury. In addition, there is a new computer-assisted technology in the form of the computerized adaptive screen for suicidal youth (CASSY), which although is not a treatment model; it may represent an improved screening for children and adolescents at risk for death by suicide or suicide attempt and therefore allow early intervention to prevent suicide deaths. Given the high rate of suicide among indigenous people, one of the CASSY studies particularly

recruited indigenous children and adolescents. There is a pressing need for development of treatment modalities as well as screening modalities to address specific needs of historically marginalized populations, who may not receive the same benefits of current established treatment protocols which often do not include these populations in initial research protocols.

While there is concern about the use of social media and increased suicide rates, there appears to be some literature that suggests moderate social media use can build social bonds which can be protective against suicide. The role of social media in child and adolescent suicide is one that still needs to be more clearly researched and delineated.

Current guidelines regarding the care of the suicidal adolescent include an assessment and psychiatric evaluation to determine the appropriate level of care to safely deliver treatment, the development of a safety plan that can be modified as needed, encouraging family and caregivers to remove or secure lethal means from the home, treatment of any underlying psychiatric disorders, and addressing specific psychosocial issues that may be affecting the child or adolescent. These issues can be associated with adverse childhood experiences, emotional regulation skills, parental mental illness, parental substance use, and parent–child conflict. Ultimately treatment of the suicidal child or adolescent will primarily be that of prevention.

Course and Prognosis

Although suicidal thoughts are strong predictors of suicide attempts, only a third of adolescents who have suicidal thoughts are estimated to act on those thoughts in a suicide attempt. According to a recent review, one factor that most consistently predicts suicide attempts among adolescents with suicidal ideation is related to suicide capability or rather, the degree to which one feels capable of making a suicide attempt. Unfortunately, suicidal behavior is highly recurrent. Approximately 15% to 30% of adolescents will reattempt suicide within 1 year of their original attempt and, in a more recent study, 5% of adolescents made another suicide attempt within 3 months of an initial attempt. Risk for death by suicide is approximately 0.5% to 1% per year. Although factors for adolescents who attempt suicide are multidimensional and heterogeneous, there are factors that discriminate between those who die by suicide compared with those who are treated for suicide ideation or attempts. Factors contributing to death by suicide are male gender, access to a gun, sleep

disturbance, mood disorder with comorbid substance abuse or conduct disorder, diagnosis of bipolar disorder, and high suicidal intent. It is important to recognize that suicide is a rare event and that suicide is preventable. Given that suicide is currently the second leading cause of death in adolescents, it is essential that we convey a message of hope when intervening with suicidal adolescents and their families.

50.2 Early-Onset Bipolar Disorder

Gabrielle A. Carlson, M.D., Manpreet Kaur Singh, M.D., M.S., Danella Hafeman, M.D., Ph.D., and Caroly Sue Pataki, M.D.

Recognition of bipolar disorder in young people has had ups and downs over the past 30 years. Some of the controversy stems from inconsistent use of terms like “childhood,” which might or might not include adolescents. We use early-onset bipolar disorder to refer to onsets before age 18; very early onset to refer to onsets through age 12.

Bipolar disorder itself has a number of meanings, but we refer to the spectrum of bipolar I (at least one lifetime episode of mania with or without depression), bipolar II (at least one lifetime major depression and an episode of hypomania), cyclothymia (hypomanic and subthreshold depressive episodes), and other specified bipolar disorder (usually symptoms of mania or hypomania that don’t meet criteria for full-fledged diagnosis. Finally, onset is a tricky concept. Unless a person’s first episode of bipolar disorder is a clear, uncontroversial episode of mania or hypomania, “onset” is something defined in retrospect. If a person has a manic episode at age 24 and remembers being depressed in sixth grade, the assumption is that their onset was in sixth grade. However, in sixth grade, no one at the time knew a manic episode would occur at age 24, and thus bipolar disorder was starting. Similarly, if a child is grumpy, or volatile, or has sleep problems, and subsequently develops a manic

episode, in retrospect, those symptoms are possibly prodromal. They are, however, common symptoms and usually do not lead to bipolar disorder. Even in the context of having a positive history of bipolar I disorder (BP) in a first-degree relative, psychopathology, in general, is much more common than BP or even bipolar spectrum disorder.

The frequency with which very early-onset BP occurs is controversial compared to onsets after puberty when the condition more closely resembles classic adult BP. It is especially challenging to identify a manic episode in a young child, partly due to the distinguishing mania from severe attention deficit hyperactivity disorder (ADHD) with comorbid oppositional defiant disorder. This confusion evolved from a series of diagnostic criteria changes in earlier versions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), in which *emotion dysregulation* was removed as a core feature of ADHD, and the delineation of an *episode* of mania was not well defined. The subsequent diagnosis of chronically irritable children with severe outbursts led to increased use of neuroleptic medication, prompting the DSM-5 committee to formulate two solutions. First, mania was redefined as: “an abnormal and persistently elevated, expansive or irritable mood” *and* “persistently increased goal-directed activity or energy,” which are present that must vary to a *significant degree* and represent an *observable change* from usual behavior. Furthermore, in an effort to provide a diagnosis for youth who were chronically (vs. episodically) irritable, explosive, and equally disabled, but without other symptoms of mania, a new diagnosis, “disruptive mood dysregulation disorder” was added to DSM-5 to identify children whose mood is “ … persistently irritable or angry most of the day, nearly every day, and is observable to others” (DSM-5) with frequent, impairing behavioral outbursts.

HISTORY

Recognition of manic depression in child and adolescent psychiatry began with the dissemination of Kraepelin’s monograph *Manic Depressive Insanity and Paranoia* after 1921. Child psychiatrists searched for the same condition in their patients but found mostly adolescent depression, which was highly familial. Mania was very rare, even in teens. Brief attempts to broaden the concept of manic depression for younger children were discouraged by a literature review conducted by Anthony and Scott

in 1960 that used very stringent criteria to identify manic depression in youth. They found only 3 of 60 cases reported prior to puberty. However, the tension between restricting the diagnosis to classical presentations versus altering the criteria to fit children continues to the present.

In the 1960s, evidence of lithium's efficacy for treating adults with manic depression led to an interest in identifying lithium-responsive clinical profiles in children. Early studies suggested that lithium response was most promising in early-onset cases resembling classic manic depression, whereas there was no support for the use of lithium in treating children with broader behavioral dysregulation. When standard symptom criteria became available in the 1970s for describing mania more precisely in adults, Weinberg and Brumback, two pediatric neurologists, adapted these criteria for use with children. The concept of a "manic-depressive variant syndrome of childhood" was subsequently introduced in 1979 and characterized children between 6 and 16 years of age who were hyperreactive to seemingly minor events and were also hyperactive, had disruptions in interpersonal relationships, and often had a family history of manic depression.

By the 1980s, there was increasing acceptance of the diagnosis of manic depression or bipolar disorder, as it became known to the field, in youth. Research efforts initially focused on describing the phenomenology of pediatric bipolar disorder and established standard assessment techniques. In more recent years, there has been a surge of genetic, high-risk, and treatment studies, as well as investigations of neurobiologic, behavioral, and physiologic markers.

As noted earlier, the diagnosis (vs. the actual condition) of bipolar disorder among youth in the community has fluctuated over the last 25 years. A study of outpatient physician visits in the United States found that juvenile-onset cases of bipolar disorder comprised 42% of outpatient mental health–related visits in 2003, an increase from 6.67% of cases in the early 1990s. Another study, using data from the National Hospital Discharge Survey, revealed increases in the rate of bipolar disorder diagnoses among psychiatrically hospitalized children from 10% in 1996 to 34.11% in 2004, and from 10.24% to 25.86% among psychiatrically hospitalized adolescents during that same period. The increased rate of bipolar disorder appeared to reflect a shift in diagnostic practices such that childhood mood lability and aggression, which previously might have been attributed to conduct problems, ADHD, or impaired family

relationships was reinterpreted as bipolar disorder. The consensus currently is that severe irritability is transdiagnostic, and while some of the children may, in fact, have a bipolar spectrum disorder, that is no longer the only diagnostic home for such children.

EPIDEMIOLOGY

Prevalence rates of bipolar disorder vary depending on whether bipolar I, II, or spectrum conditions are included, the age studied, the definitions and methods used to make the diagnosis, and the type of sample interviewed. Taking wide variability into consideration, an updated meta-analysis calculated a pooled rate of 0.6% (95% confidence interval [CI] 0.3% to 1.2%) of bipolar I in adolescents (children younger than age 9 have not been studied in community samples) (Van Meter et al., 2019). The current prevalence of bipolar spectrum disorder is much higher (3.9% (95% CI 2.6% to 5.8%) because of the use of broad bipolar criteria. Lifetime rates are also higher. While tightly defined bipolar spectrum disorder may have an up to 40% rate of conversion to BPI or BPII, manic symptoms alone are less often associated with such a conversion, as seen in both the Longitudinal Assessment of Manic Symptom Study (LAMS), where mania rarely developed and the Oregon Adolescent Depression Study, where it never developed.

ETIOLOGY, MECHANISMS, AND RISK FACTORS

Bipolar disorder is a serious, recurrent, and complex psychiatric condition. Associated conditions include a uniquely high risk of suicide attempts, co-occurring anxiety and attention deficit with hyperactivity, family dysfunction, cognitive inflexibility, and substance use, among others. While mania is the defining feature of BP, episodes of depression often precede the onset of mania and may predominate a bipolar course of illness. Despite advances in accurately diagnosing bipolar disorder in young people, as well as improvements in the pharmacologic management of this disorder, problems related to symptom relapse, medication nonadherence, and co-occurring conditions continue to affect its long-term morbidity and mortality. The adverse impact of bipolar disorder on families and society is clear, but research toward elucidating

the pathophysiologic basis of early onset of this disorder has been incremental.

Nevertheless, bipolar disorder is now well established to be brain based, with unique structural, functional, and neurochemical properties in the brain that likely underlie its pathogenesis. Early-onset bipolar disorder is also characterized by dysfunction in the regulation of emotion and cognition. Disturbances in core emotional and cognitive functions aberrant in the disorder provide a basis for understanding the origins of symptom manifestations and the pathophysiology underlying bipolar disorder. In addition, investigating the neural sources of these core features using neuroimaging may be more informative than basing paradigms on nonspecific or transdiagnostic symptoms, particularly when controversies regarding the heterogeneity of symptom presentations in youth inevitably emerge.

Altered interactions among brain networks subserving emotion and cognition must also be developmentally contextualized, with appreciation that key neural features present in adults with bipolar disorder differ from those in youth with bipolar disorder. Traditionally, subcortical gray matter development appeared to precede significant prefrontal development and pruning with a shift in functional dependence from subcortical to prefrontal structures around puberty. Contemporary research suggests there are significant increases in the expression of key presynaptic cell adhesion molecules in the prefrontal cortex prenatally and during the first 3 years of life in individuals at risk for bipolar and other neurodevelopmental disorders. This opens the possibility of a new critical sensitive period for the development of bipolar disorder before puberty when prefrontal–subcortical functional shifts have traditionally been thought to herald the onset of bipolar disorder in adolescence. Early scaffolding of such inborn errors may explain prodromal symptoms that precede mania onset, that can be severe, functionally impairing, and protracted before full threshold symptoms are declared. A family history of bipolar disorder is an independent risk factor for early bipolar development.

Genetic, inflammatory, and environmental stress diatheses have been proposed as etiologic factors for bipolar onset or recurrence. These factors might express themselves phenotypically either through dysregulation of emotion acutely or gradually over time or during a bipolar prodrome. They may also manifest as hyperarousal, hypersensitivity, difficulty with affect decoding or labeling, or as a problem with “repair” of

maladaptive emotional responses. With time, chronic illness-related physiologic modifications from emotion dysregulation may incite more stress and inflammatory states, which then may have a direct neurotoxic effect, thereby contributing to the onset and recurrence of mood episodes. Although akin to theories of kindling, it may alternatively be the case that forces that compound episodes are dynamically being counteracted by microlevel forces like remodeling or adaptive neuroplasticity and macrolevel forces like cycles of treatment exposure and adherence. These homeostatic forces may lead to episodic (a feature of illness) rather than continuous expression of emotion dysregulation or extended periods of euthymia (a feature of treatment). Indeed, the cumulative effects of familial vulnerability, inhibited temperament phenotypes, environmental stress, inflammation, and disturbances in emotion regulation may converge in the expression of precursor subthreshold forms of bipolar disorder, persistent hypomania, depression, or mixed mood states, episodic irritability, rapid mood fluctuation, and low social functioning. These pathologic processes may elevate the liability for progression to bipolar disorder and to further neurobiologic sequelae.

BRAIN STRUCTURE AND FUNCTION

Untreated or repeated mood episodes may progress into neurobiologic sequelae that could manifest as structural brain changes that are preceded by neurofunctional impairment. Data demonstrating macroscopic structural and functional changes in selective brain regions in bipolar disorder imply underlying cellular and molecular dysfunction. Aberrant prefrontal–subcortical connectivity may result in failure of normal prefrontal regulation of overreactive subcortical processes associated with emotion dysregulation. This failure may, in turn, result in the appearance of disease-specific anatomic abnormalities that may be unique to youth with bipolar disorder, such as reductions in amygdala volumes, thereby predisposing youth to downstream vulnerabilities in the development of coordinated brain networks important for adaptive emotion processing, including the ventrolateral prefrontal cortex (VLPFC), the anterior cingulate cortex (ACC), thalamus, striatum, hippocampus, and the cerebellar vermis. Abnormal emotion regulation and cognition in bipolar disorder may thus arise from aberrant reciprocal connections between the amygdala and dorsal and ventral prefrontal areas as described by others

in mood disorders in general. Comparisons of pediatric and adult bipolar studies of brain function responses to stress add a developmental component to this model. These data suggest that limbic hyperactivity (e.g., in the amygdala) may occur early in childhood and even prior to illness onset, eventually becoming associated with decreased prefrontal activation and control over amygdala activity expected during typical brain development (e.g., in the VLPFC and dorsolateral prefrontal cortex [DLPFC]). As bipolar disorder progresses, prefrontal abnormalities become more important, and neurodegenerative sequelae of the illness develop that appear akin to molecular, cognitive, and clinical manifestations of accelerated aging and dementia. In this context, the unique regulatory role of the prefrontal cortex may make bipolar disorder exclusive to humans and what challenges modeling of the disorder in other animal species.

Pathologic reactions to stress can be detected acutely by clinical symptoms, and over time, by examining brain structural and functional changes, which interrupt healthy development of networks of brain structures that are important for mood regulation. Disrupted relationships among dorsal regulatory areas, including the DLPFC and dorsal anterior cingulate cortex (dACC), and ventral areas, including the amygdala and subgenual anterior cingulate cortex (sgACC), may lead to mood dysregulation or cognitive impairments. Without adequate intervention, children may eventually develop a full manic episode displaying further functional connectivity abnormalities between nodes in mood regulation networks; for example, inverse functional connectivity between amygdala and DLPFC is lost, or task-dependent excessive medial prefrontal cortex (MPFC) activation is observed. With repeated mood episodes into adulthood, further neurodegeneration of prefrontal areas might occur, leading to rapid cycling, treatment resistance, and more severe episodes, causing increased morbidity and mortality. Progression over the lifespan is variable due to individual differences in intrinsic compensatory adaptations and the buffering effects of individual- and system-level interventions. Longitudinal studies that evaluate risk and resilience factors may clarify the episodic nature of bipolar disorder and enhance prediction about onset and recurrence.

Studies in youth at risk for bipolar disorder indicate that most structural and neurochemical differences do not occur prior to the onset of syndromal mania, suggesting the possibility of preventing disease onset

and progression if an underlying mechanism can be identified. Further, a relative lack of morphometric abnormalities in symptomatic youth at high risk for bipolar disorder points to the probability that structural effects are a consequence of illness. Studies in healthy offspring of parents with bipolar disorder suggest clues for compensatory or resilience factors that may be important in preventing the onset of illness, including enlargement and increased activation and connectivity in prefrontal regions. Therefore, magnetic resonance imaging (MRI) studies in youth with and at risk for bipolar disorder are identifying brain findings that are now showing demonstrable improvement with early intervention to prevent or ameliorate the natural course of bipolar disorder.

Thus, convergence in network-based abnormalities preceding bipolar onset supports the hypothesis that early neural dysfunction likely underlies the pathophysiology of bipolar disorder. Further, available studies in adults with a prolonged illness have been limited by confounding variables and discontinuous follow-up to make it challenging to elucidate the neurodevelopmental progression of bipolar disorder and its pathogenesis starting from childhood. Many first-generation neuroimaging studies in pediatric bipolar disorder cautiously interpreted early findings with concerns about limitations in small sizes. Although type II error must not be ruled out, and independent replication can strengthen a given finding, indiscriminately large sample sizes as the cost of quality assessments and deep phenotyping are unlikely to facilitate progress in our understanding of early-onset bipolar disorder. To make progress in our field, it is crucial that we find systematic ways of integrating neuroimaging data across multiple modalities, carefully phenotyping youth in a variety of clinical settings, and leveraging multivariate statistical approaches to be able to conduct meaningful next-generation longitudinal neuroimaging studies in at-risk and fully bipolar populations.

ASSESSMENT

The American Academy of Child and Adolescent Psychiatry (AACAP) Practice Parameter advocates (1) screening patients for mania and bipolar depression, both current and past; (2) applying DSM criteria (currently DSM-5); (3) using the designation “bipolar NOS” for children with manic symptoms with a duration of fewer than 4 days (called “other

specified bipolar disorder in DSM-5); (4) examining for comorbidities; and (5) using extreme caution when diagnosing young children.

Making an accurate diagnosis of bipolar disorder in children requires systematic and thoughtful evaluation procedures that go well beyond the simple application of DSM-5 criteria for mania and depression. For instance, defining a mood episode in children, especially younger children, is complicated by the fact that a baseline or "usual self," developmentally, is a moving target. Thus, a previously docile infant who enters the "terrible two's" may be developmentally normative and yet approximate criteria for mania if this is defined as a persistent mood state different from the child's "usual self." Using the above framework, it is also unclear how long to construe a remission if most of an individual's childhood has been considered an episode. Children stressed by school may have what appears to be mood "episodes" which subside over the summer. In adult studies, in which a typical manic episode lasts for 4 to 8 months, a euthymic period of 8 weeks constitutes remission. Does that mean that a child stressed with "manic symptoms" at school and is better over the summer has had an episode?

Efforts have been made to adapt adult definitions of the cardinal symptoms of mania for young children, taking into account developmental differences. However, children may have difficulties with the concept of elation, or increased self-esteem, which requires an ability to self-assess, a skill absent in young children. Silliness and bravado, which some clinicians construe as childhood manifestations of euphoria and grandiosity, may also be seen in children with ADHD, autism spectrum disorders (ASDs), or children with other social skills deficits. In other words, simply applying criteria using structured interviews without understanding development and context is likely to lead to either the kinds of false positives that artificially inflate rates of bipolar disorder or to cross-site discrepancies in rates of bipolar disorder.

A careful ascertainment of bipolar disorder in youth should start with screening measures completed by multiple informants (i.e., parent, teacher, older child, or adolescent). These are useful in alerting the clinician to current symptoms of mania, depression, and other possible comorbidities. Interviews with caregiver(s) and child and review of other diagnostic information are then required.

Parent rating forms about the child, including the Child Mania Rating Scale, the General Behavior Inventory, and Parent Young Mania Rating

Scale, are good for both screening and to ascertain severity once the diagnosis has been made.

It is most useful to interview caregivers first because they are likely to provide the most reliable historical and contextual information, and this material can be presented within the child interview to address any discrepant responses. Caregiver interviews should include an overview of current symptoms, developmental history, past history, and longitudinal course of depressive and manic (and comorbid) symptoms.

The child interview is critical for eliciting important information regarding manic (or depressive) symptoms the child is experiencing like euphoria, or depression, or trouble concentrating. It is necessary to interview the child to detect the presence of symptoms and features of other conditions that may be confused or co-occur with mania, including ASD, language or thought disorder, psychosis, anxiety, suicidal behavior, physical/sexual abuse, and substance use. Parents may or may not be able to provide information on these symptoms and situations.

Collateral information, such as teacher input, is helpful in determining whether manic-like symptoms are occurring across settings. Although there are the usual discrepancies between parent and teacher reports, home and school observation can be useful. For instance, a child who is quiet and well behaved for 6 hours a day in school and then dysregulated at home is unlikely to be experiencing a manic episode. Outside assessments, including neuropsychological, occupational therapy, psychoeducational, speech and language assessments, and medical records, can also be extremely helpful in identifying developmental, cognitive, and medical factors that may contribute to emotional dysregulation in other conditions as well as those that complicate episodes of mania and depression.

Structured and semistructured diagnostic interviews are used in research settings to elicit symptoms of bipolar disorder and other childhood conditions. However, they may also be useful in clinical settings to confirm a diagnosis. The Schedule for Affective Disorders and Schizophrenia in Children (K-SADS) is the most commonly used interview and has a number of versions, including the K-SADS-PL (present and lifetime version), a version developed at Washington University, the WASH-U-K-SADS, and now a computerized version. In our opinion, the structured interview is best used as a review of symptoms rather than as a history-gathering tool. Clinical judgment is required to determine whether

a respondent is under- or overreporting symptoms, misinterpreting developmentally appropriate behaviors, or misunderstanding questions about clinical behaviors. To this end, it is critical that clinicians probe beyond affirmative responses to elicit examples of specific behaviors, as well as the context in which behaviors are occurring.

Several rating scales have been developed to measure the severity of mania once that condition has been diagnosed. One is an interview measure, the Young Mania Rating Scale (Y-MRS), which is used in both adult and youth medication trials.

Family history of mood disorder, bipolar and unipolar, and comorbid psychiatric disorders including oppositional defiant disorder, ADHD, learning disorders, and ASDs should be assessed as part of the parent interview. If there is a positive family history of bipolar disorder, it is important to probe for details regarding clinical presentation, comorbid conditions, and response to treatment in the person who has had bipolar disorder.

Family History

Family history studies estimate that genetic influences explain approximately 60% to 93% of the variance in bipolar disorder. Shared and individual environmental factors account for about one-third and one-fifth of the variance, respectively. Rates of mania in high-risk offspring who have been followed into adulthood occur in 2% to 7%, whereas rates of bipolar spectrum disorder are as high as 20% depending on how broadly the spectrum is defined and how complicated the parent proband is. Mania in high-risk offspring generally starts to emerge in adolescence. There are, however, cross-national differences. Mania onset prior to puberty is not reported in European and Canadian high-risk samples, where it does occur in U.S. samples. The parent probands, however, also differ cross-nationally, with U.S. samples having higher rates of comorbidity, substance abuse, and other psychosocial disadvantages.

The rate of major depression and a wide spectrum of depressive disorders in high-risk children of bipolar parents is higher than the rate of bipolar disorder. That is, major depression, particularly if highly recurrent and remitting, is found more often in families of patients with bipolar disorder and is part of the bipolar diathesis in these families. In fact, depression is the more common mode of onset of bipolar disorder in high-risk samples. Although the estimated heritability of bipolar disorder is very

high, bipolar variants can be attributed to gene by environment variables and correlations. For example, environmental risk factors such as adverse childhood experiences (ACEs), including physical and sexual abuse, severe parental neglect, and unstable home environments with poor attachments to primary caregivers, may play a role in the risk of developing the disorders. Exposure to parental mental illness, particularly a parent with bipolar spectrum disorder, or harsh and negative parenting styles, exposure, and poor social support may interact with a genetic vulnerability. Evidence suggests that temperament, specifically high emotionality, may be a risk factor for and of mood disorders in high-risk individuals. Irritability in mothers may also be a risk factor.

Bipolar disorder with other comorbidities in parents is an important complication that further contributes to psychopathology in offspring. In utero exposure to alcohol and illicit drugs has been associated with a higher risk for an earlier onset of bipolar disorder in vulnerable individuals. Family history differs in bipolar individuals who are lithium responsive and lithium nonresponsive. Relatives of lithium-responsive patients have a higher rate of episodic, remitting bipolar and unipolar disorders and not of chronic psychiatric illnesses such as schizophrenia, schizoaffective disorder, or substance use disorders, which are found in relatives of patients with the broader subtype.

Comorbidities

Children and adolescents meeting the criteria for BP nearly always present with co-occurring conditions. Symptoms of mania may overlap with those of concurrent ADHD and oppositional defiant/conduct disorder, depression, and anxiety, precisely the conditions with which co-occurrence is highest. ADHD is the most common comorbid diagnosis among children with bipolar disorder, with published rates of 70% to 95% among preadolescent youth and 50% among adolescents. The frequency of comorbid diagnoses is influenced by how different interviews manage symptom overlap between mania and the comorbid disorder. If the interview or investigator deems that a given symptom counts toward all disorders, rates of comorbid ADHD and ODD will be higher than if symptoms counted toward mania are only those presenting an intensity significantly beyond a usual baseline. By counting any overlapping symptoms toward all diagnoses, the Treatment of Early Mania Study

found that 92.8% of the youth with BP had comorbid ADHD in their index episode.

The LAMS study identified ADHD, bipolar spectrum disorders, and comorbidity in a multisite sample of 707 children who were rated by their parents as having elevated symptoms of mania. The LAMS study found that 76.2% of their sample met criteria for ADHD, 22.9% met criteria for bipolar spectrum disorders, 16.5% had both disorders, and 17.5% of the sample had neither disorder. The majority of children who met the criteria for BP (69%) also had ADHD. The high rate of comorbid ADHD in the entire sample was best explained by independent rates of these disorders in youth rather than a hypothesis that ADHD is a risk factor for bipolar disorder in youth.

Rates of conduct disorder and oppositional defiant disorder are reported to be as high as 79% in youth with BP. The combination of externalizing disorders and bipolar disorder appears to run in families and is associated with significant functional morbidity. Comorbid anxiety disorders have been reported in up to 77% of children with narrow phenotype bipolar disorder, with particularly high rates of generalized anxiety disorder, separation anxiety, and specific phobia. There is some evidence that, in a number of cases, anxiety symptoms may intensify during episodes of depression and mania, resolving when mood symptoms are effectively treated. Finally, features of ASDs appear to be quite common among youth with narrow phenotype bipolar disorder, with one study reporting that approximately 20% of their sample met full criteria for a comorbid autism spectrum condition.

As with adults, substance and alcohol abuse are common comorbidities in adolescents with BP. ADHD and conduct disorder are both risk factors for the development of substance use problems. In an epidemiologic sample, young bipolar patients with substance use problems had conduct disorder rates three times higher (52%) than those without substance abuse (14.8%; $p < .01$). By comparison, young subjects without either mania or substance problems had conduct disorder rates of only 7.75%. Substance abuse in bipolar adults may be more related to childhood conduct disorder than uncomplicated bipolar disorder. Nevertheless, substance abuse and bipolar disorder clearly exacerbate each other, and youth with bipolar disorder are at high risk of substance abuse.

For externalizing disorders comorbid with BP, there appears to be a developmental shift over time. Rates are highest in children (greater than

75%), lower in adolescence (approximately 50%, especially if both depression and mania have onset after puberty), and lowest, but still present, in adults, in whom the rate of lifetime ADHD has been reported to be approximately 20%. Similarly, conduct disorder/antisocial personality co-occur in adults at double the rates in those with bipolar onset before age 30 years (33%) versus after age 30 years (16%).

DIFFERENTIAL DIAGNOSIS

The five most common clinical conditions to be distinguished from bipolar disorder are ones with which it is most often comorbid. Severe ADHD and oppositional defiant disorder in young children are the ones most often confused with mania. The reason for the emphasis on episodes, euphoria, and grandiosity in making the diagnosis of mania emerges because ADHD is, by contrast, a chronic (rather than episodic) disorder for which elation and grandiosity are not considered symptoms. The clearer these symptoms and behaviors are, the easier the differential diagnosis. If severe irritability and explosiveness are used as the hallmark of early-onset mania, the distinction from severe ADHD with oppositional defiant disorder is extremely difficult. Disruptive mood dysregulation disorder, which identifies youth with temper outbursts and chronic, severe irritability, cannot be diagnosed in the presence of manic symptoms lasting more than a day. This exclusion was added in order to help separate children with nonepisodic irritability from those with mania. Another difficult diagnostic issue is the development of conduct disorder in older children with ADHD. Children with conduct disorder often are very irritable and oppositional, stay out late in defiance of their parents, and thus, may appear to need less sleep, engage in early sexual behavior and drug use (pleasure seeking without regard for consequences), and are hedonistic in their self-interest, caring little for the rights of others.

A third difficult diagnostic distinction is between an agitated, anxious depression and a mixed episode of mania. This complicated differential diagnosis is not unique to children and adolescents. In adult psychiatry, the trend has been to err on the side of making a diagnosis of bipolar disorder and avoiding medications to treat depression and anxiety in order to diminish the potential risk of exacerbating mania. It is necessary to keep an open mind about this issue, and if treatments for mania are not

helpful, a diagnosis of depression and anxiety alone should be reconsidered.

Substance abuse not only may render a teen depressed, irritable, emotionally labile, and euphoric, it may also precipitate a psychosis that may be indistinguishable from mania. In the short term, it is often impossible to determine whether the psychopathology is primary or substance induced.

Finally, especially in adolescence, first-episode schizophrenia poses an important differential diagnosis. For many years, schizophrenia was considered to be the only psychosis that occurred in adolescents. It is now understood that depression with psychosis (often a harbinger of bipolar disorder) and mania with psychosis are equally likely to occur. In the clearest cases, teens developing schizophrenia will have an insidious onset of psychosis, long-standing cognitive difficulties, and prominent and bizarre delusions. However, that may not be the case, and only careful follow-up over several years will allow the true diagnosis to emerge.

COURSE

There have been five areas of investigation into the course and outcome of bipolar disorder: (1) the duration and recurrence rate of manic and depressive episodes, (2) percent time symptomatic over longitudinal follow-up, (3) functional outcome, (4) diagnostic stability (i.e., how likely is a youth to retain the diagnosis of bipolar disorder), and (5) suicidal thoughts and behaviors.

Episode Duration and Recurrence

The median duration of an episode of mania in adults is 3 to 6 months. Episodes that include both polarities (rapid cycling/mixed), which last longer, have durations of about a year. As with adults, at least 80% of children and adolescents with BD do have a period of recovery, defined as 8 weeks with no or minimal symptoms. The duration of the episode (or time to recovery) in youth is variable, though somewhat longer than typically observed in adult studies. In Geller's sample of children with a mean age at intake of 11 years, the index episode lasted 60.2 (±47.5) weeks; later episodes lasted for shorter periods of time (55.2 and 40 weeks, respectively). The Course and Outcome of Bipolar Illness in Youth study in which bipolar youth aged 7 to 17 years were combined from three

different sites reported a median episode duration of 52 weeks for BP. Purely adolescent-onset samples fare somewhat better, particularly when focusing only on mania. The median duration of an index episode from one hospitalized sample with mania (mean age 16 years) was 11 weeks, while outpatient teens with mania (average age 14 years) from India had a median episode duration of only 8.7 weeks. The mean episode duration in two other samples was 29 ± 31 weeks and 20 ± 13 weeks (mania/mixed). In older adolescents (mean age 17 years), the median episode duration was 30 weeks. The reasons for these differences in duration are not clear. However, it may relate to the polarity of the episode; as with adults, manic episodes in youth are generally shorter than depressive or rapid cycling episodes. Among those children and adolescents who achieve remission, rates of recurrence ranged from 27% among community-based adolescents at 2-year follow-up to 70% among child and adolescent outpatients at 4-year follow-up.

General risk factors for longer episode duration include nonadherence with pharmacologic treatment, rapid cycling, psychotic symptoms, earlier age of onset, low socioeconomic status, comorbid anxiety, ADHD, and/or disruptive behavior disorders. Alcohol use disorders and exposure to antidepressants have been associated with increased risk of recurrence; involvement in psychotherapy appears to have a protective effect. Notably, males diagnosed with pediatric bipolar disorder appear to have a less severe course with a greater chance of recovery from the initial episode than females. Moreover, compared to children with bipolar I or II disorder, those with *other specified* bipolar disorder endured a more chronic course of illness with persistent subthreshold symptoms and delayed treatment response. Predictors of a more rapid recovery include lithium treatment and living in an intact biologic family. Recently investigators developed a risk calculator to predict mood recurrence in the Course and Outcome of Bipolar Youth (COBY) study using variables known from the literature to increase risk. This risk calculator was able to predict, with good accuracy (area under the receiver operating curve [ROC] curve; AUC >.8), whether an individual would go on to have a recurrence in the next 2 to 5 years. Furthermore, this risk calculator was externally validated in an adult sample (Collaborative Depression Study), showing similar accuracy rates, indicating that a predictive model developed in an adolescent and young adult sample also yields across the lifespan.

Percent Time Symptomatic

Longitudinal studies indicate that youth with BD spend, on average, 60% of the time symptomatic with threshold or subthreshold mood episodes. While the COBY study found that youth spent a larger percentage of that time in subthreshold and depressive episodes, Geller's study found that youth spent 40% of the time manic.

Regardless, percentages at the group level do not describe what is going on for the individual patient. In the COBY study, latent class growth analysis was conducted on available follow-up data (367 youth followed up every 6 months over an average period of 8 years) to find subgroups of mood trajectories. Four distinct classes were identified: (I) "predominantly euthymic" (24% of the sample), (II) "moderately euthymic" (34.6% of the sample), (III) "ill with improving course" (19.1% of the sample), and (IV) "predominantly ill" (22.3% of the sample). Group I was found to be euthymic, on average for 84% of the 8 years; group II was euthymic for 47.3% of the 8-year study period; group III was euthymic for 42.8% of the 8-year period, and group IV was euthymic for 11.5% of the 8-year follow-up period. Factors related to a better course, with longer periods of euthymia, included (1) older age at onset of symptoms and first episode, (2) less severe depression, (3) less severe manic or hypomanic symptoms, (4) less frequent subsyndromal episodes, (5) fewer suicide attempts, (6) lower rates of sexual abuse, and (7) less family history of bipolar disorder or substance use disorders. The youth in the groups with greater periods of euthymia had a less complicated course overall, with lower rates of comorbid ADHD and anxiety disorders and lower rates of all psychiatric disorders in family members. In fact, almost half of the group with the most time euthymic did not experience another episode during the 8-year follow-up. However, although the other half of group I was also euthymic for about 84% of the 8-year study period, they did continue to have new mood episodes during the follow-up period. In a second cohort of 144 adolescents with BD-I/II, Weintraub, Miklowitz, and colleagues conducted a latent class analysis of mood symptoms over 2 years of follow-up, similar to the COBY study. They identified four latent classes, including a "predominantly euthymic" class (29.9% of the sample).

Psychosocial Functioning

Psychosocial impairment often persists beyond mood episodes in BD. In the COBY study, 92.8% experienced impairment in school activities, and

40.5% had difficulties with interpersonal functioning. Psychosocial impairment was more common in those with more severe illness, but 44% of the “predominantly euthymic” class continued to experience significant difficulties. Importantly, impairment in psychosocial function preceded depressive episodes, indicating a possible target for intervention. The Child Global Assessment Scale score in Geller and colleagues’ 8-year follow-up of early-onset mania was 33.5 (SD 10.6) for those with the disorder at age 18 or older. Another 1-year follow-up study reported functional recovery in only 39% of the sample. Across studies, predictors of psychosocial impairment include early BD onset, severe illness course, low socioeconomic status, poor medication adherence, and current comorbidity.

Diagnostic Stability

A comprehensive investigation of the stability of diagnosis of bipolar disorder in adults is critical for both prognosis and treatment. The questions regarding BP in youth are for whom will the cycles be mainly depressive or manic, how often will they reoccur, and for whom will BP completely and forever remit? This is important to keep in mind to determine how long a medication (mood stabilizer or antipsychotic) should be administered during and after the resolution of an episode and whether there are observable predictors of longitudinal course. There are a variety of ways to assess diagnostic stability, including via medical records, national registries, and longitudinal follow-up. Based on a Spanish study of medical records, over 95% of 72 youths (median age 12.96, 37.5% with BD-I) maintained a bipolar disorder diagnosis after a median of 3.86 years of follow-up. In an analysis of the Danish population database, 86% maintained a BD diagnosis at 3 years and 73% at 10 years; those who no longer had a BD diagnosis had changed to schizophrenia. Predictors of diagnostic change to schizophrenia included male sex, history of substance abuse, diagnosis given during hospitalization, and parent with a schizophrenia spectrum disorder. A longitudinal study by Wozniak and colleagues found that 73.1% of youth diagnosed with BD-I continued to meet the criteria for this diagnosis 4 years later (at a mean age of 13.4 years old).

The question of diagnostic stability was recently addressed in the COBY study. Investigators found that 57% of youth with child-onset BP continued to have hypomania/mania in adolescence. They found that

approximately ~40% of participants who had a manic or hypomanic episode in adolescence (13 to 17 years old) also had one during young adulthood; when this outcome was limited to manic episodes, the number was ~25%. The most important predictors of diagnostic continuity were age at most recent manic or hypomanic episode during adolescence and family history (of mania and suicide attempts). After accounting for adolescent course, the age of onset and pediatric comorbid disorders were not significant predictors of diagnostic stability. Even in those without syndromal mania or hypomania, most had subthreshold manic episodes.

Interestingly, the issue of diagnostic stability is not unique to pediatric bipolar disorder but also a challenge in adults diagnosed with BD. In a 10-year follow-up of early-episode 15 to 50 years old patients ever diagnosed with first-episode mania with psychosis by Carlson and colleagues, diagnostic consistency occurred in only half the sample. Much of the diagnostic instability was predicated on a change in the course of illness. BPI became clearer over time in 17% (as people with psychotic depression developed mania, for example), but in the rest, even though BPI seemed obvious early, other conditions emerged. The most powerful predictors of diagnostic instability (i.e., not maintaining a BPI diagnosis) were having any childhood psychopathology (OR 2.8, CI 1.4 to 5.6) and specifically having a childhood externalizing disorder (OR 4.7, CI 2.5 to 8.9). The more acute and uncomplicated the diagnosis at onset, the more stable the diagnosis; however, a poor premorbid adjustment in terms of childhood psychopathology and nonacute onset predicted diagnosis change. Prognostic implications were substantial as the consistently diagnosed bipolar group had significantly better functioning on Global Assessment Functioning (GAF) ($p < .001$), spent less time symptomatic over their first 48 months of illness (26% vs. 47%) ($p < .001$) and much less time psychotic (7% vs. 31%) ($p < .001$).

Suicidal Thoughts and Behaviors

Two separate longitudinal studies, including the COBY study, found a 5-year rate of suicide attempts to be around 20% in children and adolescents with bipolar disorder. In a public mental health system, the lifetime rate of suicide attempts in adolescents with a diagnosis of BD-I was 57%. High quality of interpersonal relationships and treatment with lithium were both identified in the COBY study as protective factors against suicide attempts.

Functional outcome outside of symptom status has not yet been addressed in longer-term longitudinal studies. The Child Global Assessment Scale score in Geller and colleagues' 8-year follow-up of early-onset mania was 33.5 (SD 10.6) for those with the disorder at age 18 or older. Another 1-year follow-up study reported functional recovery in only 39% of the sample. ADHD comorbidity and poor medication adherence were associated with poor function. However, it appeared that functional outcome was also associated with syndromal status.

TREATMENT

Our current evidence base for the treatment of mania addresses both medication and psychosocial intervention with considerably more data for the former. Industry-sponsored and investigator-initiated clinical trials have addressed the relative efficacy of atypical antipsychotics with less robust data for anticonvulsants and some recent data supporting lithium. Trials of medication for bipolar depression are much smaller, and to date, only two medications have been shown to be more effective than placebo. Psychosocial interventions are beneficial in addition to medication, not replacements for it. Medication management requires obtaining baseline laboratory tests relevant to the medication used and monitoring side effects as well as monitoring symptoms of mania and depression.

Practice parameters and clinical guidelines, such as the AACAP Practice Parameters, are consistent in advocating the importance of medication.

Pharmacotherapy

As part of the *Best Pharmaceutical Act for Children,* newly developed medications to be used in children or adolescents must be tested for safety and effectiveness in that sample. U.S. Food and Drug Administration (FDA) labeling requirements allow fewer studies to be done if the condition—in this case, mania—is the same condition that exists in adults, such that similar measures to test safety and efficacy are valid in that age group. A consensus conference convened in 2002 established that youth between ages 10 and 17 years can experience the same condition. The same BP disorder in younger children was less well established, hence the cutoff at age 10 years. This is important because it means that the medications and doses used for adults are being studied

in older children and adolescents. As a result of this mandate, we have the most information on antipsychotic medications, which will be discussed first.

As of 2021, the following medications which are approved for the treatment of acute mania in adults are also approved for youth: chlorpromazine for children down to age 1 (no studies were ever done, however), olanzapine (ages 13 to 17), for children ages 10 to 17, quetiapine, risperidone, aripiprazole, and asenapine, and lithium is now approved for mania and mixed mania down to the age of 7. There has been a positive randomized clinical trial in youth for ziprasidone, and there is a second trial underway but no FDA approval yet as of this writing.

Olanzapine was the first second-generation antipsychotic to be studied and approved. With doses ranging between 10 and 20 mg, 44.8% of youth on olanzapine showed at least a 50% reduction in symptoms compared to a placebo response rate of 18.5%. This was significant ($p < .001$). The mean decrease from the baseline Y-MRS entry score of 33 was 17.7 points, and the effect size was 0.84.

Other atypical antipsychotic trials for risperidone, aripiprazole, and quetiapine were required to use low- and high-dose alternatives. Both high and low doses of risperidone and aripiprazole were significantly effective as measured by a 50% reduction in Y-MRS entry scores and a decrease of Y-MRS scores of between 14 and 18 points compared to placebo responses of 8 to 10 points. In general, 45% to 65% of subjects improved on active medication versus 18% to 37% on placebo. The absolute treatment benefit (percentage of drug responders minus placebo responders) averaged 19% to 38%, and the number needed to treat (NNT) in successful trials in which drug was better than placebo varied from about 2.6 (high-dose aripiprazole and high-dose risperidone) to around 5 (low-dose aripiprazole and high-dose quetiapine). Side effects were usually greater for the high-dose condition without a correspondingly higher improvement. Asenapine, which is administered twice a day sublingually, was tested at low (2.5 mg), medium (5 mg), and high doses (10 mg). At the endpoint, YMRS responder rates for all 3 doses ranged 42% to 54% compared with PBO (28%). The 10-mg dose had the most robust separation from placebo on the Y-MRS in the clinical trial.

There had been small trials of lithium in children for many years, but none addressing acute mania with a placebo control until relatively recently. The TEAM study, which randomized children to risperidone,

lithium, or divalproex, had reported a lithium response rate of 35.6%. There was no placebo arm, but placebo responses in industry-sponsored trials are about 25% to 30%. Thus, lithium would not have beaten the placebo in that study. However, the Collaborative Lithium Trials (COLT), specifically designed to test the efficacy of lithium, found a 4.5-point difference on the Y-MRS scale at week 8 between lithium- and placebo-treated participants (p = .031). Even so, rates of response (≥50% drop in Y-MRS) did not differ significantly between lithium and placebo groups, respectively (37.7% vs. 28.6%, Robb et al., 2014).

Several anticonvulsants have an FDA treatment indication for mania in adults. Data for bipolar youth is less robust. An industry-sponsored trial with divalproex ER requested by the FDA, which was only 4 weeks in duration (the duration of adult trials), was negative; drug and placebo responses were 24% and 23%, respectively. Atypical antipsychotics outperform divalproex in clinical trials. In addition, where it was measured, the time to response for atypicals was shorter than for divalproex. Blood levels were adequate in both the industry-sponsored trial and in the "Treatment of Early Age Mania" study [TEAM]. In the latter study, a poor response likely was due to the >90% rate of comorbid ADHD. As noted below, comorbid ADHD is a predictor of poor treatment response.

Published trials of two other anticonvulsants in youth, topiramate, and oxcarbazepine, have not been found to be significantly better than placebo. There have been no published placebo-controlled trials of carbamazepine.

Correll and colleagues provide a meta-analysis with relative effect sizes of different classes of medication. Atypical antipsychotics for mania/mixed mania show a larger effect size than mood stabilizers (effect size [ES] 0.65, CI 0.53 to 0.78 compared to ES 0.20 CI 0.02 to 0.39), and a 50% reduction in Y-MRS entry score is seen in 50% to 70% of subjects compared to 20% to 37% on placebo. The NNT in successful trials where the drug was better than placebo varied from 3.8 to 5.3.

The presence of ADHD complicates and attenuates treatment response for youth with BP. Attempts to treat both conditions include one study in which mixed amphetamine salts were added to divalproex, decreasing ADHD symptoms in that group. In another study, children with bipolar disorder stabilized on a thymoleptic received varying doses of methylphenidate (MPH) and placebo. ADHD rating scale scores were significantly improved compared to placebo in the MPH-treated youth.

MPH added to aripiprazole did not destabilize youth in a cross-over study (though ADHD was not significantly improved, either). Finally, a small open-label study of atomoxetine added to a mood-stabilized regimen for BP and ADHD found atomoxetine was effective in treating the ADHD, although 2 subjects out of 12 reported worsening mood at some point during the 8-week study.

Given the level of severity and impairment with which most children and teens begin a bipolar treatment study, the improvement, when it occurs, is noteworthy, but it often is not sufficient. Few data are available to predict treatment response. The use of more than one medication has increasingly become acceptable for treating mania/bipolar disorder in both adults and young people. In youth, there are three types of studies: (1) comparing two medications to one—for example, combined divalproex and quetiapine versus quetiapine alone; (2) adding one to another if the first drug does not work—for example, adding risperidone to lithium or divalproex; and (3) starting two together—for example, lithium and divalproex—and discontinuing one.

Although the types of adverse effects of medication are similar in children and adolescents, the frequency and severity may differ. For instance, weight gain with metabolic syndrome, especially in medication-naive patients, is significant. Unlike other antipsychotics, aripiprazole is associated with a reduction in prolactin. However, it also may cause a dose-dependent increase in extrapyramidal symptoms. Risperidone, olanzapine, and quetiapine may increase prolactin and cause more weight gain than aripiprazole. Asenapine is very sedating and also may cause dysgeusia and oral hypoesthesia because of its sublingual administration.

Cases of polycystic ovaries secondary to divalproex may be of particular concern in young people. Similarly, disinhibited behavioral responses to many types of central nervous system medications seem to occur more often in children and perhaps slightly less so in teens. This is of particular relevance to antidepressant use, where misinterpreting the side effect of activation as a manic episode may result in withholding helpful medication and prescribing unnecessary treatments. Indeed, the DSM-5 revision has attempted to prevent that error by stating that the activation is a manic episode if it continues after withdrawal of the medication and beyond the medication's physiologic effects.

Prevention of Relapse

Children and adolescents with bipolar disorder appear to have higher relapse rates and more episodes over the course of a year than adults. Regarding relapse prevention for mania, there is some suggestion that three medications, aripiprazole, lamotrigine, and lithium, may increase the time to relapse for mania. Beyond these reports, it is prudent to assume that medications that stabilize a child with BP should be continued for at least an entire school year while a child is in school. The AACAP Practice Parameter suggested 12 to 14 months. In cases in which it has taken a long time to stabilize the child and in which there is clear evidence from symptom monitoring that treatment has been effective, it may be wise to continue the treatment until the child has improved function, academically, socially, and within the family. The decision to continue medication treatment or not should be assessed annually. In cases in which treatment response is more tenuous and side effects more troublesome, longer maintenance is more difficult to support.

Treatment of Bipolar Depression

Treatment of bipolar depression in young people has received relatively little attention. Even in adults, only three medications (olanzapine/fluoxetine combined [OFC], quetiapine, and lurasidone) have FDA-approved indications for bipolar depression; two of those, OFC and lurasidone, are approved in youths aged 10 to 17 years. Other studies in young people consist of two open trials—one of lithium monotherapy in hospitalized adolescents with bipolar depression and one using lamotrigine alone or with other medications in outpatient adolescents. Symptoms declined in both studies. In the absence of placebo-controlled studies, and given the high placebo response in depression studies in youth in general, the treatment utility of these medications in youth remains to be demonstrated. Moreover, the adolescent samples studied had considerably more subthreshold manic symptoms (Y-MRS scores were 12 or fewer) than in the adults, whose Y-MRS scores were 2 or fewer. Thus, it is not even possible to extrapolate intelligently from adult data.

Of the placebo-controlled studies, one used flexibly dosed OFC (6/25 to 12/50 mg), which demonstrated superiority to placebo (effect size of 0.46), and the other used lurasidone (mean dose 33.6 mg/day). It had a similar effect size (0.45). Both have been approved by the FDA for the acute treatment of bipolar I depression in patients 10 to 17 years of age. Neither

short- nor long-acting quetiapine has demonstrated efficacy compared to placebo in bipolar depression in children or teens.

There is a modest if anecdotal, literature on the efficacy of electroconvulsive therapy (ECT) in mood disorders in teens. The reader is referred to the AACAP's ECT Practice Parameter on its indications and contraindications.

Psychosocial Treatment

Psychosocial interventions (1) target the recognition of future episodes before they progress too far, (2) enhance treatment adherence, and (3) address environmental stressors that act as possible precipitants to further episodes, (4) help parents and children manage mood dysregulation, and (5) improve the quality of family relationships. There are a number of empirically supported psychosocial interventions. These include multifamily and individual family psychoeducation, family-focused therapy for adolescents, child- and family-focused CBT for younger children, dialectical behavioral therapy for adolescents, and collaborative problem solving. Each emphasizes the importance of psychoeducation and destigmatization, as well as increasing parental collaboration and empowerment by reducing parent self-blame for "causing the disorder." Other components include helping parents to distinguish between normative developmental behavior and bipolar symptoms, taking proactive steps to decrease the risk of relapse, developing tools for effectively managing emotional arousal, improving family communication skills, and teaching adaptive problem-solving strategies.

FUTURE DIRECTIONS

Developments in neuroscience and genetics, as well as longer-term treatment and follow-up studies, will undoubtedly help to advance the understanding of this complex and disabling disorder, in particular its relation to other psychiatric disorders such as ADHD, conduct disorder, developmental disorders, and psychotic disorders. It is hoped that such advances can shed light on the etiology and underlying pathophysiology, including the identification of dysfunctional brain circuits that may underlie pediatric mania and progress toward mechanistically informed treatments.

Anxiety Disorders in Children

51.1 Obsessive-Compulsive Disorder in Childhood

ADAM B. LEWIN, PH.D., A.B.P.P., AND JOHN PIACENTINI, PH.D., A.B.P.P.

Pediatric obsessive-compulsive disorder (OCD) is a chronic neuropsychiatric condition associated with broad impairments in functioning. Over the past two decades, OCD in childhood has garnered increased attention, given heightened public and professional awareness of substantial upward revision of the prevalence of this disorder in youth. Advances in functional neuroimaging, genetics, neurosurgery, neuropsychology, and psychoneuroimmunology have contributed to a better understanding of etiologic factors contributing to the pathogenesis of OCD in childhood. Concurrently, randomized controlled trials and subsequent meta-analyses from multiple research groups have established individual- or family-based cognitive behavioral therapy (CBT) with exposure and response prevention (E/RP) and selective serotonin reuptake inhibitors (SSRIs), alone or in combination, as first-line treatments for OCD in childhood. Despite promising interventions, OCD remains a chronic and disabling disease which

can lead to marked social, academic, and familial dysfunction as well as increased risk for depression, self-harm, substance use, and poorer quality of life in adulthood. For individuals who do not benefit from available treatment, further refinement of treatment approaches remains paramount to diminish suffering and impairment while increasing the likelihood that youth with OCD can maintain relatively normal lives. Because many youth do not receive treatment due to lack of access to child psychiatrists and psychologists trained in evidence-based intervention, improving availability of care is another key goal.

DEFINITIONS

OCD is characterized by the presence of recurrent obsessions or compulsions that are distressing, time consuming, or debilitating. Obsessions are defined as recurrent, persistent, and intrusive thoughts, ideas, impulses, or mental images that are experienced by the individual as distressing and as a product of one's own mind (to differentiate them from thought insertion). These thoughts or ideas frequently generate (or are associated with) feelings of anxiety, tension, disgust, or aversion. Table 51.1–1 lists common obsessional fears. Compulsions are purposeful, repetitive behaviors or mental acts that typically function to neutralize, prevent, or reduce anxiety. Table 51.1–1 also listed common compulsive behaviors. Often, compulsions are performed in response to an obsessive thought or according to some other rigidly applied rules. Although compulsions function to mitigate distress or anxiety or to prevent some dreaded event, they are clearly excessive or are not realistically connected with the triggering stimulus (e.g., tapping three times to prevent illness after someone in the room coughs). While obsessions and compulsions are often ego dystonic and are often recognized by children as senseless or exaggerated, such insight is not required for the diagnosis of OCD in childhood. Otherwise, symptoms of OCD in childhood resemble those seen in adults.

HISTORY

Early examples of childhood-onset OCD, consisting of case descriptions, date back to the late 19th century. In 1895, Sigmund Freud described an 11-year-old child with obsessions. Subsequently, the French physician Pierre Janet provided the first description consistent with OCD in childhood in his 1903 report on a 5-year-old boy. In the first half of the 20th century, descriptions of clinical samples and generalizations emerged. In 1942, L. Berman extracted clinical information on 62 children with possible obsessive-compulsive neurosis out of a case registry of 3,050 cases. In 1955, Louise Despert described more than 60 cases of children with "obsessive-compulsive neurosis," noting a male preponderance, children's recognition that their symptoms are abnormal and unwanted, and the tendency to attempt to conceal their symptoms from treatment professionals and others. Leo Kanner's (1962) textbook of Child Psychiatry contained descriptions of childhood OCD and the consequences of social isolation and family accommodation.

In 1965, Lewis Judd provided descriptive criteria for the diagnosis of OCD in children that closely resembles the current diagnostic criteria, including the requirement of significant impairment in functioning. Reports as recent as 1973 implicated parental withdrawal of attention as a critical causal factor of childhood OCD. However, by the 1980s, the notion that OCD was a neurobiologic disorder with possible childhood onset became more commonplace. Further, findings from the Epidemiologic Catchment Area (ECA) study indicating most adults with OCD report an onset of the disorder during adolescence prompted increased awareness of the disorder in childhood as well as research in this area. Programmatic work in the 1980s under the direction of Judith Rapoport and her group at the National Institute of Mental Health provided the basis for the first systematic studies of epidemiology, phenomenology, and treatment of childhood- and adolescent-onset OCD as well as fundamentally dismissing any notion that the emergence of OCD in youth was unusual or unexpected. The Pediatric Obsessive-Compulsive

Disorder Treatment Study (POTS) emerged as the plenary multimodal treatment trial in 2004.

Table 51.1–1.
Common Symptoms of Pediatric Obsessive-Compulsive Disorder Obsessions

Obsessions
Concerns with dirt, germ exposure, fears of illness, disgust
Fears of harm befalling self or others
Need for symmetry, order, exactness, completeness
Need to save or hoard
Excessive moral, religious, or sexual concerns
Compulsions
Cleaning rituals
Checking
Repeating behaviors
Ordering or arranging
Confessing, reassurance seeking

COMPARATIVE NOSOLOGY

Diagnostic criteria for OCD have remained relatively constant over the past three editions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM). The fifth revision (DSM-5) published in 2013 defines the following features of OCD: (1) recurrent obsessions or compulsions; (2) obsessions or compulsions cause marked distress, are time consuming (take more than 1 hour per day) or cause significant impairment in functioning; and (3) obsessions and compulsions not due to the presence of another mental disorder, substance, or other medical condition. The DSM-5 further includes specifiers to code degree of insight and to indicate whether the individual has a history of a tic disorder. The 10th revision of the *International Statistical Classification of Diseases and Related*

Health Problems (ICD-10) provides a description of OCD that is similar to the DSM-5.

EPIDEMIOLOGY

Although estimates vary, studies suggest lifetime prevalence for OCD in children between 1% and 3%, indicating that OCD is more common than previously thought and as common in youth as in adults. Sample age may explain some of the variability in these estimates. Older adolescents yield prevalence rates between 0.53% and 4.0%, whereas estimates for school-aged children remain lower. In fact, a large prevalence study from the United Kingdom showed an exponential rise in rates across age groups (5 to 7, 8 to 10, 11, 12, and 13 years). Another recent community sample found a prevalence rate of 3% for “clinical” OCD, defined as symptoms severe enough to cause distress and interference in functioning. The most accepted 6-month prevalence rate is between 0.5% and 1% of the general pediatric population. Of note, rates of OCD in late adolescence make it more common than panic disorder, schizophrenia, and bipolar disorder.

Mean age of onset for pediatric OCD is between ages 6 and 11. Onset age appears bimodal and varies by gender with a male preponderance in cases of prepubertal onset with an initial peak of incidence around puberty and subsequently in young adulthood. The gender distribution becomes roughly equivalent during adolescence. It is currently believed that up to 80% of adult OCD cases have an initial onset during childhood. Children with an early onset of OCD (below age 7 years) are also more likely to be male and to have a family history of OCD in comparison to children with later onsets, suggesting that genetic factors may play a role in development of early-onset cases. Referral bias may account for the underrepresentation of minorities and youngsters from lower socioeconomic strata in clinical samples of OCD youth, as epidemiologic studies with adult samples have not replicated this pattern.

Table 51.1–2.
Comorbid Diagnoses in Pediatric Obsessive-Compulsive Disorder

Diagnosis	Frequency (%)
Anxiety disorders	26–70
Mood disorders	11–62
Tic disorders	11–26
Attention deficit hyperactivity disorder	16–20
Disruptive behavior disorders	9–19
Autism spectrum disorders	3–7

The occurrence of OCD in childhood may be somewhat higher than reported given the secrecy that children often display in reporting embarrassing thoughts and behaviors. In addition, limited insight into the abnormality of their symptoms (and linking OCD symptoms to potential impairment), parent inability to recognize OCD symptoms, and the lack of awareness about the availability of efficacious treatments may contribute to underdiagnosis. Therefore, it is reasonable to assume that many childhood cases of OCD remain undetected.

Comorbidity

In childhood, psychiatric disorders co-occurring with OCD is the norm rather than the exception. For example, in an analysis of 70 clinical cases of youth with OCD, 84% carried at least one additional Axis I psychiatric diagnosis. It is estimated that as many as 50% of pediatric patients with OCD have two or more co-occurring diagnoses (Table 51.1–2). The most common comorbid disorders include other anxiety disorders, depressive disorders, tic disorders including Tourette syndrome, attention deficit hyperactivity disorder (ADHD), and disruptive behavior disorders. Individuals also commonly report sensory abnormalities. Major depressive disorder,

while rare in younger children with OCD, increases in prevalence over the course of adolescence and into adulthood.

ETIOLOGY

Neurobiologic Factors

Although the cause of OCD remains unknown, multiple neurochemical, neuroanatomical, and immunologic etiologic theories have been proposed. Clinical descriptions of OCD associated with Sydenham chorea (SC), tic disorders, traumatic brain injury, encephalitis, and Huntington chorea have helped to solidify the broad concept of the disorder as brain based and presumably reflecting impaired striatal functioning. Though the neurocircuitry and neurochemistry involved in OCD symptomology has been better clarified using in vivo brain techniques and evaluation of responses to psychoactive medications, there continues to be a need to further refine etiologic models of the condition.

Neurochemical. Dysfunction of the central serotoninergic neurotransmitter system continues to be a suspect in OCD symptomology. Primary support for this premise is the observed efficacy of SSRIs and altered sensitivity to acute administration of 5-hydroxytryptamine (5-HT) agonists, as well as from results of preliminary studies of 5-HT synthesis. Young patients with OCD have presented with reduced platelet (3H) imipramine binding; conversely, those OCD patients with higher (3H) imipramine binding at baseline differentiated responders versus nonresponders to SSRI treatment.

Research also suggests the involvement of the dopaminergic neurotransmitter system. This may be especially relevant to childhood OCD, given the increased rate of comorbid tic disorders. Clinically, administration of psychostimulants appears to worsen obsessions and compulsions. Conversely, the coadministration of dopamine antagonists with SSRIs may augment the beneficial effects of these agents. However, direct assessment of the dopamine system remains unstudied in children, including a lack of

controlled administration of dopamine antagonists. Further, animal studies suggest that excessive glutamatergic output from the cortex to the striatum is associated with repetitive movements. Human studies in children with OCD have reported correlations between striatal glutamate with OCD symptoms and the drop in striatal glutamate with both SSRI medication and exposure-based CBT. In sum, available neurochemical models suggest the possibility of several neurotransmitter abnormalities associated with OCD.

Neurostructural. The pathogenesis of pediatric OCD is characterized by abnormalities in the prefrontal–basal ganglia circuits, specifically frontal–striatal–thalamic–cortical (FSTC) circuit disruption. This premise is supported by imaging studies of OCD, co-occurrence with other disorders with presumed basal ganglia disruption, as well as neuropsychological studies. Volumetric analyses using both magnetic resonance imaging (MRI) and computed tomography (CT) approaches have revealed that treatment-naive children and adults with OCD have smaller basal ganglia segments than adults. For example, reduced globus pallidus volume and gray matter volumetric abnormalities in the anterior cingulated gyrus have been found in pediatric patients with OCD compared to healthy controls. Higher hippocampal volumes and abnormalities in white matter coherence have also been found in child OCD, with greater white matter irregularities linked to increased OCD severity differences compared to healthy controls.

Treatment-naive children appear to also have large thalamic volumes. Thus, it has been hypothesized that children with OCD display abnormalities in normal developmental remodeling of neuronal structures affecting integration, response inhibition, gating/cognitive control, and processing. Positron emission tomography (PET) suggests dysfunction in FSTC circuitry, with studies showing increased glucose metabolism in the orbitofrontal cortex, ventral striatum, right caudate nucleus, and anterior cingulate gyrus, at rest and in response to symptom provocation. Orbitofrontal and caudate metabolic rates are highly correlated, suggesting that interconnecting loops are freed from usual inhibitory influences and

reverberate. Disruption of affective/reward processing loops and cognitive control loops have been linked to OCD, and differential development of these systems may be expressed in OCD course and presentation. Recent studies of child OCD suggest that differential development of FSTC circuits and various interconnectivity may explain differential symptom expression (e.g., a finding suggested hypoconnectivity of cognitive control circuity in early-onset cases).

The observations that both medication and behavioral therapies reduce orbitofrontal and caudate blood flow validate the importance of these brain regions in OCD pathogenesis. Paradoxically, lower baseline orbitofrontal glucose metabolism predicts better response to pharmacotherapy. Imaging also suggests the frontal–limbic–basal ganglia system may mediate OCD symptom expression, demonstrating a wider interaction of cognitive and emotional circuits. Specifically, symptom provocation appears to activate paralimbic regions as well as insular, anterior temporal, and amygdalar regions.

Neuroimmunology. Significant attention has focused on the triggering of OCD-like symptoms following group A beta-hemolytic streptococcal infections (GABHS), similar to OCD symptoms observed in SC. These infection-triggered cases of OCD have been coined pediatric autoimmune neuropsychiatric disorders associated with streptococcus (PANDAS) and are believed to represent an autoimmune process related, if not identical to, that associated with rheumatic fever (RF) and SC. (It is noteworthy that patients with RF and SC both display higher frequencies of obsessions and compulsions versus comparison groups, and up to one-third of patients with SC meet research criteria for the diagnosis of OCD.) Immune activation leads to the inflammation of the basal ganglia and disruption of the cortical–striatal–thalamic–cortical (CSTC) function. This acquired basal ganglia dysfunction may result in choreiform movements, tics, obsessions, compulsions, and hyperactivity. PANDAS are characterized by abrupt childhood onset and episodic or saw-toothed course. Relations between the size of the basal ganglia nuclei and OCD symptom severity have been observed

using MRI. Similarly, small sample studies of immune-modulating treatments (intravenous immunoglobulin G [IgG] and plasmapheresis) have been associated with improvements in OCD patients with suspected PANDAS. However, these interventions remain experimental, and efforts to establish markers of PANDAS have been inconclusive. In addition, the proportion of child OCD cases potentially attributable to streptococcal infection remains unknown. Additional research into PANDAS is warranted. Although the association between GABHS infection and OCD remains debated, evidence-based psychopharmacologic (e.g., SSRIs) and behavioral (e.g., CBT with E/RP) approaches for treating OCD symptoms in cases with suspected PANDAS should still be strongly considered. Positive titers and exposure to GABHS does not imply an atypical ideological influence; nor does a reduction in OCD symptoms following antibiotics. Formal PANDAS diagnosis should include a sophisticated evaluation of history/course, testing, and exam. Multidisciplinary consultation is recommended prior to experimental, high-risk interventions.

More recently, the term PANS (pediatric acute-onset neuropsychiatric syndrome) was coined to characterize cases with similar clinical presentations as PANDAS but without link or presumed cause with GAS infection. Similar to PANDAS, PANS requires abrupt/dramatic/overnight onset of OCD symptoms, and severe and acute onset of at least two of the following: anxiety, emotional lability, irritability/aggression, developmental regression, academic deterioration, sensory sensitivity, or somatic symptoms (including sleep disturbance, enuresis, or urinary frequency). Similar to PANDAS, diagnosis is not straightforward and even putative PANS caseness does not negate potential benefits of CBT or SSRIs nor necessitate the need for experimental interventions. Diagnosis of PANS/PANDAS is not straightforward and there are no definitive tests; evaluation requires careful multifaceted assessment of medical and psychiatric histories and titers alone are not indicative of diagnosis. As a result, the number of patients with confirmed PANS/PANDAS is significantly lower than the number presenting for treatment or requesting immunologic treatment for these symptoms.

Youth with PANS/PANDAS can benefit from evidence-based psychopharmacology (including antidepressants and antipsychotics) and CBT, but adjustments may be needed, or side-effect profiles may vary.

Family Genetic, Behavioral, and Cognitive Factors

Family Genetic. OCD is a heritable disorder—the familial nature in most cases of OCD is well recognized. Monozygotic twins have a higher OCD concordance rate (0.52) compared to dizygotic (0.21). A meta-analysis of studies exploring familial patterns of psychopathology in relatives of subjects with OCD has documented a fourfold increased frequency of OCD in first-degree relatives of OCD probands (8.2 vs. 2.0 from control families). Rates of OCD among parents of youngsters with OCD range from 17% to 19%. A 2005 review of twin studies suggests 27% to 65% heritability rates for OCD (including nonpediatric onset). In addition, subclinical features of OCD (usually defined as typical symptom constellations without the level of interference required for formal diagnosis) are higher among family members with OCD (e.g., reported in 52% of parents). In fact, relatives of probands with early-onset OCD exhibit even higher rates of OCD and tic symptoms. Analysis of family patterns of OCD finds support for subclinical OCD as an intermediate phenotype that shares similar genetic risk factors.

The relation between OCD and tic disorders, including Tourette syndrome, has emerged from family studies. Tic disorders and some cases of OCD appear to share some susceptibility factors, leading to arguments that OCD may be an alternative expression of the risk factors underlying tic disorders. Some suggest an autosomal dominant model of inheritance with incomplete penetrance. In other words, the phenotypic expression varies in expression from OCD symptoms to tic disorders.

Data from twin and family studies suggest that OCD may be transmitted in families, but specific genes for the disorder have not been identified. Findings from the multisite Obsessive-Compulsive Genetic Association Study (OCGAS), the largest such study to date

including 1,065 families/1,406 patients with OCD, failed to identify single nucleotide polymorphisms at genome-wide significance. Investigators posit that larger samples are needed to identify genes associated with OCD. Preliminary findings suggest OCD is polygenetic and likely arises from a large number of diverse genes. Candidate gene studies have yet to produce replicable, significant genes culpable in OCD. The neuronal glutamate transporter gene (*SLC1A1*) has the strongest support, with some findings implicating the serotonin promoter variant (*5-HTTLPR*). Definitive copy number variants associated with OCD have not been identified and, to date, OCD-specific genetic markers remain to be found.

Behavioral Factors. Hobart Mower's two-factor conditioning theory provides a behavioral explanation for OCD symptoms. Via classical conditioning, a neutral stimulus (or event) becomes conditioned to elicit distress because of its association with an unrelated aversive (or feared) stimulus. Fear can be conditioned to both mental events (e.g., blasphemous thoughts) and physical stimuli or behaviors (e.g., a "contaminated" object, items perceived as dangerous, driving, eating). Subsequent to the acquisition of the conditioned fear, rituals develop to reduce or avoid distress. These rituals (or compulsive behaviors) persist and become excessive because they temporarily ameliorate the distress associated with obsessive thoughts via operant conditioning (specifically, a negative reinforcement paradigm). In other words, the escape from/reduction of anxiety associated with performing a compulsive behavior or ritual results in an increased likelihood of the ritual being used in future instances of anxiety.

However, specific traumatic events responsible for the conditioned response are rarely identified. In addition, behavioral theories do not adequately explain the acquisition of obsessive fears. Regardless, these behavioral theories are useful for understanding the maintenance of many OCD symptoms and provide the foundation for behavioral intervention.

Cognitive Factors. The cognitive perspective of the etiology of OCD posits that OCD results from the interpretation of intrusive thoughts rather than the frequency or content of these cognitions. If intrusive thoughts are interpreted in such a way that an individual perceives responsibility for causing or failing to prevent harm, obsessional patterns develop. Attempts to neutralize intrusive thoughts (or obsessions) via motor or cognitive rituals, avoidance, and reassurance-seeking behavior prevent the disconfirmation of the patient's fears and facilitate the proliferation of anxiety. The most common cognitive misinterpretations include thought–action fusion or the tendency to equate thought with action (e.g., thinking something bad is the same as doing it), and exaggerated responsibility for potential untoward consequences of inaction (e.g., "If I don't wash my hands and someone gets sick as a result, then it's my fault."). However, the specificity of these misinterpretations to OCD, especially in children and adolescents, remains unclear.

Similar to behavioral theory, cognitive theory does not adequately explain the etiology of symptoms. It is likely that cognitive misinterpretations and reinforcement theory (see above) maintain and expand OCD symptoms in individuals with biologic propensity for OCD development.

DIAGNOSIS AND CLINICAL FEATURES

Presenting problems among children and adolescents with OCD generally resemble the adult presentation. However, compared to adults, children are more likely to deny impairment due to obsessions and compulsions. Children may also be somewhat less likely to consider their OCD symptoms excessive, perhaps due to lower levels of cognitive awareness. Children do not need to recognize their symptoms as senseless or unrealistic for diagnosis to be assigned; the level of insight varies considerably related to a child's developmental level. Unlike most adults, children might not report symptoms to be ego dystonic. However, children are typically willing to discuss distress from family conflict arising from their rituals (e.g., chronically running late, excessive need for reassurance, time

burden on parents, disruption of siblings functioning) or interference in schoolwork resulting in dropping grades. Overall, most children are quite open in describing their symptoms and seek assistance in better managing the illness.

Although comorbidity is the rule rather than the exception in childhood OCD, the content of the obsessions and compulsions cannot be better explained by a co-occurring Axis I disorder. Examples include self-deprecating ruminations associated with depression, obsessive concern with appearance in body dysmorphic disorder, hair pulling in trichotillomania, and fears of harm befalling a loved one in separation anxiety disorder. Similarly, the symptoms also are required not to be substance induced or due to the influence of a medical condition. The range of obsessions and compulsions experienced in childhood is similar to that of adults with OCD, although children are more likely to engage in compulsive reassurance seeking and involve family members in their rituals. Most children with OCD have both obsessions and compulsions; pure obsessional illness is rare in this age group. In fact, most childhood cases of OCD involve multiple obsessions and compulsions (mean number of four current compulsions and four current obsessions in one report). Compulsions in the absence of anxiety-related or otherwise distress-inducing obsessions may occur in (mostly younger) children, who often describe their rituals as being performed in response to an irresistible urge or an otherwise vague sensation (the “just-right” phenomena). The absence of reported obsessions in these cases may be due to underdeveloped awareness or ability to articulate these thoughts or result of a misdiagnosed tic disorder. Specific types of symptoms (e.g., touching/tapping/rubbing) may change with age, but the number of symptoms generally remains constant.

The most common obsessions in childhood include fears of contamination (e.g., dirt, exposure to germs, toxins, contracting an illness), fears of harm befalling self or others (e.g., becoming aggressive, failing to prevent harm), need for symmetry or exactness, hoarding or saving concerns, and excessive moralization or religiosity. Obsessions also may manifest as excessive guilt, self-

doubt, or other forbidden thoughts. Common compulsions involve cleaning/washing rituals, checking, repeating behaviors (touching, tapping, rubbing), counting, ordering/arranging, avoidance, doubt/indecision, confessing, seeking reassurance, and slowness. The content and type of obsessive and compulsive symptoms may change over time. OCD is also stress sensitive, and many children experience acute symptom exacerbations during times of psychosocial stress or change (e.g., attending a new school, moving to a new home, death of a family member).

Similar to adult OCD, family members are commonly drawn into the child's OCD symptoms through the provision of reassurance to the child, modification of family routines as a result of the child's symptoms, or even actual participation in the child's compulsive rituals. Such accommodation can negatively impact the family environment and lead to increased levels of family conflict and negative emotional reactions toward the affected child. Accommodation has also been associated with increased feelings of depression and anxiety on the part of the accommodating family member (typically mothers).

Given the typically strange and senseless nature of many OCD symptoms, many children and adolescents will attempt to camouflage their rituals. It is not uncommon for children with OCD to be able to inhibit their rituals for short periods of time to avoid detection (e.g., in class). Not infrequently, teachers, peers, and even parents remain unaware of the child's OCD for months or years, only becoming aware of the problem after the child can no longer control the symptoms or becomes too overwhelmed to cope.

DIFFERENTIAL DIAGNOSIS

Developmentally Normative Rituals and Superstitions

Benign habits, transitory superstitions, or mildly excessive thoughts are not uncommon during childhood. In certain phases of early childhood, rituals or superstitions may be utilized by a child to manage new or stressful situations (first day of preschool, separating

from a parent) or achieve a sense of proficiency. For example, a child may require a particular bedtime ritual or demand to wear a particular item of clothing. These normative rituals usually fade by the time of entry into formal schooling and are rarely associated with distress, significant interference with activities, or overlap in content with typical obsessions or compulsions. The absence of functional impairment differentiates mild, age-appropriate superstitions and habits from obsessive-compulsive symptoms.

Other Anxiety Disorders

Despite the presence of preoccupation and worry about issues related to their fears, children with other anxiety disorders typically do not engage in compulsive behaviors to reduce their anxiety. The content of the worry can also be useful in differentiating syndromes. Pediatric patients with generalized anxiety disorder (GAD) present with heightened anxiety relating to their health and safety, the safety of others, and their future. The content of these symptoms, although exaggerated, is grounded in everyday matters (finances, health, grades, safety) as opposed to the unusual or even bizarre content of obsessive worries. Behavioral analogs to compulsions are rare besides the requests for reassurance from others to reduce anxiety. Patients with social anxiety have fears of negative evaluation and extreme scrutiny by others. Again, fears are, by definition, excessive but typically not bizarre. Rituals are rare, although avoidance of feared situations is common. Similarly, the content of fears expressed by children with separation anxiety disorder is, by definition, confined to themes of separation or fears of harm to self or loved ones. Besides avoidance of separation, other behavioral features or rituals are absent from the presentation.

Tic Disorders, Including Tourette Syndrome

Children and adolescents with tic disorders typically display phonic or motor tics that occur frequently and may appear behaviorally similar to compulsive actions, particularly more complex tics. Tics are differentiated from compulsions as usually being avolitional and not

preceded by precipitating obsessional thoughts. However, some patients describe their tics as partially volitional in that tic expression is triggered by, and leads to relief from, an uncomfortable premonitory sensation, a functional relationship identical to that between obsessions and compulsions. The content of tics is unlikely to be as purposeful as common compulsions (e.g., washing, arranging), although complex tics may also involve repetition, for example, tapping or touching something a specific number of times. It is noteworthy that there is substantial overlap between tic disorders and OCD in childhood; symptoms of each are not uncommon, and both diagnoses may be warranted.

Autism Spectrum Disorders

The term autism spectrum disorder (ASD) comprises children from a wide range of intellectual (and adaptive) functioning. Pervasive and stereotypic behaviors (including pragmatic language) are characteristic of ASD. In contrast with OCD, perseverations lack an association with anxiety; indeed, ASD perseverations or stereotyped behaviors may contain sought-after or pleasurable topics. Similarly, the stereotyped behavior may be elicited by excitement or frustration or may serve to manage stimulation and is generally not associated with preceding intrusive thoughts or impulses. Obsessions may be described, but they are generally better characterized as idiosyncratic interests accompanied by marked perseveration and no awareness of the disinterest of others (or the excessiveness of their focus). Examples include ordering, arranging, sequencing, and preservative speech. It is not uncommon for parents to report a child appearing “driven” to engage in their “compulsions,” especially younger children. Although OCD can overlap with ASD (6% to 20% of patients with OCD are estimated to have ASD traits), the distinction can usually be made by establishing the developmental context of the behaviors.

Psychotic Disorders

The differential diagnosis of OCD from incipient psychosis in youth can be challenging. The fixed nature of bizarre or unusual obsessions can have delusional qualities and resemble schizophrenic symptomology. Although OCD-related obsessions and compulsions may appear bizarre, insight is usually preserved, and common themes are often evident. Children with OCD are typically aware that symptoms are products of their own mind (i.e., not thought insertion). OCD can usually be distinguished from schizophrenia by the absence of other symptoms, including formal thought disorder and hallucinations, and by the ability to engage in reality testing. In severe cases of OCD, reality testing may be challenged, and the boundary between obsession and delusion may be difficult to distinguish. OCD and psychotic disorders, though rarely, do co-occur.

Illness Anxiety Disorder (formerly Hypochondriasis)

If the distressing thoughts are exclusively related to fears of having a serious medical condition based on a misinterpretation of bodily symptoms, a DSM-5 diagnosis of illness anxiety disorder should be considered instead of OCD. Behaviorally, persistent need for medical evaluation and reassurance is not uncommon. However, if the preoccupation with illness is accompanied by rituals (e.g., washing, avoidance, checking based on the concern about contracting, exacerbating, or spreading illness to others), then a diagnosis of OCD may be appropriate.

COURSE AND PROGNOSIS

OCD, with onset in childhood, is a chronic condition characterized by substantial morbidity. Follow-up studies suggest that 43% to 68% of youth diagnosed with OCD continue to meet diagnostic criteria for the disorder up to 14 years after identification. A recent meta-analysis found that the remission rate may be as high as 62% (52% to 72% within the 95% confidence interval), with shorter duration of income being linked to better outcomes. Worse outcomes at follow-

up were predicted by poor initial treatment response, a lifetime history of tic disorder, and a parental Axis I psychiatric disorder. The literature lacks long-term controlled treatment studies, and most follow-up data are from extant treatment trials following only a few months posttreatment. Further, this literature is complicated by multiple confounding variables, including treatment type, comorbidity, age or age of onset, and access to follow-up care. In sum, despite promising treatments for youth with OCD, long-term data are scarce, and there is considerable room for improvement with existing interventions. Early intervention appears to be critically important.

Even with remission following treatment, children with a history of OCD or subclinical OCD symptoms should continue to be monitored for relapse in symptoms. Likewise, relatives (siblings) of patients with OCD should be monitored closely and considered for treatment with the emergence of subclinical symptoms, even in the absence of more severe or impairing symptoms.

TREATMENT

Currently, there are two approaches supported in the research literature for pediatric OCD: CBT with E/RP and pharmacotherapy with SSRIs. According to the American Academy of Child and Adolescent Psychiatry, CBT or CBT with concurrent pharmacotherapy using an SSRI is considered the first-line treatment for pediatric OCD. Multiple controlled trials, meta-analyses, and systematic reviews support these indications and add further support for combined behavioral and pharmacologic approaches in more severe cases. Behavioral approaches are overwhelmingly preferential for parents (75% of parents prefer CBT only compared to CBT + SSRI, with the disparity increasing among parents of children under age 9). Recent data suggest both the robustness and durability of CBT. Overall, treatment methodology is improving for youth with OCD. The goals of treatment are now conceptualized as striving to achieve and maintain remission.

Cognitive Behavioral Therapy with Exposure and Response Prevention

The efficacy of CBT in children has been demonstrated in numerous open trials and at least six controlled trials. Indeed, treatment response rates in the extant CBT trials were quite high, ranging from 57% to 90%. One meta-analysis of 20 studies and 1,293 participants yielded an effect size of 1.21 and relative risk of improvement versus comparison intervention of 3.93. Unlike pharmacotherapies (for which relapse is not uncommon when medication is discontinued), treatment gains from CBT commonly endure after therapy is completed. Strikingly, the Nordic Long-term OCD Treatment Study (NordLOTS) trial found at 3 years post treatment 90% (N = 242) of youth were responders (73% in remission). Importantly, CBT with E/RP for OCD is distinguished from other "talk therapies," including role-play–based, supportive, insight-oriented, relaxation, psychoanalytic, and psychodynamic therapies, which have no supported efficacy in the extant literature. Several treatment manuals outlining CBT with E/RP for children and adolescents are available. They consist of exposure (placing the patient in situations that elicit anxiety related to their obsessions), response prevention (deterring the compulsive or ritualistic behaviors that may serve to reduce or avoid anxiety from occurring), and, in some cases, cognitive therapy (training the patient to identify and reframe anxiety-provoking cognitions). In light of the chronic nature of OCD and potential for return of symptoms following completion of acute treatment, cognitive interventions also focus on teaching management, acceptance, and/or tolerance of anxiety and distress. The first step of treatment is psychoeducation about OCD and E/RP. It is important for the child and parents to understand the rationale for exposure to fear and restraint from anxiety-reducing compensatory behaviors. Next, a "fear hierarchy" is developed rank ordering symptoms. Following this, patients are systematically exposed to the feared situations (least feared first) while being instructed not to engage in their ritualistic behavior. Over repeated exposures, the associated anxiety can dissipate through the process of autonomic habituation.

In addition, when the feared consequences of not ritualizing fail to occur, the patient's heightened expectations of harm disappear, reducing anxiety even further. In addition, inhibitory learning techniques, including prolonged exposure and a focus on disproving expectations that feared outcomes will occur (*my obsession will come true if I refrain from my rituals*), may also enhance treatment outcome.

The format and intensity of CBT with E/RP are variable. Studies suggest that weekly outpatient CBT for child OCD is equivalent in efficacy to intensive CBT. It is recommended that treatment of child OCD be conducted in vivo and in the context of the family in order to promote generalization. There is also support for telehealth-based ERP. In addition, CBT targeting OCD may also improve other anxiety and depressive symptoms.

In addition to E/RP, adjunctive cognitive strategies are utilized with pediatric patients. However, younger children and those with impaired cognitive functioning receive fewer and less sophisticated cognitive components to treatment due to developmental and cognitive limitations. A child's age, cognitive functioning, and insight into the nature of their OCD are paramount in determining the direction of treatment, as an introduction of cognitive components of therapy depends on the child's developmental level and insight.

In addition, children's rituals frequently involve parental and family participation. Moreover, E/RP requires significant out-of-session practice for understanding and extinction of OCD symptoms. Many children are unwilling or unable to complete the necessary "homework" from therapy on their own (perhaps due to anxiety, lack of motivation, or distraction). Thus, substantial parental involvement appears warranted, especially for younger children. Family treatment should include significant psychoeducation about OCD as well as mechanisms of E/RP. Parents may benefit from observing techniques presented by a skilled therapist so that they can assist their child with exercises in a supportive, noncoercive approach. In addition, this can help parents to correctly extinguish ritualistic behavior and disengage from OCD rather than scold/react/blame.

Studies suggest family-based CBT is effective for youth with OCD symptoms as young as age 3.

Table 51.1–3.
Medications and Dose Ranges for Pediatric Obsessive-Compulsive Disorder

Medication	Typical Dosage (mg/day)
Fluoxetine (Prozac)	10–80[a]
Sertraline (Zoloft)	50–200[a]
Fluvoxamine (Luvox)	50–300[a]
Paroxetine (Paxil)	10–60[a]
Citalopram (Celexa)	10–40[b]
Escitalopram (Lexapro)	5–20
Clomipramine (Anafranil)	50–200[a]

[a]Mean doses as per the American Academy of Clinical Child and Adolescent Psychiatry 2012 Practice Parameters, based on randomized controlled trials.
[b]FDA has issued some warnings for the use of citalopram in excess of 40 mg.

Pharmacotherapy

The efficacy of pharmacotherapy for OCD in pediatric populations has been demonstrated in several controlled trials with serotonin reuptake inhibitors (SRIs) and SSRIs. Table 51.1–3 lists medications and dose ranges for pediatric OCD.

Clomipramine. Clomipramine, a tricyclic antidepressant, is the most researched SRI in the treatment of pediatric OCD. In a double-blind, 8-week, placebo-controlled study, 60% of pediatric patients showed significant improvement. Patients treated with clomipramine reported a 37% mean reduction in OCD symptoms compared to 8% for the placebo group (with an effect size approaching 1.0). In another 10-week controlled trial, a significant difference was found between clomipramine and placebo, with 75% of pediatric patients

showing at least moderate improvement. Other research found that clomipramine was superior to the noradrenergic reuptake-inhibiting tricyclic antidepressant desipramine. This crossover trial found that 64% of patients who initially received clomipramine during their first treatment showed relapse of OCD symptoms during desipramine treatment. Overall, a 2003 meta-analysis of pharmacotherapy trials in children identified clomipramine to be significantly superior to SSRIs in reducing OCD symptoms. Nevertheless, the risk profile, adverse effects, and required electrocardiogram and blood-level monitoring associated with tricyclic antidepressants (e.g., antiadrenergic, anticholinergic, and antihistaminergic adverse effects) are of concern with clomipramine. Thus, clomipramine is relegated to a second- or third-line treatment choice for children and adolescents and should not be used until sufficient trials of CBT with E/RP, two or more SSRIs, and combination CBT with SSRI therapy have been attempted.

Selective Serotonin Reuptake Inhibitors. Several placebo-controlled trials have demonstrated the efficacy of SSRIs. In a 20-week, double-blind, placebo-controlled trial of the SSRI fluoxetine in children and adolescents with OCD, 44% reductions in OCD symptoms were reported. A 13-week controlled trial also demonstrated the efficacy of fluoxetine, with 55% of patients treated with fluoxetine rated as much or very much improved. Another 16-week, placebo-controlled trial of fluoxetine in children reported that 57% of patients demonstrated significant improvement. Several open trials also present favorable findings for the use of fluoxetine for pediatric OCD.

Data also support the use of the SSRI sertraline for the treatment of pediatric OCD. A 12-week, multicenter, randomized, placebo-controlled trial of children and adolescents with OCD found that 42% of patients receiving sertraline were rated as much or very much improved. Further, in a 52-week, open-label extension of the previous study, 71% of children (aged 6 to 12 years) and 61% of adolescents (aged 13 to 18 years) demonstrated 25% decreases in OCD symptoms and were rated as much or very much improved.

More recently, another multisite, randomized, controlled trial found that 21.4% of pediatric patients entered clinical remission following a 12-week course of sertraline.

Finally, controlled trials have found the SSRIs fluvoxamine and paroxetine to be efficacious and well-tolerated treatments for children and adolescents with OCD. A 10-week, multicenter, placebo-controlled trial of fluvoxamine found a 42% response rate. A 10-week, placebo-controlled trial of paroxetine for pediatric patients with OCD found that 61% of patients responded to the medication. In an open-label trial of paroxetine for pediatric OCD (N = 335), 71% of patients demonstrated clinical improvement.

Overall, clinically significant reductions in OCD symptomology have been documented in children and adolescents using SSRIs, including fluoxetine, sertraline, fluvoxamine, and paroxetine, with a relatively minimal side-effect profile (as compared to clomipramine). Based on these findings, SSRIs are the consensus first-line medication for pediatric OCD. Although there are no controlled comparisons between these medications in children, research suggests that SSRIs are equally efficacious in children, and the specific choice should be based on the patient's medical history, concomitant medications, and adverse events. Poor clinical response to one SSRI is not necessarily predictive of failure with other SSRIs, suggesting adequate trials of multiple SSRIs may be indicated before augmentation. In addition, significant clinical response is unlikely within the first few weeks of taking an SSRI; generally, 10 to 12 weeks at adequate dosage is necessary to fully evaluate the efficacy of the medication.

It is noteworthy that on October 15, 2005, the U.S. Food and Drug Administration (FDA) issued a black box warning for antidepressant medications to alert health care providers to an increased risk of suicidality (suicidal thinking and behavior) in children and adolescents being treated with these agents. In light of this warning, increased attention to symptoms of depression among pediatric patients being treated with antidepressant medications appears warranted. This should include a formal assessment of suicidal ideation prior to and throughout the course of pharmacologic

treatment. An implication of this warning, combined with strong research support for CBT with E/RP, suggests attempting an adequate trial of the CBT prior to pharmacologic intervention. Notably, a recent large-scale Scandinavian study suggested that for CBT nonresponders, continued CBT was as effective in comparison to SSRI augmentation. Meta-analyses suggest other considerations: Adding CBT to current SSRI treatment may be effective for non- or partial responders. Sertraline and fluoxetine may be superior to fluvoxamine. SSRI activation is more likely for youth with OCD versus SNRI activation, suggesting SNRIs as a second-line psychopharmacologic option for youth who become activated on SSRIs.

It is also noteworthy that the FDA issued an advisory regarding the use of paroxetine in children and adolescents (June 19, 2003), recommending that paroxetine not be used in the treatment of major depressive disorder. Although the FDA did not comment on the use of paroxetine for OCD in pediatric patients, one in every five children and adolescents with OCD has co-occurring depression. Overall, activation, disinhibition, and possible worsening of suicidal thoughts associated with SSRI or SRI exposure may be a special concern in depressed children and certainly demand caution and careful monitoring. Activation may be more common in younger children, especially when on higher SSRI doses. For these reasons and given the availability of other safer and effective pharmacologic options, paroxetine should not be considered a first- or even second-line treatment for OCD in children and adolescents.

Current FDA approval has been granted for four medications for pediatric OCD use: sertraline, fluoxetine, fluvoxamine, and clomipramine, although the minimum approved age varies by the compound. The most frequent SSRI side effects include nausea, insomnia, headache, and asthenia. During clinical trials, the inability to tolerate treatment due to side effects was reported in 15% or less of cases.

Other Treatments

In pediatric cases that are unresponsive to CBT and trials with multiple SSRIs, pharmacologic augmentation may be considered. There is growing support for SSRI augmentation with atypical antipsychotics for refractory OCD in adult patients. For example, an 8-week, double-blind, placebo-controlled trial performed to determine the efficacy of risperidone augmentation in adults with treatment-resistant OCD found a 40% response rate. In addition, two recent meta-analyses of off-label use of neuroleptics (including haloperidol, risperidone, olanzapine, and quetiapine) in adults with OCD suggest that initial findings from open trials, controlled trials, and case studies are promising despite a need for substantial further research, especially in youth. Lithium carbonate and buspirone augmentation have generally not been efficacious augmentation strategies for treatment-refractory OCD in adults but may ameliorate depressive symptoms. Thus, augmentation may also be the case in children with comorbid conditions; for example, a tic disorder may require the addition of an α_2-agonist or neuroleptics. In sum, unlike the adult literature, there is a paucity of empirical data supporting augmentation strategies for pediatric OCD. In addition, significant undesirable side effects should be considered prior to prescribing neuroleptics and benzodiazepines in children.

Kosey is an 11-year-old male of Middle Eastern ancestry from a Southeastern urban community. He lives with his parents and older brother. Kosey originally presented to his advanced practice provider with new-onset obsessive-compulsive symptoms. The parents described their son as a perfectionist. Even as a young child, he would need to know the routine, was highly sensitive to certain sounds and textures, and frequently apologized for seemingly normal behaviors (e.g., dropping a toy, coloring outside of the lines). He would worry about his own performance, health, and safety. He was always questioning adults to ascertain, “Am I doing this right?” or “You’re not angry at me?” In addition to questioning, Kosey would always check over his homework, chores, and personal details (e.g., appearance) very carefully. However, approximately 6 months ago, more unusual and atypical behaviors developed. Kosey would rewrite homework assignments six or seven times, shredding papers if he had to erase the slightest mistake. He would change his clothes several times per day, stating that items “got dirty” when there was no evidence of any need for cleaning. His parents noticed a pile of his previously favorite sports jerseys and expensive athletic shoes stashed in the attic. When questioned, Kosey claimed they were “contaminated” and could not be worn again, despite any indication of soiling. He became late for school and activities, locking himself in his room for extended periods before leaving the house. He was evasive when questioned about this behavior but stated, “There are things I need to do to make sure things will be okay.” He later clarified that he would repeat a sequence of prayers and sayings in his head until “they felt just right,” and he could subsequently go out of the house. He refused to go to school on days he would need to change for physical education, confessing to his parents that he worried he might be “gay” (despite no signs of beginning puberty). Whereas Kosey’s elementary school teachers had tolerated tardiness and late assignments, given his history of being a stellar student, his middle school teachers did not accept

late work and reprimanded him for being late. Consequently, his grades were plummeting. At the same time, his extracurricular interests appeared to be diminished, and rituals replaced the time he had spent on age-appropriate activities. Fights were erupting between Kosey and his parents because Kosey's rituals made his mother late for work, and both parents grew tired of their son's increased need for reassurance.

There was no history of OCD in Kosey's immediate family. However, his father had a history of untreated "anxiety," and his mother had suffered from "postpartum panic." His brother also struggles with panic. His uncle had been diagnosed with Tourette syndrome, and his grandmother was described as extremely "compulsive and ritualistic." Kosey's problems had never been mentioned to a health care professional before. For years, his parents felt they were just idiosyncratic aspects of his personality. Moreover, he had been functioning well, and there was no evidence of distress, except when his parents were not available to provide reassurance. Symptoms spiked during the COVID-19 pandemic, with extensive worries about contaminated packaging, air, and risks of infection and death to his family. They presented for treatment, given Kosey's increased distress and impairment. It was recommended by his nurse practitioner that he begin on 50 mg of sertraline (his mother had responded well to sertraline). Kosey's parents wondered if PANDAS was a consideration, given the spike in symptoms when Kosey's grandfather was hospitalized with COVID-19. They were reassured that PANDAS was unlikely a consideration given the long course of symptoms and lack of fluctuating course. They were reluctant to start medication but did so, given the difficulty in finding a clinical psychologist. His dose was gradually increased to 150 mg, but his parents were concerned that he was not responding, despite reading that it can take several weeks or longer for medication to work at therapeutic doses. Consequently, the family was referred to a board-certified child and adolescent psychologist in a neighboring city with expertise in child OCD. Kosey and his family presented for initial consolation with the clinical

psychologist, who agreed that CBT with E/RP was indicated, and she reviewed the treatment model with the family. Kosey and his family participated in weekly sessions for about 12 weeks, focusing on exposure to his feared thoughts and prevention of ritualistic behavior in a systematic method. He was highly motivated, and most of the visits were conducted via televideo. Therapy was family based, emphasizing family-based in vivo practice of E/RP, generalization of exercises outside of session, and minimizing disruption to school. A hierarchy of feared symptoms was developed at visit two, and in vivo E/RP commenced at visit three.

After about 3 months of CBT with E/RP, Kosey reported an improved ability to manage his obsessive thoughts and to resist rituals. He reported decreased anxiety as well as urges to ritualize. His parents reported an improved understanding of OCD as well as how to react to his reassurance seeking (and other compulsive behaviors) to facilitate his recovery. The family understood the algorithm for intervening with future obsessions or compulsions as well as the potential need to resume CBT if symptoms resurged. The family chose to remain with the psychologist for a few additional sessions to address family conflict that had developed surrounding the OCD behaviors; at this time, his presentation became consistent with clinical remission. His family desired to discontinue medication but was advised to consult with a child and adolescent psychiatrist to discuss discontinuation versus continuance to best maintain remission.

51.2 Posttraumatic Stress Disorder in Children and Adolescents

JUDITH A. COHEN, M.D.

Two-thirds of American youth experience at least one potentially traumatic event (PTE, e.g., child abuse, domestic or community violence, disaster, accidents, medical trauma, war, or multiple/complex trauma). A third experience multiple traumas, increasing the risk of serious mental and medical health problems. Up to 10% develop full-blown posttraumatic stress disorder (PTSD); many more suffer from subsyndrome PTSD symptoms with equivalent functional impairments. New criteria for PTSD in DSM-5 increase attention to developmental and cultural manifestations of trauma symptoms. Genetic and psychobiologic factors also influence the development of PTSD. Recognition of the frequency with which children develop PTSD symptoms has led to improved strategies for assessing and treating traumatized children.

DEFINITION

PTSD is defined by developing characteristic features after exposure to trauma, that is, events involving a threat to life, safety, or physical integrity, experienced or witnessed directly by the child or affecting someone close to the child (criterion A). The clinical presentation varies, and not all children manifest emotional fear, helplessness, or horror as previously required. Children aged 7 years or older must have one intrusion symptom, such as recurrent trauma-related

memories or dreams or intense psychological or physiologic response to trauma reminders (criterion B); one symptom of persistent avoidance of trauma-related stimuli (criterion C); two symptoms of negative alterations in cognitions such as persistent negative trauma-related beliefs or persistent posttrauma negative emotional state (criterion D); and two arousal symptoms (criterion E). The revised criteria include developmentally sensitive diagnostic criteria for children 6 years and younger. These children must have one intrusion symptom (criterion B), one symptom of avoidance or negative alteration in cognitions (criterion C), and two arousal symptoms (criterion D). The duration of symptoms must be more than 1 month and the disturbance must cause clinically significant distress or functional impairment.

HISTORY

Descriptive accounts of children traumatized by the London blitz during World War II, of the kidnapping and subsequent burial of children in their school bus, and of children exposed to a fatal schoolyard sniper attack were published by early child trauma pioneers. Subsequent empirical studies of children exposed to sexual abuse, peer suicide, cancer, burns, and terrorist attacks confirmed that increased levels of trauma exposure and lack of adequate social support strongly predict the emergence of PTSD and other psychological symptoms. The September 11, 2001, terrorist attacks, the Asian tsunami of 2004, and Hurricane Katrina have documented that peritraumatic panic, delayed evacuation, and perceived life threat to self or family members are significant risk factors for later PTSD development. In the past 25 years, a number of empirically rigorous randomized controlled trials (RCTs) have documented the superiority of trauma-focused psychosocial treatments over usual care for pediatric PTSD. Few pharmacologic RCTs have examined the treatment of pediatric PTSD.

COMPARATIVE NOSOLOGY

PTSD was first officially recognized in 1980 in DSM-III. DSM-III-R was the first version to include representative items for childhood PTSD. Importantly for children, this version increased the number of avoidance or numbing symptoms needed to meet diagnostic criteria from one to three. DSM-IV further elucidated childhood variants of symptomatology. The development of an alternative algorithm for diagnosing PTSD in preschool children and growing research led to the new diagnostic criteria in DSM-5 for children younger than 7 years. Research documents that many do not respond with horror, fear, or helplessness supported the removal of this criterion in DSM-5. Other research led to including a new cluster for alterations of mood and cognitions in DSM-5.

EPIDEMIOLOGY

Surveys document PTSD prevalence rates in the general youth population of 8% to 9%, with another 14.1% reaching subclinical levels. More relevant are prevalence rates among trauma-exposed children, as by definition, PTSD is only possible in this population. Nonreferred samples of adolescents exposed to various forms of trauma have documented that 25% to over 90% develop PTSD, depending on the trauma experienced, time since exposure, and the assessment method used. Chronic traumas, such as ongoing child abuse, or traumas that result in disruption of family and the broader social support network, such as war or refugee experiences, tend to result in a greater risk of PTSD than acute traumas, such as natural disasters. Exposure to multiple traumatic events is associated with an increase in PTSD. Female gender also tends to predict a greater risk of developing PTSD as well as other mood and anxiety disorders. Furthermore, the above rates only include children meeting full diagnostic criteria; several studies have indicated that the majority of trauma-exposed children develop PTSD symptoms severe enough to interfere with functioning, even in the absence of a PTSD diagnosis.

ETIOLOGY

PTSD is one of the few DSM disorders that require the presence of an etiologic agent (a serious traumatic event). Exposure factors also predict outcome with severity and frequency of trauma exposure, exposure to interpersonal violence, greater perceived life threat, death of a family member, greater peritraumatic panic, and delayed evacuation (if during a mass trauma experience), all predicting higher risk of developing PTSD. Nevertheless, not all children exposed to such events develop PTSD, so other etiologic factors must also be considered.

Biologic Factors

Female gender is a risk factor for developing PTSD. Children with pre-existing anxiety disorders are at increased risk of developing PTSD following trauma exposure, and a history of depression in first-degree relatives also predicts increased vulnerability to developing PTSD. Prior trauma exposure is a risk factor for developing PTSD upon exposure to a new trauma, with a greater number of traumas predicting a greater risk of the disorder. Recent studies have demonstrated that genetic risk factors interact with other risk and protective factors, such as social support, in determining whether trauma-exposed children will develop PTSD or will be resilient despite traumatic experiences. Numerous psychobiologic abnormalities have been found in children with PTSD, including complex alterations in hypothalamic–pituitary–adrenal (HPA) axis functioning, increased excretion of adrenergic and dopaminergic metabolites, smaller intracranial volume and corpus callosum area, as well as lower intelligence quotient (IQ) and memory deficits. In addition to these alterations, adults with PTSD have evidence of amygdala hyperactivity, medial prefrontal cortex underactivity, and decreased hippocampal volume. However, because of the paucity of prospective studies, it is unclear whether these findings are indicative of etiologic (causal) factors in the development of PTSD or the effects of PTSD on children’s developing brains.

Psychological Factors

Classical and operant conditioning are involved in the development of PTSD. Extreme stressors typically produce negative emotions (terror, anger, sadness) as well as physiologic arousal from the activation of the sympathetic nervous system (the “fight, flight, or freeze” response). Classical conditioning occurs when neutral cues that were present at the time of the trauma become associated or “paired” with the trauma to the extent that they, too, elicit these intense psychological and physiologic reactions. Operant conditioning occurs when the child learns to avoid trauma-related cues in order to reduce the likelihood of experiencing these distressing reactions. As avoidance behaviors are repeatedly reinforced, they may also generalize. New responses can be acquired through the pairing of exposure and inhibitory learning.

Children’s maladaptive cognitions are also relevant to PTSD development. Shame, self-blame, believing that one is undeserving of being loved, protected, or being treated well, or believing that others cannot be trusted are common maladaptive cognitions among children who experience interpersonal trauma. Such children may have difficulty differentiating between what was done to them (the traumatic experiences) and who they are (their identity). This has important implications for how such children’s trauma symptoms are manifested (i.e., in assessing complex PTSD symptoms as described below).

Social Factors

Many pretraumatic social factors, including lower socioeconomic status, economic deprivation, family dysfunction, parental separation or death, lower intelligence, minority racial or ethnic status, and family psychiatric history, have been found to predict a higher risk of developing PTSD. The absence of a strong social support network has been found to increase the risk of developing PTSD. Parental psychopathology has also been implicated as a risk factor in children developing PTSD following exposure to a variety of traumatic events. Thus, there is growing evidence that social factors may have a role

in the etiology of this disorder. However, a recent study demonstrated that twins who had been sexually abused were at significantly greater risk of developing a variety of adverse outcomes than their nonabused twins, despite shared genetics and family environment. Social etiologic factors should, therefore, not be overestimated.

DIAGNOSIS AND CLINICAL FEATURES

Exposure to a Traumatic Event

To qualify for a diagnosis of PTSD, the child must have been exposed to a traumatic event that consisted of direct personal experience; witnessing an event in person; learning about the trauma of a close family member or close friend (in the case of death, the event must have been violent or accidental); or experiencing repeated or extreme exposure to aversive details of the traumatic events (but not only through media descriptions). A number of qualifying traumatic events are listed in DSM-5, which specifies that in the case of child abuse, there does not have to be a threat of physical violence or injury (e.g., genital fondling without penetration would qualify).

Re-Experiencing

The child must have at least one persistent intrusion symptom related to the traumatic event. Children may have recurrent, involuntary, and intrusive thoughts, memories, images, or body sensations reminiscent of the traumatic event. In young children, this may take the form of repetitive play in which traumatic themes are present (e.g., sexually abused children may repeatedly re-enact inappropriate touching in their play). Children may have recurrent distressing dreams about the event, or in the case of younger children, there may be frequent frightening dreams without any recognizable content. Children may have dissociative reactions; these may include periods when they act or feel as if the event were reoccurring in the present moment (a flashback). In young children,

trauma-specific re-enactment may occur (e.g., sexually abused children may insert objects into their own or other children's private parts or otherwise recreate abusive acts perpetrated against them). Children may experience intense psychological distress or physiologic reactivity when exposed to triggering events, people, or situations that remind them of the original traumatic event (e.g., children who witnessed a drive-by shooting may become agitated or have difficulty breathing when they hear thunder or a backfiring car). These reminders may be highly idiosyncratic to individual children.

The above criteria also apply to diagnose PTSD for children 6 years or younger, but in these children, spontaneous and intrusive memories might not appear distressing. It may not be possible to ascertain that the frightening content of dreams is related to the traumatic event.

Avoidance and Numbing

The child must experience persistent avoidance of stimuli associated with the traumatic event and numbing of general responsiveness, as indicated by one of the following symptoms. Children may avoid or make active efforts to avoid memories, thoughts, or feelings about or closely associated with the traumatic event. They may avoid or make efforts to avoid external reminders (e.g., discussions about the traumatic event or people, places, situations, or activities that remind them of the trauma). For example, after the sudden death of a loved one, children may refuse to say the name of the deceased or insist that others not do so.

In order to diagnose PTSD for children 6 years and younger, one or more symptoms representing *either* persistent avoidance of trauma-related stimuli *or* negative alterations in cognitions and mood associated with the traumatic event must be present.

Negative Alterations in Cognition and Mood

Children may be unable to recall one or more important aspects of the traumatic event (dissociative amnesia). Children may have persistent, overly negative beliefs about themselves (e.g., "No one

loves me”); others (e.g., “I can’t trust anyone”), or the world (e.g., “Nothing is safe”); or maladaptive cognitions about why the trauma happened (e.g., “I should have known he would hurt me”) leading to distorted self- or other-blame. Children may develop negative emotional states such as shame, guilt, anger, sadness, or fear that persist after the traumatic event. Children may have diminished interest or participation in their normal activities, for example, not wanting to play with friends (social withdrawal) or participating less in the classroom. They may feel detached or estranged from others (e.g., feel that no one understands them; affiliate with deviant peers) or may experience diminished capacity to feel emotions, especially warm interpersonal emotions (e.g., children may say, “I don’t feel like I love anyone anymore.”).

In order to diagnose PTSD for children 6 years and younger, one or more symptoms representing *either* persistent avoidance of trauma-related stimuli *or* negative alterations in cognitions and mood associated with the traumatic event must be present.

Arousal and Reactivity

The child must also experience persistent symptoms of arousal and reactivity that were not present prior to the traumatic event, as evidenced by at least two of the following. Children may have increased irritability and angry outbursts, with little or no provocation; these may be expressed as aggression toward others (and are often misdiagnosed in children as externalizing behavior disorders). They may have reckless or self-destructive behaviors (e.g., self-injury, substance abuse, reckless driving, or unprotected sexual activity). They may exhibit hypervigilance (e.g., children may ask their parents to check several times every night to be sure that all the doors are locked) or exaggerated startle reactions (e.g., jumping whenever the telephone rings or a pencil drops in the classroom). Children may have difficulty concentrating or completing tasks, which may impair academic performance. Children may have trouble falling or staying asleep, or may have restless sleep, whether or not they have trauma-related dreams.

The above criteria also apply to children 6 years and younger, except that these children do not typically exhibit reckless or self-destructive behaviors.

Duration, Types, and Clinical Features

These symptoms must be present for at least 1 month and must be accompanied by significant distress or impairment in an important area of functioning. PTSD with dissociative symptoms should be specified if the child meets the above criteria and experiences persistent or recurrent depersonalization or derealization symptoms that are not attributable to substance abuse. If the onset of symptoms does not occur until more than 6 months after the traumatic event, the diagnosis is PTSD with delayed expression. “Complex PTSD,” “complex trauma,” and developmental trauma disorder have been suggested to represent the complexity of symptoms existing in children experiencing repeated, interpersonal traumas involving attachment disruption. Such children have severe dysregulation of affect, behavior, cognitive, attachment, perceptual, and biologic domains that result in marked functional impairment. It is not clear whether the new DSM-5 PTSD criteria will more adequately describe these complex problems or whether a new diagnosis will be required. The International Classification of Diseases, 11th Edition (ICD-11) conceptualizes this as two distinct disorders, PTSD and Complex PTSD.

PATHOLOGY AND LABORATORY EXAMINATION

Although several alterations in the laboratory, neuropsychologic, and neuroimaging tests have been reported in children with PTSD, there is currently no laboratory or other test that can reliably distinguish children with PTSD from other children on an individual basis.

DIFFERENTIAL DIAGNOSIS

Assessment of pediatric PTSD is complex and beyond the scope of this article. PTSD symptoms overlap and co-occur with several other psychiatric conditions. Acute stress disorder (ASD) occurs and is resolved within the first month after traumatic exposure. Children with less significant trauma-related adjustment symptoms may be diagnosed with an adjustment disorder. Several diagnostic criteria of PTSD overlap with those of anxiety disorders and major depressive disorder. For example, recurrent intrusive thoughts are a hallmark of obsessive-compulsive disorder, while avoidance of social situations, social withdrawal, and tantrums are characteristic of social phobia. The specific content of these thoughts or fears may clarify that they are not trauma-focused. However, because children frequently do not disclose traumatic experiences unless specifically asked, it is important for the assessing clinician to inquire directly about traumatic exposure whenever children present with anxiety-related symptoms.

In a similar manner, irritability, feelings of emptiness, decreased interest in normal activities, sleep disturbance, psychomotor agitation, inappropriate guilt, and decreased concentration are all symptoms shared by PTSD and major depressive episodes. Distinguishing between these two disorders may be particularly difficult in children with avoidance symptoms that prevent them from discussing the traumatic event. Careful history-taking is essential in determining whether the child's symptoms are trauma-related and to what extent the child meets the criteria for either or both diagnoses. Children with traumatic bereavement are particularly likely to meet partial or full criteria for both disorders.

Children and adolescents presenting with substance use disorder may have a past history of trauma that is either covert (never disclosed) or minimized by the child or assessing clinician. Accurately identifying PTSD in such children may be critical to their optimal treatment, as standard substance use interventions do not contain important elements of trauma-focused treatment. If such children are using drugs or alcohol to self-medicate trauma-related symptoms, it is unlikely that their substance use will improve without adequately addressing these symptoms.

Additionally, PTSD may coexist with or be misdiagnosed as behavioral disorders such as attention-deficit/hyperactivity disorder (ADHD) or conduct disorder. Particularly in younger children who are less able to verbalize their anxiety, PTSD-related irritability, sleep difficulties, and difficulty concentrating may present as classic ADHD. Eliciting a history of trauma exposure and evaluating the timing of these symptoms may be important in distinguishing these disorders.

PTSD can mimic medical conditions such as hyperthyroidism, seizure disorder, caffeinism, migraine, asthma, or side effects from prescription or nonprescription medications.

Symptoms of complex PTSD (severe affective, behavioral, relationship, and cognitive dysregulation) may resemble those of bipolar disorder. Particularly if such children are avoidant of disclosing a trauma history, they will likely be diagnosed with bipolar disorder rather than PTSD. Since first-line treatments of these disorders are very different (medications for the former; psychotherapy for the latter), it is crucial to always inquire about children's trauma histories and assess their symptoms from a trauma-informed neurodevelopmental perspective.

Psychotic symptoms may occur in up to 20% of children with PTSD; flashbacks or other intrusive phenomena must be distinguished from true hallucinations or substance-induced disorders.

COURSE AND PROGNOSIS

The natural course of childhood PTSD has not been adequately determined. Based on the available studies, it appears that while PTSD symptoms spontaneously remit in some children, they persist for years or even decades in many others. There is also growing evidence that trauma-focused treatment significantly alters the natural course of pediatric PTSD. Studies have documented continued remission of PTSD 2 years posttreatment in children who received trauma-focused cognitive-behavioral therapy (TF-CBT).

The prognosis for children with untreated PTSD has become a matter of increasing concern since research has documented the

numerous psychobiologic abnormalities associated with this disorder, and the severity of some of these (decreased intracranial volume, decreased corpus callosum area, and lowered IQ) is directly correlated with the duration of symptoms. Growing evidence that childhood sexual abuse is predictive of adult suicidality, as well as depression and suicidality in the offspring of such victims, also suggests a poor prognosis for unresolved PTSD in childhood. This emphasizes the importance of identifying symptomatic children and providing effective interventions early in the course of this disorder.

TREATMENT

Children with PTSD receive many treatments, but the effectiveness of most of these interventions has not been evaluated. To date, trauma-focused psychotherapies have the most empirical evidence of efficacy for treating pediatric PTSD. Although several selective serotonin reuptake inhibitors (SSRIs) have been shown to effectively treat adult PTSD symptoms, two RCTs have failed to show superiority to a placebo in traumatized children. Similarly, although open trials of adrenergic agents have had promising results, two RCTs have failed to show the superiority of propranolol to a placebo in treating pediatric PTSD. During the COVID-19 pandemic, treatment for children with PTSD quickly transitioned to being provided almost entirely via telehealth. Two studies have found that when trauma-focused psychotherapy is provided via telehealth, children experience equivalent outcomes with lower attrition than when treatment is provided in typical clinic settings.

Psychotherapeutic Treatments

Cognitive-Behavioral Therapies. Currently, TF-CBTs have the strongest evidence for resolving child PTSD and associated problems. TF-CBT has been found in 23 RCTs to be superior to other active treatments or comparison conditions in decreasing PTSD as well as depressive, anxiety, cognitive, behavioral symptoms, and functional impairment in traumatized children. TF-

CBT has been tested in youth who have experienced sexual trauma, domestic violence, terrorism, disaster, war, traumatic grief, and multiple and complex trauma in multicultural cohorts in the United States, Europe, Africa, Asia, and Australia. TF-CBT is typically provided over 12 to 25 treatment sessions. Its core components are summarized by the acronym PRACTICE: *Psychoeducation* about the child's traumatic experiences and responses; *Parental or caregiver inclusion* in treatment, including a parenting skills component; *Relaxation skills,* which are individualized for each child and parent; *Affective* modulation skills; *Cognitive* coping techniques (connections between thoughts, feelings, and behaviors are taught and practiced); *Trauma narration and processing*, consisting of carefully calibrated efforts to encourage the child to describe increasing details about the traumatic event and to identify and process inaccurate or unhelpful thoughts related to the traumatic event; *In vivo mastery* of trauma reminders, in which children with overgeneralized avoidance and fear develop graduated mastery of these through calibrated exposure to the feared stimuli; *Conjoint* child–parent sessions in which optimal communication is emphasized and practiced; and *Enhancing safety* and future developmental trajectory, in which the child develops and practices effective strategies for maintaining personal safety. A stepped-care TF-CBT model has been found to be noninferior to standard TF-CBT for improving young children's PTSD symptoms and for addressing cost and access issues for some families. Neuroimaging data suggest that changes in brain functioning are correlated with improvements in PTSD symptoms during TF-CBT treatment. A group CBT model for school settings, Cognitive Behavioral Intervention for Trauma in Schools (CBITS), has been tested in schools and found to be effective in reducing PTSD and depressive symptoms. Other CBT-based treatments, such as the UCLA Trauma/Grief Program for Adolescents and a child adaptation of Narrative Exposure Therapy, have also been tested with positive results among refugee or war-exposed children. Cognitive-based therapy for single-incident traumas also has been found to be effective.

Eye movement desensitization and reprocessing (EMDR) utilizes exposure and cognitive reprocessing interventions with bilateral eye movements. EMDR has been adapted for children and tested in two well-designed studies. A recent study comparing EMDR to TF-CBT found that both treatments were equally effective and efficient at improving children's PTSD symptoms, with TF-CBT being superior for improving comorbid psychiatric symptoms.

Psychodynamic and Attachment-Based Therapies. Child–parent psychotherapy (CPP) is an attachment-based treatment of trauma-exposed infants and preschool children and their primary caretakers. CPP has been tested in one RCT for preschoolers exposed to marital violence and found to be superior to case management in improving these young children's PTSD symptoms and in their mothers' PTSD symptoms. CPP includes the following components: Providers begin by providing developmental guidance or psychoeducation about the child's behavior and how it may be understood in light of normal development and changed through simple behavioral interventions. If needed, additional interventions are added to help the parent to understand the child's behaviors and enhance child–parent attunement. These may include behavior management, cognitive reframing, and processing, developing a joint narrative of the child and parent's traumatic experiences, and interpreting the child or parent's behaviors, emotions, and past experiences.

Psychopharmacologic Treatments

RCTs of sertraline (Zoloft), D-cycloserine, and propranolol (Inderal) have failed to show significant differences from placebo in improving pediatric PTSD. While open treatment trials have demonstrated clinical improvement in child PTSD symptoms following the use of adrenergic blocking agents (guanfacine [Tenex], clonidine [Catapres]), a dopamine antagonist (risperidone [Risperdal]), or an opiate (morphine [Roxanol]), none of these medications have been tested in well-designed double-blind, randomized trials.

Pharmacologic treatments thus lack evidence for treating pediatric PTSD. Children who have comorbid psychiatric conditions for which effective pharmacotherapy is established should receive the appropriate psychopharmacologic treatment of those disorders; it is not yet known whether such treatment will also impact favorably on coexisting PTSD symptoms.

Biologic Treatments

Since dysregulation of the HPA axis is generally found in both children and adults with PTSD, the use of a corticotropin-releasing factor (CRF) antagonist has been suggested as a potential intervention for preventing this disorder from developing or in reversing PTSD symptoms once they are present. This intervention has not yet been tested in children or adults.

C was a 15-year-old girl referred to treatment following hospitalization for a suicide attempt. From 6 to 12 years old, C had been sexually abused by her paternal grandfather. C disclosed the abuse to her parents at 12 years old, who were supportive; however, a week later grandfather committed suicide. The following year, C came out about being gay to her parents and close friends, who were supportive. Her parents thought C was doing well until the suicide attempt. In the hospital, C disclosed the following: Since coming out, C experienced worsening physical, sexual, and verbal abuse in school related to her gay identity but kept this from her parents. During the current school year, C was repeatedly sexually assaulted by three male peers who threatened to kill her younger brother if she disclosed the abuse. Guilt (she "froze" during these episodes and did not say "no" or fight back) and negative self-cognitions led to the suicide attempt.

During the initial evaluation, C reported intrusive thoughts and nightmares about sexual abuse and her grandfather's gory suicide. C tried unsuccessfully to push these images out of her mind. She acknowledged maladaptive cognitions, including that she "deserved to be raped for killing my grandfather" and that she was "a terrible person." She endorsed sleep disturbance, increased startle, irritability, and sadness. She scored 58 on the UCLA PTSD reaction index (RI), consistent with very severe PTSD, and 20 on the beck depression inventory (BDI), consistent with a major depressive episode. During the assessment and treatment, the therapist also used strategies from the Family Acceptance Project (https://familyproject.sfsu.edu/) to evaluate behaviors that C's parents demonstrated related to C's sexual orientation, and how they could expand these in order to further support and advocate for C. These strategies are described in the TF-CBT LGBTQ Implementation Manual (https://www.tfcbt.org/tf-cbt-lgbtq-implementation-manual/).

C and her parents attended 23 sessions of TF-CBT. Twenty of these were individual sessions (half of the session was spent

with C and half with parents); three sessions were conjoint child–parent sessions in which the family met together. During the stabilization phase (11 sessions), C and her parents learned about trauma reminders (e.g., the threat of sexual assault would serve as a trauma reminder for C in light of her history of sexual abuse), trauma impact (e.g., fight, flight, freeze, and trauma impact on affect, behavior, biology, cognitions, relationships, and perceptions), as well as a variety of coping skills for trauma reminders. C and her parents reported that this helped them to make sense of C's response to the rapists as a trauma response and was "a huge relief" for C. Although parents and C reported that parents were "supportive" of C's sexual orientation, through further psychoeducation and parenting skills, they became more aware of specific supportive behaviors they could engage in to show this support to C (e.g., encouraging her to have LGBTQ friends over, not allowing others in their family to make verbal slurs about LGBTQ individuals, and actively advocating for her with other family members, at school, and in their faith community, etc.). As her parents used these strategies, C reported that she felt more supported and happier at home. C preferred using visualization and the cognitive triangle (changing thoughts in order to change feelings and behaviors). She carried a notebook with her and practiced changing her thoughts whenever she had a negative feeling. She found that this was very helpful and, when paired with visualization, enabled her to reduce her distress level significantly in most situations. C's parents were very upset at the school for failing to protect C from harassment and physical assaults at school, and with C's agreement, they investigated other schools that C could attend. The therapist worked with parents to become more effective advocates for C in school, their extended family, and the community. C reported that this also contributed significantly to reducing her distress level.

During the trauma narrative phase (7 sessions), C developed a detailed description and cognitively processed her personal trauma experiences. Through this process, her understanding

and cognitions about these experiences changed substantially. She identified how her grandfather manipulated her into worrying about her parents' response if she disclosed it and contributed to her self-blame for his suicide. Her new cognitions were that only the perpetrators were responsible for the abuse, her grandfather chose to kill himself rather than face up to prison, and she did not deserve to be hurt for any reason. During this process, C also made the decision that she wanted to go to a different school because "they didn't protect other gay kids and me the way they should have." Her parents actively advocated for this change and helped to find an alternative school. They also prepared a brief response letter to C's narrative stating their regret for not knowing about the abuse and bullying and how they would be more actively supportive in the future.

During the integration and consolidation phase (5 sessions), C shared her narrative with her parents and engaged in safety planning with them. This included how C could protect herself from bullying going forward and how her parents could also advocate for her. C made the transition to her new school successfully and found this to be a more supportive environment. C and her parents addressed healthy sexuality together and in individual sessions, and C reflected on her future hopes and plans. At the end of treatment, C's RI score was 15, and BDI was 10 (both normal).

FUTURE DIRECTIONS

1. Evaluating DSM-5 diagnostic criteria for children ages 7 to 17 years, particularly those with complex trauma, to determine whether the new criteria adequately describe the complex difficulties of these youth or whether an additional diagnosis is needed.
2. Developing and testing effective treatments for children who have PTSD in the presence of comorbid psychiatric disorders.

3. Evaluating the relative efficacy of pharmacologic treatments for pediatric PTSD, alone and in combination with psychotherapy.
4. Developing a biomarker for pediatric PTSD and other effective neurobiologic tools for assessing pediatric PTSD.
5. Developing effective dissemination strategies for training community therapists in evidence-supported treatments for children with PTSD, including making these treatments usual care by embedding evidence-based treatments into routine graduate school training for counseling and social work students.
6. Developing and testing the use of social media applications for screening and treating pediatric PTSD. Given the large number of children who have PTSD, some will never reach mental health providers, but most have access to electronic media.

51.3 Separation Anxiety, Generalized Anxiety, and Social Anxiety

Benjamin N. Schneider, M.D., Ruben G. Martinez, Ph.D., and Tara S. Peris, Ph.D.

Fear and worries are a common and expected part of healthy child development. For most children, these worries are short lived and limited in the impairment they bring, and they track to developmental status. Among younger children, fears may focus on the dark, monsters, or strangers, whereas for older children and adolescents, fears may focus on friends, school, or decision making. These developmentally appropriate worries wane naturally over time as new experiences and skills overshadow them. Although transient fears and worries are a natural and necessary part of child development, for some youth, they will persist and bring a level of impairment that requires clinical attention.

The three most common pediatric anxiety disorders—separation anxiety, generalized anxiety, and social anxiety—share the same

underlying construct of diffuse, future-oriented worry that is often focused on unknown threats. They have significant symptom overlap, are highly comorbid with one another, and show similar familial relationships and continuity with adult anxiety and depressive disorders. For these reasons, the three disorders are often grouped together as they are in this section. The three anxiety disorders are described separately in this chapter to highlight core constructs central to diagnosis; however, treatments are discussed for the disorders as a group, given the significant overlap in approach.

Anxiety disorders comprise the most prevalent class of mental health problems among youth, affecting up to one in three individuals by the time they reach adulthood. Children with anxiety disorders have an early onset and a persistent or recurring course with high levels of short- and long-term impairment. In addition to being comorbid with one another, anxiety disorders are often comorbid with nonanxiety disorders. Fortunately, there are highly effective psychosocial and pharmacologic treatments for these disorders. Current challenges include the identification of treatment methods to optimize outcomes and address co-occurring emotional and behavioral problems and the wide-scale dissemination and implementation of evidence-based treatments.

SEPARATION ANXIETY DISORDER

Definition

Separation anxiety disorder is characterized by excessive and developmentally inappropriate fear of catastrophic separation, avoidance of such separations, and irrational beliefs about the consequences of being apart from a caregiver (Table 51.3–1). Attachment figures are usually parents but may also be siblings, grandparents, or other caregivers or for adults, children or spouses. Whereas developmentally appropriate separation anxiety typically presents around age 6 months and declines between ages 2 and 3 years, children with separation anxiety disorder have either persistent and worsening or new-onset separation anxiety in the

school-age years (i.e., ages 6 to 12 years). This section differentiates between developmentally normal separation anxiety in infancy and toddlerhood and separation anxiety disorder in school-aged children.

Comparative Nosology

Separation anxiety disorder appeared initially in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) and was classified as an anxiety disorder of childhood or adolescence. Although it was subsequently categorized in the DSM-IV as a "disorder usually first diagnosed in infancy, childhood, or adolescence," separation anxiety is currently classified in the DSM-5-TR as an anxiety disorder. Since first introduced, the diagnostic criteria for separation anxiety disorder have been modified in four ways, along with modified wording in DSM-5 (continued in DSM-5-TR) to capture symptom presentation in adulthood. Unlike earlier versions, the DSM-5 does not require onset prior to age 18 and recognizes that some adults report onset after age 18 years. The minimum duration was increased from 2 weeks in DSM-III to 4 weeks in DSM-IV and subsequent versions, and DSM-5 specifies at least 6 months in adults to avoid overdiagnosis of transient fears. Also, evidence of serious distress or impairment was added for diagnosis starting in DSM-IV. Finally, recurrent excessive distress about (1) anticipated or (2) actual separation was collapsed into one symptom in DSM-IV, and thus the symptomatic threshold for separation anxiety disorder was reduced from three of nine symptoms in DSM-III-R to three of eight symptoms in DSM-IV and currently in DSM-5-TR.

Table 51.3–1.
DSM-5-TR Diagnostic Criteria for Separation Anxiety Disorder

A. Developmentally inappropriate and excessive fear or anxiety concerning separation from those to whom the individual is attached, as evidenced by at least three of the following:
   1. Recurrent excessive distress when anticipating or experiencing separation from home or from major attachment figures.
   2. Persistent and excessive worry about losing major attachment figures or about possible harm to them, such as illness, injury, disasters, or death.
   3. Persistent and excessive worry about experiencing an untoward event (e.g., getting lost, being kidnapped, having an accident, becoming ill) that causes separation from a major attachment figure.
   4. Persistent reluctance or refusal to go out, away from home, to school, to work, or elsewhere because of fear of separation.
   5. Persistent and excessive fear of or reluctance about being alone or without major attachment figures at home or in other settings.
   6. Persistent reluctance or refusal to sleep away from home or to go to sleep without being near a major attachment figure.
   7. Repeated nightmares involving the theme of separation.
   8. Repeated complaints of physical symptoms (e.g., headaches, stomachaches, nausea, vomiting) when separation from major attachment figures occurs or is anticipated.

B. The fear, anxiety, or avoidance is persistent, lasting at least 4 weeks in children and adolescents and typically 6 months or more in adults.

C. The disturbance causes clinically significant distress or impairment in social, academic, occupational, or other important areas of functioning.

D. The disturbance is not better explained by another mental disorder, such as refusing to leave home because of excessive resistance to change in autism spectrum disorder; delusions or

hallucinations concerning separation in psychotic disorders; refusal to go outside without a trusted companion in agoraphobia; worries about ill health or other harm befalling significant others in generalized anxiety disorder; or concerns about having an illness in illness anxiety disorder.

Epidemiology

Epidemiologic studies show the lifetime prevalence rate of childhood and adolescent separation anxiety disorder is at least 4%, with peak onset between 7 and 9 years of age. Separation anxiety disorder is more common in childhood than in the preschool years or adolescence and is the most common anxiety disorder in children under the age of 12. Although the peak age of onset is in middle childhood, preschool children can be diagnosed with separation anxiety disorder (range from 0.5% to 10.5%) and can be distinguished from children with developmentally normal separation anxiety. Children with separation anxiety symptoms who do not meet diagnostic criteria are very common, with reported rates as high as 50%. Community studies suggest that girls are more likely than boys to meet criteria even in the preschool years, but clinical studies find the disorder to be equally common in girls and boys.

Etiology

Although the exact cause of separation anxiety is unknown, genetic, early temperamental, and family or environmental variables have all been associated with early-onset anxiety disorders. Although genetic factors likely play a significant role, early experiences, many of which are family-based, may play an important role in the onset of childhood anxiety disorders. Methods to sort the various contributions of genetics, temperamental and biologic vulnerabilities, and family or environment are often confounded. However, it is likely that genetically based, temperamental, or biologic vulnerabilities

predispose affected children and their parents to interact in ways that either protect children from or predispose children from developing an anxiety disorder. For example, children with separation anxiety raised by a presently anxious parent may differ in outcome from children with separation anxiety raised by parents whose anxiety is well controlled. Although in both situations, the child and the mother share genetic, temperamental, and biologic vulnerabilities, the effect of the child's anxiety on the affected (and treated) parent and the affected (and treated) parent's impact on the child may account for significant differences in both short- and long-term outcomes.

Twin studies provide perhaps the greatest evidence for the role of biologic and environmental factors (shared and nonshared) in the etiology of childhood anxiety disorders. Although historically both genetic and environmental factors have been implicated in the etiology of childhood anxiety disorders, a large well-designed study of 6-year-old twins suggests significant genetic influence for the separation anxiety phenotype. The heritability estimate for separation anxiety was high, 73%, with the remaining variance attributed to nonshared environment, suggesting genetic effects on separation anxiety are substantial and more significant than environmental effects. Another investigation of the role of genetic and shared environment effects in a sample of twins and siblings over time reported that the influence of genetic effects increased and shared environmental effects decreased with age. Finally, newly emerging data suggest that the psychobiologic trait of CO_2 hypersensitivity may increase risk for separation anxiety (and supports a proposed genetic association between separation anxiety and later-onset panic disorder).

Behavioral inhibition (BI) to the unfamiliar, characterized by fear, withdrawal, and avoidance of unfamiliar situations or things, is considered a temperament vulnerability in infants and toddlers that predicts anxiety disorder outcomes in later childhood. BI is usually assessed using observational methods in laboratory settings for children aged 9 months through 6 years. Approximately 10% to 15% of children are thought to display BI and longitudinal outcomes,

suggesting young children with BI are more likely than uninhibited children to exhibit clinical levels of multiple anxiety disorders including separation anxiety upon long-term follow-up. In cross-sectional studies, BI is associated with a range of anxiety symptoms and disorders in youth, and it has traditionally been considered a vulnerability that lacks specificity for any childhood anxiety disorder. However, longitudinal data found BI to predict *social anxiety disorder (SAD)* in middle childhood, but not other anxiety disorders.

Parental psychopathology is also highly associated with childhood anxiety disorders. Multiple pathways are operative in linking parent and child well-being. Parents and children may share the same genetic or temperamental vulnerability. Anxious parents are likely to model anxiogenic thoughts and behaviors that are readily adopted by their children. Bidirectional influence may also be operative inasmuch as anxious youth may pull for adults in their environment to maintain proximity and support. Regardless of the mechanism, children of parents with an anxiety disorder are up to five times more likely to be diagnosed with an anxiety disorder. More specifically, parental panic disorder and major depression are associated with an increased risk for separation anxiety disorder in children.

Longitudinal studies examining the role of infant–mother attachment in the development of childhood anxiety often used the Ainsworth Strange Situation to assess attachment and then follow children over time. In multiple studies, children with an anxious or resistant attachment during infancy were more likely to develop anxiety disorders than were securely attached infants. Although infant temperament or maternal psychopathology may affect attachment behavior, cross-sectional assessment of attachment status appears to be the more important factor in determining the presence of anxiety disorders at longer-term outcome.

Several decades of research identify a common set of parenting behaviors found among parents of anxious youth. These include high levels of symptom accommodation, parental intrusiveness, overprotection, and psychologically controlling behavior in the child's daily activities. Such anxiety-enhancing parenting approaches are thought to promote dependency and reduce the development of

autonomy. Controlling and overprotective parenting may contribute to the development of anxiety by preventing the child from having a range of experiences that foster broad and complex coping skills. Furthermore, parental overprotection may communicate to the child that the world is a dangerous place, introducing a chronic and pervasive response bias. Parents may also support anxious behavior by encouraging anxious cognitions and avoidance in their children or children may mimic anxious cognitions and behaviors modeled by their parents.

Diagnosis and Clinical Features

The defining feature of separation anxiety is excessive and persistent worry about harm befalling an attachment figure (e.g., parent getting into car accident, spouse becoming ill or dying) or oneself (e.g., getting lost, being kidnapped, having an accident) upon separation. Symptoms may include avoidant behaviors such as refusal to go to school or work, sleep alone, or be without the attachment figure, in order to minimize separation and to reduce distress. Other common symptoms include nightmares with references to separation, and physical symptoms such as stomachaches or nausea in response to possible or actual separation. DSM-5-TR requires three of eight symptoms, a duration of 4 weeks in children and adolescents, and corresponding functional impairment. The diagnosis can be made in adults who are typically excessively concerned about their spouses or children and symptomatic for at least 6 months.

At home, children with separation anxiety frequently shadow their caregivers. They often are reluctant to be in any room alone and may not want to sleep alone in their bedroom. These children often request a parent to fall asleep with them or find their way to their parent's bed at night. They are uncomfortable staying with babysitters and may call or text parents frequently. In public, children with separation anxiety stay close to their caregiver and prefer to sit on their lap or be in physical contact. They are reluctant or refuse to attend birthday parties, sleepovers, camps, and extracurricular

activities if the attachment figure is not present. Somatic complaints, especially gastrointestinal (e.g., stomachaches, nausea) and cardiovascular (e.g., pounding heartbeat, light-headedness) are commonly reported, particularly before other anxiety-provoking separations. Children may show their separation anxiety distress with tantrums or becoming panicky or oppositional when anticipating separation.

At school, the child may make repeated requests to call their parents to check in or visit the school nurse with physical complaints. When children experience anxiety at school they may become restless and fidgety and be so preoccupied that they are unable to attend to classroom work. Separation anxiety disorder is also a common cause of school refusal and may result in frequent tardiness or high numbers of school absences.

Younger children, in comparison to adolescents, with separation anxiety disorder tend to report a greater number of symptoms and more nightmares with separation themes. Some older children and adolescents with separation anxiety may not present obvious impairment or distress, as their parents and school find ways to accommodate the child's fears to decrease their distress.

As separation anxiety not only affects the child, disruption of family life or parent stress may result from accommodating and managing the child's anxious and avoidant behavior. It can be helpful in the assessment to attempt to quantify the amount of accommodation and to ascertain what the anxiety severity would be if the parents did not offer ongoing accommodation around the child's anxiety.

Posey is a 9-year-old Latina female living with her biologic parents and sister in a large metropolitan region. She presents for care with her mother, who reports that Posey has rarely, if ever slept in her own bed. Posey's difficulty sleeping in her own bed is disrupting family life as evidenced by parents who are losing sleep and coparenting/family conflict that has increased. At a recent slumber party, Posey began to complain of a stomachache, asking her host to call her mother to take her home. She reported being embarrassed that she had to leave her friend's house, but that she "needed" to be with her parents. Upon interview, Posey reports that she worries about the safety of her family ("something bad" happening to her parents) and that when she does not sleep near or with her parents, she has nightmares that someone will "break in and hurt them." She reports associated difficulty sleeping, and a near-constant level of stress when not in the presence of both parents. Both parents describe her as clingy and note that she needs them to stay present at extracurricular activities like soccer and piano.

Differential Diagnosis

Separation anxiety disorder can be distinguished from developmentally normal separation anxiety based on its onset or increasing severity in the school-age years, the duration of symptoms, and the degree of impairment or distress or need for parental accommodation.

Separation anxiety should also be differentiated from other emotional and behavioral disorders. Children with separation anxiety, generalized anxiety, and obsessive-compulsive disorder (OCD), all have concerns about harm. Children with separation anxiety worry about events that lead to being apart from an attachment figure. Children with generalized anxiety are more fearful of the actual event such as a dog bite, lightning striking, or getting sick than the impact on separation. Children with OCD have repetitive intrusive and senseless thoughts of harm befalling them or their loved ones if they

do not complete a ritual. Children with separation anxiety may have social avoidance (e.g., parties or school) similar to children with SAD, generalized anxiety disorder (GAD), OCD, or even post-traumatic stress disorder (PTSD), but the rationale for the avoidance will differ for each of the disorders. Children with separation anxiety may be described as panicking upon separation or anticipation of separation, but the panic is distinguished from spontaneous panic attacks that characterize panic disorder.

Finally, children with separation anxiety may exhibit defiance, irritable or labile mood, and explosive behavior when presented with a situation that involves separation. These behaviors or moods should be distinguished from oppositional defiant disorder, which involves more general patterns of argumentativeness and misbehavior, and from bipolar disorder, which has prominent elevation in mood, decreased need for sleep, grandiosity, and increased goal-directed activities.

Course and Prognosis

The course of separation anxiety is not consistent for all children. Multiple rigorous prospective studies suggest that the majority of children with separation anxiety improve with time. Indeed, some appear to spontaneously remit while some see symptoms and impairment gradually wane. For others, separation anxiety symptoms persist over time and transfer to other close relationships. In still other cases, symptoms of separation anxiety resolve but are replaced with symptoms of another anxiety disorder. In some cases of separation anxiety, affected individuals may see symptoms evolve into more adult patterns of anxiety or depression. Prospective, longitudinal studies including both community and high-risk samples have found that those meeting DSM-IV criteria for separation anxiety disorder were at an increased risk of developing subsequent panic disorder with agoraphobia, specific phobia, GAD, OCD, pain disorder, and alcohol dependence, even after controlling for the risk of parental psychopathology. Other meta-analyses indicate an

increased risk for all anxiety disorders, but less evidence for elevated risk for depression and substance use.

SOCIAL ANXIETY DISORDER

Definition

SAD, also called social phobia, is characterized by excessive, persistent, and impairing anxiety about potential embarrassment or catastrophic humiliation in social or performance situations. The worry may be restricted to a specific performance situation such as fear of being negatively evaluated during an athletic or musical performance. However, SAD is more commonly generalized such that worry about being scrutinized or embarrassed occurs across a range of activities and situations.

Comparative Nosology

SAD (social phobia) first appeared in DSM-III, with minimal alterations in subsequent editions. One impactful change from DSM-III to DSM-IV was the removal of the diagnosis of avoidant disorder. Avoidant disorder was classified as an anxiety disorder of childhood or adolescence, and characterized by fear and avoidance of strangers resulting in significant impairment in peer relationships. Concern about the overlap between the two disorders and the continuity between childhood avoidant disorder and adult SAD resulted in the removal of avoidant disorder as a diagnostic category in DSM-IV. In DSM-5 (continued in DSM-5-TR), there is no longer a requirement that individuals over age 18 must recognize their fear as excessive and unreasonable; instead, the anxiety must be out of proportion to the actual threat posed by the event after taking into account sociocultural factors. Whereas the 6-month duration was limited in DSM-IV to individuals under age 18, this criterion now applies to all ages. Finally, unlike DSM-IV, there is no longer a specifier for “generalized” but there is a specifier for “performance only” in DSM-5-TR.

Epidemiology

Social anxiety is a common anxiety disorder, with a cumulative incidence of 11%. Prevalence rates have increased over time, likely because of the removal of the avoidant disorder diagnostic category from DSM-III to DSM-IV; that is, youth who were once characterized with avoidant disorder are now diagnosed with SAD, resulting in increased prevalence rates. According to data from the National Comorbidity Survey Replication Adolescent Supplement and the Early Developmental Stages of Psychopathology Study (EDSP), the 12-month prevalence for adolescents is 5.2% to 8.2%. The lifetime prevalence of social anxiety is 9.5% for females and 4.9% for males. Like generalized anxiety, the prevalence of SAD increases with age, possibly reflecting changes in cognitive and emotional development (i.e., the capacity for self-evaluation and self-consciousness).

Age of onset for SAD is during adolescence. The average age of onset in epidemiologic studies is between 10 and 16.6 years and varies depending on the sample studied and the strategy for determining retrospective reports for the age of onset. According to the EDSP which involved a community sample of 3,021 individuals aged 14 to 24 years, the incidence of DSM-IV social anxiety was greatest among those aged 10 to 19 years.

Etiology

Similar to both separation anxiety disorder and GAD, factors that contribute to the development of SAD include genetics, temperament, and family variables. Twin studies are useful in distinguishing between environmental and genetic influences. There are many discrepancies in the literature regarding the contributions of genetic and environmental influences because of differences in measurement (i.e., rating scale vs. psychodiagnostic interviews), informants (i.e., self vs. parent reports), and criterion (i.e., symptoms vs. severity vs. clinical diagnosis). However, the literature is consistent in showing that anxiety disorders are heritable and that both shared and nonshared environmental factors also play a role. Concordance rates for anxiety disorders including SAD are higher for

monozygotic twins than dizygotic twins (34% vs. 17%). Familial transmission is also evident by studies showing a high concordance rate of social anxiety among first-degree relatives. Overall, studies investigating genetic transmission find evidence for an inherited propensity toward anxiety in general rather than for a specific type of anxiety.

As discussed earlier, BI is a temperamental construct characterized by increased physiologic reactivity and avoidant behavior in the face of novel or challenging stimuli. Inhibited children have greater sympathetic activation than uninhibited children, evidenced by higher and more stable heart rates and greater heart-rate acceleration under stressful and novel conditions. Many studies support the existence of a specific link between BI and social anxiety. Both longitudinal and retrospective studies show that toddlers with BI assessed by observational or questionnaire methods are more likely than uninhibited children to exhibit social anxiety as adolescents. In a recent prospective longitudinal study, 215 children assessed for BI were assessed for psychiatric outcomes in a 5-year follow-up at a mean age of 9.6 years. Structured diagnostic interviews revealed that BI present at age 4 or 6, but not at age 21 months, predicted social anxiety. BI was not associated with other specific anxiety, mood, or behavior disorders. In another study, adults from a clinical sample provided retrospective reports of childhood inhibition, and those with the highest levels of inhibition also had the highest levels of clinical SAD. It is important to note that less than 50% of toddlers and young children characterized as behaviorally inhibited go on to develop SAD. Similarly, children who are considered shy or have shy temperaments most likely do not develop SAD. Thus, BI is considered a manifestation of a biologic predisposition that serves as a risk factor for anxiety.

Environmental variables such as parent–infant attachment and parenting behaviors also are associated with the expression of SAD. As stated in previous sections, retrospective and observational research shows links between insecure infant attachment and the development of anxiety disorders. One study examined 172 adolescents 16 years after participating in the Ainsworth Strange

Situation test at age 12 months and confirmed that infants with insecure attachments were more likely to meet criteria for anxiety, including SAD. Adult parents with SAD may sponsor social isolation by discouraging opportunities for social engagement. They also provide information that has the potential to heighten anxious arousal.

Diagnosis and Clinical Features

The defining feature of social anxiety is excessive fear about being scrutinized in social or performance situations (Table 51.3–2). Although the same criteria apply to children and adults, some provisions are indicated for children. First, social anxiety cannot be limited to adult settings and must occur in peer contexts. Second, in children, the anxiety evoked by the social situation may involve crying, tantrums, freezing, or shrinking from social situations with unfamiliar people. Common fears related to social anxiety include public speaking, participating in class, initiating or participating in conversations, attending social events, and eating or writing in front of others. Fear of public speaking is considered the most commonly feared social situation; however, test anxiety is commonly feared among adolescents.

Table 51.3–2.
DSM-5-TR Diagnostic Criteria for Social Anxiety Disorder

A. Marked fear or anxiety about one or more social situations in which the individual is exposed to possible scrutiny by others. Examples include social interactions (e.g., having a conversation, meeting unfamiliar people), being observed (e.g., eating or drinking), and performing in front of others (e.g., giving a speech).
   Note: In children, the anxiety must occur in peer settings and not just during interactions with adults.
B. The individual fears that he or she will act in a way or show anxiety symptoms that will be negatively evaluated (i.e., will be humiliating or embarrassing; will lead to rejection or offend others).
C. The social situations almost always provoke fear or anxiety.
   Note: In children, the fear or anxiety may be expressed by crying, tantrums, freezing, clinging, shrinking, or failing to speak in social situations.
D. The social situations are avoided or endured with intense fear or anxiety.
E. The fear or anxiety is out of proportion to the actual threat posed by the social situation and to the sociocultural context.
F. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.
G. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
H. The fear, anxiety, or avoidance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
I. The fear, anxiety, or avoidance is not better explained by the symptoms of another mental disorder, such as panic disorder, body dysmorphic disorder, or autism spectrum disorder.
J. If another medical condition (e.g., Parkinson's disease, obesity, disfigurement from burns or injury) is present, the fear, anxiety, or avoidance is clearly unrelated or is excessive.

Specify if:

Performance only: If the fear is restricted to speaking or performing in public.

Some differences have been noted with respect to the presentation of social anxiety among different age groups. Adolescents endorse anxiety across a broader range of situations and more avoidance compared to children; however, both groups experience similar levels of distress. In addition, adolescents endorse more cognitive symptoms of social anxiety that likely reflect their greater cognitive maturity compared to children. Poor social skills, however, are evident across all youth with SAD.

Infants and toddlers cannot meet DSM-5-TR anxiety diagnosis guidelines primarily due to developmental issues; however, many very young children exhibit higher than normal levels of social fear and associated distress. For example, some children have difficulties playing with new children, refuse to participate in playgroups and classes, play alone at parties or on the playground, and refuse to eat in restaurants or attend public events because of severe distress. Some pilot data reveal that children aged 18 months to 5 years can be diagnosed with a modified version of SAD and are more likely than their nonanxious counterparts to display high levels of shyness, inhibition, and to have anxious parents. Many preschool-aged children meet DSM-5-TR criteria for selective mutism which involves restricted speech in social situations due to high levels of fear and anxiety.

John is a 16-year-old Caucasian male who lives with his biologic mother in a suburban area. He presents for care after experiencing an “anxiety attack” when asked to answer a question in class last week. Upon interview, John reported that he was randomly selected by his teacher to answer a difficult math question, at which point he “locked up,” began breathing heavily, and refused to respond. Upon further interview, he reported that he never raises his hand in class because “if I get the answer right, people will think I’m a nerd, and if I get the answer wrong people will think I’m stupid.” He reports that similar worries (e.g., being seen as weak or stupid) have stopped him from trying out for the football and soccer teams, as well as the debate club. He reports having few friends outside of his childhood friends, and his mother tells you she is worried that he is missing out on the high school experience.

Differential Diagnosis

SAD can be distinguished from other disorders based on the predominant feature that fears center around the potential for embarrassment or receiving negative criticism. Although social anxiety and separation anxiety may both involve avoidance of social situations, the fear with separation anxiety is associated with concern about being apart from a caregiver and is not associated with potential humiliation or embarrassment. The generalized type of social anxiety is differentiated from GAD on the basis of the individual feeling humiliated or embarrassed in public rather than a more global worry. Also, children with GAD may worry about a host of social issues (e.g., friendships, performance, how others view them), but worries are not limited to social or performance situations. Although individuals with SAD may experience panic in the face of challenging situations, the fear and associated somatic and cognitive symptoms occur in response to specific situations and are not unexpected or uncued as they are in panic disorder.

Social anxiety is also distinguished from selective mutism, which is characterized explicitly by a failure to speak in situations where speech is expected and has a much younger age of onset relative to SAD. Selective mutism is considered by some professionals to be a developmental variant of social anxiety.

Finally, it is important to distinguish SAD from developmentally normal fears. For example, it is not uncommon for children to be anxious about speaking in front of the class. However, normative anxiety does not result in significant impairment in functioning or clinically significant distress as with SAD.

Course and Prognosis

SAD that emerges by the early teen years is associated with progressive worsening or persistence of symptoms through early adulthood. Late adolescence is characterized by a waxing and waning course during which symptoms are exacerbated by social stressors. Factors associated with persistence of symptoms include early onset, more anxiety cognitions, severe avoidance and impairment, co-occurring panic, parental social anxiety and depression, BI, and harm avoidance.

Few individuals experience spontaneous remission; data from the prospective longitudinal EDSP study suggest a natural remission rate of 15.1%. Individuals with SAD withdraw from or avoid situations, limiting opportunities for optimal social, academic, and emotional development. Research shows that children with SAD are less socially skilled than their nondisordered counterparts, limiting their capacity to form intimate relationships with friends, family members, or partners. Symptoms and impairment at school may result in academic underachievement, including failure to graduate high school or pursue college. Disabilities in educational and social functioning may lead to demoralization and other emotional problems. Longitudinal studies show, for example, that SAD is consistently linked with increased risk for subsequent depression. Further, individuals with comorbid social anxiety and depression are at increased risk for suicidal ideation and suicide attempts.

Several longitudinal studies find that SAD is associated with the development of substance use problems. For example, one prospective study based on a subsample of 816 individuals from the Oregon Adolescent Depression Project found that SAD is a unique risk factor for the subsequent onset of alcohol and cannabis dependence. Specifically, a lifetime history of SAD at age 17 was associated with 4.5 times greater odds of alcohol dependence and 6.5 times greater odds of cannabis dependence by age 30. Also, results from a different prospective study showed that youth with SAD were significantly more likely 4 years later to smoke cigarettes and have a higher rate of nicotine dependence than a control group.

GENERALIZED ANXIETY DISORDER

Definition

In contrast to separation and social anxiety, which generally have one anxiety-triggering experience (i.e., separation and social humiliation, respectively) or focal fear, GAD is characterized by excessive and uncontrollable worry about a diffuse set of events. These events are often future oriented and center on possible poor outcomes related to school, friendships, health, and world events. In addition, for many youths, generalized anxiety focuses on living up to an internal standard (in school, friendships, extracurriculars) that is difficult to meet. Symptoms of this disorder occur with frequency and are experienced as difficult to stop. In addition, affected youth may report poor concentration, restlessness, and irritability, but other symptoms include fatigue, sleep disturbance, or muscle tension. As with other anxiety disorders, generalized anxiety must cause marked distress, interfere with social, emotional, and educational functioning, and is not simply a reaction to recent stressors.

Comparative Nosology

Prior to DSM-IV, a diagnosis of generalized anxiety was reserved for individuals 18 years or older, and children with multiple fears and worries could be diagnosed with overanxious disorder. Overanxious

disorder was characterized by excessive or unrealistic worry for a period of at least 6 months. Due to the poor reliability and validity of this diagnostic category and symptomatic overlap and continuity with adult generalized anxiety, overanxious disorder was incorporated into the DSM-IV GAD diagnosis. Research comparing cases diagnosed by DSM-III-R and DSM-IV criteria found that the change in terminology did not affect the characteristics of cases. Criteria remained unchanged for DSM-5 or DSM-5-TR.

Epidemiology

GAD is a common diagnosis in children, with a reported lifetime prevalence of 9.0%. Community samples of preschool children report a prevalence range of 0.5% to 6.5% for overanxious disorder or GAD. Based on data from two community epidemiology studies, the 3-month prevalence rate for GAD among children aged 9 to 12 is 1.4%. The prevalence for adolescents aged 13 to 18 years ranges between 2.3% and 5.0%. Whereas rates of separation anxiety decline with age, rates of generalized anxiety increase with age, with a mean age of onset of 8 to 9 years, and median age of onset of 12 years. Girls are twice as likely as boys to meet diagnostic criteria.

Pediatric GAD is commonly associated with other anxiety disorders and mood disorders. Data from the National Comorbidity Study—Adolescent Supplement (NCS-A) and Great Smoky Mountains Study (GSMS) found that up to 2/3 of affected youth met criteria for another anxiety disorder, and about half met criteria for a mood disorder. Preschoolers with generalized anxiety have the highest rates of comorbidity compared to preschoolers with other anxiety disorders. Few significant differences in rates and patterns of comorbidity across age and gender have been identified; younger children are more likely than adolescents to have separation anxiety as a comorbid diagnosis, and males are more likely than females to have an externalizing disorder as a co-occurring diagnosis.

Etiology

Similar to the other anxiety disorders, both genetic and environmental factors contribute to the development of GAD. However, heritability estimates are lower for generalized disorder (approximately 30%), suggesting that environmental factors, both shared (e.g., uterine environment in the case of twins, exposure to common parenting in the case of siblings) and nonshared (e.g., personal traumatic experience, peer relationships), may have a more prominent etiologic role. Twin studies show that generalized anxiety may be better explained by additive genetic factors and nonshared environmental factors compared to shared environment factors. Low heritability estimates in twin studies and high familial rates of generalized anxiety suggest that increased rates in families may be more related to environmental factors. For example, parental anxiety, parenting approaches, or exposure to stressful life events may negatively affect childhood anxiety outcomes. Similarly, childhood anxiety may also impact parental or sibling anxiety as the child's anxiety may change the larger home environment.

Anxiety sensitivity is a temperamental or trait-like factor under genetic influence that is considered a risk factor for anxiety in general. It is characterized by a tendency to interpret physiologic symptoms as a sign that something harmful will result. Such factors, while not specific to anxiety, may predispose children in certain environments to become symptomatically more anxious and impaired. Similarly, an attentional bias toward threatening cues and a tendency to interpret ambiguous situations as threatening are associated with children with current anxiety disorder. Although such relationships cannot be considered causal, it is possible that such attentional biases coupled with environmental variables such as parenting influences (e.g., hearing information from a parent about the potential dangers of a situation) may ultimately shape anxiety-related beliefs and behaviors. Anxiety sensitivity has been related specifically to panic in adolescents and otherwise has been linked to anxiety in general.

Diagnosis and Clinical Features

The hallmark feature of GAD is excessive worry that is difficult to control (Table 51.3–3). The threshold for diagnosis differs slightly for adults and children; adults are required to experience three of six associated symptoms, whereas children are required to have only one associated symptom. A diagnosis also requires the child to experience excessive worry more days than not for 6 months, the worry and associated symptoms must interfere with daily functioning, and the anxiety is not triggered by recent stressful events.

Table 51.3–3.
DSM-5-TR Diagnostic Criteria for Generalized Anxiety Disorder

A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).

B. The individual finds it difficult to control the worry.

C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms having been present for more days than not for the past 6 months):

Note: Only one item is required in children.

1. Restlessness or feeling keyed up or on edge.
2. Being easily fatigued.
3. Difficulty concentrating or mind going blank.
4. Irritability.
5. Muscle tension.
6. Sleep disturbance (difficulty falling or staying asleep, or restless, unsatisfying sleep).

D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

E. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism).

F. The disturbance is not better explained by another mental disorder (e.g., anxiety or worry about having panic attacks in panic disorder, negative evaluation in social anxiety disorder, contamination or other obsessions in obsessive-compulsive disorder, separation from attachment figures in separation anxiety disorder, reminders of traumatic events in posttraumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder).

The vast majority of pediatric patients with generalized anxiety (75% to 80%) endorse physical symptoms. Common physical symptoms include headaches, tension, restlessness, gastrointestinal distress, and heart palpitations. Cognitive characteristics of generalized anxiety include negative thinking errors such as catastrophizing (i.e., expecting the worst possible outcome) or overestimation of the likelihood that something undesirable will occur. Generalized worries cover a range of everyday issues, such as being on time, upcoming activities, failure of loved ones or friends to meet basic expectations, or whether unexpected events (e.g., inclement weather) will change daily plans or schedules. Children and adolescents with generalized anxiety are often described as perfectionistic and overly sensitive. They are plagued by negative self-image, need for reassurance, and insecurities about competence, performance, and expectations about the future.

Jesse is a 14-year-old Black female who lives with her biologic parents and two older siblings in a suburban area. She presents for evaluation with her biologic father complaining of stomachaches, fatigue, and attention difficulties. Upon further interview, her father reports that Jesse has “always been nervous,” and describes numerous domains about which she frequently seeks reassurance, such as whether her family will have enough food to eat and a place to live, the possibility of a natural disaster destroying their home, and whether her grades will get her into a good college. Though her parents provide reassurance related to these worries, she will ask multiple times. She has no history of attention issues and has always been an A student, but she recently has been having difficulty concentrating in class; she reports worrying about many things for most of the day, and that she “can’t stop” the worry. As a result, her grades have become Bs and Cs, which she reports has caused even more worry.

Differential Diagnosis

Worry associated with generalized anxiety has multiple targets that include worries regarding everyday life experiences. Therefore, it may be more difficult to differentiate generalized anxiety from normative anxiety experienced by all individuals. However, the overall amount of anxiety, poor anxiety control, the lack of amelioration with appropriate reassurance and support, and longer-term impairment associated with generalized anxiety differentiate it from normal worry.

Generalized anxiety can be differentiated from emotional disorders based on the greater number of anxiety triggers and the specific nature of the worries. Children with generalized anxiety are concerned with past and future experiences, physical health, weather, environmental changes, and unexpected events. They may appear to have similar concerns to children with separation and social anxiety but differ in important ways. For example, children with

generalized anxiety may avoid going to school, not because of separation or social concerns but because of academic performance worries. That said, it is not uncommon for younger children with GAD to also be diagnosed with co-occurring separation anxiety and older children with co-occurring SAD. Individuals with generalized anxiety and perfectionism may superficially resemble those with OCD. For example, a child with generalized anxiety and concern about academic performance may routinely check over homework for accuracy or study material repeatedly for the purpose of improving the work product or getting it "perfect." In contrast, children with OCD know the work product is good or perfect, but experience doubt that their perception is accurate and then recheck for the purpose of rechecking. In addition, individuals with generalized anxiety may have recurrent uncontrollable worries that could be mistaken for obsessions; however, worries of GAD do not appear senseless, intrusive, or unwanted, rather they are described as powerful bona fide concerns and are usually tied to events or situations that would stimulate normal concerns. For example, normal children may worry about bad weather as it happens, GAD children will worry that bad weather may happen on a cloudless day, and children with OCD may worry that if they do not count to three in sets of three then a loved one may die in a weather-related incident.

Ruminations (i.e., recurrent depressive cognitions) are characteristic of depression and tend to regard experiences negatively and hopelessly. For example, repetitive thoughts such as "No one will like me no matter what I do" can be readily distinguished from "I need to be perfect for my teachers and parents" by identifying the depressive (ruminative) quality of the former and the perfectionistic (generalized anxiety) quality of the latter.

Course and Prognosis

Prospective and cross-sectional studies of youth suggest that GAD is an episodic or recurrent disorder and that prognosis is dependent on comorbidity and severity. Individuals with a comorbid diagnosis tend to have higher ratings of severity and functional impairment.

Those with greater severity and psychosocial impairment at baseline are more likely to retain a diagnosis over time.

Like other anxiety disorders, GAD is considered a risk factor for the development of additional psychiatric problems over time. Specifically, generalized anxiety may lead to the subsequent development of anxiety disorders, substance use, depression, or behavior problems. The New York Child Longitudinal Study investigated the associations between anxiety disorders and later psychiatric disorders in 9- to 18-year-old children and adolescents. DSM-III overanxious disorder was related to subsequent major depression, SAD, and generalized anxiety. Whereas children with separation anxiety symptoms were less likely than other children to begin drinking alcohol and did so later than others, those with generalized anxiety symptoms were more likely than other children to begin drinking and did so earlier. Results from the GSMS found that DSM-IV generalized anxiety was associated only with later conduct disorder but did not predict anxiety or other psychiatric problems.

TREATMENT OF ANXIETY DISORDERS

Both cognitive behavioral therapy (CBT) and antidepressant medications are effective for treating youth anxiety disorders (e.g., GAD and SAD). Expert reviews of the literature and meta-analyses repeatedly affirm the evidence base for both interventions, whether administered alone or in combination.

The Child/Adolescent Anxiety Multimodal Study (CAMS) remains the largest double-blind, placebo-controlled trial for child and adolescent anxiety disorders. The CAMS compared the relative efficacy of CBT, sertraline, combination therapy (CBT plus sertraline), and placebo for n = 488 youth with GAD, separation anxiety disorder, and/or SAD. All active treatments were superior to placebo, and combination therapy led to significantly higher response rates than CBT or sertraline (81% vs. 60% vs. 55%, respectively). Remission rates (loss of principal diagnosis, loss of all anxiety diagnoses) ranged from 20% to 68% and followed the same

patterns as response rates based on treatment condition. Factors associated with better response and remission rates in the CAMS included the absence of comorbid internalizing disorders, absence of SAD at baseline, lower baseline anxiety symptom severity, lower caregiver strain, nonminority status, and younger age. A recent paper using CAMS data goes further to suggest that youth with mild–moderate anxiety benefit most from CBT monotherapy, whereas those with more severe illnesses may be best served by beginning with combined treatment.

Beyond acute and short-term follow-up of anxious youth, there has been considerable interest in understanding how these youngsters fare over time, particularly when they have had the benefit of evidence-based treatment. To address this question, youth who participated in the CAMS trial were followed as part of a prospective longitudinal study as they entered early adulthood (Child/Adolescent Anxiety Multimodal Treatment Extended Long-term Study; CAMELS). On average, youth were recontacted approximately 6 years following their CAMS treatment and followed for another 4 years. Findings from CAMELS suggest that roughly 20% of youth treated in CAMS remained consistently remitted over time as they entered early adulthood. Roughly half exhibited a fluctuating course marked by intermittent relapse. The remaining 30% were chronically ill, with anxiety disorder evident at every time point. These findings speak to the persistent nature of anxiety and the need to consider models of care that integrate chronic disease approaches and use surveillance and booster sessions to maintain wellness.

Psychotherapy

Over 50 years of evidence support the effectiveness of exposure-based CBT for youth anxiety. Although there is variability across treatment protocols, they are generally linked by their focus on psychoeducation, emotion identification, somatic management techniques, cognitive restructuring, exposure tasks, and relapse prevention. Traditional individual child treatment typically involves 10 to 20 weekly treatment sessions, and numerous studies support the

use of additional formats, including group, family, brief intervention, and telehealth administration. In this section, we provide a brief synopsis of the evidence base for CBT before shifting to focus on newer trends in psychosocial treatment research for anxiety.

A 2017 study reviewed 100 anxiety treatment outcome studies in children and adolescents. For symptom reduction, CBT (d = 1.19), exposure alone (d = 1.05), modeling (d = 1.42), CBT with parents (d = 1.25), educational interventions (d = 1.26), and CBT with medication (d = 2.37) garnered the most consistent symptom reductions. The review established individual CBT as the most highly supported treatment for improving functioning, with an average within-group effect size of d = 1.76. CBT with parent involvement (d = 1.99), CBT with medication (d = 2.04), and exposure (d = .96) were categorized as having good support and being probably efficacious. These moderate-to-large effect sizes and the durability of treatment effects over time support the conclusion that CBT is an effective treatment for anxiety disorders in children and adolescents. They are bolstered further by findings from a 2019 meta-analysis which included clinical trials from 1963 to 2016 and found a mean posttreatment effect size of Hedges g = .66.

Given the robust evidence supporting the use of CBT, more recent studies have focused on understanding the mechanisms underlying its effects. Research suggests that both cognitive restructuring and exposure practice offer particular benefits during the course of treatment, with the steepest clinical gains observed following the introduction of exposure. Higher doses of exposure practice, more variable distress when practicing, and greater mastery of exposure tasks are all associated with better clinical outcomes. Moreover, contrary to what many may think, exposure practice does not diminish the therapeutic relationship but, indeed, enhances it.

In addition to efforts to optimize CBT by isolating its central ingredients (exposure) and maximizing their effects (via contemporary models of fear learning and extinction), research has also continued to consider factors that affect CBT outcomes. Family dynamics remain central, given their common links to youth anxiety and the identification of well-specified targets (e.g., symptom

accommodation, overcontrol). Research consistently suggests that family-focused treatment is efficacious for youth anxiety; however, its additive value beyond individual child treatment remains a subject of some debate. This is likely due to methodologic issues across studies, including if/how putative family mechanisms are specified, how interventions map to specific family targets, and whether measurement approaches allow for tracking of family change and mechanistic effects. Certainly, there is emerging evidence from separate research groups that parent-only interventions may be comparable to child-focused CBT for anxiety.

A few somewhat distinct approaches to treating youth anxiety merit mention. First, parent–child interaction therapy (PCIT), originally developed to treat externalizing problems in young children and to treat various early anxiety problems, has been modified and adapted with success for youth anxiety. This approach targets child symptoms by reshaping parent–child interaction patterns associated with the maintenance of child anxiety symptoms. This goal is achieved through the use of live, unobtrusive parent coaching, delivered through a bug-in-the-ear receiver from a therapist situated behind a one-way mirror. Recently, the first randomized controlled trial (RCT) was conducted to test the efficacy of a 9-week PCIT treatment for separation anxiety in children aged 4 through 8 years. At posttreatment, 73% of children assigned to PCIT no longer met the criteria for a diagnosis of SAD, and results were largely maintained at a 3-month follow-up visit. Preliminary efficacy studies of another PCIT adaptation, the Coaching Approach behavior and Leading by Modeling (CALM) Program, designed to target the full range of anxiety disorders affecting young children (GAD and SAD, in addition to separation anxiety disorder) suggest the promise and feasibility of this approach.

A separate approach has focused on CBT adaptations designed particularly for social phobia, recognizing that this particular condition moderated the outcome in the CAMS trial. In a comparative treatment trial, children and adolescents aged 7 to 17 years were randomly assigned to Social Effectiveness Therapy for Children (SET-C, a behavioral approach), fluoxetine, or placebo. Results

revealed both active treatments to be superior to placebo in reducing social distress and behavioral avoidance and increasing general functioning. SET-C, however, was superior to fluoxetine on these outcomes and was the only treatment superior to placebo in terms of improving social skills, decreasing anxiety in specific social interactions, and enhancing ratings of social competence. Although both treatments are considered efficacious, SET-C provides an added benefit by enhancing social skills.

A third innovation comes in the form of efforts to expand access to CBT intervention. Computer-assisted treatments which combine computer-based sessions with online and phone contact with a CBT clinician have been developed. These include protocols such as BRAVE-ONLINE and Camp-Cope-A-Lot. Preliminary trials of these programs, including one RCT, suggest that computer-assisted and in-person CBT produce statistically similar clinical improvements. Given the initial promising findings and the capacity of computer-based CBT to increase treatment accessibility, these programs merit continued investigation. Separate from this approach, telehealth CBT has also gained traction, with preliminary evidence that it produces outcomes comparable to clinic-based care.

Finally, technologic advances are also being integrated into treatment with the goal of enhancing learning and generalization of treatment effects. One such modality uses virtual reality technology to facilitate graded, in vivo exposures. Within this approach, youth are immersed in virtual environments where they interact with clinician-operated avatars to practice socially challenging tasks (e.g., greeting peers, answering questions, and assertiveness skills). The preliminary acceptability and feasibility of this approach have been demonstrated, and further research will assess its efficacy as a stand-alone treatment and adjunct to traditional CBT.

Pharmacology

Antidepressant medications are the mainstay of psychopharmacology of pediatric anxiety disorders. We have grouped the disorders in this psychopharmacology section—as is not

uncommon in research studies (see CAMS trial)—as the treatments are mostly overlapping. Where appropriate, we will highlight key differences between disorders.

In a recent meta-analysis of the impact of antidepressant dose and class on treatment response in children with generalized, separation, and/or SADs, antidepressant-related improvement occurred early in the course of treatment, with approximately 50% of the improvement seen at week 12 occurring by the fourth week of treatment.

SSRIs are considered first-line medications for this population due to the favorable treatment response (effect sizes greater than 0.8) and low side-effect profile identified in a number of single-site and multisite RCTs. Agents that have demonstrated efficacy include fluoxetine (Prozac), sertraline (Zoloft), escitalopram (Lexapro), paroxetine (Paxil), duloxetine (Cymbalta), venlafaxine (Effexor), and fluvoxamine (Luvox). There is some data to support the use of tricyclic antidepressants (TCAs), including imipramine (Tofranil), but given the higher potential side effect burden, these are less commonly used.

Despite the demonstrated efficacy of SSRIs for anxiety in RCTs, no SSRIs are approved by the U.S. Food and Drug Administration (FDA) for use with children and adolescents. Published trials specifically targeting generalized anxiety included one effectiveness trial with sertraline and two trials—one positive and one negative—with venlafaxine (Effexor), which were combined and published together. More recently, duloxetine was found to be effective in a large, industry-sponsored, randomized, placebo-controlled trial of children and adolescents 7 to 17 years old with GAD leading to the first FDA indication of any medication for a non-OC, non-PTSD anxiety disorder in children and adolescents.

There have been three studies that have assessed the efficacy of antidepressants in SAD—two industry-sponsored trials and one federally funded study. Venlafaxine extended-release preparation was found to be more effective than placebo in a large sample of children and adolescents (n = 293) aged 8 to 17 years. Paroxetine was found to be more effective than placebo in a large sample (n = 322) of children and adolescents aged 8 to 17 years. Finally, the only

federally funded study that assessed an SSRI, fluoxetine, and found it to be more effective than placebo was the SET-C study described above.

Open-label follow-up studies of SSRIs suggest that youth who benefit acutely continue on a positive trajectory for up to 6 months. Further, since anxiety disorders tend to run a chronic course with associated impairment, longer treatment with medication may be justified to support the consolidation of initial gains and prevent the return of anxiety symptoms.

There is no clear data to determine how long to treat children with medication to maximally reduce the chance for a return of symptoms upon medication discontinuation. Therefore, making the decision when to discontinue medication is often determined pragmatically. Treatment for 6 to 12 months after remission in symptoms may provide extended benefit without undue burden and may offer an opportunity to reduce the chance for a return of symptoms after medication discontinuation. However, longer-term treatment may be necessary if children experience a return of symptoms when medication doses are missed or during known trigger points such as the start of school in the fall or after the winter holidays (separation anxiety), grade reports, or final examinations (generalized anxiety), or group activities at school or camp (social). Such tenuous symptom control suggests that continued treatment, dose increases, or more intensive psychosocial treatments be provided to stabilize the patient before considering medication discontinuation. For patients and families who choose to pursue a discontinuation trial, it is important to consider timing. For example, it may be ill-advised to try coming off a previously helpful medication during a time of likely anxiety triggers or when family or medical support is not available (i.e., start of school for separation anxiety or participation in performance activities for generalized or social anxiety).

Although adults with GAD may be treated acutely with benzodiazepines, there are few data to support the efficacy of this class of medications for youth. For example, a small double-blind, placebo-controlled randomized trial of alprazolam (Xanax) for the treatment of pediatric overanxious and avoidant disorders

demonstrated no benefit of medication over placebo. More to the point, benzodiazepines have not been extensively studied for the acute or chronic management of anxiety in children, and while potentially useful at reducing the experience of anxiety, they may lead to both psychological and physical dependence and thus complicate treatment long term. Given the efficacy of SSRIs and other antidepressants for childhood anxiety, benzodiazepines should not be considered as first-line treatment. If used at all, benzodiazepines may be considered for short-term augmentation of antidepressants early in the course of treatment for some highly anxious children.

There is little evidence supporting the use of other medications such as antihistamines, α-adrenergic agonists, or antipsychotics for the treatment of childhood anxiety disorders; however, it is not uncommon to see patients clinically who are treated with such agents to address problems with insomnia related to anxiety. Combining other medications with SSRIs to address anxiety-related insomnia should only occur when antidepressants have been maximally adjusted upward and anxiety and insomnia persist. Then the use of sedating antidepressants is preferred to the use of antihistamines, α-adrenergic agonists, or antipsychotics.

Buspirone (BuSpar), a nonbenzodiazepine, nonantidepressant anxiolytic, is effective in studies of adults with GAD and was evaluated in a large, multisite, industry-sponsored RCT. Although the trial was not published, a report of the negative outcome of the study is available on the FDA website.

Overall, the best evidence supports the use of SSRIs in the treatment of childhood anxiety disorders. The value of the SSRIs probably extends across the class so that medication choice can be based on a number of factors, including evidence of efficacy in high-quality clinical trials, half-life, the risk for drug–drug interactions, any subtle differences in side-effect profiles, and patient, family, and provider preference. SNRIs are also commonly used, bolstered by the FDA indication for duloxetine. The TCAs, which can be effective, have not been consistently able to separate from placebo in larger clinical trials, so they should be considered only as an alternative for

those who have not responded to SSRIs or SNRIs. The value of TCAs in attention-deficit/hyperactivity disorder (ADHD) may make them a second-line choice for children with anxiety disorders and ADHD.

Despite ample evidence for the use of SSRIs and SNRIs in pediatric anxiety disorders, there remains tremendous heterogeneity in response. Nearly two in five patients with anxiety disorders fail to respond to these medications. There is growing awareness that pharmacogenetic factors likely account for some of this variability. Drug-metabolizing enzymes change throughout development, and there is data suggesting that SSRI exposure may be significantly different in children than in adults given the same dose. Though the Clinical Pharmacogenetics Implementation Consortium (CPIC) has published a guideline including dosing recommendations for adults, the same is not yet available in pediatric patients. Larger pharmacogenomics studies in pediatric patients are necessary to build evidence-based guidelines for the use of such data in children and adolescents with anxiety.

Safety. The SSRIs as a class share a number of important side effects that include physical symptoms such as stomachache and headache and can also be associated with changes in behavior such as activation/disinhibition, insomnia, apathy, manic reactions, and the potential for suicidal behavior. Activation/disinhibition (and similar or related symptoms such as akathisia) are quite common in the pediatric population, with a 10% to 15% difference between SSRI and placebo groups. Activation often occurs early in the course of treatment—days after the initial dose or first meaningful dose increase (e.g., sertraline 25 or 50 mg; fluoxetine 10 or 20 mg), and goes away with medication discontinuation. It appears to be more common in younger children and those whose anxiety co-occurs with symptoms of ADHD, autism spectrum disorders, or other early developmental psychopathology. The SSRIs impact sleep in two ways: (1) activation can make it more difficult to fall asleep, and (2) SSRIs disrupt sleep architecture; hence users may recover from anxiety, may experience a restful sleep, but may sleep more lightly,

and experience middle-of-the-night awakenings. At higher doses of the SSRIs, apathy may occur, leaving patients relatively free of anxiety but unmotivated or feeling disconnected from living.

One area of concern to prescribers of SSRIs in anxious children is the induction of a manic reaction that may herald a new and more severe course of illness. However, manic reactions in the acute phase and large-scale RCTs of the SSRIs are exceedingly rare (<1%). Indeed, rates of manic symptoms are low even in longer-term follow-up studies. The concern regarding a manic switch is probably greatest when the anxiety disorder is complicated by problems with impulse control or aggressive behavior suggestive of bipolar disorder. Differentiating a manic reaction from the activation side effect can be challenging but an important distinction. Misdiagnosing an activation side effect as a manic reaction may shift the prescriber away from the antidepressants to the use of antipsychotics and mood stabilizers, neither of which are particularly effective for anxiety disorders. Manic reactions can be differentiated by their presentation, time course of onset, and response to medication discontinuation. Manic symptoms include elevated and expansive mood, grandiosity, decreased need for sleep, and increased goal-directed activities, and symptoms are distinct from the irritability and impulsivity that are commonly seen with activation. Activation occurs early in the course of treatment; manic reactions occur later. With medication discontinuation, activation symptoms decrease in relationship to blood level, whereas manic symptoms may persist and require medication treatment to reduce symptoms.

Finally, the risk of suicidal behavior emerging or worsening during antidepressant treatment is probably the public's greatest concern. A recent meta-analysis suggests that the suicidal behavior risk difference between the antidepressant and placebo in a high-quality clinical trial is <1% with numbers needed to harm of >100 and the number needed to treat in high-quality RCTs in depression (NNT = 3–4 in NIMH-funded trials), OCD (NNT = 5), and the triad of anxiety disorders (NNT = 3). These data, the observed reduction in antidepressant use with the advent of a black box warning, and the subsequent spike in youth suicide gave rise to concerns that the

black box warning may have had unintended negative consequences. While the black box warning on an antidepressant has not been changed, prescribers are regaining comfort in the use of the antidepressants.

The side-effect profiles of SNRIs are similar to the SSRIs but now include symptoms consistent with norepinephrine reuptake, including nausea, and the potential for initial worsening of anxiety (not activation per se), and for heart rate and blood pressure increases. The side-effect profile of TCAs is well known and includes prominent anticholinergic effects, dry mouth, constipation and urinary retention, and noradrenergic effects on cardiac function, elevated heart rate, and orthostatic blood pressure changes, and the potential for prolongation of important cardiac intervals including the QTc.

FUTURE DIRECTIONS

Issues that warrant further clarification pertaining to the treatment of youth with separation anxiety, generalized anxiety, or social anxiety include the identification of moderators of treatment outcome, identification of critical elements of psychotherapy that contribute to the outcome, questions of treatment sequencing, and whether youth who fail to respond to either medication or CBT as their first treatment will respond to the other treatment, strategies for enhancing outcomes and addressing treatment resistance, and elucidating long-term outcomes, particularly following medication treatment.

51.4 Selective Mutism

R. Lindsey Bergman, Ph.D., and Araceli Gonzalez, Ph.D.

Selective mutism (SM) is a childhood behavioral disorder characterized by a persistent failure to speak in one or more specific social situations despite speaking in other situations. Although the syndrome was recognized as long ago as 1877, the disorder (earlier called elective mutism) did not appear in the *Diagnostic and Statistical Manual of Mental Disorders* until its third edition (DSM-III) in 1980. Current conceptualizations of SM emphasize the relationship between considerable social anxiety and the failure or extreme reluctance to speak. In addition, researchers continue to investigate the presence of speech or language anomalies as well as oppositional symptoms among children with SM. Although there has been increased interest related to SM recently, in comparison with many other childhood emotional or behavioral disorders, there is a relative lack of consensus on many issues related to the epidemiology, phenomenology, and treatment of the disorder.

DEFINITION

The DSM-5-TR defines SM as a consistent failure to speak in specific social situations where speaking is expected (e.g., to peers at school), despite speaking regularly in other situations. DSM-5 also specifies that in order for the diagnosis to be assigned, the lack of speech must interfere with achievement or communication, must last at least 1 month (beyond the first month of school), and must not be due to a lack of knowledge or comfort with the language required in a given situation. Finally, DSM-5-TR specifies that the lack of speech cannot be better accounted for by a communication, developmental, or psychotic disorder. Criteria for SM are similar in the *International Statistical Classifications of Diseases and Related Health Problems* (ICD-11).

HISTORY

In the 19th century, the term *aphasia voluntaria* was first noted in the psychiatric literature and was used to describe children who voluntarily chose not to speak in certain situations. Many other terms

including voluntary mutism, speech phobia, suppressed speech, functional mutism, and speech avoidance have also been used to describe children who meet the current criteria for SM. The term *elective mutism* was first used in 1934 and appeared in DSM-III in 1980. Some believed that descriptors such as “voluntary” and “elective” that appeared in these early terms suggested a volitional choice to refrain from speaking, and possibly, an oppositional attitude. This attitude was also reflected in the DSM-III definition of elective mutism, which contained a reference to a “refusal” to speak in the definition of SM. In DSM-III-R, elective mutism was renamed SM, perhaps reflecting shifting conceptualizations of the disorder such that attention was more focused on social anxiety as opposed to oppositional or volitional aspects of the nonspeaking behavior.

COMPARATIVE NOSOLOGY

Consistent with the shifting conceptualization described above, SM was reclassified as an anxiety disorder in the current edition of the DSM (DSM-5) and its text revision (DSM-5-TR). In the DSM-IV, SM was included in the section Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence. In the DSM-5, disorders within that category were reorganized into different categories and SM is now included as an anxiety disorder. This reclassification of SM in the Anxiety Disorders section of the DSM-5 is a logical fit given growing evidence for the phenomenologic similarities between SM and social anxiety (see Etiology section). However, the nature of relationship between SM and social anxiety is complex and requires further research as discussed below. Other than the relocation of the SM diagnosis from Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence to the Anxiety Disorders section, the diagnostic criteria for SM are virtually identical in the DSM-IV and -5. Interestingly, a diagnosis of SM does not require the presence of fear or anxiety.

The disorder is called SM in the current (11th) edition of the ICD. In the ICD-11, SM appears in the section of Anxiety or fear-related disorders.

EPIDEMIOLOGY

SM prevalence rates vary by study but have been generally below 1%. Few community-based prevalence studies have been published and the majority of this work was completed in European samples. These studies have yielded disparate findings due to different sampling strategies and definitions of SM. A U.K. study identified 0.69% of 4 to 5 year olds as completely mute (i.e., not speaking at all) at school. However, this rate dropped to 0.08% after approximately 8 months of school. Another survey, also in the United Kingdom, identified only 2 of 3,300 (0.06%) 7 year olds as selectively mute at 36 months of age. More recent investigations have focused on the school environment to investigate the prevalence of SM. Two Scandinavian surveys found teacher-reported rates of DSM-IV-TR SM of 0.18% and 1.9%, respectively, and another study with Irish primary school children aged 4 to 12 years also found a prevalence rate of 0.18. One U.S. study surveyed kindergarten, first-, and second-grade classrooms in an urban public school district and reported a DSM-IV-TR SM prevalence rate of 0.71% (16 of 2,256). A study in Israel yielded comparable results with a prevalence rate of 0.76. Another clinic-based study in the United States found a prevalence rate of 0.50% in a primary care clinic. These studies provide evidence that the point prevalence rate for SM is comparable to rates of other childhood psychiatric disorders, including obsessive-compulsive disorder (0.5% to 1%) and major depressive disorder (0.4% to 3%).

Overall prevalence does not seem to vary markedly by sex or race/ethnicity; however, there is evidence that slightly more girls than boys seem to be affected by SM, with an average reported female-to-male ratio of 1.2 to 1. There is some evidence to suggest that this gender difference may become more pronounced among older children. Although it is commonly reported that children with SM show significant symptoms from the age at which they spoke fluently, with the age of onset typically reported from 2 to 5 years old, SM is often not noticed until the time of entry into school. It has also been reported that immigrant and bilingual or language minority children

are at higher risk of SM, and the prevalence of the disorder may be three times higher in these populations. However, this required further study, and it should be noted that SM must be distinguished from a nonverbal period that is sometimes observed in children during second-language acquisition.

ETIOLOGY

The conceptualization of SM has undergone a considerable shift in recent decades. At this point in time, evidence suggests that SM results from multiple developmental pathways involving the complex interplay of genetic, neurobiologic, temperament, and behavioral (e.g., avoidance) variables. Previously, it was often suggested that SM was related to a variety of conditions including oppositionality, trauma, or family neuroses. While a variety of psychological and developmental factors likely play a role, there is a general consensus that SM is closely related to anxiety, and social phobia in particular. Children with SM and/or social phobia tend to exhibit similar levels of nonverbal social anxiety, trait social anxiety, and cortisol reactivity to a presentation task. The body of work is consistent with a conceptualization that SM is a developmental variant or precursor of social phobia, rather than an extreme form of SM. Strong support for this position is derived from studies reporting that 69% to over 95% of children with SM also met criteria for social anxiety disorder. Similarly, family history data reveal an elevated rate of social phobia among parents of children with SM, and severity of children's SM symptoms may predict parents' diagnosis of generalized social phobia. Research regarding genetic risk of SM is in its infancy. One recent study examining genetic susceptibility factors for SM in families with social anxiety–related traits found evidence of increased risk of SM in individuals with a genetic variation in *CNTNAP2*, a gene implicated in various forms of language impairment. Notably, *CNTNAP2* has also been implicated in autism spectrum disorder (ASD). While SM and ASD may exhibit several phenotypic similarities (e.g., difficulties with social communication) and there is recent evidence for a potential shared genetic

susceptibility, they are distinct conditions (further discussed below in Differential Diagnosis).

Evidence of a relationship between SM and social phobia also come from studies demonstrating several cognitive and behavioral similarities. Recent studies also noted similarities between SM and social anxiety in the content of their reported fears, such as fear of negative evaluation by others. Researchers and clinicians have also noted the resemblance between SM children and children described as shy or “behaviorally inhibited.” In fact, reluctance to speak is often considered to be a sensitive index of behavioral inhibition. Consistent with this is the finding that parents of children with SM rate their children as not responding well to new situations or handling transitions well, both widely considered to be fundamental elements of behavioral inhibition. Since there is evidence that the presence of behaviorally inhibited temperament is associated with increased risk of future anxiety disorders, it is possible that behavioral inhibition is an etiologic factor in the development of SM. By contrast, a small proportion of children with SM do not exhibit social phobia with regard to nonverbal communication and will engage in social interaction using gestures, facial expressions, body language, and other socially engaged behavior. Such cases raise questions about the nature of the relationship between SM and social phobia, suggesting that some individuals may experience anxiety specifically related to expressive language and not to social situations more generally. Some researchers have investigated the notion that the “nonspeaking behavior” of children with SM essentially should be seen as an emotion regulation strategy aimed to reduce anxiety around social interaction. Finally, additional evidence linking SM to social phobia comes from the finding that pharmacologic agents used to treat adult social phobia are similarly effective in the treatment for SM.

As mentioned previously, oppositionality and recent trauma are often cited as etiologic factors related to SM; however, studies utilizing systematic diagnostic procedures do not provide support for these relationships. In comparing children who met criteria for only social phobia to those with both SM and social phobia and those with

no disorder, researchers found no significant differences on parental reports of oppositionality. Furthermore, mean scores for ratings of oppositionality were in the normal range for children with SM. Thus, findings suggest that the majority of children with SM do not present with clinically significant oppositional behaviors. However, 29% of children with SM were rated as meeting criteria for oppositional defiant disorder (ODD) by clinicians. Thus, a subset of children with SM may exhibit comorbid ODD.

Somewhat more confusing are conflicting findings related to the prevalence of communication disorders among children with SM and the association between developmental delay and SM. Several studies have examined possible deficits in auditory or speech and language processing in children with SM. In one study, a little over a third of children with SM displayed speech and language disorders, particularly articulation and expressive language disorders. In another study, children with SM were compared to children with an anxiety disorder and normal controls on measures of language, nonverbal working memory, and social anxiety. When compared to children with other anxiety disorders and healthy controls, children with SM had lower scores on language measures and deficits on tasks requiring them to remember verbal information. In another study, researchers found that children with SM did not exhibit deficits in visual memory, but they did show significantly poorer verbal memory than controls. Thus, some children with SM may exhibit meaningful deficits in speech and language processing. While the majority of children with SM do not exhibit speech and language disorders beyond the context of SM, it was recently purported that a subset of children with communication and language difficulties who are also behaviorally inhibited may become nervous to speak in new situations, which may in turn contribute to risk for SM.

Although some children with SM may experience language delay or dysfunction and deficits in speech and language processing, it is noteworthy that among researchers it is not suggested that these problems supersede social anxiety as a major contributing factor toward nonspeaking. Furthermore, although language delay or speech disorder may be more common among children with SM,

these problems could be a result, rather than a cause, of the disorder. Finally, speech and language problems associated with SM are likely to be subtle and are exclusionary criteria for the diagnosis of SM when they cannot be ruled out as the cause of the lack of speech. Ultimately, however, it is important to note that many in the field believe that neurodevelopmental and language anomalies occur more frequently among children with SM than among children with other anxiety-related disorders.

DIAGNOSIS AND CLINICAL FEATURES

The primary symptom exhibited by children with SM is the failure to speak in some situations where speaking is expected despite speaking in other situations. The situation in which the child has no difficulty speaking is almost always in the home environment. In fact, some families of children with SM report that the child seems to be "overly" talkative at home. However, in severe cases, there may be some members of the household to which the child with SM does not speak. If a child who is presumed to have SM does not speak at all at home, there is reason to seriously question the diagnosis of SM.

Several studies indicate that the situation in which speaking is most commonly avoided is at school. Within this common pattern (speech at home, failure to speak at school), there is large individual variation in terms of speaking patterns among children with SM. In the school environment, children with SM more commonly fail to speak to adults (e.g., teachers) than to peers, although a lack of speech with peers is not uncommon. However, many children with SM have individually distinct and stable patterns regarding to whom they do, and do not, speak. For instance, there are often particular extended family members with which the child does not speak and others to whom they consistently speak. Some children with SM have little or no difficulty speaking with strangers, whereas others place strangers at the top of their hierarchy of people with whom it is difficult to speak.

The label of SM can be used somewhat broadly to describe children who are consistently reluctant to speak or display low

frequency of speech. Although some argue that children who speak inconsistently, reluctantly, or with low volume do not, in fact, have SM, these speaking behaviors are relevant for the diagnosis of SM because children who completely fail to speak in some situations often speak inconsistently, with low frequency or volume, or reluctantly in others. For example, some children with SM may fail to speak at all in some situations and speak normally in others (e.g., home), while in other situations they might speak but not in a “normal” voice but whisper fairly readily. Also fairly common is the child who does not speak at all in some situations, but in other situations speaks in a “disguised” or odd voice that is mechanical, gruff, or baby like.

Given that SM appears to be so closely related to social phobia, it is not surprising that children with SM also have difficulty with nonverbal but socially relevant tasks such as eating in front of others, having their picture taken, and communicating nonverbally. When social anxiety symptoms not related to speech are present and meet criteria for social anxiety disorder, the additional diagnosis should be given. Even among those who are not also diagnosed with social anxiety disorder, children with SM are typically described as shy and self-conscious. However, it is important to note that not all children with SM are shy; although not typical, there are children with SM who present as outgoing, friendly, and eager to interact but only interact nonverbally (e.g., smile for the camera, raise their hand in class but not answer when called upon). This presentation has led some researchers to view SM as a type of specific phobia of speaking.

The following case exemplifies a common presentation of a child with SM.

James is a 5-year-old Chinese American boy who lives with his biologic mother, father, and older sister. James's parents reported that he speaks normally at home but that he started to have difficulty speaking to adults and children at school upon entry to preschool. He continued to have difficulty speaking throughout his preschool year and has ongoing difficulty in kindergarten. At home, his parents report that he is extremely talkative and outgoing when he is around immediate family members and extended family members close to his age. At school, James does not speak to any of the adults but answers classmates with one-word answers and speaks only in a whisper. By his parents' report, James also exhibits extreme social anxiety, to the point of "freezing" in certain situations when attention was focused on him. He often watches other children playing from a distance, does not join in group activities, and does not participate in circle time at school. James's parents also report that he hides behind them when strangers are around and that he dislikes having his picture taken. At the time of his evaluation, James had not received prior treatment for SM or any other emotional or behavioral disorders. James was born in the United States and speaks fluent English and limited Mandarin. His parents speak to him in both English and Mandarin and he mostly responds to them in English. According to his parents, he developed normally with no delays and appears to have above-average intelligence. They also reported that James enjoys riding on his bicycle, singing, and art activities.

During initial evaluation, James hid behind his parents and failed to respond in any way to the intake clinician. James's parents reported that this behavior is typical of him when in a novel situation with new people, but that he might answer with one-word answers softly, communicate nonverbally, and make eye contact with people once he gets more comfortable with them. James's parents reported that he speaks spontaneously and fluently when he is at home with his family. They also reported that he can be quite animated, is a lot of fun, and is very

talkative at home. James received diagnoses of SM (moderately severe) and social phobia (moderately severe). Behavioral treatment was recommended.

Behavioral treatment was initiated following the intake evaluation. Initially, the therapist played nonverbal games and engaged in nonverbal activities with James to help him feel comfortable in the session (e.g., coloring, blowing bubbles, hiding pennies, and giving nonverbal clues). Next, James and his mother were asked to create a list of easy, medium, and hard speaking situations and a list of small, medium, and large rewards. These lists then became the basis for assignments (and reinforcement) for speaking tasks that gradually increased in difficulty. In general, sessions included time with James and his mother together to review past and future assignments as well as time with James and the therapist alone.

When treatment began, James did not communicate at all verbally with the therapist. The therapist gradually increased rapport (via unstructured play) while having James try increasingly difficult tasks, such as first whispering to his mother with the therapist in the corner, then nodding yes or no in response to the therapist's questions, pointing, using a puppet to "talk for him," whispering to his mother while facing the therapist, and then subsequently responding verbally to the therapist. A successful technique in working with James was having him whisper to his mother while playing games with the therapist and then having his mother move a few inches away each time he was asked to respond to the therapist. As the whisper became more audible, the therapist was able to hear his speech and responded directly to the whisper (without waiting for his mother to tell the therapist what James said). James became more comfortable with the therapist hearing his voice, and he was slowly able to direct his speech toward the therapist. After three sessions, James consistently and spontaneously talked to the therapist. James received stickers for completing each speaking assignment, and after filling up "sticker charts," he received

rewards (i.e., small toy, special activity with parent, or treat from the reward list).

James was also given assignments that involved both his teacher and classmates. These were implemented in a gradual fashion and included waving to the teacher, playing a game with his parent first in an empty classroom then while his teacher was in the classroom, leaving a phone message for the teacher, playing an audiotape of him saying “hello” to the teacher, whispering to his parent loudly enough for his teacher to hear, whispering “hello” to the teacher, and speaking “hello” to the teacher in a regular voice. Assignments also involved classmates and included playing games with his parent and one classmate, asking classmates questions about their favorite things (e.g., color, animal, and food), playing games with classmates without his parent, and play dates at home. After approximately 12 sessions, James spoke a complete sentence to a group of three classmates, spoke to his teacher directly, and answered a question aloud in front of the entire class.

During the last few sessions, which were tapered over several weeks, James’s mother took an increasingly primary role in assigning and following up on speaking assignments. James’s mother had him continue practicing talking assignments with extended family members and unfamiliar adults and children. James entered the first grade and, after only a few days, began regularly speaking to his teacher (both privately and in front of peers) and to most peers in class. Following the completion of therapy, James’s mother continued to monitor his speaking behaviors and to promote speaking in new situations by encouraging (and rewarding) James’s gradual successes with novel people and situations.

DIFFERENTIAL DIAGNOSIS

As discussed above, the current understanding of SM emphasizes that social anxiety underlies most selectively mute behavior. The

resulting conceptual and diagnostic overlap between SM and social phobia complicates the clinician's determination of whether a child with SM also meets the criteria for the presence of comorbid social phobia. One of the most successful strategies for the clinician attempting to make this determination is to direct queries toward the presence of social phobia symptoms that do not involve speaking. For example, the presence of fear and avoidance of eating in public, having pictures taken, using public restrooms, or writing in front of others provide strong evidence for an additional diagnosis of social phobia in a child who meets the criteria for SM. Although some may perceive the child with SM to be oppositional, distinguishing SM from primary ODD is fairly straightforward in many cases. Most importantly, the child with SM is unlikely to engage in significant oppositional behaviors outside of the context of verbal communication. If a child who appears to have SM (failure to speak in certain situations despite speaking in other situations) also exhibits oppositional behaviors in a variety of situations, both diagnoses are given. For children whose failure to speak does not appear to follow a consistent pattern with regard to the situation and targeted individuals, appears primarily motivated by instrumental gains, and occurs in the absence of any other anxiety symptoms, it is possible that ODD rather than SM is the correct diagnosis.

There is a growing body of work examining similarities between SM and ASD. A few recent studies report a high degree of overlap in symptoms of SM and ASD, as reported in a retrospective review of medical records and parent reports on developmental and social communication scales. Additional research is needed to determine the between—group discriminative validity of existing measures of ASD among children with SM. Although children with SM can be misdiagnosed as having autism due to their lack of speech in the clinic setting, this diagnostic error can be avoided with a more thorough evaluation of autism-like features in children with suspected SM, with close consideration of (in)consistency of behaviors across settings. One study examined joint attention (one person's purposeful focus of attention with another person, often impaired in children with ASD) in children with SM, other anxiety

disorders, and a control group. Findings indicated joint attention abilities in children with SM did not differ from the other groups in an unstructured free play condition, although children with SM displayed less joint attention than the other groups during structured tasks. Although this indicates some level of behavioral or psychological overlap between SM and autistic-like features, the context-specific display of behavior in children with SM is critical to distinguishing SM from ASD and may be more reflective of behavioral inhibition than autism-related behavior. Critically, the lack of speech associated with SM is, by definition, limited to certain situations, and evidence indicates that related behaviors that overlap with other diagnostic categories (e.g., poor joint attention) might also be limited to specific situations. However, the cognitive, language, and social communication difficulties of a child with ASD are present across settings. Similarly, the diagnostic criteria requiring that the child speak normally in some situations can often rule out a severe communication disorder.

Several studies have identified subsets or profiles of children with SM who also have mild or moderate levels of oppositionality. Although one may perceive some children with SM to be oppositional, distinguishing SM from primary ODD is fairly straightforward in many cases. Crucially, many children with SM may appear to be oppositional, almost exclusively around situations during which they are reluctant to speak but are being prompted to do so. If a child with a purported diagnosis of SM consistently exhibits oppositional behaviors in a variety of situations, both diagnoses are given. For children whose failure to speak does not appear to follow a consistent pattern with regard to the situation and targeted individuals, appears primarily motivated by instrumental gains, and occurs in the absence of any other anxiety symptoms, it is possible that ODD rather than SM is the correct diagnosis.

The DSM-5 criteria state that a child should not be diagnosed with SM if the failure to speak is due to a lack of knowledge of, or comfort with, the spoken language required. Researchers in the area of bilingual children with SM report that immigrant children and those learning a second language in their new country may be overlooked

or misdiagnosed. Thus, the diagnosis of immigrant and language minority children can be difficult, and it is important to understand typical bilingual child development to diagnose SM properly. Many children learning a second language may go through a nonverbal or “silent period” due to the realization that their native language is not understood by classmates and teachers and that their skills in the new language are not sufficient. To diagnose SM in bilingual children and children who are acquiring a second language, it is important to know that bilingual children with SM exhibit a failure to speak in both their native and newly acquired languages in several unfamiliar settings and for an extended period of time (>6 months). Although a child learning a new language may not feel completely comfortable speaking a new language for several months, most children show no progression of speech as they gain mastery over their new second language, whereas a child with SM typically does not.

COURSE AND PROGNOSIS

SM appears to have an insidious onset, with most parents reporting failure to speak in some settings as a problem that was evident from the time their child began talking. However, most typically, the lack of speech outside of the home is not considered to be a problem until school entry. Although SM is generally considered to be a disorder that is difficult to treat successfully, at the same time, it is believed to spontaneously remit over time in a large majority of cases. Based in part on one study that found a large reduction in SM over a 6-month period (from the beginning to the end of the school year), it was believed that the disorder spontaneously remitted over time in a large number of cases and that in these cases, and that SM should be described as transient rather than persistent. This distinction has been refined somewhat based on a school-based study that revealed that although close to 30% of children with SM showed some improvement from the beginning to the end of a school year, as a group, the SM children remained significantly more symptomatic than matched unaffected peers.

In a controlled long-term outcome study (mean follow-up period of 13 years), young adults with SM in childhood were compared to young adults with anxiety disorders in childhood and young adults with no psychiatric diagnosis in childhood. Researchers found that 18% of patients with SM in childhood showed only slight improvement in young adulthood, while the rest of the patients with childhood SM were found to be either markedly improved or totally improved in young adulthood. They reported a complete remission rate of 58%. Unfortunately, these data did not include comparisons related to variation in course with or without treatment. The only controlled treatment study that assessed youngsters 1 year following successful behavioral treatment reported that children maintained or improved upon initial gains when reassessed.

Although it seems intuitively useful to discriminate between transient and persistent SM and to assume that persistent mutism may be related to more severe impairment, this distinction requires further investigation. Similarly, there is no information related to ongoing difficulties that might result from even relatively short-term or transient SM. Given that there is little information regarding lasting consequences related to an early disturbance in verbal communication and that nonspeaking behavior is often conceptualized as a learned behavior that is reinforced considerably over time, it makes sense to target treatment toward younger, recent-onset youngsters. Additional support for the importance of early intervention (vs. delaying treatment to establish if SM will resolve spontaneously) comes from recent findings that age of onset, duration of SM, and age at treatment all predict treatment effect size. Specifically, young age and shorter duration of SM were associated with larger treatment effects.

TREATMENT

Although in the last 20 years, there has been an increase in the amount of research on SM, the majority of published data on the treatment of SM continues to rely on single-case studies and case series of markedly varying quality. In addition, studies reporting SM

treatment outcomes tend to rely on small samples or single cases and do not identify diagnostic procedures, assessment or outcome methods, number of treatment sessions, or details of the treatment method. In spite of these limitations, the conviction that behavioral techniques are an essential component of treatment for SM is widespread. Recently, two small randomized controlled trials of behavioral treatment for SM were completed and supported the efficacy of such interventions compared to a waitlist control. Follow-up studies as long as 5 years posttreatment provide support for the durability of findings. In general, these and other published reports in the literature describing treatment efforts provide a solid basis for the development of behavioral treatments that include parent and school involvement in treatment. In addition to behavioral strategies, a small but growing literature provides support for the efficacy of a pharmacotherapeutic intervention (primarily the selective serotonin reuptake inhibitors [SSRIs]). In addition to a growing effort aimed at empirical validation of treatment for SM, recent efforts have also resulted in better instruments for the assessment of specific symptoms of SM. Instruments such as the Selective Mutism Questionnaire, a parent self-report measure of the affected child's lack of speech, and the School Speech Questionnaire, the companion teacher measure, are commonly used in the assessment of symptoms in both research and clinical settings.

Behavioral Treatment

Multiple published reports describe the successful utilization of relatively standard behavioral techniques such as contingency management, stimulus fading, systematic desensitization, negative reinforcement, and shaping for the treatment of SM. A combination of behavioral techniques is probably the most common and successful treatment approach. Behavioral approaches typically utilize a hierarchy or rank-ordered list of situations in which the child has difficulty speaking. Then, the child is guided to systematically engage in speaking-related behaviors (e.g., mouthing speech, making sounds, and whispering) in increasingly more difficult

situations. Over repeated successful attempts, the associated anxiety dissipates through the process of autonomic habituation. In addition, when the feared consequences of speaking fail to occur, patients' heightened expectations of harm disappear, reducing anxiety even further. Typically, the child receives positive reinforcement (rewards) following attempts to engage in speaking-related behaviors to shape the child's behavior. There are also several reports of treatments utilizing somewhat unique self-modeling behavioral interventions, including audio and video editing techniques and, most recently, techniques utilizing enjoyable electronic applications on mobile phones and tablets.

A number of considerations serve to complicate the behavioral treatment of SM and to distinguish it from treatment for social phobia, a disorder to which it is closely related. These factors include the child's failure to speak (even to the therapist), the young age of most SM patients, and the need for significant school involvement in almost all cases. The young age of children with SM necessitates considerably more parental involvement in treatment than is typically recommended for other anxiety disorders.

Although not without exception, most children with SM do not initially speak to the treating clinician. Obviously, treatment approaches for SM need to consider the initial communication difficulties that are often present and include strategies for facilitating verbal communication with the therapist. The initial lack of verbal communication with the therapist is assumed to reflect the general anxiety underlying failure to talk in situations outside the home and is addressed accordingly. To promote speaking in the treatment setting, traditional behavioral techniques (shaping, gradual exposure, reinforcement) are first introduced within the session. Recent reports show that the use of mobile apps in treatment is successful at reducing the time it takes children to begin verbalizing during treatment, with many study participants speaking during the first treatment session. The authors posit that the success is due, in part, to the principle of systematic desensitization: that is, the fear associated with speaking is incompatible with the enjoyment associated with the use of the app.

The SM child's failure to speak represents a somewhat unique challenge for others in the child's life, particularly parents and school personnel. Although difficulty in differentiating oppositional behavior from anxiety-related avoidance characterizes many child anxiety disorders, when failure to speak is involved, parents and others are particularly likely to attribute avoidance to oppositional motivations and to get frustrated and angry. In contrast, other reactions to nonspeaking include the tendency to accommodate the child's lack of speech and speak "for" the SM child, thus decreasing the necessity of independent communication. This tendency, along with other ways that nonspeaking may be reinforced, also needs to be addressed in the treatment of the disorder. Recently, proponents of parent–child interaction therapy (PCIT) have combined components of PCIT with more standard behavioral SM treatment to develop a treatment that teaches parents how to encourage and coach their children to increase speech while reducing accommodation relating to avoidance of speech.

Nearly all forms of youth anxiety involve school-related impairment to some extent. However, unlike SM, they do not typically revolve as extensively around the school environment. For this reason, a treatment that integrates school participation as a central component of the intervention is necessary for the effective treatment of SM. Most importantly, close rapport with school personnel that includes regular communication and support must be established to ensure the success of behavioral interventions in the school setting. Furthermore, treatment programs should include teacher education and training in the behavioral methods utilized for treatment. The utilization of teachers in the treatment of SM has been highlighted as a particularly cost-effective treatment approach. In the last few years, treatment programs have been developed that include an intensive group element that simulates the school environments while additionally providing treatment condensed over a few days. This approach also has the advantage of providing treatment over a reduced period of time to children who have to relocate to find clinicians experienced in the treatment of SM.

Other Psychosocial Therapies

Although the most common accounts of successful psychosocial treatment for SM involve behavior therapy, there are descriptions in the literature of successful treatment for SM with play therapy, family therapy, psychodynamic therapy, and group therapy. Although most of these descriptions are flawed by their small sample sizes and failure to adequately describe the diagnostic or treatment intervention processes, it is noteworthy that descriptions of play, family, and group therapy all contain considerable emphasis on the use of behavioral interventions. In general, traditional psychotherapy aimed at addressing underlying intrapsychic conflicts or other interventions (including play therapy, art therapy, supportive therapy, and family therapy) not containing the behavioral elements described above have not been found to be effective for SM.

Speech and Language Therapy

As noted by the DSM-5, the criteria for SM include a caveat that the symptoms cannot be primarily due to a speech or language disorder. However, it is not uncommon for children with SM to also have some degree of speech or language difficulty that may exacerbate speech-related anxiety or self-consciousness. Although there is a lack of research on the efficacy of multimodal approaches, the combination of cognitive behavioral techniques and speech or language therapy can be quite effective for the treatment of children with comorbid SM and speech or language difficulties. In addition, even in cases without the significant contribution of speech or language dysfunction, the small, supportive group setting of auxiliary speech services found in many schools may provide a beneficial environment in which to implement the graded behavioral intervention approach described earlier.

Psychopharmacologic Treatments

Currently, there are no approved U.S. Food and Drug Administration (FDA) medications for the treatment of SM. However, several small studies suggest that SSRIs may be effective treatments for SM in

children. This is not surprising, given the central role of anxiety in the phenomenology of the disorder. Results from a single double-blind, placebo-controlled trial of fluoxetine in children with SM indicated significant improvement in parent ratings of mutism and anxiety. Results from open trials and case studies have also supported the efficacy of various SSRI treatments. In addition, a large multisite study of fluvoxamine for the treatment of separation anxiety disorder, social phobia, and generalized anxiety disorder in children included several children with SM who appeared to benefit from this treatment. These results, along with the mounting evidence that SM is closely related to social phobia, have begun to establish SSRIs as an important treatment option for children with SM. However, given concerns about medication use in young children, medication is not the first option for many families. In practice, behavioral therapy, when practical and available, should be considered the first-line intervention strategy. In treatment-resistant cases, combination treatment (behavioral therapy plus medication) appears to be the strategy of choice.

Early-Onset Psychotic Disorders

Kaitlin Boyle, M.D., Linmarie Sikich, M.D., M.A., and Tara Chandrasekhar, M.D.

Positive psychotic symptoms such as hallucinations and delusions may be present in a number of child psychiatric disorders, including the primary psychotic disorders (schizophrenia and schizoaffective disorders) as well as more common disorders such as depression, bipolar affective disorder, severe anxiety, and posttraumatic stress disorder (PTSD). They can also occur in the context of medical illness such as delirium, or neurologic disorders, including seizure disorder, autoimmune encephalitis, genetic disorders, metabolic abnormalities, intoxication, and medication side effect. In addition, transient psychotic-like experiences, including sleep-related hallucinations and imaginary friends, may occur in young children with a mental age of fewer than 8 years who have no mental health problems. The diagnostic distinctions between these disorders are primarily related to the duration and context of the hallucinations and the presence of specific co-occurring symptoms.

Children and adolescents, as well as their families, who have primary psychotic disorders and affective disorders with psychotic features, are often devastated by these illnesses. These illnesses are frequently characterized by recurrent crises, interruption of normal developmental processes, a deteriorating course, and treatment resistance. Often the care of such youth requires extraordinary monitoring and advocacy by their parents, frequent hospitalizations, and multiple long-term interventions provided by mental health, educational, and social service agencies. Such care often incurs very high societal costs. However, many

believe that if effective treatments can be identified and implemented early in the course of illness, this may translate to improved long-term outcomes. In addition, many researchers believe that it may be easier to identify the neurobiologic processes involved in the pathogenesis of schizophrenia and related disorders in affected youth because they have a more severe but clearly developmental form of the disorder that appears more strongly associated with genetic factors than adult-onset schizophrenia.

DEFINITION

Positive psychotic symptoms include hallucinations, delusions, other sensory and cognitive misperceptions, and bizarre or disorganized thinking and behavior including catatonia. Negative psychotic symptoms include flattened affect, apathy, avolition (difficulty making choices), poverty of speech, and poverty of thought content. Early-onset schizophrenia (EOS) is defined as schizophrenia with onset of clear positive symptoms prior to 18 years of age. Onset of schizophrenia prior to age 13 is referred to as very early onset or childhood onset. The diagnoses of psychotic disorders in children and adolescents are generally made using the same criteria as in adults.

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and its text revision (DSM-5-TR) requires that youth with schizophrenia, like adults with the disorder, have at least 6 months of positive or negative symptoms and significant social or occupational dysfunction or failure to achieve expected levels of social development. In contrast, The *International Classification of Diseases* 11th edition (ICD-11) requires only a month of symptoms and does not include any impairment criteria. In addition, many researchers believe that marked neurocognitive declines in executive functioning, general cognition, social cognition, and memory are a key feature of schizophrenia, despite not being included in the diagnostic criteria. Indeed these symptoms, not positive symptoms, seem most closely related to long-term functional outcome.

Schizophrenia spectrum disorders also include schizoaffective disorder and schizophreniform disorder. Schizoaffective disorder is defined by the prominence of psychotic symptoms, presence of significant periods of co-occurring major depression or mania, and psychotic symptoms present for at least 2 weeks in the absence of any mood symptoms.

Schizophreniform disorder is defined by its short duration of psychotic symptoms (1 to 6 months) and generally evolves into either schizophrenia or schizoaffective disorder.

Major depression with psychotic features and bipolar affective disorder meets all diagnostic criteria for the respective affective disorder but also include positive psychotic symptoms that are present only during periods of affective disturbance. Key distinguishing features of these disorders and other disorders with psychotic symptoms presenting during childhood are presented in Table 52–1.

HISTORY

Schizophrenia has been reported to occur in children since the diagnosis was introduced by Emil Kraepelin. From the early 1900s to 1980s, the term childhood schizophrenia or prepubertal schizophrenia was used to refer to a range of severe psychiatric disorders presenting in youth including autism, leading to uncertainty about the diagnosis of research subjects during this period. In the 1970s, Israel Kolvin and colleagues conducted seminal work to distinguish between primary psychotic disorders and autistic disorder. Beginning with ICD-9 and DSM-III, autism has been recognized as a distinct disorder and schizophrenia has been diagnosed using identical criteria in youth as adults.

COMPARATIVE NOSOLOGY

The diagnostic criteria for schizophrenia and schizoaffective defined by the ICD-11 are similar to those of DSM-5-TR. ICD-11, published in 2019, only requires 1 month of symptoms to make the diagnosis of schizophrenia versus the 6 months required by DSM-5-TR. In addition, there is no functional impairment criteria as required in the DSM-5-TR diagnostic criteria. Jorge Armenteros and colleagues found a high rate of diagnostic agreement between DSM-III-R, DSM-IV-TR, and ICD-10 in hospitalized psychotic adolescents. Similarly, there is good agreement between the diagnostic criteria for major depression with psychotic features and bipolar affective disorder with psychotic features between ICD-10 and DSM-IV-TR. It is highly likely that the same level of agreement will be found with increased use of DSM-5-TR and ICD-11 criteria.

Table 52–1.
Disorders Presenting with Psychotic Symptoms in Children and Adolescents

Disorder	Distinguishing Features
Early-onset psychosis (EOP)	Any of a number of disorders in which positive psychotic symptoms are a prominent feature.
Early-onset schizophrenia (EOS)	Schizophrenia with onset prior to age 18. ▶ Involves a change from usual functioning, typically within 1–5 years of diagnosis, often has negative and neurocognitive symptoms rather than just positive symptoms. ▶ Affective symptoms may occur but are not present for a substantial part of the illness. ▶ If patient also has an autism spectrum disorder, positive symptoms must include hallucinations or delusions. ▶ Impact on functioning may include failure to achieve developmentally expected social functioning or deterioration in social or occupational functioning. ICD-11 does not require impairment. ▶ DSM-5-TR requires symptoms to be present for 6 months, ICD-11 requires symptoms for only 1 month.
Schizoaffective disorder (SA)	▶ During a substantial portion of the psychotic illness, the affected individual also meets criteria for a major depressive episode, manic episode, or mixed manic/depressive episode. ▶ There are at least 2 weeks during the lifetime duration of the illness in which psychotic symptoms are present in the absence of any affective symptoms.
Schizophreniform disorder	▶ DSM-5-TR diagnosis reflecting schizophrenia criteria for at least 1 month but fewer than 6 months. ▶ Not included in ICD-11. ▶ Generally evolves into schizophrenia or schizoaffective disorders but may less frequently evolve into bipolar disorder.

Early-onset schizophrenia spectrum disorders (EOSS)	▶ Includes EOS, schizoaffective disorder, and schizophreniform disorder with onset prior to age 18 and Very Early Onset Schizophrenia (VEOS) or Childhood Onset Schizophrenia (COS). ▶ At this point, there is no clear evidence that the treatment or prognosis of early-onset schizoaffective disorder is significantly different from EOS.
Major depression with psychotic features	▶ Youth describes clear depressed mood vs. numbness or apathy. ▶ Psychotic symptoms are only present if mood symptoms are present. ▶ Psychotic features are usually mood congruent. ▶ Formal thought disorder is not usually present.
Bipolar disorder with psychotic features	▶ Psychotic symptoms are only present if mood symptoms are present. ▶ There is decreased need for sleep rather than insomnia. ▶ Negative symptoms are absent.
Substance-induced psychosis	▶ Psychotic symptoms are limited to periods of substance intoxication or withdrawal. ▶ Psychotic symptoms did not precede substance use. ▶ Psychotic symptoms generally resolve within 7–30 days of abstinence.
Posttraumatic stress disorder (PTSD)-associated psychosis	▶ Positive psychotic symptoms relate directly to trauma and are not associated with other areas of life or random events. ▶ There are other symptoms of PTSD.
Anxiety-related hallucinations	▶ Positive psychotic symptoms are limited to periods of high anxiety. ▶ There are no negative symptoms or signs of a formal thought disorder.

EPIDEMIOLOGY

There are a limited number of studies reporting on the population prevalence of rare positive psychotic symptoms (≤4) in children and adolescents. A meta-analysis of 12 studies involving a total of 24,103 youths from non–help-seeking samples described a median prevalence of brief psychotic symptoms of 9.8% among youths 11 to 21 years old. Prior studies have suggested that the prevalence of psychotic episodes decreases with age. Importantly, having such symptoms is associated with a threefold increase in one's current or subsequent risk for having any psychiatric disorder and about a fourfold increase in risk for a schizophrenia spectrum disorder. In contrast, population-based studies of childhood psychiatric studies in the United States, which generally rely on semistructured interviews administered by nonclinicians, do not report any cases of schizophrenia and bipolar disorder. However, one study examining all the youths who had sought mental health care at a regional hospital in Germany serving ~100,000 children found that only 3 between 6 and 10 years old (0.003%) were diagnosed with schizophrenia. In this same sample, the incidence of schizophrenia increased by about fourfold between 10 and 14 years to 13 of 100,000 (0.013%) and by another fourfold between 14 and 18 years to as much as 0.055%. These results are generally consistent with estimates from the National Institute of Mental Health (NIMH), suggesting the prevalence of childhood-onset schizophrenia is less than 0.04%. Further, at least 5% of individuals with schizophrenia (~0.05% of the entire population) report onset of illness prior to 14 years of age and up to 40% of those with schizophrenia have been estimated to become ill prior to 18 years of age.

The reports of persistent psychotic symptoms in clinical samples are much higher and increase with the restrictiveness of the clinical setting. In one outpatient pediatric mood and anxiety clinic, 2,031 children aged 5 to 21 years (mean age 14.3 years) were evaluated using a structured diagnostic interview. Nearly 10% had definite or possible psychotic symptoms. Among those with psychotic symptoms, 62% had depressive disorders, 24% had bipolar disorder, and 14% had schizophrenia or schizoaffective disorder. Inpatient samples of children with depression have reported that as many as 60% will have psychotic symptoms. It is clear from the available studies that the presence of persistent psychotic experiences alone does not equate with a diagnosis of a schizophrenia spectrum disorder and instead serves as a marker for a variety of mental health disorders.

Given the greater prevalence of major depression and bipolar affective disorder in youth, it is likely that as many or more cases of pediatric psychosis will be related to affective disorders rather than schizophrenia. It appears that EOS and affective psychoses are more common in individuals with family histories of the respective disorders. EOS appears slightly more common in boys than girls, whereas major depression is much more common in female adolescents than in male adolescents. Both genders appear equally affected by bipolar disorder. A clear relationship with onset of puberty has not been demonstrated.

Clinicians should also be aware of potential racial disparities in the diagnosis of psychotic disorders. Studies have shown that African American patients are diagnosed with schizophrenia at a higher rate than White patients despite epidemiologic data suggesting similar prevalence rates. This highlights a very important issue suggesting potential clinician bias that needs to be recognized and addressed. A misdiagnosis can lead to many issues beyond not receiving the appropriate treatment.

ETIOLOGY

Schizophrenia is a syndrome presenting with varied symptoms and heterogeneous etiologies, almost all of which remain unknown. Schizophrenia is generally thought of as a neurodevelopmental disorder. Some researchers have speculated that multiple disruptions or “hits” to normal neurodevelopmental processes are required for schizophrenia to develop. Such disruptions might result from genetic vulnerabilities; intrauterine adversities as a result of famine, infection, or inflammation; or various environmental exposures later in life including severe psychological stress including trauma and exposure to drugs of abuse, particularly cannabis.

Disruption of normal neurodevelopmental processes, particularly those that involve maturation of the frontal cortex and its connections during the second and third decades of life have been repeatedly demonstrated in histopathologic studies. In adults, alterations in the morphology of specific subclasses of γ-aminobutyric acid (GABA)ergic interneurons and of the volume and synaptic density of pyramidal neurons that receive thalamic afferents have been repeatedly demonstrated. These differences suggest aberrations in the normal developmental processes of synaptic refinement and pruning. Further, subtle differences in neuronal connectivity,

especially in the hippocampus and parietal, temporal, and frontal cortices, have repeatedly been identified in both histopathologic and imaging studies. These differences appear to lead to less efficient cortical processing as demonstrated by functional magnetic resonance imaging (fMRI). Given the correlation between these connections and cognitive function, such connectivity alterations may be a potential underlying mechanism of cognitive issues in schizophrenia.

EOS appears to be associated with more profound neurodevelopmental disruptions than adult-onset schizophrenia. Frequently individuals with EOS have social and attentional difficulties during early childhood. Many have evidence of autism spectrum disorder (ASD) or symptoms. Structural imaging studies have repeatedly demonstrated an exaggeration of the normal pattern of cortical volume loss that occurs throughout adolescence, with excessive and progressive reductions being especially prominent in the cingulate, temporal, and frontal cortices. Further, the magnitude of cortical volume loss has been associated with the severity of positive psychotic symptoms. In addition, studies of prodromal individuals, many of whom are adolescents, have shown that regional gray matter volume reductions, especially in these same regions are present before appearance of overt positive symptoms and progress during the first few years of the illness.

The heritability of schizophrenia has also been consistently demonstrated. However, the underlying genetic links are more complicated. The ability to perform genome-wide association studies has allowed for the detection of over 100 common independent loci that are significantly associated with increased risk for schizophrenia. These account for only a small increase in overall risk, leading many to argue that schizophrenia is a polygenic disorder. However, individuals with EOS are significantly more likely than those with adult-onset schizophrenia to have chromosomal abnormalities and DNA copy number variants, which individually pose a greater risk for schizophrenia. A prominent example is the 22q11.2 deletion associated with velocardiofacial syndrome (VCFS). Interestingly, many copy number variants also significantly increase the risk for other neuropsychiatric disorders, including ASD, intellectual disability, attention deficit hyperactivity disorder (ADHD), and epilepsy. Some argue that schizophrenia lies on a spectrum of neurodevelopmental disorders with the disorders listed above. Further, youths with EOS are at least twice as likely as individuals with adult-onset schizophrenia to have

a parent with the disorder. Genetic abnormalities suggest the involvement of immunologic and neurodevelopmental functions.

Although multiple environmental factors have been associated with risk for schizophrenia, cannabis use has been of particular interest in recent years given that it may be modifiable. Several studies show a correlation between heavy cannabis use and psychotic experiences as well as higher rates of depression and anxiety. Use during adolescence has been linked with increased risk of psychosis as well as long-term cognitive deficits. Alterations to the endocannabinoid system by exogenous cannabinoids during the critical adolescent period potentially serve as the link between early cannabis use and increased risk for psychosis and cognitive effects.

DIAGNOSIS AND CLINICAL FEATURES

All types of early-onset psychosis are diagnosed using the same criteria as the adult forms of the disorder. However, the characteristics of specific symptoms often show important developmental characteristics that may be confusing for clinicians who infrequently work with pediatric patients. Hallucinations are frequently multimodal, with the affected youth seeing, hearing, and/or feeling the hallucinated being. Children will frequently name the hallucinated being, often using stereotypes such as “an angel,” “the devil,” or “a monster” or will refer to it on the basis of a physical characteristic such as “the red sweater guy” or “the man with no skin.” Youth very seldom complain about their hallucinations if not asked directly. Family members often are not aware of hallucinations but may endorse that the child asks about being called when no one has said anything. Delusions are seldom highly complex or systematic prior to age 16. Instead youth often report vague symptoms like “everyone is out to get me” or “people are laughing at me.” Often reports from collateral sources are needed to determine whether such reports are delusional or reality based. Frequently, youth with EOS present with nonspecific symptoms such as poor attention or increased aggression.

Onset of EOS is often insidious, occurring over a few years. In addition, premorbid symptoms such as being odd and socially isolated or having multiple (but generally mild) developmental delays in cognitive, motor, sensory, and social functioning are common and appear more severe than in adults with adult-onset schizophrenia. Thus, when assessing youth for EOS, it is important to ask about changes in functioning and behavior that

have occurred over the past 3 to 4 years, to specifically inquire about hallucinations and delusions using language that the child understands, and to encourage the child to describe their experiences in detail using their own words. One should ascertain whether the child is in control of the phenomena, which is not seen with true hallucinations, or whether they can only moderate their own response to the phenomena. It is also crucial to determine the frequency and persistence of positive symptoms and associated negative symptoms. Finally, often, but not always, EOS is associated with a formal thought disorder.

Clinicians are frequently reluctant to diagnose EOS even when there is clear evidence of the disorder. Although the reasons for this are unclear, unfamiliarity with the developmental variations in symptoms, concerns about overlabeling, likely poor outcome, and stigma are frequently involved. However, failure to make the diagnosis when indicated may reduce access to appropriately intense interventions and relevant psychoeducational resources, increase the likelihood of treatment nonadherence, and result in hopelessness if the youth does not robustly respond to treatment. Further, longer duration of untreated psychosis has been consistently associated with poor prognosis in adult-onset schizophrenia. Notably, a review in 2016 found the mean duration of untreated psychosis to be 3.5× longer in EOS than in adult onset.

Particular attention should be paid to risk for suicide in patients with psychosis. People with schizophrenia have a significantly increased risk for suicide compared to the general population with some studies suggesting this risk is highest during the year after the first hospitalization and may be as high as 10% during the first decade of the illness. Vignette illustrating typical presentation of EOS:

Jack was first brought to a psychiatrist at age 12 when his parents were divorcing. He was obviously upset, was doing less well in school over the past year, and had gone on a hunger strike for the past month because he thought it would make his parents get back together. His parents noted that he had always been somewhat socially awkward, had a limited number of friends, and seldom had extended conversations. He was treated with fluoxetine (Prozac) and psychotherapy. After about 2 months, he was eating normally and seemed less preoccupied with his parents' divorce. However, he would make frequent statements that he needed to protect his younger brother, because he did not trust his parents to take care of the brother. He also said he was trying to find a house where he, his brother, and his father could live together.

A year later, after his mother remarried, he became markedly more irritable and was frequently noncompliant with her requests. His mother reported that there were episodes in which he would suddenly become extremely upset with little or no provocation. For example, she described an episode when they were out walking and he suddenly jumped on her back, saying that she looked like a prostitute. On another occasion, when his stepfather had instructed his brother to wash a glass that had been left out in the living room, Jack became very upset and said he planned to beat his stepfather to death with a golf club while his stepfather was sleeping. Jack's band instructor noted that he frequently seemed preoccupied and sometimes seemed not to know what to do next. Between these episodes, Jack was frequently pleasant and engaged superficially with the family, but had very seldom seen his friends or left the house. He experimented with marijuana by himself three or four times and said it made him feel calmer.

When asked about the incidents with his mother and stepfather, Jack seemed minimally concerned and did not provide an explanation. During his psychiatric evaluation, Jack reported that he often felt extremely angry without really knowing why. He acknowledged some periods of confusion. When asked directly about ever hearing anyone or anything talking to him, he said that his legs often talked to him and told him what to do. He denied significant mood symptoms and described his mood in nondescript ways. He had some poverty of content. At times his speech was disorganized and hard to follow.

Organic workup including MRI and electroencephalogram (EEG) was noncontributory. Family history was significant for a great uncle who had been odd, socially isolated, and had been hospitalized multiple times at the state psychiatric hospital.

Jack was started on an atypical antipsychotic and showed a remarkable improvement in his oppositionality and irritability. He also became more engaged with family members and his grandfather noted he was having conversations with Jack for the first time ever. However, Jack continued to have increasing trouble in school, particularly as he entered high school. Although his positive symptoms were well controlled, he was failing all but one class. It was unclear to what extent his difficulties in school were related to sedation from the medication or cognitive limitations. Cognitive testing showed he was now functioning in the low average to borderline range and had particular difficulty with abstract thought and problem solving. Reading achievement was grade appropriate but he was significantly behind in math. Several meetings with the schoolteachers were held and an individualized education plan was developed. However, he continued to have difficulty. Various medication changes were tried without significant change in his presentation. When the antipsychotic dose was lowered to try to reduce possible sedation, he became more irritable and had thoughts of beating his mother to death while she slept because she had removed his video games for 2 days as a punishment. His school program was changed from a college preparatory program to an occupational preparation program. He felt much less stressed by this but was unable to find and maintain work at a part-time job as required for graduation. He did not seem particularly concerned by this and had no specific plans for the future. His family was considering applying for disability so that he could maintain his insurance after he turned 18 and was trying to figure out how to more effectively structure his time. Eventually, he began treatment with clozapine (Clozaril) given the persistence of negative symptoms and vulnerability to positive symptoms when his antipsychotic dosage was reduced. He did well and has been able to remain out of the hospital since that time.

PATHOLOGY AND LABORATORY EXAMINATION

The physical examination of youth suspected of having EOS should include a careful neurologic examination. If there is a focal neurologic finding or impairment of consciousness, structural MRI is indicated. However, the volumetric, spectroscopic, and diffusion tensor imaging abnormalities consistently reported showing differences in group comparisons within research studies are not of sufficiently great magnitude to be used for diagnostic purposes. If there is any indication of episodic psychosis in the absence of mood symptoms or excessive sedation or confusion following psychotic behaviors, an EEG should be obtained to rule out a seizure disorder. Exposure to illicit substances should be assessed with a urine toxicology screen. Blood work should include screening for thyroid abnormalities, electrolytes, complete blood count, liver function tests, ceruloplasmin, and urinary copper for Wilson disease, heavy metals, and serum organic and amino acids to rule out a metabolic disorder. Antibodies to nuclear proteins and other proteins associated with lupus, as well as those detected with autoimmune encephalitis panels, should be obtained from both plasma and cerebrospinal fluid (CSF). Autoimmune encephalitis should be specifically considered if the onset of psychotic symptoms is very sudden and if neurologic symptoms, including seizures, emerge at about the same time. A paraneoplastic antibody panel or ultrasounds looking for teratomas should also be considered if the autoimmune encephalitis panel is negative and the patient does not respond to standard antipsychotic treatment. Negative antibody tests do not rule out autoimmune encephalitis since it is likely that all relevant antibodies have not yet been discovered. In cases with concomitant neurologic findings, it may be appropriate to undertake a trial of immunomodulatory therapy. Graus criteria for autoimmune encephalitis include acute onset of symptoms, focal neurologic finding(s), new seizures, CSF pleocytosis or MRI suggestive of encephalitis, and reasonable exclusion of alternative causes. It is very important to consider potential medical etiologies as these are managed differently than a primary psychotic disorder. Table 52–2 describes the components of a medical workup.

Table 52–2.
Medical Workup for First-Episode Psychosis

Initial Broad Workup		
-Physical exam, including neurologic exam CBC with differential -CMP with LFTs -TSH + free T4 -B12 + folic acid -HIV 1+2, syphilis -ESR/CRP	-Urinalysis -Urine toxicology screen	-MRI brain with/without contrast (mandatory if focal neurologic findings are present)
If episodic psychosis/sedation follows episodes/confusion: -24–48 hours sleep-deprived EEG	If acute/subacute onset, + neurologic findings: -ESR/CRP, ANA -Serum + CSF autoimmune encephalitis antibodies	Other tests to consider: -Serum organic and amino acids -Ceruloplasmin + urinary copper -Heavy metal screen -Karyotype + microarray

Genetic testing including testing for chromosome 22q11.2 deletion syndrome should also be considered, particularly if the youth has a dysmorphic appearance, any congenital abnormalities or learning disabilities, or other cognitive limitations. Approximately 25% of individuals with 22q11,2 deletion syndrome become psychotic during adolescence, with most experiencing schizophrenia. Since the incidence of VCFS is estimated at 1 in 4,000 live births, as many as 10% of individuals with schizophrenia may have VCFS (Fig. 52–1). Projective psychological testing may be useful in confirming suspected cognitive disorganization.

However, failure to demonstrate psychotic disorganization during projective testing is not sufficient to reject the diagnosis. In addition, neurocognitive evaluation including intelligence quotient (IQ), auditory and visual memory, working memory, problem solving, processing speed, and attention measures may be useful in helping adapt academic expectations for individuals with EOS who often are expected to perform at the same level as prior to onset of their illness despite significant changes in their capabilities.

DIFFERENTIAL DIAGNOSIS

Misdiagnosis of EOS is a major concern. Factors that may lead to misdiagnosis include children's inherent difficulties in describing psychotic symptoms that are outside their normal experience, overinterpretation of transient psychotic symptoms, and the high prevalence of positive psychotic symptoms in child psychiatric disorders other than EOS. However, failure to recognize EOS when present may slow the implementation of appropriate treatments and worsen long-term prognosis.

Evaluation of a child or adolescent who may have psychotic symptoms should always include separate interviews of the child and their guardian with a focus on clarifying the child's developmental trajectory, changes in functioning, internal experiences elicited in a developmentally sensitive way, past exposure to trauma, and environmental stressors. Family history, including information about extended psychiatric hospitalizations and suicides, should also be obtained. The clinician can usually make an accurate diagnosis with attention to co-occurring symptoms, the time course of symptoms, and strict adherence to DSM-5-TR criteria. However, affected youth and their families should be educated that the diagnosis will be re-evaluated over time as additional information becomes available.

Schizoaffective Disorder

Like EOS, schizoaffective disorder is characterized by persistent positive and/or negative psychotic symptoms and functional decline or failure to realize expected developmental progress. However, during a substantial period of the active and residual phases of illness, the individual also experiences prominent mood symptoms that meet the criteria for a major

depressive episode, manic episode, or mixed manic episode. Psychotic symptoms must be present in the absence of any mood symptoms for at least 2 weeks during the lifetime duration of the illness. If an individual is in the midst of their only psychotic episode and has had significant mood symptoms throughout, it may not be possible to distinguish between schizoaffective disorder and an affective psychosis. However, the presence of negative symptoms would increase the likelihood of a schizoaffective disorder. EOS with a secondary major depression may be distinguished longitudinally because the depressive symptoms are not present for a substantial period of the illness.

Major Depression with Psychotic Features

Individuals with major depression are generally able to describe their mood vividly rather than simply label it as depressed. In contrast, individuals with EOS may say they are depressed but instead describe a state of apathy and emotional numbing that reflects their experience of negative symptoms. Insomnia, failure to enjoy activities, social withdrawal, lack of motivation, cognitive slowing, agitation, suicidality, and psychomotor retardation may be seen in both disorders. Likewise, weight loss and decreased food intake may be seen in either disorder. However, in EOS, these symptoms are usually the result of delusional beliefs about the food or one's weight. Although mood-incongruent hallucinations and delusions may occur in major depression, they are not common.

Bipolar Affective Disorder with Psychotic Features

It can be extremely difficult to distinguish a mixed manic state from EOS or schizoaffective disorder because hallucinations, delusions, irritability, and agitation are common in all three disorders. The primary distinguishing factors are the presence of a decreased need for sleep and hypersexuality in bipolar disorder versus negative symptoms in the schizophrenia spectrum disorders. Youth with bipolar disorder, especially those who require hospitalization, appear to have greater numbers of varied psychotic symptoms than adults hospitalized with bipolar disorder.

FIGURE 52–1. Features of chromosome 22q11 deletion syndrome (velocardiofacial syndrome [VCFS]). **A:** Demonstrates fluorescent in situ hybridization. One bright probe marks the end of each of the two chromosome 22s. Another probe, which binds to a marker within the typical large deletion in VCFS, is present on the upper chromosome 22 (noted with the larger *gray arrow*) but not on the lower chromosome 22 (noted with a smaller *white arrow*). **B:** Illustrates the facial features of three youths with VCFS. Note the elongated face, tubular nose with a wide nasal bridge, bulbous tip, and small lateral nares. Frequently individuals with the 22q11 deletion have low facial tone, small mouths, learning disabilities or mild mental retardation, and a variety of congenital malformations, especially of the heart and palate. A history of feeding problems in infancy is common.

Substance-Induced Psychosis

In substance-induced psychosis, positive symptoms are limited to periods of substance intoxication or withdrawal and are not better accounted for by a diagnosis of EOS, schizoaffective disorder, or affective disorder. DSM-5-TR notes that such symptoms should resolve within 1 month of discontinuing the substance, although in clinical practice, most substance-induced psychoses in youth resolve much more quickly (e.g., 7 to 10 days). If positive psychotic symptoms have been present prior to the onset

of substance use or during periods of sustained abstinence from substances, one of the other psychotic diagnoses is more appropriate. In addition, one is much more likely to see negative symptoms in schizophrenia spectrum disorders than in substance-induced psychosis, although a decline in functioning is common in both. Comorbid substance use is common in older adolescents with EOS. Substance use, particularly cannabis use, appears to be both a precipitating and exacerbating factor. Nonetheless, many youths with EOS appear to self-medicate with drugs of abuse.

Autism Spectrum Disorders

Studies have demonstrated a genetic overlap between ASDs and schizophrenia. Many researchers also agree that the risk of developing psychotic disorders is increased within the ASD population compared to the general population. ASD and EOS are distinguished by their developmental course and the presence of hallucinations and formal thought disorder. Although ASD may not be diagnosed until late childhood, the onset of symptoms prior to 3 years of age is required to make a diagnosis. Such abnormalities may be present in individuals with EOS and schizoaffective disorder, but additional symptoms should present later in life that leads to the psychotic diagnosis. Although individuals with ASD may be concrete and rigid in their thinking and verbal responses, they do not exhibit a formal thought disorder. Further, in order to make the diagnosis of a primary psychotic disorder in an individual with ASD, there must be clear hallucinations or delusions and a change in the level of functioning.

Anxiety Disorders and Posttraumatic Stress Disorder

Transient hallucinations may occur in youth with severe anxiety disorders. However, these youths seldom experience negative symptoms and are less likely to experience delusions or a formal thought disorder. In individuals with PTSD, the psychotic symptoms are generally limited to reliving events that occurred during the trauma and to the perpetrator of the trauma or very similar themes. Hallucinations that are very detailed or specific to certain situations can also be an indicator of a trauma-related phenomenon. Data regarding the long-term course of individuals with these symptoms is lacking.

Organic Disorders

The list of potential organic etiologic agents of EOS is extensive. Entities that must be considered include (1) delirium, (2) seizure disorders, (3) central nervous system lesions (e.g., brain tumors, congenital malformations, and head trauma), (4) metabolic disorders (e.g., endocrinopathies and Wilson disease), (5) autoimmune disorders (e.g., autoimmune encephalitis and lupus), (6) neurodegenerative disorders (e.g., Huntington chorea and lipid storage disorders), (7) infectious diseases (e.g., encephalitis, meningitis, or human immunodeficiency virus [HIV]-related syndromes), and (8) toxic encephalopathies (both substances of abuse and medications). Individuals should be specifically asked about the use of solvents, phencyclidine, hallucinogens, cannabis, stimulants (including street-acquired amphetamines), synthetic or designer drugs, corticosteroids, and anticholinergic agents. Also, it is important to examine for comorbid medical or developmental disorders that will likely impact the type and extent of psychosocial treatments required. For example, there is an increased risk of psychotic disorders associated with 22q11.2 deletion syndrome, which is also associated with significant learning disabilities.

Emily, a 16-year-old girl with no previous psychiatric history, was brought to the emergency room due to a sudden behavioral change and suicidal ideation. A previously cheerful and accommodating girl, for the past 2 weeks, she had been increasingly irritable, moody, and easily frustrated. The day prior to presentation, she began endorsing suicidal ideation and expressing a belief that her thoughts were controlled by an external presence (whom she referred to as “the man”). She also reported that her eyes had been replaced by cameras that allowed her to see ghosts. She was admitted to an inpatient psychiatric unit, where she was agitated, pacing, and continuing to endorse hallucinations. Her physical examination was notable for ataxia and movement disorder (semirepetitive orofacial and limb movements). Routine labs (electrolyte, blood count, liver enzymes, thyroid function, and urine drug screen) were unrevealing. An EEG was grossly normal, and her brain MRI showed no evidence of mass lesion or midline shift. She was treated with risperidone in escalating doses with little benefit.

On hospital day 7, she developed increasing fluctuations in her blood pressure and pulse and then experienced a generalized tonic–clonic seizure. She was transferred to the intensive care unit due to worsening dysautonomia and central hypoventilation. Lumbar puncture results showed protein, glucose, neutrophils, and lymphocytes within the normal range. Though CSF anti-N-methyl-D-aspartate (NMDA) antibodies were negative, serum anti-NMDA receptor antibody panel was positive, increasing the suspicion of anti-NMDA receptor encephalitis as a cause of her symptoms. Imaging for an underlying tumor revealed an ovarian teratoma, which was surgically removed. She was concurrently treated with corticosteroids and experienced a gradual improvement in her psychotic symptoms and remission of her movement disorder. At a follow-up visit 3 months later, she had returned to school part-time. She denied psychotic symptoms but reported residual fatigue and impaired concentration.

COURSE AND PROGNOSIS

Subtle developmental symptoms are frequently present throughout childhood in individuals who have EOS. The onset of overt psychotic

symptoms is frequently insidious, particularly in individuals younger than 15 years. In older adolescents, approximately equal proportions of youth have insidious and subacute onset, with rapid onset over the course of several days being rare. Rapid recovery from the initial episode appears rarer than in adult-onset schizophrenia. In contrast, many youths with EOS show improvement but continue to experience significant positive symptoms despite medication adherence for 2 to 5 years. The course tends to be chronic rather than episodic, as is reported in adult-onset schizophrenia. Further, there appears to be a significant decline in cognitive functioning during the 4-year period surrounding the onset of the illness. This cognitive decline appears to reflect both biologic brain processes and an interruption of normal development and learning. A recent study found that 30% of individuals with EOS attempted suicide over the first 10 years of illness, with one in six of those who attempted completing suicide. Suicidality was associated with more depressive symptoms and fewer negative symptoms in the first episode.

Long-term prognosis in EOS also appears worse than in adult-onset schizophrenia. A meta-analysis of 320 studies of outcomes in adult-onset schizophrenia found that about 40% of individuals had good outcomes, whereas about 60% had a chronic disabling course. In contrast, a number of studies have found that very few individuals with EOS (5% to 25%) experience good outcomes and that 75% to 80% have poor outcomes, with about half of those having an extremely poor outcome. Few live independently as adults (7% to 29%), participate in full-time education, or are employed in the open market (17% to 28%). Another study found that fewer (25%) individuals with psychosis complete high school compared to age-matched peers (84%). Treatment resistance may also be more common, although this has not been adequately studied. Figure 52–2 schematically illustrates the differences in the course between EOS and adult-onset schizophrenia.

TREATMENT

The treatment of EOS is multimodal and should include pharmacotherapy, family and patient psychoeducation and psychotherapy, and interventions in the community to support ongoing education and transition to employment when appropriate. The evidence is strongest for pharmacotherapy. A variety of traditional antipsychotics have

demonstrated efficacy in reducing psychotic symptoms. A series of studies have compared various atypical antipsychotics to placebo in adolescents with EOS and have demonstrated considerable antipsychotic efficacy, frequently reducing the Positive and Negative Syndrome Scale (PANSS) by about 20%. In these studies, olanzapine (Zyprexa) has been demonstrated to be associated with the greatest acute weight gain and lipid changes. Risperidone (Risperdal) seems to have more moderate acute weight changes, and aripiprazole (Abilify) more limited acute weight changes but a greater frequency of akathisia. Extrapyramidal symptoms appear infrequent but do occur. Only a few comparative trials have been done. These studies have generally found that the various antipsychotics differ in their side-effect profiles but have few differences in efficacy. Specifically, midpotency traditional agents appear to have relatively little impact on weight, lipids, and glucose tolerance but are modestly more likely to cause moderate or severe extrapyramidal symptoms, including akathisia. Significantly, these symptoms are generally well controlled with the addition of anticholinergic medications or propranolol. There is also a strong body of work indicating that individuals with treatment-resistant EOS respond significantly better to clozapine than to haloperidol (Haldol) or olanzapine.

FIGURE 52–2. The comparative course of early-onset schizophrenia (EOS) and adult-onset schizophrenia. Note the lower premorbid functioning of EOS, more insidious onset, and more chronic course with more limited periods of recovery.

There is much debate regarding the role of Electroconvulsive (ECT) in children and adolescents. Different regions of the United States have various rules and restrictions around the use of ECT in this population, often making it difficult for this modality to be considered. The evidence that is available is reassuring that ECT can be as safe and effective in the pediatric population as in adults.

Compared to the literature on adult schizophrenia, few studies of psychosocial interventions have been conducted thus far in EOS. However, both cognitive remediation therapy (CRT) and supported employment interventions show promise in improving the functioning of affected youth. A recent study found that clinically stabilized youth who received CRT experienced significant improvements in verbal memory and executive functions and modest improvement in daily living, adaptive functioning, and reduced family burden compared with controls. Most of these changes were maintained after 3 months. Similarly, a small

Australian study of supported employment (Individual Placement and Support [IPS]) found that youth engaged in IPS gained significantly more jobs (23 vs. 4), earned significantly more money ($2,432 vs. $0), and worked for a longer time period (45 vs. 19 days). An overall positive vocational outcome (return to work or education) was achieved by 85% of the subjects, compared to 6% in the control group. Therapeutic interventions must focus on functional improvement in addition to symptomatic improvement in order to facilitate recovery. Targets of treatment include reduction in self-stigma and caregiver burden and restoration of self-esteem, self-efficacy, hope, and optimism.

Specialized first-episode psychosis programs have been developed to deliver multimodal care to individuals early in their course of illness. Often these programs include interventions incorporating medication management, cognitive behavioral therapy, family interventions, and work and/or school support services. Two-year outcome studies from the NIMH Recovery Aftern an Initial Schizophrenia Episode (RAISE) Early Treatment Program revealed significantly greater improvement in quality of life and symptom improvement versus care as usual.

FUTURE DIRECTIONS

Improving the recognition and timely diagnosis of early-onset psychosis will be important in reducing the disability and personal and societal costs associated with these debilitating illnesses. It will be important to further characterize the long-term course of EOS and other early-onset psychotic disorders, particularly with regard to neurocognitive and biologic outcomes. In addition, it is essential that psychosocial treatments such as cognitive remediation, social skills training, and supported education and employment programs are rigorously evaluated and manualized where appropriate. More effective and safe medication strategies are also required to provide the most effective and safest treatment for these highly vulnerable individuals. This will require both more comparative trials and more studies of long-term outcomes. The development of additional psychopharmacologic treatments, particularly those that are more focused on the neurodevelopmental processes that appear so prominent in EOS, is also essential. Finally, EOS also can serve as a more homogenous model for understanding the pathophysiology of schizophrenia and identifying key neurodevelopmental pathways in which to intervene.

Child Psychiatry: Psychiatric Treatment

53.1 Psychodynamic Psychotherapy (Child Psychiatry)

David L. Kaye, M.D., and Michael Shapiro, M.D.

Psychodynamic psychotherapy (PDP), rooted in psychoanalytic theory and used interchangeably with psychoanalytic psychotherapy by most practitioners, has a long and storied tradition in child and adolescent psychiatry both in the United States and internationally. While for many years the backbone of child psychiatric theory and practice, it was under siege for much of the past four decades from different quarters. The ascendancy of neurobiologic approaches and understanding, third party payers' demands for briefer and less expensive treatments, and the public's demand for empirical support all contributed to the diminished influence of psychoanalysis. Despite this, psychoanalysis has remained a vibrant, and still the most comprehensive, framework for understanding psychotherapy and the human mind. In the last two decades increasing empirical support for PDP with adults, children, and adolescents has energized the

approach. The groundbreaking review by Shedler, The Efficacy of Psychodynamic Psychotherapy, published in American Psychologists in 2010 was a landmark in establishing the efficacy of PDP with adults. Since then Leichsenring has published a recent systematic review (2015) that concludes that PDP is efficacious for a wide range of adult mental disorders. In 2012, the American Academy of Child and Adolescent Psychiatry published the first ever Practice Parameter for PDP with children. Two volumes of the Child and Adolescent Psychiatric Clinics of North America (January, April 2013) were devoted to PDP. Evidence-based, manualized approaches such as interpersonal therapy (IPT) and mentalization-based therapy (MBT) are based solidly in PDP principles. Further there has been a softening of the boundaries between psychotherapy treatments with inclusion of aspects of different therapeutic approaches now commonplace in child therapy.

Although the place of psychoanalytic psychotherapy within child and adolescent psychiatry has declined from the hegemony it once held, it has remained a primary framework for many practitioners and a psychotherapeutic foundation of many, if not most, residency training programs. In the past, it was often seen as a stand-alone treatment for child psychiatric disorders. In current clinical work, practitioners work pragmatically, flexibly, and in concert with other approaches, including family therapy, behavior therapy, cognitive-behavior therapy, psychopharmacology, and school interventions. Regardless of the approach, the understanding of patients stems from an overarching psychoanalytic framework. Psychoanalytic concepts also continue to be applied broadly to clinical work in residential or other intensive treatment milieus, social services, police, juvenile justice settings, and schools. In looking over his career Leon Eisenberg, a long-time critic of psychoanalysis, observed that:

"Where I erred was in failing to appreciate the powerful and lasting contribution psychoanalysis made to psychiatry by teaching trainees to listen to patients and to try to understand their distress, rather than merely to classify them by some diagnostic algorithm, or snow them with drugs, or lock them away, or release them to homelessness. Basing care on what is unique to the individual patient is central

to clinical competence, whether in medicine or surgery or psychiatry." (Excerpt from Eisenberg L. The past 50 years of child and adolescent psychiatry: a personal memoir. *J Am Acad Child Adolesc Psychiatry*. 2001;40(7):743–748. doi: 10.1097/00004583-200107000-00008.)

Far from a single and monolithic set of ideas, psychoanalysis encompasses a wide diversity. Disagreement exists about the nature of the mind, development, psychopathology, and treatment. Despite this, psychodynamically oriented practitioners share the following precepts:

1. The primary emphasis and focus of PDP are the individual's subjective, inner experience of self and others.
2. A primary value is the search for emotional truth. Seen as elusive and often hidden from ourselves, emotional honesty and truth is sought as an end unto itself. Through this pursuit and recognition, human beings have their best chances for a satisfying life.
3. A primary goal in treatment is self-acceptance and self-understanding through the instrument of a relationship. The primary "tool" of psychoanalytically informed therapy is the relationship between the doctor and the patient.
4. Unconscious mentation is critical to understanding patient's subjective experiences and relationship patterns. Unconscious affects, motivations, and process (including defense mechanisms) are accepted as critical determinants of normal and abnormal human behavior.
5. Behavior, emotion, and relationship patterns can be understood through the lens of psychic determinism. Human behavior has a logic of its own, happens for psychological "reasons," and is understandable through following a link of multiple impulses, affects, defenses, and their associated relational experiences. Often these links are unconscious and the work of therapy includes greater awareness of the impact of defenses and warded off emotions and wishes.
6. The child is the father to the man. Early experience in a child's life is critical in initiating important and enduring patterns in perceiving, thinking, feeling, and behaving that are carried

forward in life via internalized beliefs, working models, assumptions, expectations, and attitudes (i.e., transference).

7. Treatment critically focuses on transference. Focusing on the here-and-now transference reactions of the patient are central to understanding the patient and promoting growth in the psychoanalytic process.
8. Treatment goals are focused on psychological growth broadly, not just symptom amelioration. For example, in child psychotherapy goals often include a return of the child to a healthy developmental pathway, including greater self-acceptance, self-awareness, and self-expression.
9. Emotional barriers ("resistance") to psychological growth or resolution of symptoms can be expected in the course of treatment.

HISTORY

The first psychoanalytic reference to child cases was Sigmund Freud's case of "Little Hans" in 1909. Although Freud was skeptical that children could be analyzed, in this case he provided supervision to Hans' physician-father, who successfully analyzed the 5-year-old boy's phobia of horses. A few years later Sandor Ferenczi reported his attempt to directly treat a child, but found that the child quickly became bored with the analytic process and wanted to return to his toys to play. It was not until a series of women psychoanalysts entered the scene that it became appreciated that play was the central medium of expression for children, and should be incorporated into work with those with emotional disturbance. Hermine Hug-Hellmuth, a teacher by prior training, was the first psychoanalyst to report the use of play in the treatment of children in 1921. She believed that treatment of children was primarily educational and limited in its goals.

By far, the major figures in the early development of psychoanalytic treatment of children were Anna Freud and Melanie Klein. Klein began to develop a technique for working with children while in Berlin in the early 1920s, and in 1926 moved to London,

where she continued her work. She saw children as a cauldron of passionate drives (both aggressive and sexual) with rigid, harsh superegos. Her technique relied on equally powerful and direct interpretations of unconscious impulses. She appraised play as the equivalent of adult-free association and eschewed any role for parents in the treatment. Anna Freud, also a teacher by training, began her psychoanalytic training in the early 1920s and shortly thereafter formed a child psychoanalysis study group in Vienna. She viewed children as immature and undeveloped, necessitating a gentler and educative approach that was careful not to interpret too deeply for fear of overwhelming the child. She recognized work with the parents as difficult but necessary to further the development of the child and also to support treatment with the child. She saw the goals of treatment as being to return the child to their developmental path and not to effectuate a definitive or complete cure. In 1927, Anna Freud wrote the first book on child analysis, *Introduction to the Technique of Child Analysis.* The differences between Klein and Freud led to a confrontational Symposium on Child Analysis in May 1927. These "controversial discussions" brought points of disagreement into sharp focus, and this schism has persisted to the present day, albeit lessening in the recent past. The Kleinian school became dominant in the United Kingdom and South America, while the Freudian school held sway in North America.

Into this fray entered the analysts of the "independent school" in Great Britain in the 1940s, including Donald Winnicott, Wilfred Bion, and others associated with the object relations perspective. Starting in the Kleinian camp, they attempted to bridge the divide with the Freudians. Winnicott contributed enormously to the analytic understanding of child development and treatment, remaining perhaps the most well-recognized influence in the field. His rich body of work included an emphasis on the importance of the early mother–child relationship; the role of play, mirroring, and the establishment of the "holding environment" in healthy development and in analysis; the meaning of the transitional object; and the true versus false self.

In North America an additional perspective was emerging, beginning with Kohut's work in the 1970s on the development of the self. This evolution has continued to the present with major contributions from interpersonal, relational, and intersubjective theorists. Harry Stack Sullivan, Robert Stolorow, Stephen Mitchell, Joseph Lichtenberg, James Fosshage, and Irwin Hoffman among others have been major figures representing these perspectives. All of these authors have written primarily about clinical work with adults, with a few current authors applying the concepts to work with children (e.g., Gary Landreth, Charles Schaeffer). These theorists have also been informed by convergences with infant and attachment researchers such as Daniel Stern, John Bowlby, Mary Main, and Mary Ainsworth. Rather than emphasizing the role of drives, defenses, resistance, conflict, and other traditional concepts these authors assert that the basic building blocks of mental life are relations with others upon which major psychic structures are built. This reflects a shift in the foreground from an intrapsychic focus to a relational field model, from objectivism to constructivism. Consequently there has been a shift in emphasis in treatment from *interpretation* to the *"co-creation of developmentally needed relational experiences"* (Jay Greenberg and Mitchell). Recently there has been a convergence of attachment, self-psychological, and relational perspectives. This is embodied by the work of Peter Fonagy, Mary Target, Efrain Bleiberg, and others who have written about the central importance of *mentalization*, or self-reflective function. This ability to read and understand the feelings, thoughts, and impulses associated with human behaviors is fundamentally dependent upon the establishment of secure attachments. In the past several years this has led to MBT, a manualized therapy approach that has been evaluated empirically primarily in adolescents. Even more recently neuroscience-based understandings have begun to be integrated into PDP with books such as Daniel Siegel's *The Developing Mind* and Delgado, Strawn, and Pedapati's *Contemporary Psychodynamic Psychotherapy for Children and Adolescents: Integrating Intersubjectivity and Neuroscience*.

While clinical work with infants is beyond the scope of this chapter, a great deal of parent–infant psychotherapy has been based on psychodynamic principles. Psychodynamic theory has influenced the field beginning with Selma Fraiberg and early programs developed by Alicia Lieberman, up to present-day evidence-based treatments such as Parent–Child Interaction Therapy.

It should also be noted that the term "psychodynamic" was originally used to describe the ever-changing balance of mental and neurophysiologic energy intrinsic to humans' inner life. This was contrasted with an approach that emphasized behavior, descriptive phenomenology, or anatomic structure. In this sense psychodynamic and psychoanalytic are not synonymous. In the United States there have been a number of influential writers who would be considered within this broad psychodynamic tradition, even though they were not psychoanalysts. These psychodynamic therapists (e.g., Frederick Allen, Clark Moustakas, Ann Jernberg, John Meeks, Virginia Axline, and more currently Charles Schaefer, Garry Landreth) have also had a major place in the history of child and adolescent psychotherapy and continue to influence current practice.

THEORETICAL ISSUES IN PSYCHODYNAMIC WORK WITH CHILDREN

Beginning from its earliest days child psychodynamic psychotherapists have recognized that there are developmental differences between child and adult patients. While the overarching theoretical precepts of PDP reviewed above hold, there are fundamental differences in work with children and adolescents as compared with adults.

Children Are Not "Little Adults"

Child patients differ in significant ways from adults. These differences are crucial in informing practice. First, children's limitations in language, cognition, and experience must be taken into account to engage and sustain children in treatment. Because of

cognitive and emotional limitations their understanding of the problem or the need for treatment is likely to be incomplete or inaccurate. Children tend to externalize problematic issues and have little ability to understand how therapy might help them now, let alone in the future. Further they have limited capacity for tolerating pain and anxiety, creating another barrier for keeping child patients in treatment. Meeting with a stranger who will meet and talk intimately with the child is certainly extraordinary, and may be confusing and threatening. For all these reasons the child therapist must *actively* engage, educate, and work with the child to create the secure space needed to establish a therapeutic alliance.

Another major difference is that children do not come to treatment at their own request. They are brought by their parents, often for reasons that are more of concern to the adults rather than the child. Further, the stigma associated with treatment is often difficult for children (especially adolescents, who are struggling to feel “normal” and “like other kids”). The reasons for treatment must be explored and explained in a way that is understandable and meaningful to the child. The rationale that engages the child may be different from the reasons the parents bring the child in.

A 7-year-old boy was brought for treatment by working-class parents who were concerned about depressive irritability and argumentativeness, which had created great tension in the family. When seen individually the therapist asked the child about his understanding of why they were meeting. The child responded “I don’t know.” The therapist then asked why the child thought the parents had brought him, and he again avoided the question. Later in the interview the therapist returned to the issue while the child played out a puppet scene of different animals fighting. The therapist explored how the animals felt and the child said “sad.” As the play developed the therapist explored whether the child might also be sad. This seemed to resonate and the child nodded his head “yes” and went back to playing with the puppets. As the session closed the therapist suggested that in meeting together they might come to understand “why you feel sad and what we can do to help you feel better. How does that sound to you?” The boy looked up shyly and nodded his approval.

The Child Psychotherapist Must Recognize the Critical and Central Role of the Parents or Caretakers in the Child’s Life

In the early days of child PDP the child therapist would have no contact with the parents, while a social worker would meet alone with the parents. Over the years the importance of establishing and utilizing the relationship with the parents moved more to the foreground. Contemporary psychodynamic psychotherapists endorse that at a minimum the therapist must be able to sustain enough of a relationship with the parent(s) or caretakers to support the treatment of the child. The parents must be engaged sufficiently to bring the child to treatment, pay for the treatment, and withstand their own emotional reactions that may arise as the child changes. Further, a positive alliance with the parents can sustain a child patient through the usual feelings of reluctance to coming to treatment. Ideally the parents can be assisted in fostering sturdier

attachment, boundaries, and mentalization. This all requires the psychodynamic child therapist to develop a solid working relationship with the parents while at the same time preserving a sense of confidentiality and trust with the child.

A 10-year-old girl was seen in twice-weekly psychodynamic psychotherapy. As the child left her sessions, her mother each time asked “how is she doing?” The therapist made a separate appointment with the parents to discuss these concerns further, while also exploring how the child felt about this meeting. The girl had concerns about “what they are going to say about me,” but assented with support and understanding from the therapist. After discussion with the parents it was agreed that the therapist would meet with the parents once every 3 weeks to discuss the child’s progress and current functioning, provide support and guidance to the parents, and monitor the parents’ anxiety. Once this plan was initiated, the mother’s anxiety seemed to lessen and she no longer waited expectantly after the sessions with her daughter. The therapist remains attuned to the impact of these meetings on the child patient and discusses with the child as needed.

The Child Patient Is Dependent on the Parents Materially, Physically, and Emotionally

This has profound implications and has led to the conviction, even among the most traditional child psychoanalysts, that therapeutic work with the parents is essential and necessary in working psychodynamically with children. Furthermore the ongoing interactions with caretakers have a continuing effect on the growth and progress of children in therapy. Because a child’s personality is unfolding and shaped strongly by continuing developmental experiences, the ongoing parent–child interactions have a “double-barreled” effect. They not only affect the child’s developing internal world of expectations, assumptions, and beliefs about self and

others, but also then in turn impact on the child's exposure to future developmental experiences. By inhibiting or encouraging exposure to growth-promoting developmental experiences the ongoing parent–child interaction exerts a multiplier effect on the child. This observation strongly influences the overall aim of PDP with children, which, as initially articulated by A. Freud, is to restore the child to the path of normal development. Once back on track, normal development can then take over and provide the experiences needed for internal growth. From a psychological perspective the child's dependency also impacts the individual treatment directly. Adolescents, especially during the early teen years, are struggling mightily to separate from their parents and establish an independent sense of self (i.e., identity). As a result looking to and depending on another adult, like a therapist, can be fraught with complication and ambivalence. This can interfere with the establishment of a therapeutic relationship even when the adolescent recognizes a need for help.

Children and Adolescents Evoke Stronger Emotional Responses in Psychotherapist's Attempts to Help Them

As is known by anyone who has spent any time working in child mental health settings children evoke strong feelings in the therapists who work with them. This often results in desires to protect and rescue the child, especially when therapists observe here-and-now pathogenic interactions and traumatic experiences enacted by parents. At other times the child's behaviors can be exasperating, infuriating, and frightening. All of this results in feelings within the therapist that are generally much higher in intensity than those generated in adult work. This places a premium on the therapists' recognition and containment of their own emotional responses. While these reactions may be helpful clues in understanding the child's world, they can make for highly challenging work.

Play Is the Central Medium for Communicating With Younger Children

Since its initial recognition by early psychoanalysts, play has been recognized as the critical in communicating with children in PDP. This is especially true for younger children whose language skills have developed to a limited degree and for whom play is their "natural" language. Older children are increasingly comfortable talking about their own inner states and by 9 or 10 may find playing "baby-ish." Whether or not to use play materials with an individual child must be determined on a case by case basis. Psychodynamic psychotherapists will encourage play by having a number of toys visible and accessible to the child. This helps to engage the child and conveys that the therapist is willing to meet them on "their turf" and create a safe space for talking about their problems. Much of the "talking" is done "in the displacement" of the play as opposed to the direct discussion that occurs in therapy with older adolescents and adults. Most therapists recommend a limited number of toys that allow for the symbolic expression of a wide array of affects and themes (e.g., doll house, dolls, puppets, animals, blocks). Art materials (drawing, painting, clay) and techniques (e.g., Winnicott's Squiggle Game), storytelling (e.g., Gardner's Mutual Storytelling Technique), and role playing are often incorporated into dynamic therapy. Therapists also may utilize structured games (e.g., checkers, chess) or therapeutic games (e.g., Talking, Feeling, Doing Game) in some circumstances.

As Winnicott has pointed out, play exists "in the space between" the inner world and external life, *between* patient and analyst. Play requires active participation from both the patient and the analyst. It is aimless and nonpurposeful; there are no social consequences. As such, play allows for the safe exploration of affects, conflicts, areas of concern, ideals, roles, and wishes. This accords play a self-healing effect in and of itself. Play is a forum for problem solving and experimentation. Play also offers a window into the inner life of the child. This allows for a deepening of the understanding of the child and may be the basis for targeted interventions. As Winnicott has

written, when play is not possible then the work of the therapy is to help the child to be able to play.

Transference in Children and Adolescents Is More Complex Than With Adults

Much controversy has surrounded the concept of transference in work with children. Children's internal representational world is still being actively formed and altered by ongoing current interactions with parents and others. As such transference reactions, while organized to a degree, are still in flux. Nevertheless transference reactions occur ubiquitously in PDP as children enact the beliefs, assumptions, and expectations they are developing. These reactions are here-and-now examples of the prototypical interactions that are interfering with their growth and development. Interpretations of transference phenomena primarily address this here-and-now aspect ("perhaps the nervous feeling you have is because of some anger you are feeling") and much less so address genetic roots (i.e., interpretations about the child's reaction being connected to previous experiences with parents are less applicable with younger children). PDP focuses its greatest attention on these transference reactions, seeing this as the most powerful arena to help children gain flexibility and greater freedom in their understanding of themselves and their interactions with others. Psychodynamic work with children is made more complex because the child's transference reactions intersect with the parent's emotional needs and vulnerabilities. This can lead to divided loyalties between the child's desire for growth and the parent's needs. As in all PDPs countertransference reactions require the therapist to discern what belongs to their own psychological dynamics and that which is engendered by the child's behaviors. Countertransference reactions can be invaluable clues to understanding the child's transference reactions and warded off self-experiences.

Barriers to Change Exist Within the Child Patient (i.e., Resistance) and Within the Family System

Resistance is a concept that originates in classical theory to describe the inevitable intrapsychic barriers to growth. Traditionally this is thought to derive from conflicts between the patient's ego, id, and superego. Subsequent theorists have conceptualized this differently. Some have understood these barriers as a striving for growth and attempt to master traumatic experience. Others have seen the terror and dread of changing and giving up familiar ways of seeing oneself and others as central. Still other contemporary theorists account for these impasses as a result of psychic deficits that arise from the absence of needed relational experiences and empathic failures. Resistance in this frame is further impacted by the therapist's ability in the here and now to provide these growth promoting experiences.

While resistance is typically seen as intrapsychic, there are also systemic barriers to change. As the child becomes less symptomatic and grows psychologically the parent's self-concept, parent–child or marital relationship may become challenged, likely due to the child's previous role as the identified patient in the dysfunctional system. This system can continue to create impediments to the child's progress and may require the therapist to attend and respond to the parents' anxiety about change.

A 16-year-old girl was seen in individual psychodynamic psychotherapy for generalized anxiety disorder and recurrent depression. As the teen's symptoms lessened and she developed greater confidence, she began to experiment with desires to move away from the orbit of family expectations and expressed interests outside the parents' expectations. This, in turn, stimulated the mother's criticism about the teen possibly "ending up like her father." This led to increased intra-martial conflict, revealing a longstanding issue in the marriage. The parents were not able to negotiate this in a more satisfactory way, and ultimately, they were referred to marital counseling for themselves. Without this forum for their own growth, the pressure on the child to inhibit their own growth would remain unchecked.

There Is an Increasing Focus on Attachment, Mentalization, and Self-Regulatory Issues versus Oedipal Issues

Classical theorists have highlighted the central importance of oedipal issues in understanding both psychopathology and treatment. Early case descriptions appear to explain clinical phenomena almost entirely through this lens and treatment appears to hinge on adequately addressing through interpretation these oedipal issues consistently; triadic relationship patterns and issues of competition, sharing, sexuality, and rivalry are paramount. In contrast, contemporary theorists, no doubt responding to the major societal changes and vicissitudes of life in the 21st century, have instead placed the primary focus of understanding psychopathology and treatment to early parent–infant interaction, "basic trust," attachment, separation–individuation concerns, self-reflective process (mentalization) and self-regulation. While not disavowing a place for triadic issues this has prompted a major shift in emphasis to dyadic issues.

A 12-year-old boy is brought for treatment because of multiple fears, languishing academic performance and ambivalent attendance to household responsibilities. Toward the end of the psychotherapy, after the child had made much progress, his father had a relapse of substance addition. While the original symptoms could be understood as a reflection of oedipal issues (e.g., castration fear and guilt over hostile feelings toward a parent, leading to academic inhibition and fearfulness), contemporary theorists would emphasize the boy's real anxiety over the safety of his father, and the potential for guilt for hostile feelings toward a loved one with a chronic illness.

Interpretation Was Emphasized as the Central Determinant of Therapeutic Action in Classical Theory, But Contemporary Views Place More Emphasis on Attachment Perspectives

While interpretation was seen in classical viewpoints as the central determinant of how psychodynamic psychotherapy works ("therapeutic action"), alternative explanations are now in ascendancy, namely the primary importance of a consistent and caring attachment figure. Classical analysts have emphasized the central role of interpretation and "making the unconscious conscious" in the treatment of children. Interpretations proceed from that closest to consciousness to those mental contents furthest away (i.e., unconscious). This is especially important with children. These interpretations may be directed toward defenses, wishes or intentions, or transference phenomena. Interpretations are traditionally made in a specified order, from the manifest level to what is unconscious: first affect or behavior, then defense, then impulse. In other words the analyst first would interpret the affect or behavior ("You appear to be feeling angry right now"), followed by the defense ("perhaps you are angry because you were disappointed that I did not remember your birthday"), and last the underlying impulse ("perhaps you were really hoping that someone would remember your birthday"). Timing of interpretations must be aligned with the patient's readiness and the state of the therapeutic alliance. Theorists differ in what they see as the primary impulses or fundamental motivators. Classically oriented analysts follow Freud's original drive theories and see sexuality and aggression as primary; contemporary analysts might emphasize self-cohesion, self-regulation, attachment, mastery and assertion as the most powerful organizers of motivation. Contemporary theorists hence would see therapeutic action as stemming from the provision of needed relationship experiences that allow for the development of a cohesive and vital self. Fonagy, Bateman, and others have attempted to bridge these views, attachment theory, and cognitive neuroscience by highlighting the goal of *mentalization.* Mentalization, or the self-reflective capacity, enables the child to perceive and process mental activity in the self and others. This allows the child to develop a model of the inner thoughts and feelings that underlie human behavior. Optimally this capacity develops out of the child's early attachment with parents who relate to the child as an

intentional being with underlying thoughts, feelings, and intentions. As a result of these experiences the child is then able to understand other's behaviors and inner states. These theorists posit that this is the centerpiece of psychoanalytic work with children (and adults) and success depends on the degree to which this develops.

PRACTICAL MATTERS

Psychodynamic Psychotherapy With Children and Adolescents Can Take Differing Forms and the Principles Can Be Applied in Work With Individuals, Groups, and Families

Classically, child psychoanalysis involved seeing the child four or more times per week, lasting over a period of years. In this form psychoanalysis is rarely used currently, although there is some research to suggest it may have a place with particularly disturbed children (see Research section). PDP occurring once, or perhaps twice, per week over a period of months to years, is much more common in both private practice and public clinic settings, although it is increasingly difficult because of payment issues and the hectic pace of family life in the United States. The nationalized health systems in the United Kingdom and Canada continue to support such treatments widely.

While typically open-ended in length, there have been recent adaptations of brief, time-limited PDP to work with children. For example, MBT has been applied to work with adolescents, children, and families. Psychoanalytic principles have also been widely applied to adolescent and family group therapies.

As noted previously, psychoanalytically informed principles often are integrated into all treatment efforts with the child. Owen Lewis has delineated such a model of integrated treatment in which psychodynamic principles fundamentally inform the gamut of treatment interventions (e.g., behavior therapy, psychopharmacology, family therapy, and so forth). The more recent review by Malberg and Mayes (The Contemporary Psychodynamic Developmental Perspective) elaborates on this evolution.

Perhaps Even More Than in Work With Adults, the Therapeutic Frame and Setting Are Critical in Working With Children and Adolescents

Child therapy requires a dedicated office that can serve as a concrete reminder of safety, security, and predictability for the child. Using the same office for every session fosters these goals. Some analysts create special cubby holes or boxes for children to keep their particular toys, drawings, and so forth. This also serves to personalize the space for the child. The office should be neither so small that the child feels closed in, nor so large that the child is overwhelmed and overstimulated. An explicit therapeutic contract should be discussed with the child and parents. Children should not be forced to attend therapy although reluctance is not uncommon. Assent (vs. consent) is a more appropriate goal. It is generally recommended that therapy occur at the same time, on the same day of the week. This also strengthens the predictable frame necessary for successful work. All these ingredients contribute to establishing what Winnicott referred to as the “holding environment.”

Confidentiality Is a Particularly Complex Issue With Children and Adolescents

On the one hand, there is a clear need to maintain a sense of safety and security in order for the child to reveal their deepest worries, hopes, thoughts, and desires; on the other hand, therapists may perceive parents or guardians could be instrumental in making effective change if they were aware of such deep worries, thoughts and desires that a child or adolescent may forbid the therapist from sharing. In more serious situations, therapists have a legal and ethical obligation to safeguard the child’s welfare and may be required to break confidentiality. When issues of safety (e.g., suicidality) arise parents must be informed. At other times the involvement of child protective authorities may be needed, which in some situations may end the treatment. In any event the limits and extent of confidentiality should be carefully explained to both the child and parents at the beginning of treatment.

Working With Parents Is Essential in Psychotherapy With Children and Adolescents

As already noted parents are decisive players in PDP with children. Although there are times that the parents need to honor the necessary boundaries of treatment with the child, it is seldom appropriate that the parents are excluded from the treatment. Typically parents are included from the beginning to obtain the history and to begin to establish a working relationship that can sustain the treatment of the child. At the conclusion of the evaluation period it is helpful to explicitly review the assessment and establish a treatment plan with the parents. The analyst must reach concordance with the parents on the nature of this treatment contract from the beginning and may need to re-visit this throughout the course of treatment. Regular meetings with the parents (with or without the child) are routine parts of PDP. These ongoing meetings serve to maintain the working relationship, provide further information about the child, and create a forum for parent guidance or exploration of parental psychological issues that impede the child's growth. When it becomes apparent that the parent(s) are in need of their own treatment then referral is generally made to another therapist. Providing individual PDP to two members of the same family contemporaneously is discouraged due to the inherent conflict of interest and encroachment on confidentiality that may undercut the alliance with one or both persons.

CLINICAL CONSIDERATIONS

The Aims of Psychoanalytic Psychotherapy Are Ambitious

Psychoanalytic psychotherapy aims to go well beyond the relief of symptoms and/or greater coping or adaptation. With adults, the goals have been to seek a "cure," broadly improving the quality of life (i.e., "to work and to love"), and inoculating the patient from future stressors. In contrast, A. Freud first articulated the aims of child psychoanalysis as a return to the path of normal development.

Subsequent analysts have emphasized the aims of increased mentalization, self-understanding, self-regulation, personality integration, self-expressiveness, self-esteem, flexibility, interdependence, capacity for intimacy, increased frustration tolerance, and capacity to play. It is assumed that reaching these goals in a “good enough” fashion will result in a diminution of symptoms as well as improved functioning in school, in the community, and with peers and family members.

The Indications for Psychodynamic Psychotherapy Most Likely Include Children and Adolescents With Internalizing Disorders

Indications for PDP have historically focused on the presence of certain strengths or loose categories of problems generally seen as due to intrapsychic conflict. Typically, indications have included those children with neurotic level disorders and sufficiently good internal and external resources such that the gains will be following sustainable termination of treatment. This situation rarely exists in clinical practice. Further, research has indicated that this group of children may benefit as well or better from less intensive treatment efforts involving the school, family, or community resources. At the same time, children with more severe disturbances often subsumed under the category of borderline conditions, may require an intensive effort such as psychoanalysis for effective results to be achieved (see the section on Research and Evaluation). Another way to look at indications is to consider the goals of the treatment. For example, if the goal is to understand one’s feelings, thoughts, and the connections between this inner world and the outer world of behavior (mentalization or self-reflective function), then PDP is likely to be helpful. Because PDP is now generally integrated with other treatment approaches, it is not necessary for this treatment to be all-encompassing but rather to aid in forwarding critical developmental processes.

Some Children With Externalizing Disorders May Be Helped With Family-Focused Psychodynamically Informed Therapies

Regulation-focused Psychotherapy for Children (RFP-C) and Parent–Child Interaction Therapy targeting Emotion Development (PCIT-ED) are two examples of recent manualized psychotherapies targeting the emotional regulation of young children. This is an area of increasing research (see the section on Research and Evaluation), with the best results seen with modalities that include a heavy component of parent/guardian involvement. Historically, externalizing disorders have been considered a contraindication of individual PDP; the key elemental difference perhaps being the recruitment of parents/guardians to assist children in regulating their intense emotional outbursts.

There Are Some Children for Whom Individual Psychodynamic Psychotherapy Is Not Likely to Help or Is Contraindicated

Contraindications may include some children with externalizing problems, particularly when there are “callous-unemotional” features or when there is no comorbid internalizing disorder or an inability to restrain impulses consistently enough to play. Another group of children for whom there is little to justify this treatment would be children with more than mild intellectual disability, classical autism, many autism spectrum disorders, and traumatic brain injury (and other neurologic conditions) when receptive language abilities are substantially compromised. These may be relative contraindications as there may be focal psychodynamic goals even in some of these cases. Again, treatment for many of these individuals will be multimodal, and other treatment modalities may be more critical (i.e., school interventions for children with autism-spectrum disorders).

AN OVERVIEW OF THE PHASES OF TREATMENT

Beginning Treatment: Focusing on the Establishment of a Working Alliance

This requires not only creating a therapeutic ambiance for the child but also establishing a supportive, working relationship with the parents. The initial goal with the child is to create a playful,

confidential environment in which they and the therapist can explore the world of the child's thoughts, feelings, and behaviors. In the beginning, some exploration and understanding of why the child is meeting with the therapist is useful, as well as an explicit clarification of the treatment frame and contract ("we will be meeting for 45 minutes every Tuesday at 4:00. This time will just be for us. We'll try really hard to meet every week"). It is also helpful for the therapist to explain to the child that they are "someone who meets with kids to help them with their feelings," "to see if we can understand you," "to help you feel better," "to help you understand how you feel and why you do some of the things that cause you trouble," and so forth. The gist of these comments is to explain the role of the therapist and to convey a steadfastly hopeful attitude to the child (and parents) through what will be inevitable ups and downs. For the playroom to acquire a "specialness" to the child, these messages must be communicated repeatedly. The ground rules also should be explained ("we will talk and play together during the time we are together. Anything is okay as long as no one gets hurt and nothing gets broken."). Of course, once the child begins to express themselves they will see what the therapist is "made of." This is the true acid test for the child. Only over time can the child get the sense that the therapy is not a punishment, that the therapist has hope for the child, the child can feel understood, and problems can be solved. For the most part, in the initial phase, the therapist keeps their comments and interpretations focused on the displacement of the play rather than making direct comments about the child's real-life situation. This initial launching typically takes a few weeks (in the healthiest children) to a number of months to achieve a secure working relationship.

Mid-Phase Treatment

This begins when the child has established a clear working alliance. The child has a familiarity with the frame of treatment, even though emotional upheavals may continue in the sessions. During this phase, the primary emphasis is on the "work" of therapy, that is, the

slow and repetitive recognition of feelings, defenses, and their relationship to behaviors. Over this time, the same theme in a play session may occur for months at a time. The therapist continues to create with the child a sense of hope and comfort as increasing recognition and understanding of the child's inner world accrues. It is in this phase that the interpretation of prototypic problematic patterns and transference reactions occurs. The focus on the here-and-now reactions of the child with the therapist is especially fruitful, although much work continues to be done in the play displacement. Gradually in this phase, the child becomes more able to connect this displacement with their own life. Reconstructive statements linking current emotional or behavioral patterns with previous life experiences are generally not emphasized in work with children.

Ending Treatment

Optimally treatment ends when the child is free from symptoms, has made sufficient progress in psychological growth and maturity, and is back on track developmentally. In the real world, termination generally comes about for other reasons. Frequently termination occurs when partial improvement has been made and practical considerations (insurance, finances, transportation, moves, graduation) become paramount. Termination provides an opportunity for the child to focus on issues of separation, loss, and mourning. Paulina Kernberg has elegantly stated:

> "As the child approaches the end of her treatment, the same issues that brought her to therapy once again come to the fore: (1) Do they (the parents) care? (2) Does the therapist care? (3) Do I care for you (the therapist)? (4) Do I care for them (the parents)? (5) Can I care for myself? (6) Will you remember me? (7) Will I remember you?" (From Kernberg PF. *Children With Conduct Disorders*. copyright © 1991. Reprinted by permission of Basic Books, an imprint of Hachette Book Group, Inc.)

In the process of ending, it is important to include the child actively in setting a final date. In general, 6 weeks to 3 months is sufficient time to allow the child and family to concentrate meaningfully on these issues. Setting the date so that it does not coincide with other

real-life endings (e.g., graduation, moving dates) permits the child and family to experience the fullest impact of the termination. During the ending phase, children frequently regress, with a recurrence of symptoms and defenses in the face of this stressor. Denial of the importance of the relationship by the child, parent, and therapist is not uncommon and should be understood as a reaction to the impending separation and loss. In the course of ending, the child should have an opportunity to explore and claim the gamut of feelings that inevitably arise: anxiety, guilt, anger, sadness, satisfaction, ambivalence, and so forth. This frees the child from developing defensive patterns to face the inevitable future losses of life.

After 8 months of weekly psychotherapy, an 11-year-old girl's symptoms of perfectionism and severe recurrent abdominal pain had improved sufficiently that the child came in and stated that "I don't have pain! I don't need to come here anymore." She later added that "maybe I need help with boys." This led to a series of discussions about termination, which resulted in the setting of a final date 6 weeks hence. In the first meeting after the termination date was set, she revealed that she was able to comfortably talk with the therapist, unlike with her parents, with whom she felt she could not be open. The next week she became irritated by a comment from the therapist and said, "If I had known you would say that I would have left weeks ago!" She continued to talk about other separations in her life, especially the death of her grandmother. In the final sessions, she alternated between denial and recognition of her emotional reactions to the upcoming termination. She continued to discuss other endings, moves, and friends leaving. In the last session, she said: "Okay. I have something to say. I think I'll miss you. You helped me." To which the therapist responded: "Well, we have worked well together. And I will miss you too." She left the session knowing that she could make future appointments if the need arose.

RESEARCH AND EVALUATION

Claims of lacking an evidence base have been haunting PDP for decades. Because of psychoanalysis' emphasis on the fundamental uniqueness of each individual, single case studies were historically the preferred form of publishable research. These were typically reported as detailed narratives without the systematic or objectified approach typically taken in reports of behavioral or psychopharmacologic treatments. With the ascendancy of randomized controlled trials (RCTs) and meta-analyses, this traditional psychoanalytic approach has been widely seen as lacking.

While there remains persistent criticism within psychoanalytic circles of the overvaluation of the RCT, there has been acceptance of the need for RCTs and meta-analyses involving PDP. RCTs are seen as necessary, but not sufficient, to establish a treatment as “evidence-based.” Patient values and preferences, outcome measures broader than symptom change, long-term outcomes, and clinician’s observations also are held as important factors as well. Its typical length, ambitious aims, the complexity of operationalizing goals, and the difficulty in manualizing the approach have been serious barriers to applying the RCT model to psychoanalytic psychotherapy.

Despite these concerns, there have been increasing efforts and positive results in evaluating PDP for children and adolescents, as well as adults. A more recent problem is that the evolution of psychotherapy has occurred in such a way that psychodynamic principles are increasingly integrated into more focal or modular treatments. For example, IPT is clearly rooted in psychodynamic principles and has been adapted to adolescents. Many other branded therapies, for example, Parent–Child Interaction Therapy, Mentalization-Based Treatment, Adolescent-Focused Therapy, Attachment-Based Family Therapy, and Regulation-Focused Psychotherapy, among others, have strong psychodynamic foundations. Further, the emphasis on the therapeutic alliance that began with psychoanalysis is now accepted as a key component for virtually all psychotherapy. Many of these treatment approaches have been investigated empirically, although they are not generally included in reviews of the traditional research base for PDP. Much of the literature on PDP has been conducted on small numbers of real-world patients with multiple diagnoses and with broad definitions of PDP. While the largest studies have been observational, there have been a number of RCTs sufficient to generate systematic reviews and meta-analyses. The largest empirical study of psychoanalytic therapy with children has been carried out at the Anna Freud Centre (formerly known as the Hampstead Clinic) by Fonagy, Target, Midgely, and others there. Following extensive searches and rigorous inclusion criteria, they identified over 30 primary studies that involved over 1,200 patients. This represents a significant increase

in studies from 10 years ago but still must be considered limited, especially when compared to studies of other psychiatric treatments. Building on previous RCTs, meta-analyses, and systematic reviews, Midgely et al. in 2021 published their seminal “narrative synthesis” of the evidence base for PDP for children and adolescents, including over 120 papers representing over 80 separate distinct studies. The general conclusions are:

1. There is increasing evidence to support the effectiveness of psychoanalytic psychotherapy of children and adolescents, with both the quality and quantity of empirical papers in this field increasing over time.
2. Children with internalizing disorders, primarily depression and emotional disorders, tend to respond most favorably to this treatment modality. The treatment of these disorders has the most high-quality evidence and suggests that brief PDPs are just as effective as other psychosocial interventions, including cognitive behavioral therapy.
3. A number of studies support positive responses to PDP for eating disorders and the effects of trauma in children.
4. There are small but increasing numbers of RCTs focusing on anxiety disorders, and there already exist treatment manuals for PDP for treating children and adolescents with anxiety disorders.
5. There are small but increasing numbers of studies on emerging personality disorders, with several observational studies of the psychodynamic treatment of BPD published in the last 3 years. Mentalization-Based Treatment and Transference-Focused Psychotherapy, both of which were initially developed to treat BPD in adults, have been adapted for adolescents. MBT has shown promise for self-harm as an alternative to DBT.
6. Younger children show larger effect sizes than older children and adolescents, but a sufficient frequency of sessions must be achieved to produce positive outcomes.
7. The psychodynamic treatment of externalizing disorders has received less research attention and, in general, is seen as less effective. Despite this accepted wisdom, some studies show

promising findings, particularly when the child also presents with some emotional difficulties. Young children with disruptive disorders are more likely to respond to interventions that lean heavily on involvement from parents and guardians if they are to respond.

8. There is low quantity but high-quality evidence that PDP may be helpful for adolescents with certain medical or physical conditions, such as diabetes, headache, and treatment adherence.
9. Children and adolescents with conduct disorders or psychotic disorders, receptive language disorders, and intellectual disabilities are also unlikely to respond to this form of treatment. Children with autism generally do not respond well to individual psychotherapy, although there is some evidence that there may be a place in the broader autism-spectrum group for approaches influenced by psychodynamic principles.

A range of methodologic limitations continues to abound, including small sample sizes, lack of or inappropriate control groups, and inadequate outcome measures. More high-quality research is still needed.

Following these findings, recent national guidelines have included PDP as recommended treatment for the two conditions with the most substantial evidence base; the UK NICE guidelines now include PDP as an evidence-based treatment for depression in children and adolescents; in 2015, the AACAP Practice Parameter for Eating Disorders included Adolescent-focused therapy as a recommended treatment in cases of anorexia nervosa when family-based treatment was not available or acceptable to the patient and family. While the empirical data supporting psychoanalytic psychotherapy with children is growing, larger-scale studies for additional targeted populations continue to be needed. At the same time, psychodynamic approaches will continue to be incorporated into other forms of therapy as the field continues to strive to find “what works for whom.”

FUTURE DIRECTIONS

Psychoanalytically informed psychotherapy has a long tradition in child and adolescent psychiatry. Many practitioners over many decades have found this orientation extremely helpful for large numbers of child and adolescent patients. There now exists better empirical support for PDP for children and adolescents with certain conditions, including depression, trauma, eating disorders, anxiety, and personality disorders. More methodologically sound studies are needed and underway. There is still a need to understand those patients or clinical problems for which this technique is especially or uniquely relevant, its mechanism of action, and critical areas of technique. An increasing number of manualized psychotherapeutic modalities have incorporated elements of psychodynamic thinking and practice. This trend is expected to become more prevalent as the field moves to more targeted, individualized therapies.

However, as has been highlighted by Shedler and others, there is a uniqueness to psychodynamics that ultimately may not be able to be isolated in traditional research studies. The supposition that the core elements of psychodynamics can be isolated, pre-packaged, and scripted for randomized control trials so that any therapist picking up a manual will be able to fit that manual to an individual patient will be extremely challenging to test. Evidence-based medicine is inherently designed to eliminate confounding variables and things left to chance, but in doing so, it may also eliminate the individual differences and variations that are co-created by individual patients and therapists. As Shedler has said, it is perhaps these differences and variations, the “unique rhythms,” that are both eliminated in many randomized studies and yet also compose “nearly everything that matters.”

53.2 Cognitive-Behavioral Psychotherapy for Children and Adolescents

Anne Marie Albano, Ph.D., and Sandra S. Pimentel, Ph.D.

The terms *cognitive-behavioral therapy, cognitive therapy,* and *behavior therapy* are often used interchangeably. *Cognitive-*

behavioral therapy (CBT) is a form of psychotherapy that combines behavior therapy and cognitive therapy into a broad approach composed of empirically based methods built on the fundamentals of social learning theory and experimental psychology. It is the treatment of choice for various mental health problems due to its efficacy. CBT is widely taught in various mental health training programs and is a mandated component of psychiatric residency training in the United States. CBT is a mandated first-line treatment in the United Kingdom for specific mental health problems such as anxiety, eating disorders, and depression.

HISTORY

CBT is best viewed as a multifaceted theoretical approach with a strong allegiance to the experimental method and a resultant set of techniques applied within a CBT formulation. The cognitive-behavioral approach is the convergence of distinct movements in the study and science of human behavior, including classical conditioning, operant conditioning, and the cognitive revolution. In the early 1920s, Ivan Pavlov's work demonstrated the processes of classical (otherwise known as respondent) conditioning and established the stimulus-response learning paradigm. Essentially, classical conditioning is a form of learning in which a neutral stimulus is repeatedly paired with a stimulus that elicits a reflexive response. In his classic experiment, Pavlov paired the neutral stimulus of a bell with food, a stimulus that naturally produces salivation. Eventually, the presentation of the neutral stimulus (bell) by itself elicited the conditioned response of salivation. This process is illustrated in Table 53.2–1. This work greatly influenced John B. Watson, who applied Pavlovian classical conditioning principles to understanding the origins of psychological disorders in humans. Known as the "father of behaviorism," Watson promoted the tenet that psychology should be concerned only with directly observable stimuli and responses and rejected any notion of unconscious and dynamic processes (i.e., mentalistic constructs) underlying behavior, including cognitive processes. Early laboratory research with animals

demonstrated the acquisition of the fear response through classical conditioning learning trials.

Watson and colleagues demonstrated that fear reactions are also conditioned in humans who previously did not evidence such a reaction. In their classic experiment, Watson and Rosalie Rayner conditioned a fear reaction to a white rat in a young child named Albert. Initially, Albert played happily with the rat and showed no evidence of fear or avoidance of this animal. Next, the experimenters followed the introduction of the rat with a loud noise made in close proximity to the child, causing him to startle. The pairing of the loud noise (aversive stimulus) and the rat (neutral stimulus) in a sequence of trials resulted in Albert developing fear of the rat (conditioned response). Subsequently, not only did Albert become fearful of the presence of the rat, eventually his fear generalized to other white, furry stimuli, such as cotton balls. Inasmuch as this experiment demonstrated the process of Pavlovian learning principles in the etiology of psychological disorders, Mary Cover Jones demonstrated that one could eliminate human fear conditions in children through a similar learning paradigm that would foreshadow later methods of behavioral treatments for anxiety disorders. With Watson as her dissertation mentor, Jones used an approach involving the techniques of modeling and graduated exposure to treat 3-year-old Peter's fear of rabbits. Initially, Peter was exposed to observing other children playing happily with a rabbit (i.e., modeling), and, subsequently, while Peter was eating his favorite food, the rabbit was shown to him during a time when he was in a calm state. Gradually, the rabbit was moved closer to Peter until he was able to pet and play with it without experiencing fear (exposure). Although many will recognize Jones' work as straightforward examples of the basic behavioral procedures of modeling and graduated exposure, her approach to treating Peter was revolutionary at the time. In fact, it was decades before the techniques employed in Peter's treatment were systematically studied and identified as valuable therapeutic procedures.

Table 53.2–1.
The Process of Classical Conditioning

Before conditioning		
Food (Unconditioned stimulus)	→	Salivation (Unconditioned/reflexive response)
During conditioning		
Bell + Food (Neutral stimulus) + (Unconditioned stimulus)	→	Salivation (Unconditioned response)
After conditioning		
Bell (Conditioned stimulus)	→	Salivation (Conditioned response)

While Pavlov and Watson were experimenting with classical conditioning paradigms, Edward Thorndike of Columbia University was beginning pioneering work in understanding the processes of operant (instrumental) conditioning. Thorndike demonstrated that by changing the consequences of behavior, the occurrence of the behavior is either increased or decreased—that is, providing a reward after the occurrence of a certain behavior increases the probability of that behavior occurring again, whereas withholding the reward, over time, results in the decrease of the behavior. These principles, influencing the later work of Harvard psychologist B.F. Skinner and his students, are widely used today in therapy and educational settings, such as in parent education and training. A common example is that of a young child who throws a temper tantrum in response to being denied a treat. If the parent provides attention to the child through admonishing, coaxing, or giving in and/or providing the treat, the tantrum behavior is likely to occur again at the next instance of the child's being initially denied the treat. Note that the reward in this case is parental attention, regardless of whether it is the positive attention of coaxing or giving in or the negative attention of admonishment. In any case, the child gets the parent's attention. However, if the parent refrains from giving attention and ignores the child's crying and whining, the

tantrum will stop and subsequent tantrums are unlikely to occur when the child is denied or frustrated. The child will learn that tantrum behavior does not result in positive outcomes. Skinner articulated fully the theory and principles underlying the process of reinforcement in his seminal tome “Contingencies of Reinforcement: A Theoretical Analysis.” This type of learning is central to parent management training (PMT), an empirically based treatment approach, and similar parent training programs. Change in child behavior (decrease in tantrums) is facilitated and enhanced through the simultaneous pairing of positive child behavior with parental attention, so parents are also taught to give attention and praise when their child behaves in acceptable and desired ways (e.g., “I like the way you are playing nicely with your sister”). The procedures of systematically ignoring undesirable behavior while systematically reinforcing desired behavior are known together as *differential reinforcement of other behavior.* Throughout the 1950s and 1960s the principles of operant conditioning were greatly expanded and researched by Skinner and other experimental behaviorists; eventually, this work moved from the laboratory analog studies of learning processes with animals to applied evaluations of the utility of operant procedures in the treatment of adult psychiatric inpatients. For example, Ted Ayllon and Nate Azrin introduced the first comprehensive token economy program at Anna State Hospital in Illinois. Despite initial resistance and skepticism from the hospital staff, the token economy resulted in significant changes in targeted behavior of inpatient adults with severe mental illnesses and disabilities. Token economy systems flourished in psychiatric settings and training schools and were adapted for widespread use in programs serving youth, such as hospitals, residential facilities, and schools.

The emergence of behavior therapy as a distinct field of study began in the 1950s, in part due to advances in the understanding of both classical and operant learning processes, and also because of a growing discontent with traditional psychoanalysis. A major goal of psychoanalytic treatment is for the patient to develop insight into their problems. *Insight* refers to the emotional and intellectual

understanding and acceptance of one's problems and is a crucial step in achieving therapeutic benefit, and gaining insight is associated with uncovering the unconscious conflicts and motivations underlying the problematic behavior. The assumption of unconscious conflicts is a major premise of psychoanalysis that is rejected by the behavioral approach. The focus on achieving insight, along with the often inordinate length of time spent in psychoanalytic therapy, contributed to discontent with psychoanalysis. South African psychiatrist Joseph Wolpe, dissatisfied with his patients' progress in psychoanalysis, was among the founders of contemporary behavior therapy and moved its applications from experimental settings and institutions to more mainstream psychotherapy contexts. In the 1950s, Wolpe developed procedures of systematic desensitization and assertive training, directly stemming from Cover Jones' work with children in the 1920s. In each procedure, phobic and anxious patients are taught to replace fear reactions with deep relaxation and proactive communication behaviors, respectively. These procedures provided a more rapid therapeutic response than traditional analysis and proved to be more cost-and time-effective to patients. Very quickly, Wolpe's procedures were extended to individual and group therapy contexts and adapted for use in children and adults. Worldwide, behavior therapy was developed, advanced, and promoted by pioneers such as Wolpe, Cyril Franks, Hans Eysenck, Stanley Rachman, and Arnold Lazarus. As a field, behavior therapy took shape through the systematic study of behavioral principles and the testing of its methods in single-case and large research trials. In 1966, Franks became the first president of the newly formed Association for Advancement of Behavior Therapy (now the Association for Behavioral and Cognitive Therapies), the flagship professional organization whose missions remains that of promoting the development and dissemination of behavior and CBT therapy.

Radical behaviorists, steeped in the tradition of Watson, eschewed the study of cognition, in that thought processes were viewed as mentalistic constructs not readily observable or verifiable by others. From a purely behavioral perspective, directly addressing inappropriate or abnormal behavior will change any upsetting or

inappropriate thoughts and feelings associated with the behavior, and, hence, direct access to thoughts is not necessary. During the 1960s however, the cognitive revolution began with the work of Albert Bandura, Aaron T. Beck, and Albert Ellis. The cognitive therapist takes a different view, espousing that, if one changes dysfunctional thoughts, change in functional behaviors will follow. The cognitive therapist assumes that thoughts are made observable through methods such as direct interviewing, self-report scales, journal or diary entries, and listing of thoughts. At Stanford University, Bandura integrated the principles of classical and operant conditioning with observational learning to formulate the tenets of social learning theory. Through observational learning, the process of observing the actions and reactions of others can effect a change in the behavior of an individual. In essence, observing the actions of others and their resulting consequences, without the individual needing direct experience with a situation, can shape the emotional and behavior repertoire of an individual. Of course, risk and protective variables interact with observational learning to shape behavior such that the temperamentally inhibited child may learn to respond with anxiety and withdrawal when watching the distress of a peer who is teased by the class bully, whereas the child with a more rambunctious disposition may focus on the behavior of the bully and learn to respond in similarly aggressive ways. This theory places critical importance on the role of cognitions in the development and maintenance of behavior, both normal and abnormal, in that cognitions involve thoughts, images, beliefs, expectations, memories, and attributions, among other simple and complex cognitive processes. In the bully example, the inhibited child may think, “oh no, that can happen to me and embarrass me.” This type of thinking leads to anxious withdrawal and fear reactions. Conversely, the more extroverted child may think, “It is fun making this kid cry and I want to do it next,” leading to imitation of the aggressive behavior. The response of the environment to either child’s response then becomes involved in the complexities of this learning paradigm to further influence the observational learning by either rewarding/accepting or punishing/extinguishing the particular

response. The process of observational learning is the basis for concern expressed by parents and other concerned parties over violence depicted in television, movies, social media and video games and one of the reasons for parental ratings found in the media and music industry.

The cognitive revolution continued with the work of psychiatrist Aaron T. Beck at the University of Pennsylvania, who observed within the course of his psychoanalytic treatment of patients that certain problems were evident in the thoughts of depressed individuals and that traditional psychoanalysis did not allow for the direct confrontation of these thoughts. Beck's study of depressed patients revealed a certain negative triad of thoughts related to pessimistic views of the self, the world, and the future. Through the Socratic method of questioning the veracity of these thoughts, Beck was able to assist patients with gathering evidence to refute the thought and engage emotional and behavioral resources to counter the depression and increase healthy functioning. Cognitive therapy emerged from this work and became a mainstay in the treatment of a wide range of emotional disorders, including depression, anxiety, personality disorders, and, more recently, psychoses. Concurrent with the development of Beck's approach, psychologist Albert Ellis took note of the irrational beliefs guiding his patients and undermining their ability to proactively manage activities and stressors in everyday life. Ellis developed rational emotive therapy, which seeks to challenge certain core irrational beliefs such as "I must be loved by everyone" and "I must be perfect in my performance/relationships." According to Ellis, irrational beliefs are conditioned cognitive responses that serve to render an individual vulnerable to disappointment and failure and engender a sense of helplessness and eventual psychopathology. Both Beck's and Ellis' therapies integrate behavior principles and processes, such as behavioral exposure and behavior activation, to activate and challenge negative, irrational thinking. From these roots, the cognitive approach, integrated with behavior therapy in forming contemporary CBT, was expanded and adapted to meet the needs of children, adolescents, adults, and families to address a wide range

of psychological and behavioral problems. Recent “third wave” influences on the practice of CBT reflect the integration of mindfulness and meditation principles found in dialectical behavioral therapy (DBT) as well as the acceptance and commitment therapy (ACT) focus on values and committed action. The foundation of the third wave approaches rests on the theoretical and empirical foundation of CBT.

THEORETICAL ISSUES

The value of CBT as an evidence-based and front-line treatment is ever-expanding and evolving. Since its inception and integration of the behavioral and cognitive movements, treatment packages such as self-instructional training, problem-solving therapy, harm reduction, behavioral family therapy, and behavioral couples therapy have been advanced. Problem-specific treatments have emerged and include the Coping Cat for childhood anxiety disorders, the Adolescent Coping with Depression Course, Brief Behavioural Activation for Adolescent Depression, CBT of Childhood OCD: It’s Only a False Alarm, The Incredible Years and Parent-Child Interaction Therapy for disruptive behavior in young children, Multisystemic Therapy for serious child and adolescent disruptive behavior and substance abuse, the Maudsley Approach for adolescent eating disorders, and the Unified Protocols for Transdiagnostic Treatment of Emotional Disorders in Children and Adolescents. All CBT protocols are based on the principles of social learning theory and several basic theoretical assumptions of CBT (Table 53.2–2). First, the cognitive-behavioral therapist does not assume that an underlying unconscious process or drive is fueling the behavior of any individual. Rather, the cognitive-behavioral therapist assumes that all behavior, whether adaptive and pathologic, is subject to conditioning principles, although there may be limits on learning due to constitutional constraints (e.g., intellectual capacity, physical limitations) or contextual constraints (e.g., dysfunctional home, depressed community settings, systemic racism or bias). As such, the therapist works with the patient (and

with the parents in child cases) to examine samples of behavior across contexts to uncover the antecedents and consequences of behavior. The *ABCs of therapy* refers to the antecedents-behavior-consequence chains that serve to establish and perpetuate behavioral patterns. Rather than assume that an individual is predisposed to behaving in a certain way due to traits such as aggressiveness, introversion, or obsessiveness, the cognitive-behavioral therapist takes a more interactionist approach and assumes that the individual is interacting with the environment in developing response patterns to discrete and specific stimuli that may bear a resemblance to prior similar stimuli or experiences, thus shaping apparently trait-like responses. Through the process of CBT, behavioral antecedents and resultant consequences are identified and addressed within the treatment plan. The cognitive-behavioral therapist, based on empirical findings, applies procedures steeped in the principles of learning to change or modify the patient's behavior. Through a process of collaborative empiricism, the therapist and patient (including parents or caregivers in the case of dependent youth) specify clearly defined goals for treatment and establish a time frame for achieving subgoals and overall goals. The therapist and patient will then engage in a continual process of evaluating whether goals are achieved and, if not, examining impediments to change, including resistance, throughout the course of therapy. CBT is applied flexibly to meet each individual patient's needs. That is, techniques are adapted to be developmentally appropriate for a given age or cognitive level and otherwise adapted to meet the needs of an individual patient.

Table 53.2–2.
Assumptions of Cognitive-Behavioral Therapy

Cognitive-behavioral therapy, relative to traditional psychotherapies, concentrates on behavior (this includes verbal behavior and covert behavior, such as thoughts, beliefs, memories, attributions, and images), rather than on some presumed unconscious underlying cause.
Cognitive-behavioral therapy assumes that maladaptive behaviors are acquired through learning in the same way that any behavior is learned.
Psychological principles, especially learning principles, are highly effective in changing and modifying maladaptive behavior.
Cognitive-behavioral therapy involves setting specific, clearly defined, and observable treatment goals.
Cognitive-behavioral therapy rejects classic trait theory—that is, the notion that an individual has an inherent predisposition to similar behavior in a wide range of situations.
The cognitive-behavioral therapist adapts the method of treatment to a patient's problem.
Cognitive-behavioral therapy is focused on the here and now yet does not neglect the past or history of the patient.
Cognitive-behavioral therapists place great value on the empirical testing of their assessment and treatment methods.

Contrary to popular belief, CBT does not ignore historical information. The patient's history, including parental and related family members' histories, are essential for understanding the original setting events and learned reactions comprising the etiology of the problem. However, the work of CBT is focused on the present maintaining factors that prevent healthy functioning and allow the persistence of the patient's problem. Thus, CBT is focused on the here and now, with emphasis on understanding the current reinforcement paradigm, allowing persistence of the problem and teaching new skills to promote adaptive behavior. Finally, scientific

rigor, whether on a large-group scale or within the single-case approach, is highly valued by the cognitive-behavioral therapist. It is expected that the cognitive-behavioral therapist will be current with the empirical literature and apply the scientific method to their practice of therapy. Thus, within the clinical practice, each patient is regarded as an individual case study in which the therapist and patient again collaborate to test hypotheses of behavioral change and refine their techniques or approach to maximize the potential for therapeutic benefit.

TECHNIQUES

Techniques are not the essence of CBT, nor are they sufficient for the resolution of any clinical problem. A thorough understanding of the empirical bases and theoretical principles of CBT, along with appropriate training and experience, is a prerequisite to the development of competency to formulate a sound treatment plan and deliver CBT to persons in need. In addition, CBT is a very action-oriented approach focused on the here and now. It requires a directive rather than passive stance. Therapists must be ready to teach, model, guide, and reinforce the patient in working toward their goals. Cognitive-behavioral therapists are very active in treatment and often conduct sessions in vivo—that is, in the situations in which the child or adolescent may be experiencing distress. The cognitive-behavioral therapist should expect to make a trip to the school, home, or other settings in which the child has difficulty, as appropriate, with careful planning to maintain confidentiality while promoting therapeutic benefit. Moreover, certain disorders, such as the phobias and obsessive-compulsive disorder (OCD), require the therapist to model the handling or touching of phobic or feared objects such as dogs, insects, and potentially “contaminated” objects such as doorknobs or toilet seats. Cognitive-behavioral therapists take care to devise these in vivo experiences to be maximally beneficial to the child while minimizing risk.

Behavioral Assessment

A classic phrase coined by Barrios and Hartmann in their review of CBT is that “behavioral assessment is the cornerstone of (cognitive) behavior therapy.” In essence, CBT is dependent on a carefully constructed and thorough functional analysis of the patient’s presenting problem. The functional analysis involves the use of appropriate assessment methodologies to uncover the relationships and conditions under which the patient developed and has maintained their problematic behavior (the ABCs defined earlier). Assessment in CBT involves multiple methods, multiple informants, and multiple time periods. Assessment involves multiple methods to capture the most useful and valid information concerning the patient and their functioning across a variety of contexts. Thus, diagnostic interviews, self-report questionnaires, diary forms, and behavioral observation techniques can all be used, given time and cost restraints. The use of multiple methods and multiple informants allows for data to be captured without relying on any one form of assessment or individual that may be subject to biases or limited in scope. For example, although children generally are able to report internal states with accuracy, younger children tend to report what is within their immediate experience, and, as such, even recent events may be distorted or inaccurately represented. In addition, the nature of some disorders may interact with youth report on any particular method of assessment. Adolescents with social phobia in general have difficulty admitting to this form of anxiety and tend to minimize or deny symptoms. In contrast, parents of youth with social phobia are able to identify and report the behavioral avoidance associated with the syndrome. Consider, for example the comparison of responses to questions from a diagnostic interview by a 15-year-old boy with social phobia and that of his parents (Table 53.2–3). Although the youth denies a lack of friendships and minimizes his social anxiety, the parents’ report establishes his isolation due to avoidance of social interaction and activities with peers. In this case, the youth may be unable to admit to the anxiety due to self-presentational demands; however, the parents are readily able to identify the specific behavioral contexts (after-school activities, mobile phone use) in which behavioral avoidance is apparent. This

information, taken within the broader context of a diagnostic interview, will be compiled to establish a diagnosis and specify goals for treatment (e.g., engage in social activity outside of home and school; engage with friends on the phone or texting).

Behavioral assessment often involves obtaining samples of behavior through behavioral approach tasks. The behavioral approach task can be individually tailored for each patient or standardized for a particular disorder. Standardized behavioral tests for youth with social phobia involve giving a speech in front of a camera or a small, live audience. Youth with separation anxiety disorder may be asked to stay in the clinician's office while the parent is sent on an errand. The behavioral approach task allows the clinician to assess the behavioral limits of the patient. If the child refuses to attempt the task, important information about their initial reactivity and ability to manage anxiety is accessed. No child or adolescent is ever forced to attempt a behavioral approach task; rather, they are allowed to avoid or quit the task at any point. The behavioral approach task also provides information on how long the patient can stay in the situation and what methods make the situation better or worse for the patient. For example, children who fear the dark may be better able to sit in a darkened room with the use of a flashlight or with another person with them. These safety signals provide information about what coping strategies the child is using and whether the strategy needs to be refined or removed through treatment. The behavioral approach task also allows for access of specific cognitive, physiologic, and behavioral content by having the patient list their top six thoughts that occurred during the task, taking measures such as heart rate or respiration, and recording the length of time engaged in the task or how close the patient can be to a feared stimulus. Optimally, the real stimulus that is feared (e.g., separation situation, small animal, heights) should be used in a behavioral test for maximal effect. However, certain stimuli or situations are inherently difficult to create in a therapist's office due to confidentiality (e.g., social situations) or practical matters (e.g., airplane travel, heights), setting a limit on the ecologic validity of the stimulus and patient's experience. Virtual reality environments,

found to be efficacious and of high utility in the assessment and treatment of adult psychiatric conditions, offer a promising medium for creating age- and developmentally appropriate situations that mimic real-world stimuli and scenarios for behavioral tests as well as for use in exposure therapy in youth. Overall, the behavioral approach task provides both qualitative and quantitative information to establish baseline functioning and evaluate the progress of treatment. Sample behavioral approach task situations for anxiety disorders are given in Table 53.2–4. These tasks can also be used in designing exposure situations during treatment.

Table 53.2–3.
Comparison of Adolescent and Parent Reports in the Assessment of Social Anxiety Disorder

Interview Question[a]	Adolescent Report	Parent Report
Do you worry about what other people think of you or that you may do something embarrassing in front of others and then they'll think badly of you? Do you worry about this social anxiety more than other kids your age?	Yes, I worry I'll sound dumb sometimes. But I don't think it's any more than anyone else. I don't think so.	He is always worried about what he says and often says he does not know what to say. He fights with us about this. We try to push him to go out and talk to people, but he's too shy. He won't speak up and he is anxious that others will think he's stupid or awkward. This is different than our other kids who are quite social.
Do you think you have the same number, fewer, or more friends than other kids your age?	About the same as other kids.	Fewer. Actually, we don't think he has any friends that we're aware of and hasn't had since elementary school.
How often do you see your friends outside of school? What kinds of things do you like to do with friends?	Well, not much, maybe once a month. There's not much to do and nothing's really going on. And I have a lot of homework.	He doesn't see anyone outside of school. He just stays in his rooms and plays videogames. He doesn't go to any parties or to school events. We feel like

		we are constantly nagging him to go.
Do you text your friends to do things, or do you wait for them to reach out to you?	I text them back sometimes.	He doesn't seem to call or text anyone. We see our other kids always texting or on social media. Not him. One classmate called to get homework and even that was hard for him.

[a]Questions are modified appropriately when addressed to parent.

The use of multiple informants involves obtaining information from the child, parents, teachers, and, potentially, peers, other relatives, and former caregivers or therapists. The use of multiple informants addresses issues of responder bias while accessing the opinion of individuals who have experience with the child over a sustained period and in multiple contexts. Information gained from parents and teachers, for example, may reveal the occurrence of behaviors that are not likely to present in the therapeutic environment. However, reports from others may be limited by an inability to appreciate the antecedents or consequences of behavior and the inability to understand the child's internal dialogue or ideas. Critical to maximizing the use of the information gathered through behavioral assessment methods and the input of multiple informants is an understanding of role of inequalities related to social determinants of health (e.g., poverty/economic instability, housing and food insecurity, access to healthcare and resources, discrimination/racism). Structural racism and systemic bias continue to result in marginalized youth and families experiencing inequities and disparities leading to unmet or poorly administered mental health care. A comprehensive assessment needs be grounded in a competent and informed evaluation of the cultural and contextual

factors affecting the child's strengths and impairments in functioning. This then allows for a personalized, culturally responsive conceptualization and pragmatic treatment plan. Failure to include and address culture and context in the assessment risks perpetuating the disparities experienced by the youth and family. Finally, assessment occurs throughout the course of CBT. The initial assessment is used to establish a baseline diagnostic picture and establish the limits of functioning and identify behavioral excesses, strengths, and deficits. The goals for treatment are defined through data accessed during the assessment, and specific treatment protocols or techniques are chosen based on the assessment results. Assessment continues throughout the course of treatment to track progress, continue to gather data in specific domains (e.g., daily ratings of anxiety or depression, number of social contacts, diary forms to elicit though patterns and beliefs), and inform the therapist and patient about treatment response.

Table 53.2–4.
Sample Behavioral Approach Tasks for Child and Adolescent Anxiety Disorders and OCD

Social anxiety disorder: Reading aloud in front of the therapist and office staff, initiating a conversation with an unfamiliar person, sending a text to a peer, “liking” a social media post, dropping books in a crowded waiting room, asking for assistance from a store clerk, asking for directions to the restroom.

Selective mutism: Whispering to the parent in front of the therapist, speaking at a low volume/whispering to the therapist, asking a question in a normal voice to the therapist, speaking on the phone with a relative, leaving the therapist a voice mail, asking the teacher a question, calling and inviting a friend to get together, video talking with a friend or teacher.

Separation anxiety disorder: Staying alone in the therapy room for 10 minutes, staying alone in a darkened room for 10 minutes, parents leaving the child at the clinician’s office to run an errand, being dropped off at therapy and not knowing parent’s whereabouts, parent being late to pick up child at school.

Generalized anxiety disorder: Purposefully making mistakes on a homework assignment, being late for an appointment, reading an upsetting story online or watching an upsetting news clip about crime or world events, being told of unexpected changes to routines or plans.

Animal/insect phobia: Being in the same room with a caged animal, staying in the room with the animal on a leash, touching the animal, allowing the animal to roam free in the room, allowing the animal to interact freely with self.

Injections/doctor phobia: Entering an examination room, looking at the medical instruments, holding a syringe, allowing self to be examined by a physician, allowing needle to rest against skin.

Darkness phobia: Sitting in a dimly lit room with another person, sitting in the dimly room alone for 10 minutes, sitting in the room for an unknown period of time, sitting in complete darkness while holding a flashlight, sitting in complete darkness.

Obsessive-compulsive disorder: Touching “contaminated” objects (e.g., doorknobs, shoe soles), not washing hands, shaking hands with various office staff, saying “forbidden” words or thoughts

aloud (e.g., “God is dead”), using “unlucky” or “bad” numbers on purpose.

Table 53.2–5.
Daily Diary for an Adolescent With Major Depressive Disorder During the Early Phases of Treatment

Column A What was happening? (stimulus)	Column B Mood Rating (0 = best, 10 = most depressed ever)	Column C What was I thinking?	Column D What did I do?
Parents were arguing.	8	This is miserable. I hate it here at home. Why don't they stop?	Went to my room and cried. Didn't eat dinner and stayed there all night.
Had an essay due in English class.	7	I can't think of anything to write about. There's nothing interesting to write. I can't do this.	Listened to music and lay in bed. Tried to write but couldn't. Watched some TV and then went to sleep.
Friends posting pictures while at a party I didn't know about.	5	No one tells me when there's something going on. I never get invited. I'm no fun and they know it.	Blocked all those people on social media. Didn't answer any of their texts when they tried to reach me. Felt like cutting myself.

Psychoeducation

A core component of CBT for just about any disorder or problem is psychoeducation for the child or adolescent and parents. Psychoeducation typically begins in the first treatment session and is carried on throughout therapy. Developmentally appropriate information is delivered to the youth and parents concerning the nature of the disorder in question (e.g., addressing the proposed etiologic pathways and maintenance of depression) and the process and procedures of CBT. It is important for patients and parents to learn that certain emotions may be “charged up” or “cooled down,” given changes in the environment (being teased by a bully, getting an A+ on a difficult examination, canceling a picnic due to rain), physical state (e.g., hunger, fatigue), time of day or year (school holidays, final exams) and other internal and external factors. Individuals may be born with a predisposition or vulnerability to experience certain emotions more strongly and readily than others, and over time, by interacting with the wider environment, a person can develop a style of thinking or psychological bias to interpret things in a more emotional manner (the “negative filter”). Although these biases exist, children and parents are further taught that individuals can learn strategies to manage their emotional reactions to a large degree, either with or without the assistance of medications. Emotions are broken down into three components—the physical (e.g., tension, irritability, physical symptoms of anxiety and depression), cognitive (e.g., automatic thoughts, beliefs, cognitive distortions), and behavioral (e.g., actions, aggression, withdrawal, avoidance). The relevant cognitive-behavioral techniques and principles tied to each component are offered as the ways in which the child will learn to recognize the triggers of their emotional reactions and use appropriate coping strategies effectively to manage the emotion and situation. Parents are also given specific information to address any gaps in their understanding and expectations for normative child development.

Table 53.2–6.
Daily Diary With Cognitive Restructuring Component for an Adolescent With Depression

Column E Which dispute handles can I use?	Column F What is my Rational Response?	Column G New mood rating based on evidence and realistic thoughts	Column H What is my action plan?
How often do they argue? Is this the worst thing that could happen? What are they usually like together?	Mom and dad are loving to each other, and all couples disagree and argue at times.	3	Focus on what they are usually like together. Sit with the family for dinner and, if the time is right, let them know I was upset hearing their argument.
How many times have I written an essay? How likely is it that I wont be able to think of anything if I try? Do I have to do this all at once?	I've prepared for class and read all the material, so I do have ideas to use in this essay. I still have 4 days to get this finished and that gives me plenty of time to work on this.	3	I will review my notes from class and make an outline for the essay. After a short break for a snack, I will begin to prepare the content of the essay. If I get this done tonight, I can rest and finish tomorrow.

How important is this particular party to my social life? Am I jumping to conclusions that no one tried to tell me about it? Do I have all the facts?	This is just one party and I've been invited before to others. With multitasking school, part time job and my social life, I'm going to miss things here and there.	2	Breathe and use my calming skills, and be proud of myself for not cutting. Reach out to my closest friends and ask if they had a good time. Make plans to get together for lunch and some fun.

Psychoeducation also involves the introduction and training of the child and parents in self-monitoring. Structured diary forms are often used to guide the monitoring of triggers to emotional states (both "positive" and "negative") and rating of the intensity of emotion (e.g., from 0 to 10). Monitoring sets the stage for later tracking of cognitive and behavioral responses that become the focus of other treatment components. A sample monitoring form for an adolescent with depression is shown in Tables 53.2–5 and 53.2–6.

Somatic Management Techniques

The vegetative and physiologic symptoms accompanying anxiety and depression are addressed through structured relaxation and exercise assignments. Deep diaphragmatic breathing and progressive muscle relaxation training form the mainstay of techniques used to dampen anxious or aggressive arousal and increase a child or adolescent's ability to control their unhelpful or inappropriate responding. Mindfulness exercises may also be introduced to teach children and adolescents strategies for nonjudgmental awareness of their bodies. Prescribed exercise regimens involving dancing, walking, bicycling, pilates, yoga, playing

team sports, and engaging in similar physical activities are geared toward behavioral activation to reduce fatigue and increasing stamina and energy in the depressed adolescent. Nutritional counseling and sleep hygiene methods are also used as indicated to address concomitant problems such as eating and sleep disturbance accompanying the internalizing disorders.

Cognitive Interventions

The goals of cognitive interventions are to build on psychoeducation and provide corrective information concerning the presenting problem while systematically uncovering and refuting the automatic thoughts and schema that drive the youth's emotional distress. Automatic thoughts are discrete, rapid, and often context-specific thoughts that vulnerable individuals treat as fact about themselves, the world, and their future. All individuals have automatic thoughts each day. Typical automatic thoughts for youth with anxiety and depression are listed in Table 53.2–7. Cognitive restructuring involves identifying these thoughts through the use of diary forms, employment of Socratic questioning in the therapy room, and then developing rational responses based on actual evidence for the thoughts to assist with their emergence in everyday life. Apps have also been developed and disseminated to assist youth in monitoring and challenging thoughts in the moment. In effect, patients are taught to treat the thoughts as hypotheses, not facts. The therapist then guides the patient in planning home-based behavioral experiments to test whether the thoughts are true through the process of gathering evidence to either accept or refute them. Dispute handles, also shown in Table 53.2–7, are questions used to examine the evidence for the thought and guide the child or adolescent toward considering alternatives to their negative biases.

Table 53.2–7.
Typical Cognitive Distortions and Dispute Handles for Youth With Anxiety and Depression

Cognitive Distortions
I'm not as smart as other kids.
I don't know what to say to others.
I'm not as attractive as others.
No one wants to hang out with me.
They think I'm a geek because I was nervous giving that oral report.
What if I do something stupid?
Nothing will work out for me.
This is the worst situation anyone could ever be in.
I know I'm going to fail.
If I don't ace this test there's no point in trying anymore.
I should have done better.
Dispute Handles
Am I 100% sure that ____ will happen?
Do I have evidence that ____ will happen?
How many times has ____ happened before?
Is ____ really so important that my whole future depends on its outcome?
What is the likelihood that ____?
Does ____'s opinion reflect that of everyone else?
Do I have a crystal ball?
Am I responsible for this entire conversation?
What is the worst that could happen?
What can I do to cope/handle the situation?

Depending on the age and cognitive developmental level of the child, cognitive interventions can be simplified or rendered more complex. Young children and those who are more concrete in thought processes can be presented with a simple cue to "stop and think" when experiencing strong emotions such as fear or disappointment. A picture of a stop sign or favorite cartoon character

holding up a stop sign may suffice to teach the child to resist the negative emotion and engage in proactive coping. Emotive imagery is a technique by which the child's favorite superhero or character provides "guidance" in managing the difficult situation. For example, a 7-year-old boy with separation anxiety disorder might be taught to imagine how Spider-Man's parent was late in picking him up from school. The therapist would coach the child to imagine Spider-Man handling each situation and then have the child imagine himself in each situation, with Spider-Man "standing by" in the image and assisting the child with coping strategies, such as deep breathing and thinking realistic, helpful thoughts. Older children are often provided acronyms to remember a series of steps in cognitive restructuring: Feeling frightened? Expecting bad things to happen? Actions and attitudes to help me cope with this situation. Results on how the situation turned out and how I handled it and reinforce myself for trying. Homework in cognitive restructuring involves the use of additional columns in the diary for (see Tables 53.2–5 and 53.2–6). These forms are reviewed in session, whereby the therapist and patient evaluate each step of the restructuring process and work through plans to overcome challenges and reinforce success experiences.

Exposure/Behavior Change Techniques

In the anxiety disorders, behavioral exposures are used to provide systematic success experiences while managing difficult situations and refining cognitive restructuring skills. Anxiety is partly maintained by avoidance of or escape from challenging situations, and thus the child does not gain experience to refute anxious thoughts and learn that the feared negative outcomes are unlikely to occur or can be managed. A child with separation anxiety disorder tries to avoid, at all costs, the experience of being away from loved ones for fear that something terrible will happen to result in permanent separation. By avoiding separation situations, the child maintains a focus on the catastrophic fear and does not learn that the feared negative outcome is highly unlikely. Moreover, avoidance prevents the child

from learning that, when adverse or less-than-desirable or expected events occur, such as a parent returning home late from work, the event is independent of the child's fear and avoidance behavior. Exposure directly addresses the fear and avoidance partly through the process of habituation, by which the anxiety response naturally dissipates during the exposure. Exposures also provide opportunity for inhibitory learning, in which the child can learn that catastrophic feared events did not occur and new beliefs about potential outcomes come to inhibit previous beliefs. The child concurrently gains experience with coping and interacting with the feared stimulus or situation. Exposure is usually conducted in a stepwise manner of introducing increasingly challenging situations. Flooding, which is not recommended for young children or those with more severe anxiety levels, involves having the patient confront a situation that provokes the highest levels of anxiety and stay in the situation until the habituation occurs. Exposure may be imaginal or in vivo but is typically arranged hierarchically for children, from least to most challenging. Role plays with the cognitive-behavioral therapist may be included in preparation for exposures; however, they do not substitute for exposures. During imaginal exposure, the therapist may construct scripts about anxiety-provoking situations and ask the child to listen to the scene as if it were really happening. As the child's subjective anxiety decreases, scenes of greater intensity are presented in succession. In contrast, in vivo exposure involves having the child actually engage in the feared situation. Again, when the child reports tolerable levels of anxiety, the situation may be enhanced to produce a greater challenge to the child and require a new level of cognitive and behavioral coping. In contrast to situational exposures, interoceptive exposure involves inducing the sensations of panic through certain exercises and activities that cause physiologic responding, such as tachypnea, tachycardia, palpitations, diaphoresis, and paresthesias. Again, these exposures are designed to break the fear of internal sensations of anxiety and increase tolerance for normative changes in body functioning. Recent experimental studies indicate that habituation may not be necessary to reduce anxiety, but rather, exposure may assist in the

learned tolerance of expected anxiety reactions that would previously have resulted in avoidance. For example, learning to tolerate the discomfort of dental procedures, the arousal accompanying asking someone for a date, and other situations that are inherently challenging to anyone, can result in improved functioning and quality of life, and reduced anxiety overall. In all types of exposures, children are encouraged to use their somatic management skills, as well as cognitive restructuring. Use of safety signals may be allowed for less challenging exposures, but systematic removal may be necessary for increasing exposure potency and testing potential feared outcomes.

Behavioral activation tasks are structured experiences planned for youth with major depression or persistent depressive disorder. The reinforcement theory of depression asserts that low rates of contingent reinforcement contribute to depressed mood and anhedonia and set up a cycle by which withdrawal behavior occurs and, thus, the youth is even less likely to engage in or have access to reinforcing events. For example, withdrawal from team sports, procrastination in homework assignments, and loss of interest in self-care may occur over time in depressed adolescents. By withdrawing from the team, social reinforcement and contact with peers comes to halt. Withdrawal also may have transactional effects on the teen as peers may disengage and taper contact in response, thereby further reinforcing potential distorted beliefs about themselves. Procrastination leads to a sense of dread and failure in school activity, and the drop in self-care compounds the youth's negative self-image. The result is a systematic decrease is positive reinforcement and corresponding increase in negative feelings about the self. In CBT, the therapist surveys the youth for activities that may bring social reinforcement, success (self-efficacy or accomplishment), or pleasant feelings (e.g., relaxation). Typically, monitoring of mood occurs concurrently with the monitoring of these activities to provide feedback to the youth that engaging in such activity that the youth is likely to attempt, setting up parameters for engaging in the activity, and self-monitoring and processing the outcome of the event. Planned activities increase in type and

number as treatment progresses, with the goal that the youth will assume the responsibility of planning these activities and that they will again become a natural and fixed part of their behavioral repertoire.

Parent Involvement in Treatment

Parents and family members are often inadvertently drawn into the cycle of negative affect accompanying the internalizing disorders. Family members may provide reassurance or reinforce escape and avoidance as a way of calming the anxious child or protecting the child from becoming upset and anxious. In depression, parents may take over tasks the adolescent is unable to complete due to anhedonia and vegetative symptoms, such as doing the teenager's homework or other compulsory acts. The intention of the parents is to prevent the child or adolescent from becoming even more anxious or depressed and, thus, to allay the distress experienced by their child. Unfortunately, although well intentioned, these parent behaviors are incorporated into vicious cycles of continued anxiety or withdrawal. In CBT, parents are provided a model of negative affect and education about the proposed etiologic mechanisms and maintenance of these states. The therapist and parents collaborate to examine maintaining variables in the child's environment and family system, to develop plans to change parental behaviors when necessary, and to rearrange contingencies in the immediate environment to foster the child's recovery. For example, in selective mutism, usually another child or family member will speak for the child and reinforce the child's mutism. The parents of adolescents with social phobia order for their adolescent in restaurants, speak to teachers on the adolescent's behalf, and have fewer expectations for their adolescent's social life. Parents of depressed youth may fear worsening the child's depression by challenging or encouraging participation in activities and thus prefer to "leave well enough alone." Parents are often taught to be good CBT "coaches" for their child. In essence, parents are taught to ask questions (use the Socratic method) to guide their child in arriving at a coping/action

plan rather than providing an answer for the child. Much like a good coach, parents are taught to provide opportunities to practice the skills learned in CBT while refraining from judging the child. Reinforcing and praising the child's effort at coping, no matter how small, is essential for parents to learn in CBT. Parents are also taught systematic skills to ignore certain child behaviors (e.g., whining, refusal to speak, irritability) and to reinforce with positive attention those behaviors that approximate the goal behaviors. Parents are also trained in the use of contingency management procedures that may involve setting specific goals and contracts, such as "If Jonathan sleeps alone is his bed until 7 a.m., he gets 15 minutes of extra iPad time after school." The goal of contingency management procedures is to rearrange the reinforcement paradigms in the child's environment such that the child receives contingent positive reinforcement for appropriate behavior—in some cases, this may be stickers, small treats, or special privileges—whereas reinforcement is removed or withheld when inappropriate behavior occurs. These procedures also provide structured and, if necessary initially, scripted opportunities for parents to attend to positive behaviors and to effectively communicate this reinforcement. Cognitive-behavioral therapists do not advocate the use of punishment, which has been found to be ineffective in maintaining long-term behavioral change, in addition to being ethically unacceptable.

There are a few guidelines and caveats when planning the level and type of involvement of parents in the child or adolescent's therapy. First, the greater the distress and impairment for the child, the more likely it is that the parents are needed to reinforce the treatment program in the home environment. This is especially indicated in cases involving school avoidance behavior, in which the parents must rearrange contingencies in the home and actively work in cooperation with the school and therapist to promote attendance. Second, externalizing disorders or other complex comorbid conditions tend to fare better in CBT with parent involvement. Third, younger children have been found to respond better in acute treatment when parents are actively incorporated into the treatment

plan. Fourth, the developmental goals of adolescence involve forming independent self-identity and behavioral skills; thus, parent involvement should take this and other developmental issues into consideration. Finally, in cases in which parental psychopathology or marital or family discord is present, the involvement of the parents may hinder rather than help the child's progress in treatment. In these cases, involvement of the unaffected parent or minimal parent involvement may be indicated, with referrals given as appropriate for concurrent marital or family therapy, parent management training, and individual parent therapy.

Relapse Prevention

As treatment draws toward a close, the therapist begins the process of transferring the responsibility for continued progress from the therapist to the child. That is, specific strategies and techniques are used to consolidate gains, reinforce coping skills, generalize gains to a wide range of contexts, and bolster the child's sense of self-efficacy. In the initial phase of relapse prevention, treatment sessions are moved to a biweekly and then monthly schedule to allow the child time to practice skills on their own and decrease reliance on the therapist. By identifying upcoming events or changes in the child's life (e.g., starting school, moving to a new neighborhood, facing developmental challenges calling for increased independence), the child is encouraged to develop a coping plan for each event and to plan their self-guided exposures in advance of the event. Hence, if a child is changing to a new school, plans to visit the school and meet the teacher or some peers are encouraged, and cognitive restructuring is completed for any negative thoughts or expectations that may occur. Similarly, booster sessions can be planned for anticipated tough times (e.g., the start of school, before annual examinations) to reinforce coping skills and assist with transitions. Throughout treatment, therapists can work with parents and children to incorporate technology to optimize coping. For example, deep breathing or mindfulness exercises can be recorded on smartphones, or coping reminders can be set for a specific date or

time to encourage regular practice or situation-specific coping. In addition, smartphone applications and websites are available that provide age-appropriate CBT support (e.g., Kids Feelings App; Camp Cope-A-Lot). Finally, the child's diaries, workbooks, and journals from treatment become excellent relapse prevention aids for the child to refer to after the end of treatment. Photos taken during exposures or behavioral activation tasks that illustrate the child's accomplishments are pasted into these journals, bookmarked on the child or adolescent's smartphone, or put on posters in the child's room to reinforce gains. Finally, the Coping Cat program for anxious youth advocates the development of "commercials" by which the therapist and child produce a recording that incorporates all of the skills acquired during treatment. The child is the "star" of the recording and is shown as if teaching others how to overcome a problem. Commercials can also be produced in the form of comic strips, short books, poems, and other creative methods that inspire the child. Whatever the form the commercial takes, the child can refer to it for relapse prevention purposes and to reinforce gains. A resource for parents' "Do's and Don'ts" can also be generated for the parent component of relapse prevention. Table 53.2–8 presents a summary of the CBT components reviewed here.

CLINICAL ISSUES

Indications

CBT is indicated for the treatment of a range of disorders of childhood and adolescence, including anxiety and mood disorders, attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder, conduct, and oppositional disorder, habit disorders, OCD, PTSD, substance abuse, eating and feeding disorders, and parent–child discord, in addition to other conditions and behavioral disturbances. CBT is generally accepted as the first-line treatment for a range of disorders in childhood, with a combination treatment of CBT and medication preferred for more intractable or complex cases.

Limitations

Child or adolescent-focused CBT may not be the treatment of choice in situations involving extensive parent–child discord or marital problems. In such cases, as noted previously, the preferred course of treatment would involve family or marital therapy. The level of training and experience of the therapist typically limit the effectiveness of CBT, and, despite the widespread dissemination of CBT manuals and workshops, partially trained or inadequately trained therapists are no substitute for specialists in CBT. Hence, families and referral sources must be fully informed as to the degree of expertise in CBT of the therapist and adjust expectations accordingly. Similarly, the motivation and adherence to the treatment plan demonstrated by the patient and family may limit CBT. The therapeutic relationship, contrary to popular belief, is of critical importance to the cognitive-behavioral therapist. Thus, the cognitive-behavioral therapist will work to establish trust, positive regard, openness, and collaboration with the patient and family, no matter how rapidly a course of treatment is planned, to facilitate treatment progress.

Complications

Incomplete assessment and failure to fully uncover the antecedents and consequences of behavior may result in complications in therapy. It is not unusual for younger children or those who have successfully avoided phobic stimuli to underestimate their true level of fear. Hence, exposure may be too complex or overwhelming for a child, requiring the therapist to break the situation down into smaller, more manageable parts. Therapists who allow a child to escape or prematurely end an exposure session before adequate habituation and processing of the exposure can reinforce the anxiety and escape. Thus, it is essential that enough time is allotted for an exposure session and that the parameters of the exposure be clearly and fully examined with the child or adolescent. CBT does not purport to teach positive thinking but rather to teach optimistic,

realistic, and coping-focused thinking. As such, exposure to less-than-ideal situations and outcomes is a part of treatment.

Contradictions

CBT is a flexible set of techniques and approaches that has been effectively applied to a wide range of child and adolescent disorders. There are no known contraindications for the use of CBT in young people.

CASE EXAMPLES

SOCIAL ANXIETY DISORDER

James was a 15-year-old boy in a single-parent, middle-class home and enrolled in the 10th grade of a public school. His mother sought evaluation and treatment for him for a longstanding history of “shyness” and anxiety in social situations. The evaluation revealed social anxiety disorder as the primary disorder in an adolescent who was temperamentally inhibited since early childhood. James had a great fear of making mistakes, looking foolish, and otherwise being the focus of attention when performing academic tasks or simply trying to engage in conversations with peers and teachers. At the same time, James was forthcoming with the evaluator and revealed that he knew he had always been attracted to other boys but did not act on his attraction for fear of rejection due to being gay. Also, he had not told his mother or other close relatives or friends of his sexual orientation. These concerns led him to feel dysphoric more days than not, as “I can’t even be my true self.” James was motivated for treatment and reported that he wished to make friends and feel more comfortable opening up and being himself with other people, and be more confident in social situations. Consequently, James was treated with cognitive-behavioral group treatment for adolescents with a social phobia —a 16-session course of treatment combining psychoeducation, cognitive restructuring, social skills, behavioral exposure, relapse prevention, and four sessions of parent involvement. James was initially quiet in the group; however, as treatment progressed, the other group members encouraged his interactions, validated his feelings, and expressed unconditional and nonjudgmental positive regard for him, resulting in James fully engaging in the therapy. The therapists designed social interaction exposures geared toward his engaging in conversations at school, volunteering to speak in class, making mistakes in front of others, and attending school-related social activities (e.g., clean up in the public park, car wash) where he would need to have

conversations with others. A self-identified key goal for James, and among his most challenging homework exposures, however, was talking with his mother about his sexual orientation. The therapist role played various ways this could go—from his mother being accepting and open to her questioning whether he was confusing his feelings with a “phase.” Although he was prepared for a less-than-desired outcome with his mother, in actuality, she expressed relief that he had “finally” come out to her (“A mother knows these things”), and she encouraged their making plans to seek outlets for greater support and connection for him and for her to know how best to support James. He considered the school and peer-based exposures successful and subsequently went on to other social events and increased his class participation and engagement with school-based activities. In this case study, the importance of exposing youth to a range of potential outcomes for a given personal or social situation was crucial to James’s trust in the therapy and therapists and belief in the credibility of treatment. Moreover, he was appropriately prepared through behavioral exposure and practice to handle what could have been an awkward and discouraging situation.

Table 53.2–8.
Summary of the Main Components of Cognitive-Behavioral Therapy

Component	Focus/Goals	Associated Techniques
Psychoeducation	Provide corrective and accurate information about the nature of the disorder or problem in question.	Didactic instruction, self-monitoring (diaries, journals), assigned reading
Somatic management techniques		
Anxiety-related	Target autonomic nervous system arousal and related physiologic symptoms.	Breathing retraining (deep diaphragmatic breathing), relaxation training (progressive muscle/cue-controlled/applied relaxation), meditation, exercise
Depression	Plan behavioral activation tasks involving increase in activity to counteract negative, vegetative symptoms.	Exercise- and employ-related physical, social, mastery, and pleasurable activities
Sleep hygiene	Restructure sleep cycle through scheduling of awake activities and self-soothing activities to promote healthy and restful sleep.	Set tasks and guidelines geared toward decreasing arousal and promoting relaxation prior to bedtime; decrease/extinction of arousal activities such as exercise or

		use of stimulants (caffeine) in close proximity to bedtime.
Cognitive restructuring	Identify maladaptive (automatic thoughts, schema, irrational beliefs) thoughts, beliefs, and images and challenge thoughts with realistic, coping-focused thinking; in children, uncover “unhelpful self-talk” and replace with coping-focused self-talk (“coaching”).	Monitor thought processes through the use of diaries, apps, or questionnaires to reveal thinking styles, identification and labeling of automatic thoughts; teach rational disputation of automatic thoughts using realistic evidence and problem-solving steps.
Exposure/behavior change techniques	Systematic exposure to avoided situation(s) to provide experience with using cognitive restructuring and other deficient skills (e.g., social skills, problem-solving skills, conflict resolution, affect regulation).	Imaginal exposure, in vivo exposure, gradual or massed (more intense) exposure to anxiety-provoking situations; in depression, use of behavioral activation tasks or behavioral experiments to counter negative and self-defeating behaviors and gather evidence to refute depressive ideation.

Reinforcement techniques	The systematic application or withdrawal of stimuli to either increase desired behavior or decrease undesirable behavior.	Patient earns reinforcement through behavioral contracts, level programs, or parent-, therapist-, and/or school-administered contingency management programs; reinforcers can include tangible items (stickers, money), social reinforcers (praise, positive attention, elevation in status), or desired activities (free time, computer/videogame use, extended curfews); time out from positive reinforcement is the removal of the individual from a reinforcing situation for a set period; punishment, which is the application of a noxious or undesired stimulus, does not result in long-term behavioral change and is not
Positive reinforcement	Provide a desirable stimulus (praise, attention, tangible reward) after a desired behavior to increase the probability of the behavior occurring again.	
Negative reinforcement	Remove an undesirable stimulus after the production of a desired behavior to increase the probability of the behavior occurring again.	
Punishment	Apply a noxious stimulus after an undesirable behavior to decrease the probability of it occurring again.	

		recommended for use by child behavior therapists.
Relapse prevention	Focus on consolidating cognitive-behavioral therapy skills and generalizing treatment gains over time; decrease reliance on therapist and others (e.g., parents, spouse) for managing problems.	Fading of sessions (from weekly to biweekly), role reversal (patient acts as therapist for a session), planned booster sessions.

SELECTIVE MUTISM

Anna was a 5-year-old girl from an intact middle-class family referred by her kindergarten teacher due to selective mutism. Anna was described as always having been a shy child who was behaviorally inhibited. Although she would speak and interact with immediate family members, she would withdraw and become quiet around peers and strangers. When she started preschool, she did not speak to her teachers or any school personnel and also began to withdraw from speaking around extended family members at holidays and parties. She also experienced distress about separation from her mother, who would generally respond to her and make requests for her. The school had also allowed her to nod and use nonverbal cues to communicate her preferences, and she was not required to read aloud or speak in front of her peers. She occasionally played and engaged with peers on the playground and was otherwise pleasant and friendly. During the evaluation, it was revealed that Anna enjoyed eating Skittles as a treat. Treatment was designed to provide an incentive for speaking through the delivery of a contingent reinforcer of high value, the Skittles. Hence, Skittles became available only in the school and therapist's office and, temporarily, were not available in her home. The therapist enacted a process of graduated shaping of communication behaviors—first nonverbal and then vocal noises—and trained the teachers to do the same. Skittles were kept in full view of Anna at all times during the initial phase of treatment, and when she was "caught" gazing at the package, the therapist or teacher would prompt her for acknowledgment that she wanted the treat. Pointing, looking, and nodding in their direction resulted in receiving two Skittles. While in session, the therapist would also leave the room while she and her mother were left to play; if the therapist returned and she continued to vocalize or speak, she would receive additional reinforcement via Skittles. Next, the therapist and parent spent time "making noise" with objects (e.g.,

rattling keys, pressing telephone buttons) and then with their mouths (e.g., animal sounds, silly sounds), and Anna was prompted to join in and make similar sounds to receive the Skittles. Finally, prompts to ask for the Skittles were enacted, first with an “Ssss,” then the full word, and finally the full sentence/question (e.g., “Can I have a Skittle?”). This shaping procedure took three extended-length sessions and collaboration, along with telephone consultation with her school teachers. In addition to treat requests, Anna was increasingly reinforced for additional situations on her fear and avoidance hierarchy: making eye contact, saying hello to neighbors, ordering her own food in a restaurant, purchasing her own Skittles from a drug store, singing in the park, etc. The treat was faded over time—that is, delivered on a variable ratio schedule of every three to eight times that she spoke to promote further speaking and decrease the association with the treat. As a part of their relapse prevention plan, Anna’s parents were reminded to allow or prompt Anna to speak for herself in various pre-identified possible situations.

OBSESSIVE-COMPULSIVE DISORDER

Ayana was a 13-year-old girl with a family history of anxiety and mood disorders. Her parents brought her to treatment due to recurrent obsessions involving contamination and germs and corresponding compulsions by which she had her parents overcook her food, check her food for contaminants, and wash her hands repeatedly to the point of their becoming raw and bleeding. The evaluation revealed a fear that, unless her parents checked her food for bugs or germs, the meal was contaminated, and she would get sick and die. Hence, after cooking it, her parents had to pull apart her food physically and examine it to her satisfaction, which could take upward of 1 hour for each meal. This caused much distress and family discord. In addition, Ayana washed her hands repeatedly after opening a door, using a cell phone, tying her shoelaces or putting on or taking off her shoes, or touching any object that she deemed dirty. First, Ayana, her parents, and the therapist mapped her OCD and constructed a hierarchy based on her compulsions, rituals, and avoided situations (from the least upsetting, checking food prepared by her mother, to the most upsetting, touching something that was wet and slimy and then touching her mouth). The process of exposure and response prevention was introduced in combination with a contingency reinforcement plan for Ayana's completion of "brave challenges." Systematically, the therapist had Ayana first engage in imaginal exposure to a scene (e.g., "You watch dad take a bite of his medium rare burger, then you imagine taking a bite of a medium rare burger with the red juice oozing out. You realize it is not super well done, and they did not check it for germs.") until her anxiety dropped to minimal levels. This usually occurred after 20 to 30 minutes. Next, in vivo exposures were gradually introduced, by which foods were introduced with "contaminants" in them (e.g., putting pieces of uncooked rice into the burger to mimic "grit"), phasing out the parents' checking of meals as well as her own checking

behaviors. As treatment progressed, Ayana learned that her feared consequence of becoming sick was not likely to occur. Washing rituals were addressed by having her touch items with various substances coating them and then touching her face and mouth. At first, she was asked to delay washing her hands over increasing time increments and then to resist for larger blocks of time. Importantly, it was critical to address some of Ayana's mental ritualizing thoughts regarding when she would be next able to wash her hands. Treatment occurred over a 14-session program, with some sessions including extended time to allow for exposure and response prevention to occur. Her parents were taught to assist her with these exposures in the home and refrain from engaging in her rituals or accommodating them (e.g., removal of antibacterial sanitizing gels). They were also provided coaching scripts so as not to engage in disputes over meals. Relapse prevention plans were enacted to expand her range of food choices and situational contexts (cafeterias, food stands, restaurants) for exposure. By the end of treatment, Ayana was eating without the need for checking and with minimal to no anxiety, and her handwashing had decreased to within the normative range of daily washing.

GOALS OF TREATMENT

In the abstract, the overall goals of CBT are to increase an individual's freedom of choice—that is, to free the individual from the confines of a disorder which removes the opportunity to make decisions and choices for one's self out of personal preference and which, instead, determines an individual's choices as a result of fear, depression, anger, or other emotional constraints. The goals of CBT are symptom relief, education about the nature of one's symptoms, vulnerabilities, and patterns of behavior, and the teaching of adaptive, coping-focused, realistic, and optimistic behavior (cognitive and overt) to maximize the person's potential, prepare them to meet the challenges of everyday life and improve their quality of life.

ETHICAL ISSUES

CBT is a safe, tolerable, and effective treatment for a range of behavioral health problems, with increased efficacy linked in some clinical studies to more seasoned and well-supervised therapists. The main risks of CBT may lie within exposure-based treatments, which are associated with temporary emotional discomfort when confronting feared situations. Contrary to the myth that exposure may result in adverse reactions (e.g., unrelenting anxiety, psychosis, breach of therapeutic alliance), any discomfort and boundary issues in conducting exposure can be skillfully and carefully managed by the experienced therapist. When conducting exposure in community (in vivo) settings, such as schools, parks, and playgrounds, therapists need to be mindful of confidentiality concerns and take precautions to minimize compromising the patient's right to privacy.

RESEARCH AND EVALUATION

CBT is considered the "gold standard" psychosocial treatment approach with more empirical support than any other psychosocial intervention. Efficacy in the treatment of childhood internalizing and externalizing disorders through a number of controlled, randomized trials, including combined trials of medication and CBT. Long-term follow-up of youth treated for anxiety, OCD, or depression suggests maintenance of treatment gains, in addition to further improvement over time. It is incumbent on clinical trial researchers in CBT to test this approach in youth presenting with variations in cognitive and developmental functioning, comorbidity patterns, and various environmental adversities to test the effectiveness of therapy programs in mental health service settings. Further research is needed to evaluate treatment algorithms, discontinuation procedures, and pretreatment factors that predict the maintenance or relapse of treatments over the long term. The critical issue faced by today's clinical scientists involves moving treatments from the laboratory to the community. This rests on the collaboration and cooperation of clinical scientists, clinicians, patient advocates, and

consumers for critical feedback to flow in multiple directions to adapt and adopt evidence-based treatments in community settings.

53.3 Group Psychotherapy

MARGO L. THIENEMANN, M.D.

Group therapy is the counseling, guidance, or training of children and adolescents involving interactions of three or more members that has the potential for reciprocal influence. Empirical support for group therapy for children and adolescents is growing. In 1997, Matthew J. Hoag and Gary M. Burlingame published a meta-analysis of the 56 English-language studies of child group therapy that used randomization or matching in their experimental designs. Compared to wait-list or placebo control, group therapies helped to a moderate degree (effect size 0.61, range –0.04 to 2.99). More recent studies have addressed specific populations, as discussed below.

Group interventions for children and adolescents can be categorized by goals, therapeutic processes, duration, and population served and may be referred to as *psychotherapy groups, psychoeducational groups, support groups,* and *self-help groups.* Delivering therapy via groups may be better than individual therapy for addressing specific illnesses or may more effectively address treatment issues such as motivation for change or the need for social reinforcement of learning.

HISTORY

Therapists have been describing group treatments for children for approximately 100 years. Early in the 20th century, adolescents met for psychodrama groups in Vienna. In the 1930s, *activity group therapy* developed. In these groups, children played among therapists who used nonverbal, noninterpretive interactive strategies to effect “ego repair.” After World War I and during the Depression, when delinquent youth needed constructive supervision and

resources, and manpower was short, adolescents were treated in groups. After World War II, understaffed military hospitals in the United States and England used groups to deal with psychiatric casualties. The 1960s saw the emergence of encounter groups, the community mental health movement, antiestablishment groups, and increased tolerance in society for talking openly about one's feelings.

Today, groups are used frequently and ubiquitously. Psychotherapy, support, psychoeducational, and self-help groups may be found in all human service facilities, including schools, hospitals, clinics, and on the internet. Conceptual understanding and beginning clinical skills of group therapy are listed among the required core competencies for child and adolescent psychiatrist training, according to the Accreditation Council of Graduate Medical Education (ACGME), though Pollock and Kymissis noted that few training programs include adequate training in group psychotherapy.

Environmental factors have shaped these historical trends. Pollock and Kymissis, discussing the future of adolescent group therapy in 2001, posited that theoretical and clinical developments, training opportunities, scientific research, economics, social change, and public and professional attitudes all influence the type, quality, and availability of group therapy. Psychoanalytic theory informed early groups, which aimed to use group interactions to recapitulate family interactions. Developmental theory, considering the peer group's role in identity formation, pointed to using the group for adolescents' therapy. The development of learning theory and cognitive-behavioral therapy (CBT) has led to problem-focused, time-limited group interventions.

Societal changes and economic factors have increased the appeal of group interventions. According to Miffitt, the current health care climate of high demand and limited resources makes the group therapy format cost-effective and fiscally responsible. Due to the developmental tasks of adolescence, which include identity formation and development of the concept of self through peer relationships, peer approval, and belongingness, group modalities are perhaps especially useful for pre-adolescent and adolescent children (paraphrased from Miffitt, 2014). Today, many group

therapies have been researched, and as all evidence-based therapies require treatment manuals, the practitioner will have access to guidance.

Some factors serve as potential obstacles to the use of group psychotherapies. Managed care, because of group therapy's potential cost-effectiveness, initially provided an incentive for increasing the use of outpatient group therapy. Despite increased societal comfort with self-disclosure, therapists and patients may reject group therapy, considering it diluted and less effective. Perhaps, as has been the case for pharmacologic, individual, or other treatment modalities, research will demonstrate that specific group therapies for specific problems administered by specifically trained individuals help, and the interventions may gain adequate support for dissemination.

THEORETICAL ISSUES

Therapeutic Power of the Group

Gathering individuals together for therapy may help them more than working with them alone. Existential psychiatrist Irv Yalom published The Theory and Practice of Group Psychotherapy, in which he described factors that make psychological treatment in groups especially effective. Yalom listed the instillation of hope, universality, imparting of information, altruism, corrective recapitulation of the primary family group, development of socializing techniques, imitative behavior, catharsis, the addressing of existential factors, cohesiveness, and interpersonal learning as factors leading to change. In children and adolescents, the use of the group to address developmental issues may also be an advantage.

Hope. In groups, children can meet other children with similar troubles. As they see peers overcome obstacles and actively addressing problems, they can develop hope that they, too, can help themselves get better. Families may gain hope; a parent of an unmotivated anxious child remarked that seeing other children

tackling their anxieties gave her hope that her child would be able to do so. Similarly, in multi-family groups, parents often remark that seeing other children improve behavior-wise gave them hope that their families could also begin to function in a healthier manner.

Universality. Children with psychiatric disorders frequently feel they are “weird,” “crazy,” or “losers.” Getting to know peers with similar issues can lessen the pain and reduce the erosion of self-esteem that comes with having a mental health disorder. Adolescents are in the midst of exploring and consolidating their identities during the time that a number of major psychiatric illnesses begin to manifest themselves. Having the opportunity to interact with others with similar difficulties can help teenagers integrate having a psychiatric illness into a broader sense of self. In a recent pilot study by Straub et al., reviewing the most positive evaluations of their time-limited cognitive-behavioral group for teen outpatients, the most positive elements identified by participants were being with other adolescents and feeling comfortable in the group. By seeing others in the group, teens can come to see a disorder as only one of many aspects of themselves.

Imparting Information. Children learn together at school, on teams, and in families. In group therapy, children can learn about the course and characteristics of their disorder. In addition to presenting live examples, the group format is suited to psychoeducation via leaders’ instruction, educational videos, and structured learning activities. When the child teaches and helps other members, their learning is reinforced. Following the Coping Cat anxiety protocol model, members of one adolescent group treatment for obsessive-compulsive disorder (OCD) ended the group by making a didactic video. The group members delighted in their educational video, which taught about the etiology, symptoms, treatment, and impact of OCD. They watched it repeatedly and shared it with their families.

Altruism. Supporting others in the group is gratifying and a positive coping mechanism. Altruistic actions can boost one’s sense

of well-being and self-esteem and help to defend against upsetting feelings. Children and adolescents in group therapy often make thoughtful suggestions to other members. One study of adolescents participating in cognitive-behavioral group therapy reported that most participants tried to help their peers to design behavioral interventions in every session.

Corrective Recapitulation of the Primary Family Group. Through examining psychodynamic processes and addressing treatment resistances, the group format can provide a wealth of opportunities for addressing family conflicts. In a group setting, children develop transference relationships with leaders and peers. Providing a safe, constructive atmosphere in which maladaptive interpersonal patterns are addressed and reworked may provide group members a chance to work through dynamic conflicts originating in the family.

Development of Socializing Techniques. Yalom stated that all therapy groups help patients develop social skills. Social deficits, social dysfunction, and isolation are prominent concerns for children with psychiatric disorders (including those with pervasive developmental disorders), learning disorders, attention-deficit disorder, other externalizing disorders, and social anxiety and depressive disorders. Groups allow patients to practice new skills and receive feedback from professionals and peers in real-time. In one controlled group therapy study of girls without friends, girls in the treatment group did learn to approach peers and begin conversations. Reinforcement and criticism from peers may be the most meaningful feedback for adolescents.

Imitative Behavior. Seeing how others behave greatly influences what children and adolescents do. Children in groups observe other children working on solving problems like theirs. Group leaders often demonstrate strategies, like social problem-solving and conflict resolution, as ways to deal with these. Many group protocols call for role-playing and rehearsal of skills. Sexually abused children

practice acting assertively, and impulsive children practice entering an ongoing conversation successfully. In the pilot study by Straub et al. examining a CBT group for depressed teens, participants reported that they felt understood by and comfortable with the group leaders and rated their advice as helpful. Imitating effective behaviors modeled by leaders whom children respect and peers with whom children may identify effectively teaches functional behaviors.

Catharsis. Group therapy can allow one to express one's distress in the presence of individuals who can truly understand one's suffering. Although catharsis provides some relief, catharsis alone is insufficient for change. Members of one adolescent trichotillomania treatment group noted that talking at support groups had helped initially but left them feeling dejected after hearing about others' experiences. They felt more hopeful when they could learn new tools with which to address their behaviors.

Existential Factors. In the trichotillomania group just mentioned, one member openly expressed hopelessness and refused to address her hair-pulling. The other group members challenged her stance, urging her to take responsibility for attempting to change her behavior. Unwilling to take charge at that time, she left the group. Issues of personal responsibility will change, loneliness, and demoralization frequently emerged in the context of group therapy, which provided a rich format in which to discuss these universal existential concerns. Adults in one substance abuse group rated the group's ability to address existential issues as its most powerful component.

Cohesiveness. The experience of being part of something, being self-revelatory *and* accepted, and working together feels good and can improve children's motivation to work in therapy. When children and adolescents are secretive about their disorders, they may have a sense they do not belong anywhere. In a group, they can enjoy a sense of closeness when they can be open about their troubles, are accepted, and are understood. A study by McConachie et al.

investigating group therapy for anxiety in children with autism spectrum disorder found that the most helpful strategies were learning alternative coping strategies, sharing experiences, and feeling accepted.

Interpersonal Learning. By working in the here and now of relationships in the group sessions, individuals have an opportunity to address dysfunctional interpersonal difficulties. The group can be a safe place to develop and practice healthy ways of interacting. For example, in a mentalization-based therapy group, teens are often encouraged to discuss when they find other participants' behaviors confusing or distressing so that the behaviors can be understood and improved.

Developmental Factors

Each stage of development has its tasks. Younger children's egocentric focus differs from preadolescents' yearning for same-sex soul mates and from adolescents' empathic, individuating, and affiliative capacities. Understanding the developmental needs and capacities of a set of children or adolescents is necessary for designing and enacting a successful group therapy intervention. A parent-only, group cognitive-behavioral intervention for children with anxiety disorders was used to take advantage of the collaborative working relationship between school-age children and their parents (and of the benefits of parents working together at their common stages of parenting). Aronson delightfully discussed ways in which adolescent developmental issues are addressed in a paper, "Where the Wild Things Are." In it, he likened the journey of Maurice Sendak's Max trying on his new identity—affiliating with peers, individuating, and returning with a new relationship to his family—to psychological processes occurring in adolescent group therapy. Whether the group is a cluster of same-age peers or contains a range of ages, the group interaction can foster developmental stage-appropriate maturation.

Other Factors

Most geographic areas have an inadequate number of psychotherapists, and most individuals have little surplus money for psychotherapy. The group format uses therapist resources in a lower-cost way to provide care that otherwise might not be available due to a lack of resources.

TECHNIQUES

Gains made in symptom resolution and psychosocial development in groups can result from general therapeutic factors and from learning specific information and skills. Before discussing specific diagnoses and problem-focused interventions, this subsection reviews general technical issues.

Selection of Patients

Number. A typical group contains 6 to 10 members—a size large enough to allow for a rich exchange but small enough to prevent members from being neglected. Having enough at the outset ensures against depletion due to dropouts and absences. Sometimes, goals call for a smaller or larger group. In one treatment study, aggressive young boys practiced coping with being teased. Because of the intensity of the intervention and the potential for strong emotions and behavioral acting out, the interventions were done in triads. On the other hand, Meezan and O'Keefe studied a large-group format used to address abusive and neglectful caregivers and their children. Two or more members of at least two generations of each family met with five to seven other families and four therapists. More change (including a reduced incidence of child abuse and improved child behavior) occurred in the families in the intervention group than in a control group using an individual family treatment. The authors believed that families improved more because they met families who had "been there" and other families who motivated them and encouraged them to change. Families felt that compared to feedback from therapists, feedback from other families was easier to take and helped them the most.

Describing an inpatient community group of 18 severely disturbed and conduct-disordered boys between the ages of 11 and 16 years, another author remarked that although maintaining structure and creating a safe environment presents a challenge with a large group of disturbed children, the larger group was powerful and a good choice for reluctant participants and those limited in their capacity to share their thoughts and feelings.

Age and Sex. Participants' age defines the nature of the interactions and the structure of the intervention. Some investigators have included children of different ages and have found that members benefit from the interesting modeling and teaching opportunities provided by the family-like grouping. Most often, groups are composed of children at similar developmental levels (e.g., 8 to 12 years and 12 to 18 years). When patients are of elementary school age, mixed-sex groups are often appropriate, especially for the younger grades. For this age group, games and activities can be fun while they facilitate interactions and learning. As the children age, they can tolerate a format increasingly focused on verbal interaction. Children in preadolescence prefer same-sex peers and can be distracted and inhibited by members of the opposite sex. Adolescents enjoy and can use mixed-sex groups again. Mixing highschool–aged adolescents with younger ones may expose the younger children to topics with which they are not comfortable.

Gathering Group Members

Difficulty gathering a cohort of patients at once can impede the initiation of group work. Wood and coworkers studied a group format for treating adolescents who deliberately harm themselves. Sixty-three adolescents who had intentionally injured themselves were randomly assigned to either group therapy along with routine care or routine care alone. The group format was chosen for both clinical and administrative reasons: because poor peer relationships and impaired problem-solving were thought to be amenable to group

intervention and because group therapy was hoped to decrease the use of individual therapy and train a team of therapists for dealing with self-harm. The authors advanced the field by writing a manual describing necessary complex psychotherapeutic techniques. The manualized therapy—a developmental group psychotherapy—included a variety of techniques, including problem-solving, CBT, positive corrective therapeutic relationships, dialectical behavior therapy (DBT), and psychodynamic group therapy. After the assessment, six acute sessions were followed by long-term group therapy, which was open-ended. Group members could join the groups at any time. The themes of acute sessions included relationships, school problems, peer relationships, family problems, anger management, depression and self-harm, hopelessness, and feelings about the future. While the group therapy did not reduce levels of depression or suicidal thinking, participation in the group (the median number of sessions was 8; the range was 0 to 19) did lead to a change in the incidence of deliberate self-harm and the use of other therapy resources. Those who had more group sessions were less likely to harm themselves again, whereas those who had more individual sessions were more likely to repeat self-harm. This study is interesting not only for the clinical outcome but also for a model for running a continuous group, adding newcomers after a six-session lead-in.

Excluding Patients

Certain individuals in group therapy may undermine the process to the extent that, although the individual might benefit from participating, their detriment to the group calls for exclusion. Particularly in adolescent groups, individuals who actively use drugs may disrupt the group by showing up under the influence or reveling in escapades. When this does not serve the group's goals, these individuals should be excluded. Fragile children and adolescents may experience the group as unduly stressful, thus contraindicating their participation. Most group protocols exclude actively suicidal or psychotic individuals, who may monopolize the leader's attention,

upset other members, and require the leader to leave the session to appropriately triage the patient. On the other hand, crises and decompensations are part of the territory of treating mentally ill children and adolescents. Witnessing the therapist compassionately and competently handle a troubled peer may be reassuring to a group member. Including an unwilling “captive” member in a group could drag the group down in a mutinous way or, skillfully handled, highlight issues of motivation and personal responsibility for each member.

Investigating the importance of carefully selecting members (considering such factors as level of acting out or ego development), Johnson and Gold sorted 34 latency-aged boys into four groups based on a measured leadership quality score. Groups met weekly for 20 sessions. All group-treated boys improved in popularity ratings and leadership. The authors remarked that the therapist’s ability to match techniques to the characteristics of the group members was more important than group composition.

Parents

Parents spend many more hours with their children than the therapists can and are able to influence their children by teaching, shaping, and modeling. A growing literature supports including parents in group interventions, often in parallel parent groups and sometimes as a sole intervention. A University of Michigan group tested the effects of a child-only, child-plus-mother, and waiting-list intervention for children who had witnessed intimate partner violence. The children in the child-only group participated in a 10-week group therapy aimed at increasing their knowledge about families and family violence, managing their emotions, and managing interpersonal conflict. The separate mothers’ group taught the mothers about the influence of violence on children’s development and worked to improve parenting and disciplinary skills. The child-plus-mother therapy was the most effective in improving externalizing behaviors, with gains continuing after the group ended. When sexually abused children aged 3 to 12 (n = 617) were treated

using group therapy with a concurrent parent group, it was found that children who participated in the group improved significantly in their symptoms, which included somatic complaints, interpersonal difficulties, psychological state, and behavioral problems. These children were less likely to be revictimized or become sexual offenders, particularly when the parents also attended the group. Parents are an important resource for the reinforcement of skills and psychoeducation taught in groups.

Setting

Group therapies for children typically take place in the clinic or school. The advantages of clinic-based groups include confidentiality and coordination of care. The more available school setting offers the specific advantages of convenience for the children, opportunities for developing friendships with schoolmates who are accessible, and the potential for doing primary prevention work. Some social skill group therapies based in clinics have improved socializing with group members, but results have failed to generalize to school peers. Conducting social skills groups in the schools increases the chance for generalizability of skills. At the time of this writing, most school and clinic work was performed online due to COVID sequestration. Over time, the effectiveness of this distance therapy will be researched and more understood.

Therapist

The effective group psychotherapist understands child development, psychodynamic concepts, characteristics of the child-targeted psychopathology, and facility with the therapeutic intervention. In addition, the therapist needs knowledge of factors particular to groups. The therapist must foster a climate of security, tolerance, and acceptance for differences in feelings and behaviors; be able to control the tensions and anxiety levels in individual group members within acceptable limits; and control group phenomena such as bullying, scapegoating, monopolizing, and instigating. Groups benefit from therapists who are flexible and playful, can regress without

becoming a peer, have the ability to provide structure in an authoritative (not authoritarian) manner, and provide a good co-therapy relationship. The group therapist must be aware of and contend with their countertransference to the group and its members. As with all countertransference reactions, the therapists' anxiety and resistance can be used to further understand the group process. By analyzing one's countertransference, one can alert oneself to possible enactments. Group resistance may reflect the therapist's own anxiety.

Co-Therapist Relationship

Having more than one therapist expands the capacity for simultaneously processing multiple members' reactions and allows more efficient administration of the group. Having a co-therapist also provides back-up in the event a leader is absent. The co-therapist relationship has been likened to a marriage or sibling relationship: It takes a cooperative, complementary partnership that must withstand multiple potential stressors. Often, co-therapists are individuals with unequal training and experience. The pair must withstand group members responding to them as a parenting duo and/or mentally assigning them good therapist/bad therapist roles. Throughout the therapy session, co-therapists must negotiate the dips and turns of members' (and their own) emotions in front of the group. Witnessing how co-therapists problem-solve together provides the group's child and adolescent members with an opportunity for modeling and recapitulation of the family. The co-therapist relationship requires a respectful, egalitarian stance in which therapists are open to processing their interaction and their reactions to the group. Unfortunately, due to declining reimbursements, co-therapy is becoming less feasible in community settings.

Tools

Creative group therapy tools range from simple games to video interventions and can facilitate the therapeutic process. One author described a low-tech approach—a variation of pass the parcel, in

which a package is passed around the group for each member to remove a layer of wrapping and answer the question written on it.

Heiman and Ettin used a variety of interesting techniques in a therapy group for sexually abused girls. They began with a puppet-making exercise included to promote disclosure and build group cohesion. Girls built puppets in dyads and used them to introduce each other and as a supportive “friend.” Girls named the group in the second session, a task that began their working together as a group and set the stage for them to take ownership and define the goals of the group. Other tools included a board game that asked questions about specifics of abuse, a coloring book about girls’ rights and bodies, a collage project about girls at different ages used to facilitate a discussion of appropriate sexual behavior at different ages, letter writing to perpetrators to express strong feelings, and throwing into the trash drawings and writings symbolizing things they would like to put into the past.

A group for sexually abused boys made a group flag, which required creativity and compromises that led to group solidarity. This same group rolled a “feelings cube,” which directed them to describe a situation causing a certain feeling, act the feeling out, or answer questions posed by group leaders and members. They made and photographed clay figures portraying their abuse. Each of these tools was chosen to help the girls and boys confront and process difficult issues.

Videos can facilitate learning and discussion in groups for children. Prevention films for sexually abused children can be used to teach self-protection skills. Films of social vignettes can provide a take-off point for discussion and role playing for social skills groups. Watching the video stories together is an efficient teaching medium and provides a shared experience from which discussion can flow in a lively way.

Activities can also serve to introduce levity that promotes camaraderie and communication. In DBT groups, games are often used to enforce mindfulness techniques such as observing one’s feelings and radical acceptance. In one activity, members choose a favorite from a bowl of mixed candies. Then they are asked to pass

the favorite to the person on their left and mindfully eat the new piece of candy. In a mentalization-based therapy technique, teens are encouraged to “play the doctor” using a stethoscope and dressing in white coats to empower themselves in discussing what they think may be going on in the minds and hearts of other family or group members. Similarly, playing freeze tag where participants “freeze” showing how they look when feeling a certain emotion can help teens understand the concept of the “opaque mind” and illustrates that they can only guess at what goes on in another’s mind. Role play is yet another effective tool to promote perspective taking and communication.

In the era of social media, creating original video recordings can be an exciting developmentally appropriate and available tool. For instance, to consolidate knowledge of information and skills acquired in one anxiety group, members chose to make an instructional video. In one report, therapists introduced a continuously recording video camera to a group to spark group interest when it was waning. They observed that the camera’s eye acted as both an additional group member and as a transference object.

Food, obviously symbolically and physically nurturing, may be included in group therapies for practical and therapeutic reasons. Children coming to the clinic after school may be hungry and feeding them may help to improve their attention. Some treatment protocols use a snack break to allow practice in a less structured socializing for socially phobic or impulsive children. Others use food as reinforcement for specific behaviors. The group therapist must decide whether the distraction caused by food is a reasonable cost for the gained therapeutic benefit.

Length of Intervention

The rate of improvement is greatest in early therapy sessions. With increased emphasis on cost containment and measuring outcome, most recent group therapies are scheduled to last only between 8 and 12 sessions. Therapeutic factors may also call for time-limited work. Formally dividing time into phases like introductory/group

forming, working, and consolidation/termination phases may help with focus and momentum. This is not to say that longer interventions are not beneficial. For some children, more sessions are needed before there is significant improvement, still others benefit from more time for reinforcement of learning and perhaps taking on of leadership roles.

Group Rules

For individuals to feel safe in taking the risks necessary for change and for therapists and group members to serve multiple individuals' needs, groups need rules. Developing a set of rules is usually a group activity early in the intervention. Fairly universal rules include those regarding confidentiality, personal safety, attendance, not coming to the group while intoxicated, and respecting others. Deblinger notes that the use of praise, reflective listening, selective attention, positive reinforcement, and negative consequences such as time-out may improve focus in more unruly groups. While, at first glance, prohibiting socializing with other group members outside of sessions may seem unnecessary, it has proven consistently to be an important rule. For example, after members of a structured adolescent cognitive-behavioral group met with each other outside of the group, one member left the group, uncomfortable with feeling pursued by the other and others felt left out. Members of a trichotillomania group requested permission to use instant messaging on the internet to seek support from each other when they had urges to pull. Although most felt that this was helpful, some eventually desisted, feeling that boundaries were impinged on.

Family Involvement

Families may be involved in group therapies for children and adolescents in a variety of ways: they may be included with the children in the session (multifamily group), in parallel parent groups, with families included in parts of each session, certain sessions, or not included at all. Childhood anxiety disorder researchers have examined the role of family involvement in treating anxious children.

One study compared outcomes of group therapy in three conditions: parent-and-child parallel group therapies, a child-only intervention, and a parent-only intervention. Its authors found that, although all groups improved, those children in the parent-and-child parallel group intervention used new coping strategies more actively outside of the group. Barrett and coworkers included parents in group therapy for anxiety disorders because the parents were at increased risk for having anxiety disorders and because the therapists believed that family interactions play a major role in the development of children's anxiety. They randomly assigned 79 children to group CBT, group CBT with family involvement, and wait-list control. The family component encouraged parents to reinforce courageous behavior and ignore excessive complaining and anxious behavior and it taught them communication and problem-solving skills to deal successfully with their children's emotional upsets and anxieties. After treatment and 1 year later, those in the combined-treatment group had a better outcome than those in the child-only condition (95% diagnosis-free vs. 70%).

Similarly, in a recent multi-center randomized controlled trial by Scholten et al., parent involvement in group therapy for children with chronic illnesses did reveal additional positive effects on parent-reported internalizing, child-reported externalizing, information seeking, and social competence, when compared to the child-only arm. Parental involvement also appeared to contribute to durability of improvement.

Process in the Structured Group

Group therapies increasingly use structured and manualized treatment protocols. Critics and skeptics of manualized treatment fear that therapy from a manual will be stiff and "cookie-cutter." Kendall, who developed the first manual for treating childhood anxiety disorders, the Coping Cat, noted that the therapist cannot be a "cookbook" therapist but must have a sound understanding of the theory behind the intervention and adequate flexibility and creativity to use the tools in a way that suits the needs of each patient.

Manuals and outlines of therapy interventions inform and guide but do not control the group therapist. The therapist will lose effectiveness and opportunities to help if they ignore psychodynamic forces and other resistances to treatment. In an article on group therapy for sexual abuse patients, Heiman and Ettin stated that group dynamics and collective process do not disappear even within a highly structured psychoeducational group. If group members' affective reactions are not monitored and the collective dynamics are not acknowledged, then the group curriculum may have little impact. Especially in a group of adolescents, joining is crucial to promote learning. In some cases, the group process can act to disrupt the viability and stability of the group. For example, if a group member decides that a game or activity is silly, it may be difficult to have the rest of the group participate. At times, it may be necessary to pull such an individual out of the group to explore their reasons for disagreement or isolation and encourage rejoining. Group processes can be harnessed to maximize therapeutic impact. By responding to the messages underlying children's behaviors, rather than suppressing them, an opportunity exists to respond and transform the function of children's actions and maximize the efficacy of structured activities.

CLINICAL ISSUES

Indications

Group therapy should be considered if the child or adolescent has a condition for which there is evidence that group therapy is effective. This subsection provides descriptions of empirically supported group therapy interventions for specific pediatric populations. Rather than being an exhaustive review of all reported studies, it presents examples of treatments with support to describe the treatment elements and factors that made group therapy the choice. For some children, group therapy alone may be sufficient, whereas others require concomitant pharmacologic, individual, or family intervention.

Addiction, Substance Abuse. Many interventions for substance abuse are in use, many with little empirical support. Exposure to a credible peer: the type of peer who could be a negative influence under other circumstances, but, when seen in the therapy where each has a goal of not using may be helpful through positive modeling, positive reinforcement, and an alternative peer group.

The mutual self-help groups, Alcoholics Anonymous (AA) and Narcotics Anonymous (NA) may be a cost-effective option for supporting treatment gains for some substance-abusing adolescents; one study reported a decrement in health care costs over 7 years of 4.7% for each session attended! While a number of researched treatment programs have up to moderate effect sizes, the rate of relapse is high. Participation in AA and NA improves abstinence and recovery in a dose-dependent way. Research suggests that general group elements, including meeting others with similar troubles, learning from others' experiences, receiving encouragement, hope and support are powerful contributing factors. In a review, Nash notes that initially, adolescents gain most from participation with same-age peers, with peers improving the likelihood of engagement. Later, adolescents have been found to improve more in groups that also include older members. Research has elucidated particular potential barriers for adolescent participation in 12-step groups: adolescents may not see substance use as a problem due to short duration of use and the feeling that they do not need help. Adolescents' developmental need for autonomy may not mesh with accepting powerlessness against a problem; limited insight and enjoyment of substance use may not align with considering lifelong abstinence. Finding peer role models may be important to buy-in and continuing participation. For instance, Kelly and colleagues followed 160 adolescents at intervals for 8 years (84%) after an in-patient stay for substance abuse. They found that a high initial program participation dropped consistency over the 8 years. Those who attended most were with those with more episodes of alcohol intoxication and those who felt they had a problem with alcohol. Those attending most frequently during the first year had significantly better outcomes over the 8-year duration

of the study. Those who perceived that they could use alcohol in moderation attended fewer groups and were consistently less abstinent. The data suggested that in adolescents with substance abuse, attendance at one or two AA meetings per week increased abstinence and that attending at a frequency of three times per week was associated with *complete* abstinence. The authors speculated that the mutual self-help group model succeeds because it may help maintain motivation, provide a new social context of sober peers, enhance coping skills and improve self-efficacy. Nash summarized, “Though not the only model for post-treatment recovery support, research to date suggests that similar to adults, adolescents’ involvement in 12-step groups predicts improved AOD use outcomes, and greater participation (i.e., frequency, duration, and extent of involvement) predicts abstinence and SUD remission better than attendance alone.”

With the internet being one of the most commonly used methods of communication and entertainment (and, in COVID sequestration times, school) internet “addictions” are emerging among adolescents. There have been growing concerns that online video game play may be addictive and invite people to escape from their problems or daily responsibilities. Snodgrass and coworkers sought to explore some of these concerns using the online game World of Warcraft (WoW), played by groups of people regularly, simultaneously, internationally, and day and night. They also investigated online gamers’ motivation, looking at the factors of achievement, social connectivity, and immersion factors that tend to foster problematic play in the online worlds. “Achievement” refers to competitiveness drawing players deeper into game, where they spend more time online than they might wish. “Social connectiveness” refers to getting drawn into communities or associations that also demand more of their time. “Immersive play” refers to players who not only temporarily escape but more persistently or maladaptively avoid real-world problems. Researchers conducted 30 formal interviews and 252 people participated in a web survey. Results showed that subjects’ online play could be a source of distress in their lives. They also showed

that players lacking high levels of offline success (i.e., good job, high income, having a good social network of family and friends) may attempt to compensate by playing excessively and players *with* high levels of offline success are less likely to overplay. Players who experienced dissociation (losing track of the real world while immersed in the virtual world) were more likely to have problematic play. Playing multiplayer WoW to gain a sense of social connectiveness correlated with such dissociation and problematic play. While WoW group interaction can be problematic when players, who dissociate too fully and lose themselves in the virtual world of WoW, use it as a primary social outlet, thereby risking more problematic behaviors both online and offline.

Du and colleagues used a school-based, multimodal cognitive-behavioral group therapy to treat internet addiction in adolescents. Fifty-six adolescents aged 12 to 17 (with their parents and teachers) were randomly assigned to group therapy or a control group. Group CBT involved 6 to 10 students participating in an eight, 1.5-to-2-hour session group CBT run by two child and adolescent psychiatrists simultaneously with parent group therapy. Teachers attended workshops that included didactics, discussion of cases, and role plays. Groups focused on recognizing and managing one's feelings, fostering healthy family communication, strengthening relationship skills, using the internet in a healthier way, controlling one's impulses, recognizing when behavior is becoming addictive, and coming up with ways to stop addictive behavior. Parents also learned skills to improve emotional awareness and behavior, communication, problem-solving techniques, and managing adolescents with internet addiction. After the intervention, and 6 months later, the intervention group demonstrated better time management skills. As well, the treatment group showed large effect sizes for improvement in anxiety which is important, as anxiety is often associated with internet addiction and emotion and behavior regulation.

Aggression/Conduct Disorder. Children who are aggressive and have conduct disorder have social difficulties, especially in frustrating circumstances. Concerned that parent training for oppositional

defiant and conduct disorder did not help all families or generalize to school, Wester-Stratton and coworkers designed a social skills and problem-solving training protocol (Incredible Years: Dinosaur Curriculum) for children between the ages of 4 and 8 years. The investigators used the group as a supervised place to practice social skills. Ninety-nine children with the diagnosis of Oppositional Defiant or Conduct Disorder were randomly assigned to a control condition or a group intervention that included directly taught social skills, problem solving, and anger management. Groups of five or six children met weekly for approximately 6 months. Children in the treatment condition watched videotaped vignettes of children coping with stressful situations. They discussed the vignettes and collaborated to practice a repertoire of acceptable solutions and coping skills. They also discussed feelings they had about troubles caused by their own behaviors. To enhance motivation, attention, and learning and provide a developmentally appropriate milieu, therapists used puppets, cue cards, coloring books, small reinforcements, group activities, and games. The treatment group demonstrated more significant clinical improvement in conduct problems as rated by parents and teachers. Those gains were persisted at 1-year follow-up. The authors noted that many of the children made their first good friends in the group therapy and postulated that intervention might be even more effective if delivered in the subjects' actual peer setting.

In response to a paucity of resources for treating conduct disorder in South Africa and in the hope that group cognitive-behavioral treatment could help children and adolescents with conduct disorder to respond more appropriately to social situations, a group of investigators designed and studied a 12-week intervention program. An occupational therapist and a psychology student were trained and supervised by an experienced adolescent group therapist. The sessions included: (1) an overview of rules, expectations, and rewards; (2) teaching problem solving/decision making; (3) impulse control, response gap thinking; (4) assertiveness training; (5) requesting behavior change; (6) reward session; (7) empathy, perspective taking; (8) sex differences, interactions, relationships; (9)

sex education video, relationships; (10) norms, values, role models; (11) giving compliments; and (12) closure. Parents of treated and control subjects were invited to six sessions of parent behavior management training. The treatment group showed significant improvement in defiance, physical aggression, and delinquent aggression posttreatment and at 6 months, whereas the control group demonstrated improvement only in defiance and a remarkable increase in truancy. The authors noted that this brief intervention using community workers showed promise as a sustainable intervention.

Attention-Deficit/Hyperactivity Disorder. Although the Multimodal Treatment Study demonstrated that stimulant medication is the treatment of choice for uncomplicated attention-deficit/hyperactivity disorder (ADHD), children with greater difficulties may require additional psychosocial interventions to optimize function. Willis and colleagues summarized that socially, children with ADHD are often disruptive and/or developmentally inappropriate, act impulsively and in a self-centered way, and are less sharing, turn-taking, and cooperative than other children. They also demonstrate deficits in social cognition, perspective taking, and social problem solving—all of which may alienate peers, who may see them as immature, intrusive, and/or inept. Moreover, children with ADHD do not realize these things; peer relationships may represent their greatest impairments.

Hinshaw and coworkers designed a CBT intervention for boys with hyperactivity, including peers for practicing social skills. An initial study compared outcomes for a group CBT intervention for boys between the ages of 8 and 13 years treated with methylphenidate or placebo. A second study compared the treatment on a daily basis in the context of an intense summer program with a psychoeducational intervention. In each, the boys were first taught problem-solving strategies: (1) define the goal or problem, (2) generate multiple solutions, (3) consider the outcome of the various solutions, and (4) choose and operationalize a behavior. In groups of 3, the boys first practiced applying these problem-solving strategies to a series of

academic and fine-motor tasks; then they applied them to interpersonal problem vignettes. Practicing recognizing signs of anger, rehearsing strategies for dealing with provocation, and then maintaining self-control while experiencing planned provocation in the form of teasing from group peers and group leaders improved significantly in the group intervention and with medication, significantly more than the psychoeducation only subset.

Post hoc analysis suggested that children who had more experience seeing peers model coping behaviors in the group benefited most.

Pfiffner and McBurnett randomized 27 children with ADHD to receive an 8-week group social skills training—with either a parent group and teacher feedback, or wait-list control. A group format was selected so children could practice newly learned social skills and receive social reinforcement from peers. Children reported on their behavior points earned during the week, pooled their points for a group pizza party, role-played specific social skills with immediate peer feedback on performance, and shared fun activities. Evaluation after several months supported the utility of social skills training, with or without parents' and teachers' involvement. The authors noted that strong group reinforcement in a stimulating, developmentally appropriate program led to significant improvements in social skills and problem behavior.

Hoping to improve chronic management of ADHD, a larger (71 subjects in 3 clinics completing) controlled study compared a monthly group therapy intervention with a computerized clinician decision support system, the Child Health Improvement through Computer Automation (CHICA). CHICA promotes clinicians' adherence to clinical care guidelines for ADHD. Up to nine families per group participated in a 60-minute group discussion followed by a 30-minute medication visit, with parents and children in separate, simultaneous sessions, scheduled at the end of the day. The authors randomized treatments to sites, acknowledging the system-level changes necessary for personnel and scheduling. The parent group intervention included psychoeducation about ADHD, educational advocacy, and positive parenting strategies; the child intervention

also included psychoeducation and reflection on ADHD's impact, and what they saw as strengths and challenges for themselves. Compared to those in individual therapy with therapist participation in CHICA, families in the group improved in measured outcomes: they attended more visits over 12 months, experienced better parental emotional health, had fewer challenges related to misbehavior, reported significant improvements in child functioning at home and more time for themselves, other siblings, and routine household activities. Unfortunately, children receiving individual intervention reported a significant drop in mean emotional health. Bauer and colleagues, in this extension of earlier work, concluded that, especially with nearly half of children with ADHD being managed in primary care, group intervention in the familiar primary care clinic may carry less stigma and serve as an effective adjunct to competent medication management, filling a gap between primary and specific mental health care services.

Willis and colleagues, in a recent review of studies of stand-alone social skills training for children with ADHD, while expressing concern about the degree of current studies' rigor, still suggested that parent training is beneficial. They noted that the most powerful elements included emphasizing to parents that they, as parents, have important roles as their children's social skill educators and peer relationships coaches. Reviewers also endorsed the concept of simultaneous parallel parent and child sessions and recommended maximizing opportunities for positive peer interactions, even making friends. The review suggested that targeting the child's natural peer group to increase inclusiveness of the child outside the group setting (such as at school) would help.

Anxiety. Avoidance, social isolation, and difficulty with social skills are significant troubles for most anxious children and adolescents. An opportunity for direct exposure to peers, practicing social interaction, and receiving social support and reinforcement make group therapy a theoretically attractive treatment modality for anxious youth.

In 1998, Barrett reported the results of a CBT group for anxious children and their families. The manual-based treatment focused on providing children and families with skills in managing anxiety and avoidance, problem-solving, and mutual family support. Posttreatment and 12 months later, 65% of children in the child-only group, 85% of those in the group with family involvement, and 25% of the wait-list control group were free of diagnosis. Silverman and coworkers also compared a group intervention for anxious children and their parents to a wait-list control group. They considered the disadvantages of group therapy—dampening of the therapist–child relationship, overly taxed therapist resources, and possible negative modeling—along with possible advantages. Sixty-four percent of the treated subjects versus 13% of the wait-listed subjects were free of their primary diagnosis posttreatment. At 6 months, 79% of the treated group no longer had their primary anxiety diagnosis.

Beidel compared a combined 12-week group and individual treatment for latency-age social anxiety disorder with an active control condition—the Test Busters study skills protocol. The treatment condition consisted of child and parent education about social anxiety, social skills training, peer generalization experiences, and in vivo exposure. In the group social-skills training component, children learned about greetings, starting conversations, maintaining conversations, listening and remembering skills, skills for joining groups, positive assertion, negative assertion, telephone skills, using instruction, modeling, behavioral rehearsal, corrective feedback, and homework. Immediately after the social skills training session, the anxious children joined a group of not-anxious peers for a 90-minute “fun” unstructured group activity (such as bowling or in-line skating). Each week, the children met individually with the therapist to engage in exposure activities, practicing a single task, such as reading aloud in front of others. In this treatment, investigators thoughtfully combined two forms of group intervention and an individual session. The first part allowed for economic use of resources for teaching and an opportunity to practice skills in a structured session. The second part, an unstructured group activity, included non-affected peers and provided an opportunity to expand on and generalize the skills in a

more challenging situation. The individual exposure session allowed for customized, individual, symptom-driven intervention. At the end of the group, 67% of those in the treatment condition and 5% in the study skills condition no longer met diagnostic criteria for social anxiety disorder—with gains maintained at 6 months.

A Cochrane Database of Systematic Reviews of CBT for anxiety disorders in children and adolescents in 2015 reviewed 41 studies of adequate quality with a total of 1,806 participants. It concluded that CBT is significantly more effective (60%) than no therapy (waiting list, 16%) in reducing symptoms of anxiety in children and young people. Group, individual, with and without parent therapy formats were indistinguishable in their outcome. CBT was found no more effective than other "active therapies" such as psychoeducation, other supportive interventions, bibliotherapy, and treatment as usual. This suggests that group therapy for childhood anxiety is as effective as other active interventions, and it may offer the advantage of lower cost. It also points to the need for a better understanding of what makes treatment effects more durable.

Bereavement. Universality may be an especially powerful therapeutic factor in groups gathered to deal with loss. Pfeffer and coworkers used manual-based group therapy to assist children after the suicide of a parent or sibling. Families of children between the ages of 6 and 15 years were contacted within 3 weeks of the suicide death of a parent or sibling and were randomly assigned to receive or not receive intervention. Children with psychiatric diagnoses were excluded. The intervention consisted of ten 1.5-hour weekly group sessions of two to five children within 3 years of age of each other, with simultaneous parent groups. The children's curriculum consisted of offering psychoeducation about death and its permanence, identifying feelings of grief, defining what suicide is, and discussing why people commit suicide. Children's groups discussed preventing suicidal urges and presented problem-solving skills. The therapy facilitated expressions of grief and promoted identification with the positive aspects of the deceased. Parents learned about childhood bereavement, learned to help their children

express their grief and discuss the suicide, learned to identify morbid reactions in the children, and learned to promote children's healthy functioning. The parents' grieving was also supported. Children in the therapy developed new supportive relationships. They showed greater reductions in anxiety and depression than did the nonintervention children.

Depression. Group therapy is among the most empirically supported therapies for adolescent depression. A large study compared group CBT, group CBT with families, and a wait-list control group and three intensities of follow-up care for depressed adolescents. One hundred and twenty-three adolescents with major depression were randomly assigned to 16 sessions of group CBT, group CBT, plus nine sessions of a parent group or a waitlist. Mixed-gender groups of up to 10 adolescents met for 2 hours twice weekly for 8 weeks. The therapy used a manual and workbooks and taught skills of mood monitoring, improving social skills, increasing pleasant activities, decreasing anxiety, and depressogenic thoughts, and improving communication and conflict resolution. In the parent condition, parents reviewed the adolescent course content and met once per week and twice jointly with the adolescents. Posttreatment, 67% of treated and 48% of wait-listed subjects were diagnosis free. Neither parental involvement nor booster sessions made a significant difference in the measured outcome.

Hypothesizing that treating depressed Latino youth in groups would be successful, researchers recently compared group and individual CBT and interpersonal therapies (IPTs). Authors considered that Puerto Rican cultural value placed on *personalismo* (preference for personal contact in social situations) and *familismo* (placing the interest of the family over the individual) would be served in the group therapy format. Analysis of outcome favored CBT over IPT, which may have resulted from its increased structure and directiveness (consistent with *respeto*) and found results to be similar in the individual and group formats.

Stallard and coworkers designed a clinical and cost-effective study of classroom-based CBT for depression in high-risk adolescents. Of

the 5,030 students that were asked to participate, 1,064 adolescents aged 12 to 16 years old were considered high risk and were randomized to a CBT group, the usual school curriculum: Personal, Social, and Health Education (PSHE) delivered by teachers, or an attention control group (the usual school PSHE with two additional facilitators). This study examined whether these preventative interventions for depressive symptoms could be both clinically effective and cost-effective. All three groups showed decreased depression scores with no significant differences between groups. Because it required trained therapists, classroom-based CBT was not shown to be cost-effective compared to the teacher-administered groups. The study did suggest that a preventive school-based group intervention could decrease adolescents' degree of depressive symptoms.

Internet-based interventions may be useful in decreasing social isolation, which may contribute to depression. Van der Zanden et al. studied a treatment that involved groups of six or fewer people aged 16 to 25 in 90-minute chat-room therapy sessions. Participants were randomly assigned to this online cognitive-behavioral group course known as Master Your Mood (Grip op Je Dip) and a wait-list control group. The therapy focused on restructuring thinking patterns by recognizing one's unproductive, unrealistic thoughts and transforming them into more helpful, realistic thoughts. Performance of daily activities and mood monitoring were also done. Reductions in depression and anxiety and an increased sense of mastery were seen after intervention and at 3-month and 6-month follow-ups.

A functional MRI study by Straub and colleagues found alterations in the strengths of brain area connectivity after only 5 sessions of group psychotherapy for 19 depressed adolescents. Compared to controls, after therapy, depressed adolescents demonstrated a change in functional connectivity consistent with their clinical improvement; conductivity changes were consistent with decreased rumination and self-referential processing and increased cognitive control.

Suicidality, Self-Harm, Borderline Personality Disorder Traits. DBT is the first well-established, empirically supported treatment for decreasing repeated suicide attempts and self-harm in youths.

Two independent randomized controlled trials with diverse samples of 250 self-harming youths have demonstrated that DBT is effective in reducing self-harm in adolescents. Recently, McCauley and colleagues in Washington State, California, Pennsylvania, and Texas compared two manualized therapies: Dialectical Behavioral Therapy and Individual and Group Supportive Therapy (IGST), each of which employ individual and group elements, with adolescents at high risk for suicide. DBT aims to teach patients skills and encourages the employment of those skills. The DBT intervention is comprised of weekly multifamily group meetings and daily patient diary cards for teaching DBT skills, weekly individual sessions to reinforce engagement and skill use, up to seven family sessions, weekly therapist team consultation, and 24-hour brief crisis coaching. DBT uses mindfulness and CBT skills to enhance emotion regulation, distress tolerance, and building a life worth living. IGST is a manualized supportive therapy that considers “thwarted belongingness” as a suicide risk factor; IGST emphasizes acceptance, validation, and feelings of connectedness and belonging. IGST contained the same therapeutic intervention types (minus diary cards) as DBT.

173 adolescents who had attempted suicide, had self-harmed more than 3 times, rated high on suicidal ideation, or had more than 3 diagnostic criteria for borderline personality were randomized to DBT or IGST, then treated for 6 months, and followed up for 1 year. The authors postulated that the DBT treatment’s greater family involvement, with all learning coping skills, may have been responsible for its advantage.

Eating Disorders. Outpatient group therapy for eating disorders (EDs) has hardly been examined. Heinicke and colleagues did complete a study of manualized group therapy for girls who identified themselves as having disordered eating, using a self-help manual, My Body, My Life: Body Image Program for Adolescent Girls, in

which subjects were asked to read and complete contained activities each session. The intervention consisted of six weekly group sessions facilitated by a trained therapist and postintervention sessions at 2-month and 6-month follow-ups. Seventy-three adolescent girls were randomized to the intervention group or delayed treatment. The 28 girls who completed the intervention showed improvements in body dissatisfaction, disordered eating, and depression postintervention and at 2-month and 6-month follow-ups.

Many individuals with EDs participate in group therapies in the context of residential ED treatment programs, which generally have large effect sizes on ED pathology. Group therapies may include daily process groups, topic-focused groups on ED symptoms, creative arts therapy, nutritional counseling, trauma, and substance use-focused therapy groups, group exposure for food, body image (e.g., mirror exposure), and co-occurring emotional problems. Detangling the effects of group therapy from individual therapy and other aspects of residential treatment seems very difficult. Thompson-Brenner and colleagues worked to implement the Unified Protocol for Transdiagnostic Treatment of Emotional Disorders (UPTTED) at 2 residential and 14 partial hospitalization sites, following 616 patients (mean age 26 +/– 11 years) with anorexia nervosa, bulimia nervosa, and ED not otherwise specified over 3 years. Transdiagnostic approach elements include motivation enhancement, mindfulness and emotion awareness, cognitive appraisal and reappraisal, addressing maladaptive avoidance, developing interoceptive awareness, and emotion exposures. After the implementation of UPTTED, individuals improved significantly in experiential avoidance, anxiety sensitivity, and mindfulness. Groups assessed before and after UPTTED was instituted had large positive effects on depression and ED symptoms at discharge, with postimplementation UTM patients showing larger reductions in ED and depressive symptoms and pre-UTTED patients worsening at 6 months follow-up. Length of stay had a significant positive effect on symptoms, experiential avoidance, anxiety sensitivity, and mindfulness. This study adds to the literature in its effort to examine

the effects of residential treatment in a systematic way and to address psychopathology using an accepted transdiagnostic psychotherapy.

Gender Identity Issues. Choosing group therapy to address shame and isolation, Rosenberg used supportive group therapy as a component of treatment for children with gender identity issues. In a case report, she described her regimen of individual plus group treatment for working with 12 children and their parents. All but one child had comorbid symptoms of anxiety, inattention, and social isolation. Each of the children had been taunted and derided. The child group component of treatment was proposed to help self-esteem through the experience of universality. In the parent group, parents expressed relief to talk openly, for the first time, about their children. They shared their experiences and fears that their children might be harmed physically, emotionally, or by sexually transmitted illnesses. They were coached on ways to interact assertively with school personnel, friends, families, and neighbors and on how to access resources. The author reported that the children made significant clinical improvements in comorbid symptoms. The author of this 2002 study noted, “None of these children abandoned their stereotypically cross-gender interests, but they added gender-syntonic interests. All of the children in treatment for several months or more begin to express acceptance of their biologic gender.” A recent World Professional Association for Transgender Health Standards of Care notes that 6% to 27% of prepubertal children who were referred to clinics for assessment of gender dysphoria had dysphoria that persisted into adulthood.

Menvielle and Tuerk also reported the benefits of a group for parents of non–gender-conforming children. In the monthly parent support group, therapists focused on child themes and parent themes. Discussions focused on reducing the polarity of gender-based interests (girl stuff vs. boy stuff), communicating acceptance of the child’s thoughts and feelings about gender and interests, setting limits on behaviors that invite trouble, facilitating peer relationships, dealing with bullying, and discussing the possibility that

the child will be homosexual as an adult. Parent-focused themes included helping parents to grieve, developing coping mechanisms for dealing with embarrassing situations, and learning to intervene when necessary in social and school situations. The authors noted that the group helped to destigmatize the nonconformity for parents and that humor helped the group to build cohesiveness and reduce tension, elicited compassion, and provided insights.

Improving Adherence to Medical Regimens in Chronic Illness. Parents of children with chronic illnesses must deal with many demands: attending to their sick children, dealing with insurance and the health care system, continuing to work their jobs, caring for the rest of their families, and struggling with their own emotions. In New Zealand, investigators developed and tested a Strong Parents–Strong Children 6-week group intervention to help parents to manage these stresses and learn practical skills for accessing services. Parents learned to plan time for themselves, address catastrophizing cognitive distortions, and use relaxation techniques. They practiced strategies for obtaining and sharing information from relevant health professionals and maintaining family life and social contacts with the goal of handing off aspects of illness management to the child when developmentally appropriate. Parents who participated in the group perceived themselves as more effective and more able to manage stress and perceived the family as more cohesive, less anxious, and better able to cope than those on the waiting list.

For some adolescents, adherence to life-saving medical regimens is poor. Some preliminary studies suggest that treating adolescents in groups together with parent or “treatment buddy” involvement may help. Viner and colleagues compared a measure of diabetes control (hemoglobin A1c) in adolescents who elected group therapy with that in adolescents who were assessed but declined therapy. The intervention consisted of motivational enhancement therapy, analysis of strategies that help (solution-focused therapy), and a parallel parent group. Those treated in group therapy improved in glucose. A “treatment buddy” model also led to improved antiviral medication

regimen adherence in a pilot of a group intervention involving adolescents; nearly all participants increased adherence to medication, as well as other important health behaviors.

Obsessive Compulsive Disorder. Recent years have seen the development of a number of centers offering intensive group-based CBT with family involvement for children with OCD. An intensive outpatient program for children with OCD and social anxiety disorders at McLean engages children in group psychoeducation, unstructured group snack time, and group exposure therapy, where participants work on their particular exposures 4 days per week. Other weekly sessions include exposure therapy in a public setting, a caregiver guidance group, and a multifamily group. Six patients participated per group meeting for a minimum of 4 weeks, after which children and their parents reported that children's functioning had improved at school, at home, and in social environments.

Youth with severe OCD are also treated within residential treatment programs. In one, Rogers Memorial, patients participate in 27 hours of exposure therapy per week alone and with staff, with process groups and school on weekdays, and experiential therapy groups several times per week. An examination of outcomes found that participation in the program (average 78 days) was associated with improvement in OCD and depressive symptoms. Anecdotally, a number of participants have reported that meeting and living with other adolescents with OCD was significantly helpful to them.

Posttraumatic Stress Disorder/Sexual Abuse. Group therapies are widely used to treat individuals who have been traumatized by molestation or other events. In an Indonesian community plagued by poverty and a decade of armed violence between religious groups, Tol and colleagues introduced a 15-session school-based intervention administered in schools by volunteers with no formal mental health training. The manualized CBT protocol included 18 group sessions, with an individual pull-out session to establish a stimulus hierarchy at week 10. Elements included an overview, information gathering, group rules, relaxation training, anger

management through problem-solving, examination of self-talk and cognitive restructuring around PTSD, the introduction of a narrative about the trauma, imaginal and in vivo exposure, confrontation of PTSD-induced dysfunctional beliefs, summary, and graduation party. Subjects treated with trauma-processing activities, cooperative play, and creative-expressive elements improved and maintained improvement over 6 months in measurements of posttraumatic stress disorder (PTSD) symptoms and hope in the setting of continued environmental conflict and stress. Girls showed greater improvement than boys. The authors concluded that a classroom-based intervention could be an appropriate approach to target large numbers of children with stress-related symptoms, in which the start dates but not the psychometric assessment dates were staggered. The authors hoped that such time-limited manualized treatment might help in situations of severe natural or human traumas.

British investigators Trowell and coworkers randomly assigned 71 symptomatic, sexually abused girls between the ages of 6 and 14 to participate in either 30 sessions of manualized, focused, weekly individual psychoanalytic therapy or 18 sessions of manualized psychoeducational and psychotherapeutic group psychotherapy (hours spent in therapy were comparable). In the individual psychoanalytic therapy condition, play materials were provided, and topics to be addressed were designated in the manual, but the topics were addressed as they arose, and each was covered. The group topics were prearranged with notebooks, task sheets, and play material. Time was also allowed to address the relationships between the girls and their relationships with the co-therapists, and this was linked to past and current relationships, losses, and disruptions. The outcome was measured posttreatment at 1 and 2 years. Individually treated subjects had significantly greater improvements in PTSD symptoms. Each treatment led to improvement in general functioning and in anxiety and depressive symptoms.

Deblinger and coworkers performed a randomized comparison study of group supportive versus group CBT for young children who had been sexually abused and their mothers. The interventions

aimed to improve the adjustment of the children by helping them to learn to communicate their feelings, identify inappropriate touching, and learn abuse response skills. In the children's support group, the material was presented in a didactic format. The children's CBT format was interactive, using a workbook, role play, behavioral rehearsal, and joint parent–child exercises. In groups parallel to the children's, the parents were randomly assigned to cognitive-behavioral group therapy or support groups. In the CBT condition, parents were assisted in coping with their emotional reactions to the abuse and their children, taught about effective communication with their children in general and about sexual abuse, and provided behavior management skills. The support group was run with a manual guiding the therapist with skills of active listening, unconditional positive regard, reflecting feelings and empathy, and providing information about group dynamics. The magnitudes of effect sizes for changes posttreatment and at 3 months for children and mothers who participated in the CBT groups were large on most measures. For the support group subjects, the effect sizes were medium. Parents in CBT expressed greater satisfaction with the therapy. Children in the cognitive-behavioral groups (which used interactive behavioral methods) demonstrated greater knowledge and retention of body safety skills.

In the specific context of child sexual abuse, group psychotherapy might be considered a "treatment of choice" because of its impact on the negative effects of sexual abuse: isolation, stigma, and self-esteem. The group format can foster a sense of belonging among peers and help overcome the element of secrecy, which is a common component of child sexual abuse. Group and individual treatments of sexually abused children and adolescents have now been found to be equally efficacious, finding that the adjusted expense of individual therapy is 64% more than group treatment formats. However, a 2016 Cochrane review of child therapies and adolescent therapies for PTSD with a variety of traumas found that the evidence for psychological therapies versus treatment, as usual, was low overall for longer-term outcome but found that the effectiveness of CBT in decreasing PTSD symptoms was moderate

in the short term. The review found no difference in the change of symptom scores between group and individual therapy. As with most psychotherapies, well-designed studies with well-defined populations looking for moderators of change are needed.

Social Skills. Group treatment settings provide obvious opportunities for learning and practicing social skills. Children and adolescents with various disorders may have impaired ability to perceive important aspects of social intercourse, deficient knowledge of what to do to interact effectively, and/or ineffective means of being with others. Social skills have been reported to improve using therapy in groups for children and adolescents with autism spectrum disorder, aggression, or ADHD.

Kolko and coworkers described one model that illustrates the use of many child group therapy components. Targeting social perception, knowledge of social rules, and peer group behavior in hospitalized boys with ADHD and conduct disorders, compared outcomes of three times per week, 5-week group social skills training with social activity group participation. Fifty-six boys were assessed by self-report on assertiveness and loneliness, by staff reports on social problems and social acceptance by peers, and by peers on popularity. The subjects were rated on 15 role-plays for competence and on behavioral observations that detailed social involvement, gaze, physical space, appropriate voice loudness and inflection, using openers and compliments, making assertive requests, responses to provocations, and appropriate play. In each session, group rules were read, the last lesson was reviewed, and questions were asked to assess retention. Skills training was accomplished by reviewing and rating videotaped role plays of situations handled correctly and incorrectly. Incorrectly played situations were correctly role-played, discussed, and then rehearsed in the group. Points earned in the unit's token economy were recorded in the group. Outside the group, a "Secret Agent" awarded stars when the group members were caught appropriately putting the skill learned into action.

However, the Cochran Database in 2019 reviewed 25 randomized trials of social skills treatment programs involving 2,690 participants. Each study had methodologic issues. Analysis revealed that by teacher report, the main outcome variable, social skill training did not improve social skills, emotional competencies or general behavior compared no social skills training. The authors found no adverse effects of the therapy but did note possible improvement in ADHD in those treated.

A meta-analysis of group social skills interventions for children and adolescents with autism spectrum disorder noted that while many studies have been published, the formats, subjects, measures, and durations varied. The effect sizes of included randomized, controlled studies were small according to parents, observers, and teachers and large by self-report. Gates and colleagues observed that learning about particular skills and actually using them are two different things. They recommended that providers work to provide opportunities for practicing the skills in real-life situations.

The same year the above review was published, a randomized controlled study of a social skills group training was published. Olsson and colleagues recently reported the results of a randomized, controlled multisite (12 sites) study of 296 youth engaged in a 12-week intervention for youth with autism spectrum disorder. The manualized SSGT KONTAKT is described as follows: it “aims to improve social interaction and communication skills, social motivation, awareness of self and others, problem-solving capacities, and self-confidence. The program applies elements of cognitive-behavioral therapy (CBT), computer-based cognitive training, behavioral activation, psychoeducation, observational learning, and parent involvement through various mandatory, recurring, and variable treatment formats. Training sessions focus on understanding social rules and relationships, initiating social overtures, developing conversation skills, identifying and interpreting verbal and nonverbal social signals, managing conflicts, and developing social communication strategies. The teaching formats include individual goal identification, group discussions, social and role play, emotion-processing training, group activities, and tailored

homework assignments aiming to facilitate the generalization of skills to everyday life. Elements such as group discussions and role plays are applied more among the adolescents in the variable parts of the training, whereas more playful elements are used in the children's group." Authors reported a small to moderate effect size in autism symptoms and adaptive function in female adolescents compared to standard care, according to parents unblinded to the treatment group. Authors urged that work to improve social skills training is needed, perhaps by adding strategies to improve motivation, focus, and developmental relevancy, along with a longer intervention, is important. The protocol encouraged flexibility within structured sessions. Flexible elements included social interaction games, role play, group discussion, group discussions, pantomime games, and computer-based affect recognition games focused on the recognition of emotions in human faces and eyes. In this pilot study, the youth showing the most improvement included those with higher IQs and higher initial levels of communication difficulties.

A meta-analysis of group social skills interventions for children and adolescents with autism spectrum disorder noted that while many studies have been published, the formats, subjects, measures, and durations varied. The effect sizes of included randomized, controlled studies were small according to parents, observers, and teachers and large by self-report. Gates and colleagues observed that learning about particular skills and actually using them are two different things. They recommended that providers work to provide opportunities for practicing the skills in real-life situations.

Terrorist Attacks. In the 9/11 terrorist attacks, at least 6,000 children lost a parent, and many others developed PTSD. Group psychotherapy served as a place where children could put their experiences into words and play, find support, and begin self-repair. Scheidlinger and Kahn made several observations during their group work with children after 9/11. They used play, drawings, and discussion questions with elementary school–aged children to help them to express their feelings and fears. Play was especially important for traumatized children aged 4 to 8 years, helping them to

describe their experiences. Expressing feelings and thoughts in the group setting allowed other group members to share their experiences and relate to others, a significant step toward building trust and unity within the group. The clinicians observed that traumatic events can continue to affect processes of social and mental development, and they emphasized the importance of making effective interventions like group therapy available in events with global impact.

Haen described a two-phase group therapy intervention for children directly affected by 9/11. Many children felt alone and feared for their safety. It was imperative that a safe environment be provided for the children to minimize the sense of isolation they often felt. The first phase of group therapy aimed to develop trust, safety, and security and included work toward psychoeducation and connecting to one's support system. The second phase was designed to provide an open forum to address and discuss distortions and misconceptions developed by the children after 9/11. When children blamed themselves for the loss of their parent(s), work focused on correcting cognitive distortions. To facilitate the second phase of group therapy, Haen used play, art, and other nonverbal tools to communicate feelings and thoughts. In one example, drama therapy allowed group members to role-play and alter endings to traumatic events. In some cases, they were able to prevent imagined disasters. These tools helped participants to accept and cope with losses and improved the perception of security and safety for young clients.

Limitations of Group Therapy

When nonbehavioral approaches such as nondirective and psychodynamic models are used, meta-analysis found that group therapies demonstrate a smaller effect size. In group therapy, the therapist is constrained in their ability to attend to specific individual troubles and has less flexibility in a crisis. Gathering sufficient group members may prove difficult for individual practitioners.

Training

Running group therapies requires more organization up front: Enlisting co-therapists and patients, locating facilities, establishing a mutually acceptable meeting time, obtaining materials for the participants, coordinating communications, obtaining insurance authorization, and much more. The cost of training therapists to administer empirically supported therapies (which is of course most desirable) can be large and present a barrier to adopting them in clinical practice. Crome and colleagues modeled analysis of costs of adding a CBT intervention using psychologists. Considering direct and indirect costs as well as the opportunity cost of lost income during training, they predicted that at the lower end, reading manuals and attending workshops might cost $9,000, while the upper level reached $55,000; the largest expense was the missed income during training. While the field wants to move toward using the most evidence-supported treatments available, authors expressed concern about scalability.

Complications

A patient's ability to discuss emotional issues and be vulnerable practicing new skills in a group is dependent on their feeling safe and respected. When confidentiality is breached, when occurrences of disrespect are inadequately processed, or when individuals feel physically unsafe or threatened by interaction outside of the group, the group is counter-therapeutic. Adequate therapist training and supervision, careful screening of patients, and close attention to the group rules and process may guard against these occurrences.

Choice of Treatment

Each group therapy aims to ameliorate symptoms and promote psychosocial growth. The rationale for choosing to provide therapy in a group format must be that group therapy either has evidence to support its choice or has qualities that make it theoretically suited to address the patient's individual problems.

ETHICAL ISSUES

As implied previously, group therapy, although possibly cost-effective, should not be prescribed with that sole consideration in mind. It is properly used as one tool of many in the armamentarium of psychotherapists when evidence supports its use or, lacking other more empirically supported therapy, theory provides a rationale.

RESEARCH AND EVALUATION

As delineated by the ACGME Program Requirements for Graduate Medical Education in Child and Adolescent Psychiatry ACGME-approved focused revision: June 13, 2020; effective July 1, 2020, those treatments possessing empirical support should be identified, developed, disseminated, and used. A bustling movement is growing to develop well-established treatments. Doubtless, group therapies for children and adolescents will be among those whose use will be supported, but as the reader may surmise, more work needs to be done to establish which interventions, and which elements of interventions, work best for whom in well-designed, multisite, controlled studies.

The author would like to acknowledge Drs, Sonal Rana and Nicole Quiterio for their contribution to this chapter in a previous edition and Abby Miller for her help in manuscript preparation.

53.4 Family Therapy

John Sargent, M.D., and Neha Sharma, D.O.

Family therapy represents an organized, well-developed, and variable set of interactions with family members that addresses mental health and substance use problems that affect them. It also has been used to assist with recognized relationship problems, including communication difficulties and difficulties occurring within spouse and parent–child relationships. (In this section, “parent” refers to any adult with custody of the child and responsibility for the child’s well-being and development.) Tenets of family therapy can also be used to address conflicts among colleagues and family members including those that are created by implicit bias, racism, and discrimination.

These interventions take advantage of the importance of family relationships to individuals and the willingness of individuals to alter their behavior and thinking to help family members. Family therapy theory and practice are based on a range of ideas and ideologies (Table 53.4–1) and are oriented to respond to a wide range of problems. The therapist’s responsibility is to appreciate the nature of the problem, develop a shared appreciation of the problem with family members, and collaborate with the family to develop the best overall adaptation of family members, including ameliorating the manifestations and effects of the problem.

Table 53.4–1.
Family Tasks as Child Development Unfolds

Infancy

- Ensuring parental availability
- Ensuring resources to enable parental caretaking
- Providing support to parents when stressed
- Providing education about infants and parenting
- Encouraging balance between jobs of adult and parent, especially during times of transition

Preschool Children

- Enabling parents to respond to separation/individuation efforts of the child
- Encouraging parental consistency in discipline and limit setting
- Supporting positive parent–child connections based on individual nature of the child and the child's competencies
- Encouraging play, use of fantasy, and creativity in the interactions between parents and child
- Encouraging child's relating ability with other children and with other caretaking adults

School-Age Children

- Ensuring parental consistency in understanding, accepting, and being available for the child
- Developing rule-based behavioral expectations and consequences for the child
- Encouraging the child's competent engagement with school, friendships, and community activities
- Gradually assisting the family in developing a consistent, positive, and hopeful appreciation of the child
- Encouraging the child's independent perception of and participation in family life

Adolescence

- Assisting the parents with adolescent problems that require rules, consequences, and consistency
- Encouraging parental figures in assuming a supervisory role with children, with parents willing to allow for experimentation and learning, although also establishing essential rules

Encouraging the adolescent's voice and role in family life, as well as their competency and involvement in extrafamilial experiences

Assisting the parents in encouraging self-direction, self-definition, integrity, and values in adolescent children

Assisting parents with refocusing on important aspects of their lives as they separate from their children

Table 53.4–2.
Assumptions of Family Treatment

Family therapy is an integral part of the practice of child and adolescent psychiatry.

Child and adolescent emotional and behavioral difficulties always affect family life and relationships.

Family relationships always affect child development, emotional status, and behavioral capacity.

Adaptation of the child and adolescent with psychopathology to the family is always a goal of treatment and requires change on the part of the family, accommodation by the child when possible, and consideration by treating professionals.

The family can always be a source of understanding, support, and healing for children and adolescents.

The family should agree to, participate in, and assist in directing all mental health interventions at all levels of care.

Family involvement in all treatment should be defined and structured to achieve family goals and facilitate achieving goals for the child with psychiatric difficulties.

Various therapeutic interventions and classes of interventions can be used to achieve these goals.

Family interventions address problems that have neurophysiologic and genetic elements and have developed in relation to unique environmental occurrences. Interactional responses often naturally occur that reinforce the problem. Family members are also

emotionally affected by their relatives' difficulties, leading to a further mismatch between family members' needs and others' behavior. A child may be identified as the patient while the family struggles with a poor marital relationship or with parental mental health concerns. Family therapy is much more interested in the solutions to problems and improvement in the overall well-being and functioning of the family than in the etiology of the problem. This leads to a future-oriented focus of treatment and also suggests that assessment is carried out in a manner that is engaging and therapeutic. Often, family members are frustrated and frightened, and often their interactions are unproductive and repetitive, reinforcing and maintaining the problems. Therapy occurs through the interventions of the therapist and the relationships they develop with family members and with the family as a whole. The therapist's behaviors are intentional and carefully chosen and carried out to facilitate engagement, mutual care, support, and a resolution of problems that the family is experiencing. The therapist also appreciates that improving family relationships and interactions often leads to improved overall functioning, which can become mutually reinforcing and self-perpetuating. Family therapy is a treatment approach strongly supporting social justice, equity, and opportunity for all family members.

This section focuses on the use of family assessment, family interventions, and family therapy to address the problems that families have with their children's development (see Table 53.4–1), emotions, cognitions, and behavior. It is based on the premise that the practice of child and adolescent psychiatry always involves interacting with and understanding family interactions and functioning, and always involves engaging the family in the treatment and monitoring process (Table 53.4–2). At the core of family work, there is acceptance of each family's cultural and social values. The section includes case examples demonstrating the range of applications of family therapy with diverse families, as well as the various forms that family treatment may take. Tables reviewing these significant models of family therapy (Table 53.4–3), the theoretical foundations of family therapy (Table 53.4–4), specific treatment

approaches for common child mental health problems (Table 53.4–5), and unique family treatment approaches to differences in family composition, family history, and the culture and ethnicity of the family (Tables 53.4–6 and 53.4–7) are included. Family distress brought on by the effects of racism, discrimination, and exclusion is universal target of family treatment.

Table 53.4–3.
Varieties of Family Therapy

Psychodynamic

- Assumptions and Major Concepts
  - Family relationships are based on previous parent–child relationships of each parent.
  - Difficulties arise from developmental arrest, current interactions and projections, and current stressors.
  - Improvements develop through the process of family members gaining insight into problematic relationships from the past.
  - Therapy consists in shared exploration of past relationships and current distortions and role confusions.
  - Therapy also encourages the development of mutual appreciation of the needs and limits of family members.
- Major Theoreticians and Practitioners
  - Nathan Ackerman
  - James Framo
  - Ivan Boszamenyi-Nagy

Experiential/Existential

- Assumptions and Major Concepts
  - The family is a developing organism, and the goal of therapy is to encourage the growth of the family and its members through the process of therapy.
  - This process is best supported by encouraging expressiveness, openness, and communication within the family throughout the therapeutic encounter.
  - The family is responsible for its solutions; the therapist is a facilitator who encourages growth and confronts stagnation.
- Major Theoreticians and Practitioners
  - Carl Whitaker
  - Virginia Satir

Intergenerational/Bowenian

- Assumptions and Major Concepts
  - The family is an emotional relationship system, with the goal of relationships to promote engagement, foster differentiation, and avoid fusion.

In conflictual situations, engaging a third party (triangulation) stabilizes the family system.

Individuals marry partners at the same level of differentiation, leading, at low levels of differentiation in married couples, to severe personal and relationship difficulties.

Therapy is aimed at clarifying current relationships, promoting individuation, resolving current conflictual interactions, and working through intergenerational and introjected difficulties and patterns of behavior.

Major Theoretician and Practitioner

Murray Bowen

Structural

Assumptions and Major Concepts

Focused on current organization of the family as demonstrated through repeated patterns of interaction.

Particularly attentive to how the family's organization promotes or inhibits task performance, especially child rearing.

Analysis of interactions allows the therapist to determine the nature (distance vs. closeness) and the flexibility of family relationships in relation to task performance.

The therapist promotes interactions in sessions to determine family relationships and then intervenes in those interactions to introduce greater flexibility, alternative patterns and structures, and more effective task performance.

Enmeshment (ineffective closeness) and disengagement (excessive distance), as well as rapid fluctuations between extremes, are manifestations of dysfunctional family relationships when associated with significant symptoms in a family member.

This form of family therapy was developed to respond to child and adolescent emotional and behavioral problems and is particularly effective in those situations.

The therapist is both the director of therapeutic action and participant in the process of therapy.

Major Theoretician and Practitioner

Salvador Minuchin

Systemic/Strategic

Assumptions and Major Concepts

Symptomatic behavior is embedded within the patterns of communication and relationships in a family.

Ineffective attempts at solutions to problematic behavior become part of the pattern also and thus part of the problem.

The therapist is responsible for developing and prescribing tasks and behaviors that disrupt usual patterns of interaction while strengthening other, more productive patterns.

The therapist maintains a stance of neutrality and distance with respect to the family as whole and individual members.

Specific methods of questioning designed to elicit information about family relationships (circular questioning) are used; posing hypotheses, reframing, externalizing blame, and the use of positive connotation are common techniques.

Major Theoreticians and Practitioners

Jay Haley

Cloé Madanes

Mara Selvini-Palazzoli and colleagues (Milan group)

Cognitive-Behavioral

Assumptions and Major Concepts

Concepts of learning theory—conditional contingency, reinforcement, extinction—explain problematic behavior and identify therapeutic interventions.

Sessions are entirely problem- and solution-focused in the present.

Skills training is emphasized throughout treatment; homework, record keeping, and between-sessions tasks are used regularly.

Therapy is aimed at changing both cognitions and behavior and uses new cognitions among family members to direct and evaluate behaviors.

- Particularly useful for managing mild to moderate disruptive behaviors in children and adolescents, focusing treatment on parent skills training.

Major Theoreticians and Practitioners

- Gerald Patterson
- James Alexander

Table 53.4–4.
The Theoretical Foundations of Family Therapy

General Systems Theory

The whole is greater than the sum of the parts.

Actions that affect one part of a system affect the whole.

Each part of a system is in a constantly changing relationship with all other parts.

Cybernetics

Interaction among family members is circular and continuous, with each behavior being the effect of one behavior and the cause of another.

Circular causality encourages attention to pattern of interactions and feedback between behaviors and relationships.

Communication Theory

All behavior is communication (both actions and words); behaviors define the nature of the relationships among family members.

Structural Theory

Relationships are structured in a hierarchical, potentially developmentally oriented fashion.

The structure of a family can only be determined by noting the patterns of interaction among family members.

Structures are functional or adequate insofar as they provide for the achievement of family goals.

Social Constructionist Theory

Each individual constructs or makes sense of their experience from their perspective.

Therefore, many different interpretations of a set of circumstances may be simultaneously true.

Families, therefore, must and do develop shared constructions of their situation.

The constructions may become unsatisfactory when problems or changes require interaction with systems (health care, school, extended family, community agency, etc.) that have alternative constructions of events.

Psychodynamic Theory

Early experience is formative in defining who people are.
The capacity for projection and projective identification can seriously inhibit the flexibility, resilience, and growth of relationships.

Attachment Theory

Affect regulation occurs within close relationships.
Secure attachment facilitates social relationships and the ability to know and communicate about mental states.

Over the last 20 years, manualized family therapy treatments have been developed and identified as evidence-based treatments through randomized, controlled trials. These treatment approaches have been developed for specific child and adolescent disorders, such as traumatic stress, substance abuse, anorexia nervosa, and conduct disorder.

PROCESS OF FAMILY THERAPY

Engagement

The key to successful family treatment is successful engagement of the therapist with the family and with family members. This process requires that the therapist possess the skills of connecting with more than one person at the same time and making each person feel understood, comfortable, and cared about. Engagement conveys the therapist's hope for the family's successful future and their belief that with effort, patience, mutual care, and concern, changes can occur and that a successful future can be realized. Family therapy in whatever fashion is always a creative act, an act of vision. The therapist's connection with the family and its members is based on their assertion of the meaning and value of this family. Through the acceptance inherent in engagement, the therapist works to create a context of safety that promotes greater flexibility in the interactions of family members and greater possibility that the situation can be accepted and improved. In addition to warmth, curiosity, hope, and vision, the therapist must be able to hold and act on opposite ideas:

that the family possesses strengths and has difficulties, that the family is doing the best it can, and that the family needs to change, and that the family and its situation are unique and also resemble other families in their connections to each other, their concern for each other, and their wish that every other family member have the best life possible.

The therapist also engages with the family as an entity. By acting in a manner that reflects the therapist's belief in the integrity of the family, family members can begin to relax, see each other differently, and behave in a manner that reflects their interest in membership in their family and their commitment to its well-being. The therapist asks about the family's history, culture, rituals, and beliefs; respects what they hear; and treats the family as an entity in which they believe in and cares about. This helps the family members to come together, work together, and change the ways in which they treat each other. In doing this, family members begin to understand that relationships can improve, conflicts can be dissolved, and mutual understanding and mutual support can develop. Through successful engagement with individual family members and with the family as a whole, the therapist creates a solid foundation for family change and symptomatic improvement.

Safety

Throughout the engagement and assessment process the therapist's first responsibility is to ensure the safety of the child, the family members, and others in the community, as well as their safety. In some families aggressiveness is a part of their interactions, emotions may run high when disappointments, hurts, and conflicts have occurred, and family relationships may feel and at times be unsafe. Thus the therapist must be attentive to signs of the possibility of violence, aggressiveness, abuse, and suicidal behavior. If there is concern about safety, consideration of hospitalization or involvement of human services or the justice system must be considered. The therapist's role is to work with the family to decide together on the level of care necessary to promote the safety of all while also

beginning treatment in a manner that ensures the safety and connection of all. The therapist creates a safe space where family members can speak to and listen to each other and where hurts and disappointments can be spoken about, and reconnections can be achieved. The therapist can establish ground rules for sessions and, if concerned, meet with family members individually to ensure a commitment to self-control and mutual respect in treatment and ultimately throughout family life. The quality of the therapist's engagement with the family and their presence, integrity, and his belief in their vision of successful resolution of problems are crucial in leading the family to the changes needed to ensure nonviolent family life. This sense of safety also leads to a space for advocacy when needed for issues of equity and justice.

Assessment

Family therapy is based on an ongoing assessment of the child's problem and family life. It is important for the therapist to recognize that the assessment is part of the therapeutic process. Assessment is completed in an interactive manner that is based on the therapist's interest in the family's strengths and individual capacities and interests, as well as the therapist's professional responsibility to appreciate the family's problems. The therapist, connected to the family in the treatment system, elicits a discussion about the questions the family has about their child and the concerns and issues the family experiences in their life.

Table 53.4–5.
Family-Oriented Treatment Approaches for Specific Clinical Problems

Psychosis

- Ensure appropriate diagnostic evaluation, accurate diagnosis, and adequate antipsychotic treatment.
- Psychoeducational treatment model is very helpful, providing education about the disorder, outlining family roles in treatment, and providing guidelines about how to respond to crisis and specific problems.
- Efforts at reducing blaming and intensity of affective expression within the family are often helpful.
- Ensuring family collaboration with the treatment approach, especially concerning communication with professionals, medication, vocational training, and work and placement, is extremely helpful.
- Parent support is an important aspect of treatment.

Depression

- Ensure that all involved recognize and accept the child's depressed mood.
- The therapeutic orientation should include attention to building attachments and connections, reducing personalized criticism, and building support among family members.
- Building individual competence is essential.
- Cognitive-behavioral strategies are most effective.
- Setting limits to deal with acting out, personal irritability, and poor academic performance is often helpful.
- Special attention should be paid to parental psychiatric problems.
- Psychopharmacology should be integrated within the therapeutic approach.

Anxiety Disorders and Phobias

- Collaboration in treatment reduces the power of the child's fears and vulnerability.
- Cognitive-behavioral approaches with the family are helpful.
- Agreement about the expectations for the child, especially regarding fears, is necessary.

- Distraction, relaxation, social skills assistance, and focus on building peer relationships all are helpful for the entire family to focus on.
- Recognition of temperament and the possibility of recurrence of worries during stressful periods often aid long-term outcome for the family.

Disruptive Disorders

- Attention-Deficit/Hyperactivity Disorder (ADHD)
- Agreement about diagnosis is essential.
  - Education concerning the various aspects of ADHD is helpful.
  - Family involvement in measuring and monitoring the results of behavioral interventions and psychopharmacology is helpful.
  - Parent support groups can help long-term adaptation.
  - Specific plans for impulsivity, reactivity, and aggressiveness are helpful.
  - Independence, self-regulation, self-organization, and personal responsibility are goals of treatment.
  - Special attention should be directed to developing the strengths, competencies, and self-esteem of the ADHD child and the family as a whole.
- Conduct Disorder
  - Collaboration among parents and all involved professionals and agencies is essential.
  - Responsibility and accountability for the child are primary goals of treatment.
  - Parameters of treatment must be explicitly stated.
  - Behavioral approaches highlighting consistency, expectable consequences, and predictable responses to transgressions are the cornerstone of treatment.
  - Plans must be made for responses to violence and other serious problems.
  - Impulsivity in treatment should be avoided; treatment must be consistent, continuous, developmentally oriented, and

focused on building successful adaptation of the child, as well as on reduced behavior problems.

Medication is to be used for specific target symptoms, and its use and effectiveness must be supported by all participants in treatment.

Substance Abuse

Agreement about avoiding substance use among all involved adults in necessary.

Family tolerance for affective expression usually needs to be expanded.

The family must also attend to comorbid problems, depression, learning problems, ADHD, and so forth.

The role of consequences and limits for substance use must be expressed clearly.

Parental substance use also must be addressed in treatment.

Family participation in mutual support groups (Narcotics Anonymous, Alcoholics Anonymous) is often very helpful.

Peer problems, legal difficulties, and relapses should be addressed directly with the family.

Eating Disorders

Structural techniques build family cohesiveness and a consistent approach to the disturbed eating behavior.

Simultaneous support for individuation and connection is necessary.

Cognitive-behavioral techniques assist in establishing consistency in family relationships, as well as in responses to eating disorder symptoms.

Family therapy offers an opportunity for dealing with gender issues, as well as concerns associated with control and perfectionism.

The age of the eating-disordered individual defines how treatment is structured; early adolescents respond best to family-oriented treatment; older adolescents and young adults respond better to family therapy approaches that they arrange

and manage in conjunction with simultaneous individual therapy.

Abuse (Physical or Sexual)

- Safety of the child is paramount.
- Parents should collaborate with the therapist and social service agency staff.
- A clear role for parents in the treatment process should be outlined, with specific expectations and consequences defined.
- Parent training and skills building are helpful, especially if the unique contributions of the child to the family situation are highlighted and the parents have the opportunity to practice responses and receive praise and support when they demonstrate competence.
- Honesty, clarity, and directness often reduce defensiveness and evasiveness on the part of family members.
- As much as possible, the child should have a developmentally appropriate, active role in treatment.
- Encouragement of verbal expression can be helpful in affect regulation and maintenance of consistent responses to behaviors among family members.

Academic or Learning Problems

- The child's learning or academic problem must be defined to the satisfaction of parents and school professionals.
- Parents assist with developing questions to be addressed through psychological, psychiatric, and educational evaluations.
- Roles and responsibilities of parents, school professionals, mental health professionals, and the child should be clearly identified.
- Specific educational and school-based goals should be set; these should be development of academic competency, self-esteem, and greater connection between the child and school.
- Steady progress through school marks development and achievement and builds greater maturity.

Other difficulties influencing learning (e.g., depression, anxiety, ADHD, and other disorders) need to be addressed simultaneously.

Table 53.4–6.
Variations in Family Composition

Single-Parent Families

- Recognize the strength, responsibility, burden, and stresses of the custodial parent.
- Support the independent competence of both the parent and the child.
- Encourage the parent's use of alternative caretakers and other modes of personal connection and support.
- Encourage the child's exploration of their relationship with the noncustodial parent.
- Assist with transitions that may occur with new relationships that the parent might develop.

Divorced Families

- Encourage parental collaboration in divorcing and parenting processes.
- Assist the independent emotional reactions of each family member to the separation and divorce process, including the recognition that this is a highly painful experience for children.
- Encourage the development of effective separate relationships between each parent and each child.
- Build strengths of sibling relationships.
- Assist the competency and expression of each child.
- Assist parents in collaborating in parenting tasks.

Grandparent- or Relative-Headed Families

- Recognize the effort and strength of the child-rearing adult.
- Encourage the child's emotional adaptation to not living with their biologic parents.
- Encourage effective limit setting and adult affiliation with the child in these families.
- Emphasize the child's competency and extrafamilial engagement and accomplishment.
- Support consistency in involvement of biologic parents to the greatest extent possible.

Adoptive Families

Recognize that the child's problems may be associated with preadoptive phenomena.
Support with sensitivity the parents' emotional reaction to their child's difficulties.
Possible special attention to the child's background and special attributes.
Build connections among family members while dealing with the losses and separations associated with adoption.

Families with Same-Sex Parents

Similar strategy as adoptive families
Support parents to feel empowered and effective in their parental role.
Guide parents to differentiate between their personal childhood experience and their child's experience.
Build connections in the community such that family members feel welcomed and accepted.

One can view the process of assessment in child-oriented family therapy as the iterative development of an imagined video of the child and family at home, their relationship with the child's school, and their presence in their community. This understanding appreciates not only the child's symptoms and abilities, but also the interactions within which those symptoms and strengths are embedded. Thus, symptoms—either those that are spontaneous or those that are reactive—are viewed within the interactions that precede them and those that follow them. One way to understand the patterns in which symptoms are embedded is to encourage interaction among family members in sessions and to be attentive to spontaneous interactions as they occur in sessions. Understanding these patterns provides the therapist with many possibilities for discussion and intervention.

Table 53.4–7.
Family Therapy Approaches: The Effects of Cultural Differences

Cultural Differences and Family Worldview

- Worldview defines the relationship of a family to people, institutions, and objects.
- Cultural experience affects a family's worldview.
- Race, religion, and traditional position within the power structure also affect a family's worldview.
- These factors influence family relationships, family roles, and expectations of parenting, child rearing, and child development.

Examples of Cultural Considerations in Family Treatment

- White families: focus on individuals, use verbal expression, and distinguish between physical and mental factors.
- African-American families: focus on actions and behavior; realize that extended family is important, as are religion and church; also realize that history of oppression and racism affects relationships with institutions.
- Hispanic families: acknowledge bilingual background with intrafamilial differences in acculturation and language use; religion and extended family are important; respect for the family's heritage and background is very helpful in ensuring engagement in treatment.
- Asian-American families: recognize specific national origin; family, privacy, and saving face are central to family life; recognize intrafamilial differences in acculturation and language use.

Attending to Cultural Issues in Family Therapy

- Basic Values
  - Any family is a microculture.
  - The family's culture is necessarily a synthesis and amalgam of cultures.
  - Problems develop when the family experiences conflict internally between the cultures of the extended family or with external cultures, institutions, or systems.

- The family is responsible for defining itself and its culture and for developing the most successful adaptation with other cultures.
- The therapist's responsibility is to support and facilitate that adaptation, recognizing (1) that there are many ways to be a family and raise children that are healthy and (2) that there may be issues that raise ethical concerns for the therapist, and in those situations further knowledge of the family's culture and consultation or supervision may be helpful.

Interactive Approaches

- The therapist must assume a stance of respect for and acceptance of the family as it is.
- The therapist should ask about the meaning of requesting mental health assistance for the family.
- Honest curiosity expressed in open questioning about how the family operates and how the family's cultural background influences its operation is essential.
- The therapist should refrain from judging the family, but rather should ask about how it achieves its goal.
- The therapist should avoid behaviors based on assumptions about a particular cultural background.
- The therapist should inquire about child-rearing practices in the family and responses to academic, emotional, behavioral, and social problems in the child as they reflect cultural beliefs and cultural expectations.

Clinical Approaches

- Specific responses to the child's symptoms and assistance with parenting skill need to be embedded within the therapist's and the family's understanding of cultural beliefs and expectations.
- Negotiation of the therapist's role and behavior should be based on the family's sense of their culture's expectations of professional behavior.
- The therapist can help the family to understand their cultural background as a method of helping the family to define and

understand themselves and clarify their approach to therapy.

Explorations of culture assist the family in assuming direction and responsibility for treatment.

Discussions about respective cultural backgrounds and what those backgrounds mean can assist in conflict resolution and enhance the development of the children.

The therapist can assist the family in making accommodating measures with schools and other institutions based on cultural considerations.

The family and the therapist can also decide together on other questions to be answered through the treatment process. Intellectual concerns, educational abilities, and vocational aptitudes all can be evaluated if questions exist. Diagnostic questions and the use of psychopharmacology also can be discussed in a collaborative fashion with the family. The guiding issues are always: What are your questions? What are your goals? What of these alternatives do you want to do? The key to understanding this process is to appreciate several key principles:

1. Assessment results are impressions and not judgments.
2. All assessments of the family are hypotheses based on limited data and thus are subject to change.
3. Because interactions can change and are largely dependent on context, the therapist holds the belief that if the context changes, the interactions can change.
4. Any intervention represents a question: will this intervention be successful in achieving the goal? If not, a different intervention is required.

The process of developing a shared opinion of both the child and the family, including an appreciation of strengths and difficulties among members of the treatment system, is another opportunity for therapeutic intervention. There may be opportunities to discuss and resolve disagreements between caregivers about the child's capacities and problems. There may be opportunities, depending on

developmental ability, for the child to participate in this discussion. The therapist supports the child's voice and expects the child to participate responsibly. As this process proceeds, the family's ability to negotiate effectively can be supported and reinforced by the therapist.

If other agencies or systems are involved with the family, especially in response to the child's problem, their representatives also will need to participate in the agreements about strengths and problems. This can be difficult, especially if the family has a history of conflict with these systems. The family may believe that a system with which they must be involved, such as the child's school, is treating the child ineffectively. The family will need the therapist's encouragement and potentially the therapist's coaching to be able to come to a collaborative approach with school personnel so that the child's education proceeds successfully. Similar negotiations will need to occur with the child protective system, the juvenile justice system, after-school programs, coaches, extended family, and church leaders, depending on who is involved with the child and what the child's needs, abilities, and problems are. At times the therapist will need to convene meetings of the family and those involved. The therapist, with the family's permission, may need to speak individually with the teacher, probation officer, and so on. These individuals may need to change their impressions of the child or family, and at times they may need to change the way in which they interact with the family. Supporting these new impressions is part of the therapist's responsibility for the success of their interventions. These changes become part of the therapeutic effort and goals for the treatment and become the focus of addressing implicit bias and social injustice when needed.

PROMOTING EFFECTIVE AND REWARDING PARENTING

Ensuring the safe and effective development of children is one of the main responsibilities of parents and caretakers. Caretakers need to

recognize and provide structure to ensure an immature child's ability to grow and explore their world in a way that supports developmental change and newly learned skills. They also need to provide the love and care that encourages the growth of self-confidence and self-esteem while also reinforcing developmental gains. Caretakers must also be observant to note situations in which children may have the maturity to recognize and safely navigate them. Parenting provides the foundation for secure attachment including the availability needed to support the stressed child while also modeling effective emotion regulation. Through parenting children learn to recognize situations they cannot master and to ask for help and support when necessary. Family life changes as children mature and develop. Parenting approaches need to appreciate these changes and be adjusted and modified to respond to changes and growth in the child's aspirations and abilities. Parenting that included physical control of the child during toddlerhood will need to change to parenting based upon clear and agreed upon rules and consequences for a school aged child and then to more supervision that encourages judgment, impulse control, and the development of prosocial values during adolescence. Not only do parenting approaches need to change and transform in step with developmental maturation caretakers will need to be alert to situations that demonstrate lack of skills and regression and require parenting approaches more appropriate for less mature children.

Family therapy is very helpful in addressing parenting challenges in families. The therapist will need to appreciate the source of these problems which can be a mismatch between parenting approach and the child's developmental capacity, an inherent difference in the child impacting development and function, a lack of agreement or cooperation between parental figures or external stressors impacting parental ability to recognize or address the child's needs. Stress related to immigration and acculturation can further magnify these mismatches and differences between the parent and child. During acculturation, the child often gets accustomed to the new culture faster than the parent. This separation in the acculturation process can cause more conflicts in the family, also referred to as

acculturative family distancing. Furthermore, the parents' added challenge of imparting culture to the next generation in isolation can make parents more rigid and less open to child's need to integrate two cultures. Thus, engaging and empowering parents to be effective in a culturally sensitive manner is an important target of family therapy. The therapist's ability to engage the parents and the child, appreciate the source of parenting difficulty and ensure the caretakers' trust and motivation often utilize all of the family therapist's skills in connecting, directing, and reinforcing new and effective behaviors in both caretaker and child. An accurate assessment, psychoeducation about children's difference, enactments during family sessions and a relationship of respect and regard with caretakers are important skills in enhancing parenting and building family competency and flexibility which in turn build family connections and affection.

Ensuring a Balance between Support and Limits in Parent–Child Interactions

One of the most challenging aspects of child-focused family therapy is developing an effective balance between, on the one hand, enhancing parent–child warmth, support, and the interactions that reflect secure parent–child attachment and mutual respect, and on the other, working to establish effective rules, supervision, and consequences for misbehavior and rule-breaking. This often requires skill, focused attention, and persistence on the part of the therapist. Because parental warmth forms the foundation of the mutual respect needed for effective discipline, the therapist's first task is to build that warmth. This often occurs at a time when parents feel betrayed, helpless, angry, and victimized. Parents may mistrust the therapist based on experiences of racism and health inequities within the health care system. An open discussion of these experiences and recognition of the impact of discrimination and difference upon the family can be extremely helpful in ensuring the partnership and relationship necessary for family therapy to be effective. At this point, it is the therapist's belief in the parents, in their love for their child,

and in the possibility that they might help their child grow up safely and successfully that matters most. The therapist models warmth in their relationship with the parents. Compassionate understanding characterizes these interactions. Interactions that caringly convey the therapist's belief that the parents care for their child and believe in the child's future characterize the therapy. This must occur even if the child expresses skepticism or disbelief about the parents caring for them. As trust develops between the therapist and the parents, who know that the therapist believes that they care truly about their children, a wide range of interventions is possible. These include establishing parent interactions with the child aimed at understanding the child's disagreements with their parents in a nondefensive way and in a dispassionate fashion while establishing expectations for their child's behavior as well as consistent consequences for failing to meet expectations. In this process, the therapist helps the parents to deal with their disappointments with their child so that consequences are not vindictive and helps the parents appreciate that their child could want their approval and could wish to earn their regard. In this approach, parents understand and support their child's emotions, disappointment, frustrations, and anger while also holding firm expectations, limits, and consequences. In a sense, parents are feeling one way—frustrated and angry—and acting another way—calm and firm—while allowing the child to act one way—frustrated and angry—and expecting the child to feel another way—accepted and respected even while adhering to parental limits and appreciating parental involvement and concern.

Parents often want advice about establishing discipline and limits, especially in situations in which the child has a disruptive behavior disorder and defies parental rules and limits. This often represents a challenging therapeutic concern. Often in these situations there is a difference in approach between parental figures. Everyone is exhausted, hurt, frustrated, and angry. The parents will frequently claim that consequences do not work. Disrespect and defeat characterize parent–child interactions. In these situations the therapist might choose to meet alone with parents to help them to

begin to work together, as well as to develop strategies to reinstitute effective limits. The therapist can help parents to prioritize their expectations and plan to establish one rule at a time. In the process the therapist can also help the parents to develop realistic expectations of their efforts with their child. The parents can receive validation of the experience of frustration and their sense of being betrayed by their child. As long as the parents hold on to their experience of being hurt by their child, it is very unlikely that they will notice small attempts at improvement on their child's part. They also will have difficulty holding to their expectations if the child becomes angry or has a temper outburst when a limit is imposed. In such frustrating situations, guided by the therapist, a parent can gain support from their partner that could result in decreased emotional intensity and improved ability to maintain positive expectations. Another frequent occurrence that can be discussed with the parents alone is the possibility that the child will act in a totally unaffected way when the limit is imposed, as if to say that the parents have no effect on the child. By discussing these possible scenarios, the therapist can help the parents prepare to institute appropriate limits in a planned and controlled manner. In these sessions the parents can practice talking with their child and maintaining firmness even if the child is particularly challenging. The therapist may also choose to meet alone with the child to see whether they have concerns that the therapy might resolve. Defiant, disruptive children and adolescents often want to be trusted and understood, and to have autonomy.

The therapist can help the child to receive parental approval if the child performs acceptably and gains autonomy in relation to their ability to act responsibly. When both parents and child are prepared, a session with all of them together can be held outlining the rules, expectations, and consequences. The child has the opportunity to ask for what they want, and the therapist can help the parents to promise the child the desired autonomy if the child abides by the rules and accepts the consequences. The consequences should be simple, easy to undergo, brief, and have some relationship to the transgression. The key to consequences is that they are meaningful but not onerous. Losing access to a cell phone or computer for one

evening is a meaningful but transient consequence. If the parents and child form a committed relationship with the therapist, the therapist can then, with patience and time, bring them back together in an initially tenuous but gradually caring manner. Building understanding and trust, establishing a realistic plan for limits, and noticing small successes provides a pattern of improvement that all can recognize and believe in.

Engaging Families in All Levels of Care

Family members should be actively involved in decisions about treatment programs, levels of care and care delivered, and inception and discontinuation of treatment. This expectation helps the parents or caretakers develop monitoring, supervisory, and organizational skills that they might be lacking. Because the parents possess decision-making power, they must learn to understand their child, make the child's behavior make sense, and begin the process of accepting the child's differences. This can accentuate feelings of support and understanding, which may have been undermined by their responses to symptoms and their consequences. This is especially true in the case of families with children with disruptive disorders, in which difficulties in school or with the justice system may have felt hurtful and shaming.

The journey to get out-of-home services often results in parents feeling ineffective and disempowered. The purpose of family intervention is to empower parents to conduct effective parenting. Thus, family involvement is essential for children being treated in treatment programs such as hospitalization, day treatment, or residential treatment. For the home environment to reinforce positive behaviors and not reinforce negative behaviors, it is necessary for program clinicians and staff to be attentive to the interactive sequences of which the symptoms were a part and intervene with the family to alter those sequences so that the home environment is different when the child is discharged or the program ends. If discipline is problematic, parents can be consulted when program rules are broken and consequences are required. Parents can be

informed by the child of successful experiences so that their praise is added to that of the staff. These successful experiences can translate into hope for change for parents. Parents can be expected to meet regularly to have a meaningful voice in treatment review, learning to develop realistic expectations of their child based on how the child is able to function rather than based on everyone's wishes about how they might function. It can be difficult at times to share power with parents, but with patience the staff can help the parents to feel empowered throughout the treatment program. If passes home are part of the treatment program, activities can be planned for the entire family that emphasize practice with new interactions at home prior to discharge.

FAMILY THERAPY FOR SPECIFIC PROBLEMS

Attention-Deficit/Hyperactivity Disorder

Families with a child with attention-deficit/hyperactivity disorder (ADHD) need to learn about the disorder, understand appropriate treatment, and support the development and functioning of their child. This requires that parents agree about the presence of the problem, agree to seek the help of a physician, and agree to have their child take medication if prescribed. It is also important for the parents to learn to be consistent with behavioral expectations and to appreciate and reinforce the child's strengths. Often, prior to diagnosis, the child may have experienced failure at school and rejection by peers and marked negative interactions at home. Family therapy after diagnosis of ADHD may be needed to help the family assist the child with these previous difficulties, and also to help the child to be more successful at school and with friends and to feel consistently accepted at home. Comorbidity with learning disability is common, and the family may need assistance with ensuring appropriate education for the child. ADHD often occurs in association with complex trauma in situations of abuse and trauma. Sometimes the concentration problems of the child are a manifestation of anxiety caused by trauma and sometimes the child

has both ADHD and Complex PTSD. Therapeutic flexibility and accurate assessment are important aspects of family treatment. Transitions, including moving and changing schools, can be challenging. The family may also need assistance during the child's adolescence, particularly with impulse control, exposure to drugs and alcohol, and self-management as the child becomes a young adult. A chronic illness framework often is extremely helpful for families with children with ADHD.

Jason was a 7-year-old boy who attended the second grade and who had been noted by his teacher to be extremely active in class and to have significant difficulty concentrating and following class rules. He especially had difficulty during unstructured time in school, both in the cafeteria at lunchtime and on the playground at recess.

When his teacher checked with his previous teachers from kindergarten and first grade, they stated that Jason had difficulties with his attention and activity level in both of those grades. Despite these concerns he was quite bright and had been able successfully to complete his grades and pass to the second grade. Jason's teacher invited his mother to come to school for a meeting after having sent home reports concerning his overactive behavior and his inability to finish his work.

At the meeting with Jason's mother, his teacher spoke about her concerns and suggested that Jason should undergo a psychiatric evaluation and might need medication to help him concentrate and manage his activity. His mother reported that she was also concerned about how active he was at home and how difficult it was to help him get ready for school in the morning or finish his homework in the afternoon.

Jason lived at home with his mother, stepfather, and 4-year-old stepsister. His parents had divorced when Jason was 3 years old, and his mother remarried his current stepfather 1 year prior to Jason turning 7 years old. Jason saw his biologic father on a regular basis and spent alternative weekends at his father's house. His father had also remarried, and Jason had an 18-month-old half-brother who lived with his father and stepmother.

Jason was seen by a child psychiatrist shortly after his mother and teacher met. The child psychiatrist believed that Jason was a child with ADHD and suggested to the mother that a trial of stimulant medication might be helpful for him. The mother was given rating scales to complete after Jason had started on the medication, along with written information about both ADHD and the stimulant that was prescribed for him.

The child psychiatrist also recommended that there be a meeting of all four adults involved in Jason's life—his mother, stepfather, stepmother, and biologic father—so that they could talk together about Jason's difficulties and ensure consistent treatment. The goals of the meeting were to encourage regular use of the stimulant medication and to help everyone to understand the need for clear and focused directions, focused attention, follow-through on homework, and consistent discipline in both households.

The family attended this meeting. The psychiatrist noted that Jason's biologic father was concerned about the use of medication and asked about the risks and side effects of the medicine. Jason's stepmother was concerned that there was no way successfully to help Jason without medication. As the family talked together with the child psychiatrist, asking questions and gathering information, they came to the conclusion that the best approach was to institute a trial of stimulants. The trial was begun, and Jason's teacher reported to the family that he was much more able to focus his attention and manage his behavior in school. He was noted to have less difficulty during unstructured times in school and was also able to do better academically than he had previously.

The child psychiatrist also suggested that the family come back for a second meeting, after Jason had been on medication for 6 weeks, to review everyone's impression of Jason's progress. The child psychiatrist recognized that the biologic father and stepmother were now comfortable using medication for Jason. They agreed to follow through with the medicine and to help Jason manage his behavior better in their home.

Three years later, as Jason continued to do well in school on stimulants, during a routine medication review with the child psychiatrist, Jason's mother reported that his father was getting divorced for a second time. Jason tearfully admitted that he was very upset by this and that he was going to miss his times with his stepmother and younger half-brother.

The child psychiatrist asked to speak to the father, who agreed to come for a session with Jason and talk with him about what was happening in his family. Jason's father agreed to help him have continued phone contact with this stepmother as the father and stepmother proceeded with their plans for divorce.

Six years later, Jason was old enough to obtain a driving permit. He had continued to take stimulants daily and had done well in school. He had grown up without significant emotional and behavior troubles and was eager to learn how to drive. Jason's father and mother had continued to meet with the child psychiatrist every 4 months to review Jason's medication and to check in with how everyone was doing. They were concerned about Jason driving. Jason was sure that he would be able to drive perfectly well even though he was known to be more impulsive and more disorganized than other teens his age. The child psychiatrist helped the family to discuss the privilege of driving. They decided that they would let him drive with one of them in the car and not let him drive after dark for the first several months that he was driving. They decided not to allow him to drive with peers until he had driven successfully for several months. This negotiation was difficult for Jason, but Jason's father and mother both felt very supported by the child psychiatrist. They were comfortable with their decision that Jason could learn to drive as long as he was monitored quite closely and supervised very carefully.

Oppositional Defiant Disorder and Conduct Disorder

The primary goal of family therapy for oppositional defiant disorder and conduct disorder in one or more children is the establishment of a warm and mutually respectful relationship between parents and child, which forms the foundation of effective limits, appropriate supervision, and responsible prosocial behavior by the child. Often the family situation is complicated by any or several of a variety of family risk factors. These include parental stress, parental psychopathology or substance abuse, criminality and incarceration,

poverty, marked parental preoccupation with time-consuming work, or preoccupation with other children. Overcrowding, living in a violent community, and domestic violence also occur frequently. Negative coercive cycles often occur in the interactions between parent and child, in which the child is demanding and the parent becomes controlling, leading the child to seek attention through misbehavior and leading the parent to believe that only direct control will make the child behave appropriately. The child fails to learn self-control and self-direction, and the parent becomes gradually and insidiously disempowered and negative toward the child. As the child grows, the parent increasingly becomes hopeless about the child and begins to believe that the child will fail to grow up successfully. This results in parents feeling helpless and re-emphasizes that improvement must come from outside the family. Therefore, the parent hopes that something else will lead the child to develop responsibility and seeks placement of the child in residential treatment or in the juvenile justice system. This perspective localizes the problem in the misbehaving child, leaving the child feeling blamed and even more disconnected from their family.

Two forms of family therapy deal specifically with these issues. Parent–child interaction therapy is specifically designed to treat families with young (preschool) children with oppositional defiant disorder. Multisystemic therapy has demonstrated effectiveness for families with adolescents with delinquency who are involved with the juvenile justice system. Parent–child interaction therapy focuses on building the positive aspects of the relationship between the parent and young child. Through the therapist's praise, the parent relaxes and becomes more accepting and more openly caring toward the child. The parent receives the therapist's praise and care and passes that on to the child, leading to closeness, the experience of being understood and cared for, and warmth and attunement in the parent–child relationship. This also leads to improved cooperation between parent and child, greater compliance on the child's part, and, on the part of the child, much greater interest in the parent's praise and positive regard. Parent–child interaction therapy has been shown in more than 30 clinical trials to be effective for families with preschool

children (between ages of 2 and 6 years) with oppositional defiant disorder. It has also frequently been requested by child protective services to improve parent–child relationships in situations in which mild physical abuse has occurred.

Multisystemic therapy has been shown to be effective in reducing recidivism and delinquency for children and adolescents in treatment trials and through follow-up. Trained therapists with very small caseloads help the parents to manage the stresses in their lives and supervise and set limits on their child. The therapist is available to the family consistently and the treatment is intensive, with three or four contacts with the family weekly over 4 months. The therapist builds family cohesion and encourages the child to identify and earn privileges by being responsive to parental direction. Rules are defined and consequences are specified early in treatment. Parents are expected to be available, observant, and consistent in monitoring their children. For this to occur, other difficulties that the family experiences need to be addressed through the therapy. This treatment is best suited to moderate delinquency and works best early in the course of delinquency.

Another form of family treatment for conduct disorder is parent management training. In this therapy, parents attend sessions without the child and learn and practice techniques of setting limits and imposing consequences. Most important in this treatment is helping the parents plan and practice how they will withstand the child's demanding and defiant behavior and how they will respond if the child's behavior becomes worse before it gets better (as is expected). In this treatment the therapist supports a united front among adult authority figures and builds mutual support among these authorities. Parental self-control is another goal of these parent-coaching sessions. The therapist needs to ensure that the parents learn the skills necessary to set effective limits and manage their lives at the same time.

Isaac was a 4½-year-old boy who was brought to a child mental health clinic for evaluation of defiant, challenging, and difficult behavior. He had been referred by his pediatrician after his mother discussed his defiant and difficult behavior with the pediatrician during a regular checkup. The history also revealed that Isaac had been expelled from his preschool and had to be looked after by a neighbor in her house because of aggressive and difficult behavior at school.

When the clinician met with Isaac and his mother, Isaac appeared to be a well-behaved, quiet child who was able to focus his attention and play easily with the interviewer. However, it was noted that his mother was extremely negative about him, and was frustrated, angry, withdrawn, and sad. During the interview the clinician noted that Isaac's mother was exhausted, overwhelmed, and observably sad and irritable.

The more comfortably Isaac played with the clinician in his mother's presence, the more upset and withdrawn she became. She reported that Isaac's father had left before he was born and that she had an older, 8-year-old boy with developmental disability and cerebral palsy. That child was in special education classes. She lived alone with the children. She stated that she was estranged from her mother and that she worked as a cashier in a grocery store. The family lived in a small apartment in an impoverished area of the city, and the mother reported that at times it was difficult to have enough food for her, Isaac, and his brother to eat.

The clinician was struck by the poignancy of Isaac's mother's situation, by her isolation and lack of support, and by her level of exhaustion and sense of being overwhelmed. The therapist was also touched by Isaac's attention to his mother and his tendency to watch her and comfort her when she became sad during the interview. The clinician was attentive to and supportive of the mother, and during the interview she began to calm down and admitted to being depressed, sad, and lonely.

Isaac and his mother arrived for their second session on time and both seemed eager to talk. The mother had noticed that Isaac was a little bit better behaved at home, and she seemed more relaxed and comfortable.

The therapist continued to support the mother and encouraged her to engage with Isaac in a game during the session. The therapist was warm, caring, and praising of the mother's efforts with her son. The therapist also recommended that Isaac and his mother have some regular time to enjoy each other's company during the week and suggested 15 to 20 minutes every day, during which their neighbor could look after Isaac's older brother. As Isaac received more attention from his mother at home, their negative interactions decreased. He seemed to relax and become less quick to anger, both at his babysitter's house and at his mother's house.

The clinician also encouraged the mother to reconnect with her siblings and her mother, who were in the community, and to reach out to them for support and understanding. The mother noticed that she was more relaxed and less stressed and that she was more able to experience enjoyable times with her sister. She also began to communicate in a more open way with her mother.

As the sisters became more involved with Isaac's family, there were more family gatherings and more opportunities for the mother to experience some relief from her caretaking obligations. Over a period of 3 months of weekly sessions and 2 months of biweekly sessions, Isaac's mother became much more relaxed, was able to obtain babysitters for her children, and got more involved in her older son's special education programs. She became more assertive about obtaining a raise at work and socialized with her colleagues. She spent more time with her family and her neighbors. She also resumed attending church, and Isaac became involved in the church-sponsored preschool kindergarten group.

The therapist stayed in touch with Isaac and his mother and heard from her that Isaac had successfully begun kindergarten

during the next academic year. His behavior was much improved and his curiosity, desire to play and learn, and attentiveness to adults had helped him to learn and grow in kindergarten.

Joseph was referred to the intensive in-home treatment team after his discharge from the juvenile detention facility in his community. He was 15½ years old and had been placed in the detention facility after his arrest for vandalism and breaking curfew. The vandalism involved breaking windows in his school, and well as painting graffiti on several businesses in his downtown neighborhood. Joseph lived with his mother, stepfather, 12- and 19-year-old brothers, and 17-year-old sister.

When the in-home treatment therapist went to meet Joseph and his family, the mother was at home with the younger brother. Joseph was not at home. He had told his mother that he needed to visit his friends after school and that he would be home in time for the appointment. He was late and had not informed his mother.

The history the therapist obtained was that Joseph had been a very good student and a fine boy until the age of 9, when his grandfather suddenly died and his mother moved the family into the grandmother's house to look after her. Joseph had been close to his grandfather and had reacted to his death with sadness and withdrawal from the family.

His mother noted that he began to act up at that time and said that he had started hanging around the "wrong kids" at the age of 11 and had begun truancy when in middle school. Joseph had regularly received reprimands from the school administration, mostly for fighting, defying teachers' authority, and misbehavior during recess or lunch period. Joseph's mother said that at this point she believed that Joseph was outside of her control and she had hoped that 8 weeks in the juvenile detention facility would help him to learn to manage his behavior. Because he had not come home for the therapy appointment, she was worried that perhaps things were just as bad as they were prior to his arrest and stay in the detention center.

The therapist noted that the family lived in a cramped apartment in a rundown building that needed maintenance. When the therapist asked Joseph's mother about her husband,

she stated that he also was supposed to have come home for the therapy session. She said that he often stopped at the bar on his way home to hang out with his friends and drink. Joseph's mother was increasingly worried about her 12-year-old son, who seemed to be following in Joseph's footsteps, and reported that her 17-year-old daughter would likely be moving out of the home with her boyfriend when she had her baby in approximately 3 months.

Joseph's 19-year-old brother was in and out of the house, and his mother was never sure whether she could expect him home on a specific evening. She thought that Joseph's older brother was having difficulties with substance use, and she reported that there were times when she smoked marijuana or drank just to get away from her concerns and feel better for a little while. The therapist asked Joseph's mother about the family's economic situation and learned that the stepfather had a regular job as an auto mechanic but was not paid well and that the mother worked part time in a department store as a cashier.

The family had Children's Health Insurance for the children. This managed Medicaid program would provide financial support for the intensive home-based treatment program. During the first meeting, the therapist worked to understand the family's situation and recognized Joseph's mother's affection for her children and the dismay that she was experiencing because of their difficulties. The therapist spent 90 minutes getting to know Joseph's mother and her youngest son. During this first meeting, Joseph's sister came into the house during their conversation and told her mother that she had seen Joseph hanging out on the street with friends whom he used to get in trouble with before he was in the detention center.

The therapist proceeded with the assessment and commented on the strengths of the family, including their strong connections with each other, and on the hopes of the family for the futures of the younger brother and the sister. The therapist developed a deep respect for Joseph's mother and closed the first session by saying that she would come back the next day and meet with the

mother again. The therapist wrote a message to Joseph, saying that she had been there and that she had heard about him and knew that she would very much enjoy meeting him and invited him to be present next evening for her visit.

Over the next 6 weeks, the therapist visited Joseph and his family in their home three to four times a week. She invited Joseph's mother to call any time if she had concerns, and she helped Joseph's mother to think about her priorities for their treatment process. Joseph's mother said that her goals included helping Joseph stay out of detention and resume school; repairing her relationship with the children's stepfather and encouraging him to take care of his chronic alcohol use; improving the family's financial situation by obtaining a full-time job; and deciding with the stepfather whether to continue to allow Joseph's older brother to come and go in the household.

Mother and stepfather set up rules and consequences for Joseph with three expectations: (1) that he would attend school all day, each school day, (2) that he would attend an afternoon program at the local Boys and Girls Club, where he could receive tutoring to complete his homework, as well as engage in basketball and video games with other young people at the center, and (3) that Joseph would return home after the Boys and Girls Club for dinner and that he would have access to his cell phone and his video game set in the evening if he followed through with the plan.

Joseph initially strongly resisted the rules and expectations, telling his mother that "she had no right telling him what to do," that he was grown, and that "he could make up his own mind and make his own decisions." The therapist helped Joseph's mother reiterate to her son that she would be happy for him to have greater freedom if he demonstrated greater responsibility and was able to comply with the house rules. The therapist also visited Joseph's school and talked to his counselor and teachers and encouraged them to be warm, engaging, and supportive of Joseph to help him know that they wanted him to be in school every day and that they wanted to get to know him and learn

about him. The therapist helped Joseph to write a biography of his grandfather, which Joseph researched by talking with other community leaders and neighbors who had known him. The therapist also encouraged Joseph to resume his interest in basketball and baseball and to learn as much as he could about the history of his family and the history of his family's role in his community.

As adults who expressed interest in him and his ideas surrounded Joseph, he began significantly to improve his mood, decrease his level of anger, and increase his hopes for the future and his interest in school and his after-school program. The intensive treatment program continued to work with Joseph and his family for 3 months and encouraged the adults in Joseph's life to express more responsibility and interest in him and to offer him more opportunities to be a part of his school and a part of his neighborhood. The therapist also encouraged the mother and stepfather to resume attending their church, which the family did, and the therapist talked to the minister about being particularly welcoming for Joseph, his older sister, and his younger brother. The therapist also talked with Joseph's stepfather about his alcohol use. The stepfather was receptive to decreasing his alcohol use and being home more in the evenings and paying more attention to his family and his wife.

Together with consistent, nearly daily contact with the family, involvement with several important adults, and child-serving institutions in Joseph's community, the therapist, by creatively using Joseph's interest in his family and in his grandfather and identifying Joseph's interest in telling the stories of his family, was able to improve Joseph's school attendance, sense of himself, and the family's overall sense of well-being in the 12 weeks of contact. When the program ceased, Joseph had several adults involved in his life, his mother had a full-time job that felt rewarding, her relationship with her daughter who was about to have her first child had significantly improved, and Joseph's younger brother had resumed his academic progress and his athletic activities.

A family therapist at the local mental health center was able to meet Joseph and his family for the last 3 weeks of the intensive program once a week at their clinic. That therapist continued to meet with Joseph and his family over the next several months on a weekly or bimonthly basis.

At the close of treatment, 1 year after Joseph had been discharged from the detention center, he was at home consistently, was attending school, had caught up academically, and had resumed regular activities with peers who were interested in sports and academic success. Joseph's mother and stepfather had decided to remain married and had improved their relationship.

Family Therapy for Depression

The core of treating depression in children is the consistent building of competence and connections for the child. The problem in accomplishing these goals is that the depressed child has problems with concentration, which directly interferes with competence, especially at school, and marked irritability, which greatly interferes with successful relationships with family, peers, and important adults. Furthermore, the depression creates a marked lack of motivation, which leads the child to not believe in or pursue treatment. Substance abuse is often a comorbid problem, which may leave the child feeling better in the short term but with a significant long-term problem in addition to the symptoms of depression. The longer depression persists, the more likely it is that such a child will develop significant and persistent secondary problems, including academic failure, legal difficulties, and further alienation from parents, who may also be experiencing stress.

In the face of these difficulties, family treatment offers several advantages. The parents can be asked to ensure that the child participate in treatment, even if the child would rather not, as long as the child's problems persist. Suicidal ideation, plans, and attempts can occur at this point and require specific focused attention by the therapist and the parents. Parental warmth and encouragement can

be achieved by linking the child's problems to the experience of depression. Depression can be defined as a phenomenon that has taken over their child, and which is painful and hurtful while draining the child's energy and motivation. The therapist can reinforce and support the parents caring for and commitment to their child. As the parents express their care for the child, the therapist can build the child's trust in the parents.

The therapist can then encourage the parents to expect the child to participate in school, both in academics and in activities while enlisting school personnel to engage with the child and provide remedial support if needed. The therapist encourages parents to be available and attentive to the child's accomplishments and supportive of the child's emotional experience. Therapeutic support for building on the child's interests, strengths, and abilities is also important, as are efforts to build relationships with prosocial peers while also limiting substance use. Prescription of selective serotonin reuptake inhibitors (SSRIs) while monitoring suicidality can promote this process for the child and family if needed.

Lydia was a 14-year-old girl who was brought to the emergency room of her local hospital after ingesting an overdose of 15 acetaminophen tablets. Lydia had taken the overdose after an extremely difficult day in which she was teased by friends at school, was criticized by her teacher for not having completed her homework, and then engaged in an argument with her mother about her wish to go out with friends that evening. Lydia challenged her mother and threatened to leave the house. Her mother was worried that Lydia might be meeting a teenage boy and got very angry at Lydia and called her a demeaning name. During the argument Lydia rushed into the bathroom and found the bottle of acetaminophen tablets and took the overdose. She then became quite frightened and told her mother that she had taken the pills. Her mother called an ambulance, and Lydia was brought to the emergency room.

Lydia maintained consciousness and talked openly with the clinician in the emergency room about her increasing distress over the last 12 months. She had become increasingly involved with peers who were in trouble, and her performance in school had declined. She also reported that she had stopped participating in her usual activities at school, including quitting the cheerleading squad. She had been sexually active with a 16-year-old boy on one occasion and reported that the boy had stopped going out with her after they had had sex, and he had talked about the experience in an embarrassing way with other young people at her school. She had previously been a good student and popular in her class but had recently become more irritable, more isolated, and less interested in academics and her friends.

Lydia's mother reported that her daughter had changed from a happy, upbeat teenager to a surly, irritable child who was very difficult to communicate with. Lydia lived with her mother and her three younger brothers, who were 9, 7, and 5 years old, respectively. Their father had left the family to work in another community and was sending money home to the mother. He was

away for several months at a time doing construction work and was only in contact with the family by phone once a week. Lydia had been very close to her father, and his recent occupational absence had been distressing for her. She had felt isolated and disconnected from her family.

Lydia's relationship with her mother had always been ambivalent; she had been very helpful but not very emotionally close to her mother and had become more quick to anger and argumentative with her mother over the last several months.

Lydia was admitted to the adolescent medical unit for monitoring because of the possibility of toxicity from the acetaminophen. While in the hospital, she and her mother were seen by a child psychiatry consultant, who invited Lydia to talk openly with her mother about why she had made the suicide attempt and what had happened that day that had so upset her. The consultant also encouraged Lydia to talk about missing her father and her recent sadness. Her mother, while being somewhat defensive, was supported by the clinician to listen to her daughter's difficulties and concerns.

Lydia was able to be open with her mother about the problems she was having in school, the difficulties that she was having with peers, and the fact that school suddenly had become very difficult for her. The clinician held daily sessions in the medical hospital over the next 3 days with Lydia and her mother to enhance the closeness and supportiveness of their relationship. He encouraged Lydia's mother to listen to her daughter in a nonjudgmental and nonreactive fashion. As the mother felt the support of the clinician and his encouragement to be clear with Lydia about her concern about the impulsive suicide attempt, her mother was also able to be more understanding and available to her daughter during these meetings. The clinician also arranged a phone session with Lydia, her mother, and her father.

After 3 days of medical hospitalization, Lydia was able to apologize to her mother for taking the overdose and to ask her for enhanced involvement and understanding at home. The family was then referred to an outpatient clinician at the local

mental health center, where they were seen 3 days after discharge. Lydia reported improved mood and increased attention from her mother at home and had returned to school. The new therapist asked permission to contact Lydia's teachers to arrange more support at school. She strongly praised the enhanced closeness between Lydia and her mother.

Lydia was not initially placed on psychopharmacology. She had noted improved mood at home and had managed her behavior with less irritability and impulsivity in the initial week following her hospitalization. Future sessions were held weekly and were divided, with half the session for Lydia individually and half of the time with Lydia and her mother. The therapist focused with Lydia on her life at school, her schoolwork, and her peer relationships. The meetings between Lydia and her mother led to enhanced understanding, improved communication, and greater mutual support. Regular phone calls involved Lydia's father.

With the enhanced family support and Lydia's increasing competence as a teenager, her mood improved dramatically, and her relationship with her mother grew closer. The telephone contact between Lydia and her father re-engaged them and restored the warmth they had shared.

After 3 months of outpatient treatment, Lydia was doing well and came for sessions once every 2 weeks. The therapist noted that Lydia's mother was sad and missed her husband and offered the mother the opportunity to come for individual meetings to talk about this and how she could carry on at home while her husband was away.

Traumatic Stress in Children

Trauma-focused cognitive-behavioral therapy for children has been identified as an evidence-based treatment for traumatic stress in children. It is important to recognize that this treatment has an essential family component. Family education, emotional support for the parent who may be distancing themselves due to the child's traumatic experience, and family involvement in supporting the child

while developing and sharing the trauma narrative are essential elements in this treatment. This often requires that parents accept the reality that they could not protect their child from harm or that one or both of them might actually have perpetrated the harm. Helping the parents acknowledge their feelings and the realities of their child's experience of exposure to or injury by trauma can often be quite challenging. The therapist has two goals: to support and care for the parents and to assist the child in understanding and dealing with what has happened to them. This can be horrific and is often frightening or infuriating for the therapist. Therapists in this situation often need an opportunity to discuss cases with colleagues or with a supervisor. Attention to the safety of all participants provides the foundation for engagement, and engagement builds the trust needed to share the painful, shameful, and sad aspects of trauma and its aftermath. These realities are present regardless of the source and nature of the trauma. Focusing on a successful resumption of family life founded on the belief that the trauma has led to closer relationships and greater resilience is often healing in itself. The recognition of family resiliency is then coupled with acceptance of the unpleasant emotions that are normal responses to trauma among them all. A step-by-step therapeutic approach, including the family, is extremely helpful. This approach leads from providing safety to ensuring that basic needs are met. It continues with education for understanding, behavioral competence, emotional support, and narrative creation and validation. The trauma becomes a remembered but not excessively arousing experience. As with family treatment of other child problems, the treatment can lead not only to the resolution of traumatic stress but also to an enhanced awareness of family strength among all members.

Monica was 6 years old and was referred by her pediatrician to a child psychiatrist for evaluation after she had been involved in a serious motor vehicle accident. One month prior to the referral, Monica had been riding in the car with her mother. She had been seated in a booster chair in the back seat. Their car was hit by another car that was driving very fast. Only Monica and her mother had been in the car, and Monica's mother was seriously injured in the accident. When the ambulance came to pick Monica up, they noticed that she was crying for her mother and that she was shaking in the back seat, although she did not seem to have been physically injured in the accident.

Monica's mother had lost consciousness in the front seat and needed to be taken to the emergency room in a helicopter. The police had removed Monica from the back seat, and one of the policemen held her on his lap while she was crying out for her mother. They found the mother's pocketbook and called Monica's father at work. As Monica's mother was being flown to the emergency room in the helicopter, Monica's father came to the scene of the accident and picked up his daughter.

Monica had previously been a healthy girl attending first grade. She had two younger sisters, ages 4 and 2 years, respectively. Her father was a lawyer in a firm in the community, and her mother was a part-time bookkeeper for a local physician. The family had significant resources, and the children attended either private school or private daycare.

Monica was slow to warm up and approached new situations with fearfulness and reticence. Now, 3 months into the school year, she had established friends and had a very positive relationship with her teacher. When her father brought her home and got a neighbor to stay with his three daughters while he went to the hospital, everyone noted that Monica was extremely upset.

During the mother's hospitalization, which lasted for 2 weeks, she required abdominal surgery to remove her spleen and was found to have a fractured tibia and fibula in one leg and required a cast and crutches. Monica had been able to talk with her

mother by phone several times in the hospital beginning on the fourth day after the accident, and near the end of her mother's hospitalization, Monica had been able to visit her in the waiting area of the hospital.

When Monica's mother came home, she learned that Monica had been crying every morning on the way to school and also while at school. Monica also had become increasingly withdrawn at home from her younger sisters and at school from her peers and from school activities. Because of this withdrawal and problems with separation, Monica's pediatrician recommended that she and her family see a child psychiatrist.

The child psychiatrist obtained the history just described and noted that Monica's mother was also having nightmares and flashbacks of the accident and was increasingly hypervigilant. She had become frightened to drive the car. Monica's father was very concerned about his wife and about Monica and attended the initial session with them. He stated that he knew that his wife and his oldest daughter were both quiet and shy and were very much alike and very close to each other.

The child psychiatrist determined that Monica's father was deeply invested in his marriage and in wanting to help Monica and his wife recover from the physical and psychological effects of the automobile accident. During the conversation Monica's mother stated that she felt extremely guilty for having the accident and was frightened both about what had happened to her and also the possibility that the accident could have hurt her daughter. She began crying in the session and it was obvious that her distress deeply affected both Monica and her father.

The child psychiatrist talked with the family about the fact that they had a normal reaction to an extraordinarily frightening and traumatic event. He also explained that the trauma for Monica was somewhat different from the trauma for her mother. Monica's trauma involved not only the accident but also her fear of her mother's well-being and her experience of being separated from her mother at the scene of the accident and during her mother's hospitalization.

The psychiatrist contrasted that with the mother's fears from her injury and treatment, her worries about her daughter, and her guilt from the car accident. The child psychiatrist also spoke about the strengths he recognized in the family: the father's intense connection to the family, his dedication to being helpful to his wife and his daughter, and their impressive closeness and love for each other. As he said this, the family relaxed. The therapist suggested realignment of the family's energy now that the threat to survival was over. He suggested that the family begin to orient themselves to resume their lives as a family while also recognizing their fragile emotional state.

The child psychiatrist recommended a family-based course of therapy over the next 8 to 10 weeks in which the mother, father, and daughter would work on reconnecting with their future lives while integrating their experience of trauma, injury, and anxiety into their past. The psychiatrist proposed homework for the family; he suggested that the father spend time alone with Monica, talking with her about the fact that her mother was better now and that it was her job to resume being a big sister to her little sisters, a student at school, and a regular 6-year-old girl. The therapist also suggested that the mother and father talk together to help the mother to accept the accident and also to appreciate that because of her appropriate attention to her child's safety, her child was in the booster seat in the back seat and was not injured. They could discuss the fact that the mother had taken very good care of Monica and that Monica was having trouble because she continued to be frightened that her mother was not all right.

Over several sessions, Monica's mother was able increasingly to reassure her daughter that she was okay and encouraged her daughter to re-engage with her school and friends and enjoyment of activities and fun as a child. She also gradually reassumed her role as an effective and caring mother for her three daughters. The father stayed actively involved with all of the children and maintained his belief in his wife's ability to recover and resume her role as his wife and their children's mother.

It became apparent to the therapist and Monica's parents that they had too rigidly adopted complementary roles as breadwinner and caretaker and that some readjustment of their partnership would need to be addressed in the therapy and recovery process. Monica's mother was grateful to her husband for being more flexible and responsive to her and their children's needs. He continued to be invested in his career, but with less intensity and less single-mindedness.

After 4 weeks of treatment, Monica was increasingly acting as she had prior to the accident, as a successful student, a confident big sister, and someone who could more easily separate from her mother and the family. She had fewer episodes of tearfulness and was able to sleep through the night.

After 8 weeks, Monica's teacher reported to the parents that she had, in fact, resumed the previous functioning and had caught up academically and appeared to all to have recovered. Her mother was less frightened and was sleeping well, and had resumed work and driving. She and Monica could discuss the accident openly without crying.

Treatment of Anorexia and Substance Abuse

Family therapy–based treatment models have demonstrated effectiveness for both anorexia nervosa and adolescent substance abuse. While anorexia was formerly thought of as a disorder of middle and upper class families, it has more recently been recognized in children and adolescents of all classes and ethnicities. In both of these problems the child is involved in an engaging, self-reinforcing, and dangerous behavior. This behavior often is pursued in an extreme fashion and ultimately leads to failure to achieve other developmental skills. The lack of these skills also often renders the child anxious and further narrows the child's orientation to their life. There may be a genetic predisposition to either anorexia or substance abuse. Despite this, the child will need to learn to manage the impulse to diet or the impulse to use substances in a dangerous manner. In the majority of these situations, the parents will bring the

child for treatment and will be concerned about their inability to lead their child out of their self-destructing behavior patterns. Two evidence-based family treatments have been developed for these problems, and their effectiveness has been documented through randomized, controlled treatment trials. These treatments are multidimensional family therapy for adolescent substance abuse and family-based treatment for anorexia. Both of these treatments assign responsibility to the parents for reducing the intensity of the symptomatic behaviors. In family-based treatment for anorexia, the parents are given the responsibility of helping their child gain weight with the therapist's support. As the parents take on this responsibility, the therapist helps them to be successful in attaining the child's attention and the child's compliance. The child gains greater support and autonomy as they participate in treatment. The therapist also supports the child's interest in and competence with activities and with peers. If treatment is initiated early in the course of the disorder, it can be effective and relapse is rare. Family treatment for substance abuse in adolescents is similar. However, often school failure, legal difficulties, a history of poor supervision, and the influence of negative peers complicate the clinical situation. The treatment manual for multidimensional family therapy identifies ways of addressing these challenges while simultaneously providing the supervision, support, and limits necessary to reduce substance use. Once again, the keys to treatment effectiveness are opportunities to behave in prosocial ways with intense family support for competency and success associated with consistent, unwavering expectations and reasonable but not excessive consequences.

Joan was 14 years old and lived with her parents and 12-year-old sister. She was referred to a child psychiatrist by her pediatrician, who had recently evaluated her for significant weight loss and dramatically reduced food intake.

Joan's parents were middle class, and both worked long hours. They had become concerned about her dieting and weight loss but had been unable to have it cease. When Joan and her mother met with the child psychiatrist, Joan stated very clearly that her weight was a major concern to her, that she still felt that she needed to diet and lose weight and that under no circumstances was she going to eat what the pediatrician and nutritionist had recommended. Joan's father was a busy executive who traveled twice monthly and who had grown increasingly distant from his daughters over the last year. Joan's mother stated her concern that her husband was not as involved with his daughters as he should be and that now his sole interaction with Joan concerned her eating. He yelled at her, trying to get her to eat. Joan's mother had thought that her daughter was experiencing anorexia nervosa, and the therapist concurred. The therapist strongly suggested that Joan's mother and father come to a session later that week to discuss a plan to help Joan with her anorexia. The therapist received a phone call from the father stating that he needed to be out of town on business, but the therapist firmly stated that he should postpone his trip and attend the session with his wife and daughter.

The therapist's first efforts in the meeting were to emphasize to both parents the need for them to work together and to assist Joan with rules that would encourage her to follow through with the food recommendations of her pediatrician and her nutritionist.

As the therapist helped Joan's parents plan how they would expect Joan to eat the required amount and gain weight as suggested by her pediatrician, the therapist also suggested that Joan finish her meals before she left the table and pursued other activities or completed her homework. Joan was upset and frightened at the prospect that she would gain weight. The

therapist helped the parents to be understanding but firm and to reiterate their expectation of consistent weight gain. The parents were also advised to be explicit about caloric expectations and meal planning.

As Joan gained weight, she gained more freedom to choose which foods the family had in the house, but she was still required to eat the required amount of calories. Her rate of weight gain was consistently 1 lb per week, and she went from 80% of her ideal body weight to 95%. As Joan began gaining weight, the therapist noted increasing distress in her parent's relationship. The therapist suggested private couple sessions for the parents to discuss their relationship. Individual sessions were held with Joan to assist her with assertiveness, peer relationships, and ways of decreasing her perfectionism with regard to her schoolwork.

Joan participated in her individual sessions eagerly and was soon noted to be spending more time with friends and less time preoccupied with food, dieting, and weight. When she reached 100% of her ideal body weight, her menses resumed. The therapist was also meeting regularly with Joan's parents. Joan's mother expressed her concern that her husband was more involved in work than with the family and that this was not all right with her. She became assertive with him, and they began to negotiate a different approach to family and work. They also were advised to spend some time alone together. Joan's father responded well to the couple sessions, and her parent's marriage improved and became more satisfying for both of them.

Over the 8 months that therapy continued, Joan resumed normal adolescence, family relationships improved significantly, and Joan's father became more engaged with his daughters.

Stephanie was a 15-year-old girl who was referred to the substance abuse treatment program because her parents were concerned about her alcohol and marijuana use. She lived with her stepmother and biologic father. Prior to this school year, she had been a successful student and had played in her high school band.

Stephanie's biologic mother had significant trouble with alcohol and drugs when Stephanie was a preschooler. After failed attempts at treatment, Stephanie's father separated from her mother and gained full custody of his daughter. Stephanie knew that her mother was in another state and believed that she was still having trouble with alcohol use. She had not had contact with her mother for 12 months prior to her referral.

Stephanie's father had remarried when Stephanie was 6 years old, and Stephanie had two younger half-siblings, a 7-year-old brother and a 4-year-old sister. This year Stephanie had increasingly felt disconnected from her stepmother and her younger half-siblings. Her relationship with her father had begun to deteriorate as she became more defiant of rules and more involved with peers. She was home less frequently and was less involved with family activities. Stephanie's stepmother had been called by her school when she had been found somnolent and disoriented at school.

Stephanie's stepmother and father took her to the emergency room, where she was found to be intoxicated with alcohol. She said she had gotten the alcohol when she and some friends had gone to a friend's house during lunch period. Stephanie's father and stepmother had been concerned that Stephanie might be using substances frequently and in a problematic way. Over the last several months, she had been coming in late after curfew, staying over at friends' houses frequently, and had been less involved with her previous friends and more involved with a group of friends that the family did not know very well. Stephanie had also dropped out of the band and stopped playing her

instrument. Her academic performance had decreased significantly.

Stephanie agreed that she was using drugs and alcohol but steadfastly stated that she did not have trouble with them and that she was only doing what her friends did. When Stephanie, her father, and her stepmother met with the family therapist at the drug treatment center, it became apparent to all that Stephanie's problems were quite significant and were seriously jeopardizing her physical safety as well as her developmental progress.

In the first session Stephanie tearfully admitted to involvement with unprotected sex, especially when she was intoxicated. With guilt and shame she admitted that she did not want to be doing what she was doing but had found it very difficult to refuse substances or affection and physical intimacy when she was with peers.

The family therapist suggested to Stephanie's father that she was scared and lost rather than defiant and delinquent. Stephanie's father, with some difficulty, acknowledged that this might be true. The family met with the therapist three times a week at the program while Stephanie participated in the adolescent after-school drug treatment groups. The therapist helped Stephanie's parents to institute a curfew and ensure adult supervision after dinner and on weekends. Stephanie reluctantly, but in fact with relief, accepted these rules and adhered.

Regular drug testing was part of Stephanie's program, and over the first month of treatment, she was consistently free of evidence of drug and alcohol use. The therapist also strongly recommended that Stephanie attend the adolescent 12-step program meetings with the teens in the treatment group. The therapist also spoke with Stephanie's counselor and teacher at school. They were advised to strongly encourage Stephanie to rejoin the band, resume her musical practice, and participate in tutoring and additional homework to improve her academic standing. Stephanie responded to this with some initial reluctance, but ultimately with the support and encouragement of her teachers, school counselor, therapist, and band leader, she

was able, after a rocky period of a couple of weeks, to be more involved in school and more involved with the friends she had distanced herself from after she had gotten involved with her substance-abusing friends.

During this time, Stephanie was also seen by a child psychiatrist. The child psychiatrist reported that Stephanie was sad, but he did not believe that she warranted antidepressant medication. The child psychiatrist told Stephanie, her father, and her stepmother that he was very pleased with the progress that they were making in the intensive substance abuse treatment program.

Stephanie's mood continued to brighten. She was encouraged to have evening and weekend times with her father and stepmother. Her stepmother was advised to spend time talking with Stephanie about her friends and her activities. She was encouraged to avoid disciplining Stephanie but to inform her father about any concerns. Stephanie responded to this with improved connections with both her father and her stepmother. She also spent more time with her half-siblings.

Three months into treatment, at the time that Stephanie's discharge from the intensive treatment program was planned, her urine tested positive for alcohol. Her parents also discovered that she had come home after curfew, apparently intoxicated after attending a party without parental permission.

The therapist helped the family to recognize that Stephanie had had a difficult weekend and continued to have difficulty resisting the attraction to alcohol and the encouragement of peers to use substances. The therapist worked intensively for the next 2 weeks to reconnect Stephanie with her father and stepmother and to re-establish more-intensive supervision for Stephanie. The therapist encouraged the father and stepmother to maintain hope for Stephanie's success in the future. Stephanie asked her parents to be understanding and forgiving of her episode of alcohol abuse. Her father and stepmother realized that they could not yet expect Stephanie to be able to make

mature decisions when exposed to substances and that they would need to provide intensive supervision.

The therapist also spoke with Stephanie's father and stepmother about the difficulties they were having as a blended family and worked with them to understand the challenges of that experience. They worked on building one family of five rather than two families, one with four members and another with three members. At the same time, the therapist spoke with Stephanie about her experience of abandonment and hurt in her relationship with her mother and about her worries about her mother's well-being. Stephanie talked about her fear that she would grow up to be like her mother. As Stephanie held these conversations with her therapist, she was able to be increasingly mature and thoughtful about herself and her previous experience of neglect and abandonment. She also was encouraged to speak about this with her father in a session.

The involvement of the entire family in treatment, the appreciation of the family's history and experiences, Stephanie's involvement in a teen substance use program, and the active involvement of her school had all been elements in treatment. Individual therapist support to help her to understand and accept her difficult relationship with her mother was also essential. All of this helped the family to bond together more openly and to be increasingly successful in the developmental challenges that they were facing.

Family Treatment for Divorcing and Blended Families

Family transitions occurring as a result of parental separation and divorce and remarriage are disruptive to children. If parents are able to be congenial with each other and to amicably resolve issues related to the divorce (including financial issues, grieving the end of the marriage, and child care and custody issues), the children, though they still grieve the end of their family and accommodate the changes to family life with sadness, will usually do so without significant relationship problems and persistent behavior problems.

However, if significant resentment, anger, and conflicts continue between the former partners, the effect on the children can be significant and persistent. Problems with academic performance and mood and behavior problems can develop. The conflicting parents often do not manage these difficulties successfully, and family treatment can be necessary. The first step in this treatment process is to identify and support the concern that each parent has for the children and for resolving the children's problems. Parents may be motivated by different concerns—for example, one by a child's academic difficulties and the other by the child's sadness. In any event, bringing together antagonistic parents is an important element in treatment. The family therapist should work extremely hard to help the parents to understand that their children need both of them and need them to work together in parenting for the children's well-being. This process may be difficult and time-consuming, but it provides the best foundation for the children's successful outcome. As the therapist helps the biologic parents work together, they can also help the children express their concerns with each parent individually in separate therapy sessions.

Several aspects of post-divorce life can be problematic for children. Often a parent can be very involved in their life, including work and relationship building. This can lead the children to be unsupervised and to further engage in problematic behaviors. To address this, both parents (if possible) will need to supervise the children and reiterate their belief in the children's strengths and capacity to be successful.

When stepparents are involved in problematic post-divorce situations, matters can worsen. Stepparents may decide that enhanced discipline is needed and may attempt to act to deliver that. As the stepparent works to impose discipline, a child often becomes indignant and defiant. The more forceful and demanding the stepparent becomes, the more defiant the child becomes. Family therapy can reorganize this situation and lead both biologic parents to take a central role in the child's life and success and address challenging behaviors. Family therapy can also help stepparents to take a peripheral but very important role as supporter and ally for

both the child and biologic parent. The stepparent can express concerns and worries about the child, but rather than to the child directly, these concerns can be expressed to the biologic parent, who can act on them in concert (if possible) with the biologic parental partner. The therapist can also encourage the stepparent to develop a warm, accepting, and caring relationship with the child based on mutual interest. This decreases the child's antagonism toward the stepparent and may significantly improve the mood of the family while also enhancing trust and attachment between the child and the biologic parent.

As time passes, the child can adapt to the changing family and maintain a supportive and engaged relationship with both biologic parents and accept stepparents and step-siblings. The therapist can also help the new partners build their relationship while they manage successful relationships with all children and with former spouses.

Kevin was an 11-year-old boy who lived with his mother, maternal grandmother, 17-year-old sister, and 14-year-old high-functioning autistic brother. Kevin was referred to see a child psychiatrist because his mother was concerned about his excessive worries. The whole family had been living with their maternal grandmother since Kevin's parents separated and divorced when he was a year old. Post-divorce, the parents had a long history of custody battles. At the time of the initial visit, the parents had shared legal custody, but the mother had physical custody. Their divorce agreement specified that if there is a disagreement regarding medical and academic needs and decisions, the mother's decision supersedes the father's preference. The father's consent to provide psychiatric treatment was received, though he did not see a reason for an evaluation. Kevin and his brother would stay with their father every other weekend and have dinner with him at least once a week.

Kevin's mother wanted him to be engaged in treatment because she believed that he suffered during the custody battles. He always had difficulty academically, but his performance deteriorated when his sister refused visitation with their father 3 years ago. When he was anxious, he would be short of breath and would pace around the house and scream. This would occur specifically when he was struggling with his homework and when he was supposed to visit his father. This behavior would take place every 3 to 4 days. Nightmares would wake him up shaking in the middle of the night.

His father was invited to participate in the evaluation and treatment. Initially, his involvement was limited, but when he realized that some of Kevin's difficulties were related to his upcoming wedding, he became more engaged.

Kevin and his father were encouraged to engage in conversations to communicate his difficulties with "his growing family." Kevin was able to feel safe in therapy to inform his father of his grievances, including his concerns about his stepmother taking over his mother's role. He worried about his mother being

alone while also grieving the permanency of their divorce. With the support and involvement of his father's fiancé, his mother and his father were able to hear his concerns, to encourage him to speak-up, and to compromise when necessary. They were able to validate the loss of his original family but also to reinforce that they all had a special relationship with him individually. He was reassured that these relationships were going to remain unchanged and that one relationship could not take the place of the other. The family members were able to discuss their expectations of him in both households. They agreed to keep the rules and these expectations consistent so that it would be less confusing for Kevin. As all relationships improved, Kevin's anxiety and difficulty in school were resolved.

Family Therapy for Families from Diverse Backgrounds

Family therapists, and all providers, should be sensitive to the family's cultural norms in order to provide the best care. When discussing diversity, one often thinks of ethnicity and race exclusively. Concerns about diversity must also include differences in socioeconomic status, sexual orientation, and nontraditional family units (i.e., same-sex parents). Each family has its own culture and values that define its norms and guiding principles. Culture is the foundation that dictates one's sense of how to be, what is "normal," right and wrong, and reactions to others. The degree of assimilation to the culture of the local area (community, region, or nation) plays an important role in the family's goals for the treatment. A family's culture also influences the degree of mental health stigma and directly impacts the level of trust in mental health care. Family therapy may be tailored to increase engagement with the family to overcome distrust, mental health stigma, and past experiences of being misunderstood, misperceived, or discriminated against. Being curious about the family's history of hardships, trauma, losses, and experiences of discrimination and exclusion early in treatment helps the therapist understand the family.

As the therapist engages with a family of a different culture, they will need to be aware of how the family meets three challenges that families from diverse background experience. The first challenge is to assimilate into the culture of the host country without losing their traditional values. The second challenge is to balance passing on their cultural traditions to the next generation with supporting the youth's success in the western culture. The third challenge is to manage how different family members adapt to the mainstream culture at a different pace which can result in acculturative family distancing (AFD). AFD can increase family conflicts while decreasing family cohesion through miscommunications and misunderstandings among family members.

Family therapy addresses where each family member is in their acculturation process. The therapist will also need to appreciate each member's expectations from treatment, the caretakers' parenting approach, the strengths of parent–child relationships, and parent–child conflict. The therapist can navigate AFD by highlighting the love and affection between parent and child and by creating an atmosphere of mutual acceptance and compromise, a both/and approach that is based on connection and shared commitment to family life and the development of the child's independence. By elaborating on the narratives of the parents and the child, the therapist increases mutual understanding, further fostering trust and collaboration. The therapist's task is to honor and respect how the family understands their differences. By recognizing and elaborating on the different ways family members express their love, the therapist can open the door for acceptance and growth.

Success with diverse families is defined by the family's ability to promote the value of success in America as well as their traditional cultural values, traditions, and rituals while also dealing with the presenting concerns.

Ana is a 17-year-old Mexican-American girl who was sent to the ER from her school. At school, her English teacher had raised concerns because of an essay that she submitted for an assignment. The assignment was to share reflections on a difficult moment. Ana shared her challenges at home and her struggle with living in two worlds that sometimes have opposing expectations. She also shared that she felt trapped and wished there was a way to escape her situation. Subsequently, the teacher reached out to the guidance counselor, who spoke to Ana in depth. When probed, Ana admitted to having thoughts about walking onto a high-traffic highway. She was unclear whether she wanted to die, but she was clear that she found her situation to be unbearable. The guidance counselor also felt that Ana had a flat affect, a depressed mood, and was socially isolated. The teacher had also endorsed her declining grades and decline in the quality of her class and homework. Following the school protocol, the guidance counselor called the parents, shared her concerns, and informed them that Ana could not return to school unless a psychiatrist had deemed her safe to return.

This information was surprising to the parents. As suggested by the pediatrician and the guidance counselor, they took their daughter to the nearest hospital. After prolonged waiting in the emergency room, they spoke to the psychiatrist. Ana shared her story with significant shame and guilt. She felt that she was burdening her parents, who worked hard to take care of her and her siblings. She also knew that her father had to request time off from work to be with her. Though the psychiatrist was thoughtful, the parents felt attacked, as if they were too demanding and uncaring about their daughter. They also felt a bit ashamed that they were not aware of the degree of stress on their daughter. Once the psychiatrist understood the family's concerns, she referred the family for an outpatient family therapy visit with a child psychiatrist at the same institution. She also informed the

outpatient psychiatrist of the parent's experience in the emergency room and at the school.

At the first visit, it became clear that though the mother spoke English, a Spanish interpreter would be preferred so she could share her thoughts more freely. It was also apparent that the parents felt forced to engage in this service and were not happy about sharing their family stories with a stranger. Ana was palpably aware of these concerns and appeared shut down. The child psychiatrist understood these challenges and tried to gain trust by asking about their goal for the meeting. Mother and father shared that they want Ana to be safe, be less stressed but also acknowledge that the family is the most important. For them, family included her siblings but also grandparents, aunts, uncles, cousins, and sometimes even family friends. Ana's goal was to feel normal among her friends at school and be accepted by her parents. She felt that too often, her actions were divided between "an American" or "a Mexican" way of living.

Through the second, third, and fourth visits, the psychiatrist was humbly curious about the parent's experience in Mexico, their journey to America, and their hopes for their children. Ana's father came to America in his 20s in search of opportunities. He struggled with poverty and the loss of family support upon coming to America. He worked hard at a retail store, a restaurant, and as a truck driver to support his family and to make his parents proud of him. Throughout his time in America, he had been discriminated against and had to deal with prejudice. But, with hard work and dedication, he was able to bring his other siblings to America. Together, they were able to open a small business and navigate the ups and downs of the economic challenges. He married his wife when he was visiting his family in Mexico. Her transition to America was very isolating since he worked long hours, she did not have a Visa to work, and she did not speak English. Though they had been in America for over 20 years, they had adhered to their cultural values to retain their "way of life." They spent a significant amount of time with

their own family members (including Ana's uncles) as a way to be protective of their culture.

The family therapist learned that Ana's parents valued family time, gender roles, and importance of cultural involvement as they had learned prior to immigration. Ana's parent's expectation of "family first"—taking care of brothers', helping with chores, and being involved with the Mexican American community—conflicted with her own desires to be more like her peers. She enjoyed American pop music and wished that her family would be accepting of her new white American boyfriend. They worried that Ana would drift away from them as she was more comfortable American culture. Furthermore, Ana would often be playing the role of translator for her mother and explaining the American cultural norms to her. This situated her in a unique position of supporting her parents to navigate American culture but, also increased the burden on her as well. She felt that they didn't understand her hopes to feel "normal" and not be isolated from and different among her peers. She also felt that the more she tried to fit- in among her peers the more isolated, disconnected, and she was in her family.

Over time, the psychiatrist was able to appreciate the parents' worries about losing their traditions and language (as Ana preferred to speak in English rather than Spanish.) He also recognized that the parents were completely dedicated to the well-being of their daughter and her future success. With the psychiatrist's support, parents were able to appreciate Ana's burden of straddling two cultures. They began to be more lenient with their expectations and allowed Anna to spend more time with her friends and boyfriend. Though they had still not met the boyfriend, they were more curious about him. They were accepting that Ana would only flourish if they embraced both cultures. The psychiatrist spent a significant amount of time processing their grief over losing some traditions while supporting their unique ways of retaining Mexican cultural values.

Ana was also encouraged to appreciate her parents' challenging journey to America in search of more opportunities

and privileges for her and her siblings. She was able to respect their dilemma in holding on to their Mexican roots while trying to raise children with Mexican values and American values. Ana was proud of her parents for creating their own path to success and opportunities with limited support. She was inspired by their resilience, their dedication, and their love. This also resulted in her feeling less isolated now that her parents were accompanying her in navigating both American and Mexican cultures.

The child psychiatrist continued to support open communication between Ana and her parents. Ana reported improved mood at home and was less irritable with her parents. She also improved her grades and her participation in school. Therapy sessions were now taking place less frequently but continued meetings between Ana and her parents led to enhanced understanding, improved communication, and greater support for all to manage a bicultural lifestyle.

Family Therapy for Families with Children with Developmental or Medical Challenges

Families with children with developmental delay, autistic spectrum disorders, or chronic medical illness face unique challenges. Family therapy can help those families who are having difficulty managing emotions, behavior, and illness treatment or achieving the optimal development of the affected child or siblings. These situations often are extraordinarily sad and difficult to deal with. There can be financial challenges, career advancement can be negatively affected, illness or handicap care routines can be onerous, and opportunities for parental intimacy and family enjoyment can be threatened. Parental burden and stress can be extreme, and at times the expected positive effects of medical treatment may not occur. Marital relationships may be threatened, and siblings may not receive adequate attention and supervision. Parental isolation may also seriously jeopardize family well-being. Family therapy can address these difficulties by offering the parents, the affected child,

and siblings a safe environment in which to discuss reactions to the child's problems and to collaborate on making the situation the best that it can be. Parental cooperation and parental mutual understanding are goals. All those involved can be guided by the therapist to learn about the child's condition, current and potential treatments, and prognosis. The parents, the child, and siblings can be encouraged to ask questions and to be assertive with the medical care team. The family and child can be encouraged to recognize the areas of the child's life that are not affected by the illness or handicap and the child's strengths and abilities. The therapist can also recognize the courage and care of all in dealing with the challenges of the child's condition. As the family recognizes their commitment to the affected child, they can come to see themselves as heroic and resilient, and the child can note their courage and competency regardless of the illness or handicap. The therapist can help the family work with the school and teachers and with extended family members to understand and support the affected child while also helping the child engage teachers, neighbors, peers, and extended family in an assertive, positive, and confident manner. Finally, the child's active participation in their care can be noted and recognized as a sign of competence and mastery that will help the child throughout life. The family therapist can also support the family if the child's condition fails to improve or deteriorates. The therapist elicits and ratifies legitimate responses of sadness and powerlessness and accepts their powerlessness over the illness while staying involved with and attuned to family members' sadness and grief.

Dave is a 9-year-old boy who lives with his parents and 1-year-old brother. He had been undergoing treated for high-functioning autism spectrum disorder, attention-deficit/hyperactivity disorder, and anxiety disorder for 2 years. His treatment included a low-dose atypical antipsychotic, a low-dose selective serotonin reuptake inhibitor, a stimulant, and an alpha agonist. Additionally, he was receiving individual therapy every 2 weeks to increase his coping skills. The family had been referred for family therapy but, due to both parent's full-time jobs and other commitments, they had not engaged in that treatment. The family self-referred to a different child psychiatrist because they felt that Dave's treatment had become stalled.

The family's chief complaint was Dave's explosive behavior around limit setting at home and social difficulties with his peers. His father struggled to follow through with consequences, whereas his mother was always able to do it. This inconsistency had resulted in confusion for Dave and also increased conflict between the parents. Dave's mother felt that she was not being supported by her husband. Dave's father felt that his wife was very strict with Dave and would attempt to compensate for this strictness. He felt that Dave's developmental delay made school so difficult for him that he deserved to have a less demanding environment at home. As the parents talked with the therapist they realized the need to negotiate expectations and consequences for Dave. They also recognized the need to support each other more and redevelop the warmth in their relationship. Although Dave remained difficult and challenging, he gradually improved and became much less explosive.

FUTURE DIRECTIONS

Family therapy has evolved from a therapy developed in opposition to common psychiatric care to a basic orientation to the treatment of child mental health challenges. All situations require the assessment

of the involvement and education of family members. Some situations require the specific and monitored engagement of family members in the treatment plan. In many instances, treatment of the child requires the involvement of the family in the manner outlined in the manual of an evidence-based model of family intervention. Knowledge of these treatments and skills implementing them are necessary elements in child mental health care. For many child mental health problems, the problem leads to intuitive family interactions that are counterproductive and often worsen the situation. Family therapy stops these negative cycles and can introduce successful, self-reinforcing, positive family interactions that promote family life and optimal child development. These interventions can help the child's situation to improve, and the family's experience of warmth, care, and effectiveness can emerge and persist.

53.5 Pediatric Psychopharmacology

JEFFREY R. STRAWN, M.D., AND LAURA B. RAMSEY, PH.D.

Psychotropic medications play a critical role in treating many psychiatric disorders in children and adolescents. However, using these medications effectively and appropriately requires an understanding of pediatric pharmacokinetics and pharmacodynamics, in addition to the nuances of response that are revealed by numerous double-blind, placebo-controlled trials. In this chapter, we review the developmental pharmacology that is relevant to psychotropic medication use in pediatric populations and the evidence for multiple psychotropics across internalizing and externalizing disorders.

DEVELOPMENTAL PHARMACOLOGY

Pharmacokinetics and pharmacodynamics in children and adolescents differ considerably from adults, and these differences give rise to differences in dosing, differences, response, and differences in tolerability. Importantly, pharmacokinetic and pharmacodynamic factors interact (Fig. 53.5–1) and are mutually influenced by development. These pharmacokinetic factors and pharmacodynamic factors subtend differences in side effects (e.g., extrapyramidal symptoms), dosing (e.g., lithium), and efficacy (e.g., benzodiazepines) between children, adolescents, and adults.

Pediatric Pharmacokinetics

In general, metabolic capacity at birth is less than in adults and increases to levels seen in adults by approximately 2 years of age. However, near pubarche, metabolism may be greater than what is commonly observed in adults. In addition to developmental differences in hepatic metabolism, renal function, and changes in fat distribution during childhood and adolescence affect the pharmacokinetics of many medications in youths.

Also, children and adolescents have greater total body water and relatively less adipose tissue compared to adults. This affects the distribution of many medications and the accumulation of lipophilic medications (and their metabolites).

FIGURE 53.5–1. Schematic representation of the components that comprise the pharmacokinetic-pharmacodynamic interface. (Reprinted with permission from Capparelli EV. Clinical pharmacokinetics in infants and children. In: Aranda JV, van den Anker JN. *Yaffe and Aranda's Neonatal and Pediatric Pharmacology: Therapeutic Principles in Practice*. 5th ed. Wolters Kluwer; 2020.)

FIGURE 53.5–2. Factors affecting the rate and extent of drug distribution. (Reprinted with permission from Stancil SL, Chapron A, Abdel-Rahman AM. Drug absorption, distribution, metabolism, excretion, and transporters in newborns and children. In: Aranda JV, van den Anker JN. *Yaffe and Aranda's Neonatal and Pediatric Pharmacology: Therapeutic Principles in Practice*. 5th ed. Wolters Kluwer; 2020.)

Absorption and Bioavailability. Absorption is influenced by the route of administration of a drug and, for orally administered medications, is influenced by gastric pH and the presence of food in the stomach. Bioavailability is the fraction of the drug that reaches the systemic circulation and is also influenced by concurrently administered medications and first-pass metabolism.

Drug Distribution. Drugs are distributed throughout the body through the bloodstream, and distribution of psychotropic drugs to the site of action is affected by protein binding and transport across the blood-brain barrier. The volume of distribution (V_D) reflects the degree to which it is distributed in body tissue (rather than the plasma). Larger V_D indicates a greater amount of tissue distribution. Smaller VD suggests that the drug stays primarily in the plasma. Drugs with high lipid solubility (e.g., some benzodiazepines), low rates of ionization, or low plasma protein binding have higher volumes of distribution compared to drugs which are more polar, more ionized or those that have more plasma protein binding and differs across development (Fig. 53.5–2). Additionally, age-dependent changes in body composition can also influence distribution.

Metabolism. Many psychotropic medications are metabolized by cytochrome P450 enzymes CYP3A4, CYP2C19, or CYP2D6 in the liver. The activity of CYP2D6 is fairly constant from 1 year of age through

adulthood, but the activity of CYP2C19 and CYP3A4 may be increased in children compared to adults. Drug–drug interactions can occur through inhibition or induction of these enzymes. In addition, in younger children, hepatic clearance of drugs may be increased as liver blood flow is increased compared with adults. This is largely related to the larger ratio of liver to total body mass in the children compared to adults and adolescents (Fig. 53.5–3) and, as a result, the first-pass effect of some drugs may be increased.

Excretion. Most drugs and their metabolites are excreted through the kidney or liver. Renal clearance is substantially higher in pediatric populations compared to adults and decreases from ages 2 to 20 years.

Pharmacogenetics in Children and Adolescents

Variants in the genes encoding the metabolizing enzymes (e.g., CYP2C19 and CYP2D6) influence the enzyme activity, so that patients can be poor metabolizers (with little to no activity), intermediate metabolizers, normal metabolizers, rapid metabolizers, or ultrarapid metabolizers (with more than normal activity). Dosing recommendations based on these metabolizer groups are available from the Clinical Pharmacogenetics Implementation Consortium, the Dutch Pharmacogenetics Working Group, and some are included on the FDA labels. The CYP2C19 and CYP2D6 enzyme activity affects the systemic concentration, which can be normalized with dose adjustments, using lower doses in poor metabolizers and higher doses in ultrarapid metabolizers. Individual genes should be used to adjust medication dosing rather than using combinatorial pharmacogenetic testing for medication selection.

ROLE OF PHARMACOTHERAPY IN CHILDREN AND ADOLESCENTS

While psychotropic medications often play an integral part in the treatment of children and adolescents with psychiatric disorders, they are usually used in combination with other modalities. Education about diagnosis, course of illness, prognosis, and available treatment options is important. Additionally, depending on the individual, a treatment plan may warrant individual, group, and/or family therapy; educational interventions; parent

training; substance use disorder treatment; or any of several additional interventions.

FIGURE 53.5–3. Change in relative liver and kidney mass expressed as a percentage of body weight (WT) from infancy to young adulthood. (Reprinted with permission from Kauffman RE. Drug action and therapy in the infant and child. In: *Yaffe SJ, Aranda JV. Neonatal and Pediatric Pharmacology: Therapeutic Principles in Practice*. 4th ed. Wolters Kluwer; 2011.)

With all disorders and symptoms encountered in children and adolescents, thorough and developmentally sensitive assessment is critical prior to and throughout psychopharmacologic treatment. Such treatment plans are developed from comprehensive and accurate diagnostic evaluations, consideration of comorbidity, subsyndromal symptoms, family factors, personality/temperament, and learning issues (including learning disorders and learning weaknesses). Failure to address comorbidities or other factors may limit the benefits of pharmacotherapy or any therapeutic intervention.

Additionally, rating scales can be used to inform screening and diagnosis of some psychiatric disorders, although these are not a substitute for full clinical assessment by trained clinicians. Standardized

measures generally provide normative data that allows a clinician to compare a particular patient's symptoms to those of children of similar age. In each section, common symptom rating scales will be discussed in addition to the evidence supporting their use.

ANXIETY DISORDERS

Selective Serotonin Reuptake Inhibitors in Anxiety Disorders

Multiple meta-analyses suggest that selective serotonin reuptake inhibitors (SSRIs) are superior to other medication classes in pediatric anxiety disorders, but patients are more like to discontinue SSRIs because of adverse events compared to SNRIs and SSRIs are more likely to produce activation in children and adolescents with anxiety disorders compared to SNRIs. To date, sertraline, fluoxetine, escitalopram, fluvoxamine, and paroxetine have been evaluated in pediatric anxiety disorders. These individual clinical trials are reviewed in detail elsewhere.

In pediatric patients with anxiety disorders, the probability of SSRI-related improvement increases over time although response is, overall, logarithmic—70% of the improvement, observed at week 8, occurred in the first 4 weeks of treatment. This trajectory may not be unique SSRIs in pediatric anxiety disorders as SSRIs appear to produce similar, early improvement in youth with major depressive disorder (MDD) and OCD. Additionally, compared to SNRIs, SSRIs produce faster and greater improvement. Only 40% of the treatment response observed for SSRIs occurs in patients receiving SNRIs by the eighth week of treatment and the divergence in SSRI–SNRI trajectory emerges near the fourth week of treatment.

SNRIs in Pediatric Anxiety Disorders

Several studies have examined venlafaxine in youth with generalized (κ = 2, pooled analysis) and social anxiety disorders (κ = 1) as well as duloxetine in generalized anxiety disorder (κ = 1) and atomoxetine in pediatric patients with ADHD and comorbid generalized, separation and/or social anxiety disorders. These studies have generally suggested benefit compared to placebo. However, meta-analyses of SSRIs and SNRIs in youth with anxiety disorders suggest that SSRIs produce faster, and greater improvements compared to SNRIs.

Other Agents in Pediatric Anxiety Disorders

While SSRIs are the most commonly prescribed initial medications for children and adolescents with anxiety disorders in the United States and approximately half of these youth continue treatment for at least 6 months. However, nearly one-third of anxious who are treated with medication in the United States begin treatment with a non-SSRI medication.

Benzodiazepines in Pediatric Anxiety Disorders. Despite evidence for the use of benzodiazepines in the acute treatment of anxiety in youth, studies of chronic use of benzodiazepines in youths with generalized, separation, and social anxiety disorders have failed to show benefit.

α_2-Agonists in Pediatric Anxiety Disorders. The α_{2A}-agonist, guanfacine has been evaluated in youth with generalized, separation, and/or social anxiety disorder. Extended-release guanfacine was well tolerated although somnolence and fatigue were more frequent in GXR-treated patients compared to those receiving placebo. Differences in response were observed between placebo and extended-release guanfacine, although statistically significant differences were not observed for the dimensional measure of anxiety.

5-HT_{1A} Modulators in Pediatric Anxiety Disorders. Buspirone was evaluated in one flexibly dosed (n = 227) and one fixed-dose (n = 341) trial in children and adolescents with generalized anxiety disorder. Buspirone was not statistically superior to placebo in any of these trials. Discontinuation related to an adverse event occurred more commonly in patients treated with buspirone relative to those treated with placebo.

Tricyclics in Pediatric Anxiety Disorders. Two randomized, placebo-controlled trials evaluated imipramine in pediatric anxiety disorders. In the first study, imipramine was superior to placebo in the study's primary outcome measure (response rate: 81% vs. 47%, $p < .05$). With the exception of dry mouth, no side effects were significantly more common compared to the rates observed in patients receiving placebo. However, a second study of imipramine in children with SAD failed to replicate the earlier study's findings. Imipramine was associated with behavioral activation (e.g., "angry outbursts," irritability, etc.) and dry mouth was commonly observed.

Tricyclics (i.e., tricyclic antidepressants, TCAs), have fallen out of favor since the introduction of SSRIs and SNRIs due to comparatively poorer tolerability, including anticholinergic side effects, the need for electrocardiographic monitoring as well as their narrow therapeutic index that results in an increased risk of lethality in TCA overdoses.

SSRIs + Psychotherapy in Pediatric Anxiety Disorders. Few studies have examined CBT in comparison to an SSRI or in combination with an SSRI in pediatric anxiety disorders. CAMS (*n* = 488) found CBT + sertraline to be more effective than CBT or sertraline monotherapy. Remission rates for CBT + sertraline were superior to CBT (66% vs. 35%) after 12 weeks of treatment. Yet, youth in CBT continued to improve relative to COMB such that by 24 weeks, the gap in remission rates narrowed (65% vs. 45%) with no significant difference by week 36 (67% vs. 58%). Interpretation of the effects of CBT in CAMS has always been complicated by design decisions that may have diminished the effects of CBT: (1) CBT was shortened to conform to the ethically acceptable duration of pill placebo exposure; (2) sessions focused on exposure tasks; the key ingredient in CBT were reduced. (3) At the end of CAMS' 12-week acute phase, regardless of remission status, CBT participants entered maintenance phase with a reduced visit schedule, and no initiation of any new CBT treatment potentially limiting restricting potential gains from weeks 12 to 24 and beyond. (4) CAMS CBT had no parent involvement until well into treatment, and even then, it was limited, an approach that is at odds with current practice. In youth with social anxiety disorder, Social Effectiveness Therapy for Children (SET-C) + fluoxetine and SET-C both improved anxiety symptoms relative to placebo.

Select Key Studies

The largest study of an SSRI in pediatric patients with anxiety, the Child/Adolescent Anxiety Multimodal Study (CAMS), compared sertraline (*n* = 133), cognitive-behavioral therapy (CBT) (*n* = 139), combination therapy (CBT + sertraline) (*n* = 140), and placebo (*n* = 76). CAMS included youth with separation, generalized, and/or social anxiety disorders. In CAMS, sertraline was initiated at 25 mg/day and titrated to 200 mg/day with a mean dose of 134 ± 60 mg per day in the combination-therapy group and 146 ± 61 mg per day in the sertraline group. More than half of sertraline patients (55%) exhibited improvement based on Clinical

Global Impression-Improvement (CGI-I) scores while 81% of youth treated with cognitive-based therapy (CBT) + sertraline met response criteria for ($p < .001$) (compared to 60% in patients receiving CBT ($p < .001$). All active treatments were statistically superior to placebo. While this is the largest randomized controlled trial of any psychopharmacologic or psychotherapeutic combination (or their combination) in pediatric patients with anxiety disorders, there was no CBT+ placebo treatment. Some have suggested that the "absence of such a group prevented the investigators from determining whether the addition of sertraline to cognitive behavioral therapy resulted in more improvement than each treatment given separately because of an additive effect of two active treatments or because of the placebo effect of adding a pill to cognitive behavioral therapy." In this regard, those receiving CBT in conjunction with a tablet knew they were receiving active medication, thus accentuating the expectation of treatment success in patients receiving sertraline + CBT.

PHARMACOTHERAPY FOR MAJOR DEPRESSIVE DISORDER

Multiple RCTs support the efficacy of fluoxetine and escitalopram in youths with MDD—and both are FDA approved for MDD in pediatric patients. There is also support for the use of medication in conjunction with CBT for initial outcome and to reduce the risk of relapse. In an RCT of 46 adolescents who responded to 12 weeks of fluoxetine treatment, relapse-prevention–focused CBT was associated with lower relapse rates compared to medication alone. In fact, the booster effect of CBT substantially reduced the risk of relapse eightfold. Beyond fluoxetine and escitalopram, several other SSRIs have demonstrated efficacy in youth with MDD. However, interpretation of the clinical trial literature for SSRIs and SNRIs in youth with MDD is complicated by several factors. In recent meta-analyses of these medications in youth with MDD, funding source differentiated medication-placebo differences with smaller medication-placebo differences being observed in industry-funded versus federally funded trials. Thus, the impact of study sponsorship on trial outcome supports the assertion that industry-funded trials with high placebo response rates and small drug-placebo differences are "failed trials" and should not be described as "negative trials" or used to determine public

health estimates of antidepressant efficacy in children and adolescents with depression.

Despite the efficacy of the SSRIs, no controlled pediatric trial data suggest benefit in pediatric patients with MDD. Monoamine oxidase inhibitors have very limited data in pediatric use, although one large, double-blind, placebo-controlled trial of transdermal selegeline recently failed to show benefit in youth with MDD, although it was compromised by a very high placebo response rate.

Treatment resistant MDD, in adolescents is prevalent and associated with a substantial psychosocial burden and mortality. In approaching medication-resistant MDD in adolescents, it may be useful to quantify the degree of treatment resistance which may help to identify treatment-responsive phenotypes, and this can be done using the Antidepressant Treatment Record (ATR), which has been evaluated in adolescents. Aside from the Treatment of SSRI-resistant depression in Adolescents (TORDIA) study described below and two recent trials, few have systematically evaluated treatments for this population. In a large study of 10-Hz transcranial magnetic stimulation (TMS) for adolescents with TRD (n = 103), daily treatments over 6 weeks failed to demonstrate superiority to a sham intervention in change in the Hamilton Depression Rating Scale score. Dwyer and colleagues examined a single intravenous infusion of either ketamine (0.5 mg/kg over 40 minutes) or midazolam (0.045 mg/kg over 40 minutes), and the alternative compound 2 weeks later in 17 adolescents and found ketamine to be well tolerated and associated with short-term (2-week) efficacy in reducing depressive symptoms compared with midazolam.

Suicidality

In 2004, an FDA advisory Committee reviewed results of a meta-analysis of 24 controlled clinical trials of 9 antidepressants, which included approximately 4,400 pediatric patients. While there were no completed suicides, the cumulative risk for suicidality (suicidal thinking or behavior) when adverse events were simply collected by spontaneous report was approximately 4% on active medication versus approximately 2% on placebo. This resulted in the FDA issuing a boxed warning that any antidepressant use in children and adolescents and young adults was accompanied by an increased risk for suicidal thinking and behavior.

Subsequent meta-analyses have failed to replicate the original analyses from 2004, even as newer data were incorporated. However, there may be specific increased risks for some SSRIs. Among SSRIs, a meta-analysis found differences in suicidality, with sertraline potentially having lower rates of treatment-emergent suicidality while paroxetine had higher rates of suicidality compared to placebo. That medications within the SSRI class are differentially associated with both higher and lower rates of suicidality compared to placebo with class-wise comparisons (e.g., SSRI vs. placebo) finding no significant differences call into question the boxed warning applied to all antidepressants regardless of indication and specific medication (US Food and Drug Administration. Relationship between psychotropic drugs and pediatric suicidality: review and evaluation of clinical data. Available at: http://www.fda.gov/ohrms/dockets/ac/04/briefing/2004-4065b1-10-TAB08-Hammads-Review.pdf). However, unlike recent network meta-analyses of SSRIs and SNRIs in youth, the analyses that gave rise to the boxed warning on SSRIs and SNRIs as well as earlier analyses of suicidality utilized older meta-analytic techniques could not compare individual medications.

Select Key Studies

Treatment for Adolescents with Depression Study (TADS). In TADS, adolescents with MDD (*n* = 439) were randomized to (1) fluoxetine monotherapy (10 to 40 mg/day), (2) CBT monotherapy, (3) CBT + fluoxetine (10 to 40 mg/day), or (4) placebo. Following 12 weeks of treatment, patients who received fluoxetine + CBT were significantly more improved compared to patients who had received either CBT or fluoxetine monotherapy (Fig. 53.5–4**)**. Additionally, fluoxetine was superior to CBT and all active treatments were superior to placebo.

FIGURE 53.5–4. Time course of SSRI response in NIH-sponsored trials of anxiety disorders (Child/Adolescent Anxiety Multimodal Study [CAMS]), depression (Treatment of Adolescent Depression Study [TADS]), and treatment-resistant depression (Treatment of SSRI-Resistant Depression in Adolescents [TORDIA] Study) in children and adolescents. (See eBook for color images.)

Treatment of SSRI-Resistant Depression in Adolescents (TORDIA) Study. In TORDIA, adolescents with MDD aged 12 to 18 (*n* = 334) who did not respond to an adequate dose of an SSRI, for at least 8 weeks, were randomized to one of four treatments over 12 weeks (March et al., 2004). Importantly, these patients had, on average, a more chronic course than those enrolled in TADS. In TORDIA, patients could switch to (1) a different SSRI (paroxetine, citalopram, or fluoxetine); (2) a different SSRI + CBT; (3) venlafaxine ER; or (4) venlafaxine ER + CBT. CBT + medication switch (either to another SSRI or venlafaxine ER) was associated with a marked decrease in depressive symptoms compared to simply changing medication. The two arms with CBT plus medication demonstrated a higher response rate (55%) than a medication switch alone (41%). In the original analysis, no differences in final outcome were detected between switching to venlafaxine ER relative to another SSRI, but patients who were switched to a second SSRI had less suicidal

ideation than those treated with venlafaxine and fewer adverse events. Additionally, when tolerability and efficacy of the SSRIs were considered together, adolescents treated with citalopram and fluoxetine fared better than those treated with paroxetine.

Recent reanalysis of the TORDIA data, using contemporary statistical approaches, found that in patients not receiving CBT, SSRIs produced greater and faster improvement in depressive symptoms compared to venlafaxine ER. However, for CBT-treated patients, SSRIs and venlafaxine produced similar improvements in anxiety and depression.

Clinical Implications and the Role of Pharmacotherapy. For children and adolescents who present with a more complex MDD, or have a limited response to supportive psychotherapy, a more specific psychotherapy and/or an SSRI is indicated. Severe MDD and/or chronic recurring MDD will generally require pharmacotherapy, either alone or in combination with psychotherapy. For youths with SSRI-resistant depression, switching to another SSRI represents a reasonable approach and one RCT of adolescents with treatment-resistant depression, suggests that IV ketamine is superior to active placebo in the very short term (i.e., 2 weeks). However, in RCTs of adolescents with treatment-resistant depression, rTMS was not superior to sham.

PHARMACOTHERAPIES FOR BIPOLAR DISORDER

Bipolar disorder in children and adolescents is associated with significant long-term morbidity and disability. Owing to the severity and persistence of bipolar disorder into adulthood, safe and effective long-term treatments are needed.

Mixed Dopamine Serotonin Receptor Antagonists

Placebo-controlled studies suggest that multiple mixed dopamine, serotonin receptor antagonists are efficacy in pediatric patients with acute mania and six agents have received FDA approval for pediatric mania (lithium, risperidone, aripiprazole, quetiapine, olanzapine, and asenapine). In general, antimanic effects are observed within the first 2 weeks of treatment and mood stabilizers may be used as second-line treatments or in combination with mixed dopamine receptor antagonists. While monotherapy is generally preferred, combination pharmacotherapy may

be required—such as a mixed dopamine receptor antagonist and mood stabilizer, or an antimanic agent with treatment for comorbid ADHD, anxiety, and/or OCD. Following initial response, most youth require ongoing treatment with medication to prevent relapse. Current recommendations suggest the regimen needed to stabilize the acute mania should be maintained for 12 to 24 months.

Mixed dopamine serotonin receptor antagonists, in youth, have been associated with changes in prolactin, fasting glucose, fasting total cholesterol, necessitating close monitoring (at least bi-yearly to yearly). Some have advocated the use of metformin to decrease weight gain and metabolic risk in youth treated with mixed dopamine serotonin receptor antagonists. Additionally, long-chain omega-3 fatty acids may decrease the risk of hypertriglyceridemia associated with some mixed dopamine receptor antagonists in youth.

Lithium

Based on two NIH-sponsored studies, the Collaborative Lithium Trials (CoLT), lithium is FDA approved for the acute (short-term) treatment of youths 7 years of age and older with manic and mixed episodes associated with bipolar I disorder and for maintenance treatment in pediatric patients ages 7 to 17 years. In the first CoLT study, children and adolescents were randomized to lithium (n = 53) or placebo (n = 28) for up to 8 weeks. Greater improvements in manic symptoms and response were observed in lithium-treated youth compared to those who receive placebo. Additionally, in the second CoLT study, responders were randomized to continue lithium or to be cross titrated to placebo for up to 28 weeks. The primary outcome measure was relative risk of study discontinuation for any reason. Significantly greater maintenance of response was observed in patients who continued lithium. In youth, the half-life of lithium is significantly shorter than in adults, largely related to increased renal clearance. In youth, pediatric trials have generally used doses of 25 to 30 mg/kg/day and average serum concentrations have been 1.05 mEq/L. Regarding the kinetics of lithium in youth, a population pharmacokinetic study found suggested a maintenance dose of 25 mg/kg/day (divided BID), although this study underscored the importance of ongoing therapeutic drug monitoring. Finally, the tolerability of lithium has been like that observed in adults with gastrointestinal side effects and elevations in TSH being common.

Anticonvulsants

While the anticonvulsants likely have primary roles in the treatment of adults with bipolar disorder, these agents have produced very mixed results in youths. In this regard, improvements in manic symptoms are significantly greater for mixed dopamine serotonin receptor antagonists (approximately 0.65) compared to mood stabilizers (approximately 0.24); however, anticonvulsants are associated with less metabolic side effects in youth compared to mixed dopamine serotonin receptor antagonists. Further, their teratogenic and metabolic effects have limited their usefulness in youth.

Depression Associated with Bipolar Disorder

For youth with depression associated with bipolar I disorder, two medications have received FDA approval, olanzapine-fluoxetine combination (10 to 17 years of age) and lurasidone (10 to 17 years of age). Double-blind placebo-controlled trials of quetiapine and extended-release quetiapine have failed to demonstrate superiority to placebo in youth adolescents with bipolar depression. Open-label studies suggest that lamotrigine and lithium are associated with improvement in depressive symptoms in youth with bipolar I disorder.

Clinical Implications and the Role of Pharmacotherapy. Pharmacotherapy is the primary treatment for mania in youth. However, adjunctive psychosocial treatment may be useful to address disruptive symptoms and their sequela, which often impact family and community. These include interventions that focus on coping and emotional regulation, family therapy (including multi-family psychoeducation and family-focused treatment), CBT and there is emerging evidence that dialectical behavioral therapy may also be helpful. Due to the difficulty of stabilizing active bipolar and frequent comorbid symptoms, mixed dopamine-serotonin receptor antagonists are recommended as first-line treatments, although it is often necessary to employ combined pharmacotherapeutic strategies in these youth. As one example, multiple studies have shown that stimulants can be used in youth with stable bipolar disorder to treat comorbid ADHD.

OBSESSIVE-COMPULSIVE DISORDER (OCD)

OCD affects between 1% and 2% of children and adolescents and is characterized by impairing rituals and obsessions. Pediatric OCD often continues into adulthood. Psychotherapy is recommended as first-line treatment for OCD in youth, but several pharmacotherapies have also demonstrated efficacy.

Pharmacotherapy for OCD

Several SSRIs have demonstrated efficacy and been approved by the FDA for the treatment of OCD in children and adolescents. These medications include fluvoxamine, fluoxetine, clomipramine, and sertraline. Based on the currently available evidence, the American Academy of Child and Adolescent Psychiatry recommends CBT for youth with mild to moderately severe OCD; patients with more severe symptoms of OCD, the combination of an SSRI and CBT may be more effective than CBT alone. Regarding the efficacy of SSRIs for the treatment of OCD in youth, several meta-analyses suggest benefit although the effect sizes in these studies are smaller relative to the effect sizes of these medications for patients with non-OCD pediatric anxiety disorders. The choice of antidepressant may be important; findings in one meta-analysis suggest that in pediatric patients with OCD, the tricyclic antidepressant, clomipramine—which is FDA approved for the treatment of OCD in youth—may be associated with larger effect sizes. Nonetheless, SSRIs are considered first-line psychopharmacologic interventions for youth with OCD and three SSRIs are approved for this indication in youth: fluoxetine, fluvoxamine, and sertraline.

Selected Studies

THE PEDIATRIC OCD TREATMENT STUDY (POTS). POTS randomizing 112 youths with OCD (aged 7 to 17 years) to CBT, sertraline, the combination of the CBT + sertraline and pill placebo. All active treatments were superior to placebo in reducing OCD symptoms, although remission rates for combined treatment was 53.6%, for CBT alone 39.3%, for sertraline alone 21.4%, and for placebo only 3.6%. In POTS (II), 124 youths with OCD (aged 7 to 17 years) were assigned to one of three treatment strategies, all of which included SSRIs. The positive response rates for medication management only (30%) and medication management plus instructions in CBT (34%) were significantly lower than combined medication

management plus CBT (69%). These findings indicate that truncated versions of CBT are not efficacious comparatively, and that efforts should focus on making the full CBT protocol available more widely in community settings.

Clinical Implications and the Role of Pharmacotherapy. SSRIs are effective in reducing symptoms of OCD in pediatric patients and are well tolerated. However, in light of the POTS I/II findings, recommendations would be for children and adolescents with OCD to begin treatment with either CBT alone or in combination with an SSRI.

POSTTRAUMATIC STRESS DISORDER

Exposure to traumatic events, including neglect, domestic violence, as well as physical and sexual abuse, is not uncommon for many children and adolescents. A significant number of traumatized children and adolescents develop posttraumatic stress disorder (PTSD), a condition intrinsically linked to the experience of extraordinary stress and characterized by intrusive hyperarousal and avoidant/numbing symptoms. Though the prevalence varies by report, 10% of physically abused adolescents may meet criteria for PTSD. Other samples of youth exposed to urban violence suggest that PTSD rates may be as high as 24% to 34% while following a single motor vehicle accident, the prevalence of PTSD in children at 6 months is approximately 12%. Finally, pediatric patients with PTSD or clinically significant posttraumatic stress symptoms often have comorbid with depression, bipolar disorder, substance use disorders, and externalizing behavioral problems. Additionally, preschool age children with posttraumatic stress symptoms or PTSD may experience dysfunctional attachment, aggressiveness, and impulsivity.

Pharmacotherapy for PTSD

When considered, medications should be utilized adjunctively with evidence-based trauma-focused therapies. Additionally, as sleep difficulties and nightmares are common among youth with PTSD, addressing sleep is an appropriate first step when considering adjunctive pharmacotherapy.

SSRIs. Clinical trials comparing adjunctive antidepressant treatment with placebo in pediatric patients with PTSD are limited and, in general, do not suggest benefit of these medications, although, SSRIs may be considered in youth with co-occurring MDD or anxiety disorders in addition to PTSD.

Antiadrenergic Agents. Medications that centrally modulate noradrenergic tone are supported by clinical research as potential treatments for PTSD. The α_1-antagonist, prazosin has been studies as a treatment for dyssomnias, including nightmares and frequent nighttime awakenings in youth with PTSD. Case reports and a retrospective case series of 34 youth ages 5 to 17 years of age suggest that prazosin, an α_1-adrenergic antagonist, may be effective and well tolerated in treating sleep disturbances in youth with most youth responding to <5 mg qHS. Prazosin should be initiated at 1 mg 30 minutes before bedtime due to concern for first-dose hypotension and may be increased by 1 mg every 3 to 4 days for the first 2 weeks, starting lower and titrating up more slowly in younger children and/or in children and adolescents experiencing nausea, dizziness, or other side effects related to changes in blood pressure. Additionally, an uncontrolled trial suggested that guanfacine may reduce intrusive and hyperarousal symptoms in children with PTSD symptoms.

Mixed Dopamine Serotonin Receptor Antagonists. Limited, uncontrolled trials of second-generation antipsychotic medications in youth with PTSD symptoms have found mixed results and high rates of treatment-emergent adverse events.

Clinical Implications and the Role of Pharmacotherapy. Current evidence for the treatment of PTSD in youth suggests that trauma-focused psychotherapies be considered first-line treatment for children and adolescents with PTSD, with SSRIs and antiadrenergics, considered potential treatment options for comorbidities and for dyssomnias.

SCHIZOPHRENIA

While the onset of schizophrenia is rare prior to 13 years of age, numbers steadily increase throughout the adolescent years, and by 18 years of age

12% to 33% of patients who will ultimately develop schizophrenia will have symptoms.

Pharmacotherapy for Schizophrenia

Aripiprazole, lurasidone, olanzapine, quetiapine, risperidone, and paliperidone have received FDA approval for the treatment of adolescents aged 13 to 17 years. The mixed dopamine serotonin receptor antagonists are considered first-line medications for adolescents with schizophrenia. Studies involving clozapine in treatment-refractory early-onset schizophrenia-spectrum disorders have demonstrated superiority of clozapine compared to haloperidol and olanzapine, with regard to reduction in negative symptoms and to a certain degree with overall response. Finally, based on the results of one RCT, the use of omega-3 fatty acids may delay the onset and/or reduce the ultimate expression of psychotic symptoms in high-risk children.

Clinical Implications and the Role of Pharmacotherapy

Psychopharmacology plays a critical role in the treatment of schizophrenia, with the atypical antipsychotics considered among the first-line treatments. Fish oil may be useful in adolescents at high risk to develop fulminant psychotic symptoms. Psychosocial interventions are considered adjunctive to the medication but are strongly recommended.

EXTERNALIZING DISORDERS

Attention-Deficit/Hyperactivity Disorder (ADHD)

ADHD affects 6% to 9% of children and adolescents worldwide and persists into adulthood in roughly 50% of patients. Stimulant medications represent the first-line pharmacotherapy for ADHD, and their efficacy and tolerability are supported by multiple randomized controlled trials and meta-analyses. In recent decades the utility of stimulant medications has been boosted by the development of long-acting/delayed/extended-release preparations. These newer formulations have allowed patients to sustain treatment effects throughout the day and lower potential abuse liability. Similarly, there have been successes in the development of novel medications and devices for the treatment of ADHD.

Pharmacotherapies for ADHD. Stimulant medication—including both amphetamine- and methylphenidate-based agents are highly efficacious in treating youth with ADHD. In general, 65% to 75% of stimulant-treated youth response and response rates are similar for methylphenidate and amphetamine in immediate-release as well as extended-release preparations.

STIMULANTS. For ADHD core symptoms, amphetamines and methylphenidate are associated with improvement relative to a placebo, and this efficacy has been demonstrated in multiple meta-analyses. While network meta-analyses have failed to detect differences in efficacy between one amphetamine derivative over another or between amphetamines and methylphenidate, their tolerability may differ considerably, and there may also be differences in response at the individual level.

Immediate-release stimulant medications must be taken BID or TID and are both rapidly absorbed and metabolized which results in their therapeutic effects wearing off within several hours. To address these limitations, sustained-release formulations were developed, although in some cases "acute tolerance due to a lack of a steep absorption phase and a flat (i.e., zero-order) drug delivery profile" potentially degraded response. Given this, modified extended-release formulations have been develop which include varying amounts of immediate- and extended-release stimulant and which produce ascending (e.g., first-order) delivery profiles (Table 53.5–1). Longer-acting formulations are considered the first-line stimulant formulation and enhance adherence. However, it is not uncommon to need a "booster" dose of a stimulant in the afternoon with many extended-release proportions to extend the duration of coverage. Dosing is important with stimulant medication and in general, adequate trials of methylphenidate consist of >0.8 mg/kg/day while 0.5 mg/kg is often considered an adequate trial for mixed amphetamine salt-based preparations.

Table 53.5–1. Common Stimulant Medications and Formulations

Proprietary Name	FDA-Approved Age Range	Formulation	Route	Immediate Release/Extended Release	Molecule
ADHANSIA XR	≥6 years	Capsule (composite beads)	Oral (whole or sprinkled)	IR 20%; ER 80%	d,l-MPH
APTENSIO XR	≥6 years	Capsule (composite beads)	Oral (whole or sprinkled)	IR 40%; ER 60%	d,l-MPH
Azstarys	≥6 years	Capsule (composite beads)	Oral (whole or sprinkled	IR 30%, pro-drug 70%	Ser-d-MPH/d-MPH
CONCERTA	≥6 years ≤65 years	Tablet	Oral (whole)	IR 22%; ER 78%	d,l-MPH
COTEMPLA XR-ODT	6–17 years	Orally disintegrating tablet	Oral (whole)	IR 25%; ER 75%	d,l-MPH
DAYTRANA	≥6 years	Transdermal	Topical (hip)	N/A	d,l-MPH
FOCALIN XR	≥6 years	Capsule (mixed beads)	Oral (whole or sprinkled)	IR 50%; ER 50%	d-MPH
JORNAY PM	≥6 years	Capsule (composite beads)	Oral (whole or sprinkled)	N/A	d,l-MPH
METADATE CD	6–15 years	Capsule (mixed bead)	Oral (whole or sprinkled)	IR 30%; ER 70%	d,l-MPH
QUILLICHEW ER	≥6 years	Chewable tablet	Oral (chewed)	IR 30%; ER 70%	d,l-MPH
QUILLIVANT XR	≥6 years	Liquid oral suspension	Oral	IR 20%; ER 80%	d,l-MPH
RITALIN LA	≥6 years	Capsule (mixed beads)	Oral (whole or sprinkled)	IR 50%; ER 50%	d,l-MPH
ADDERALL XR	≥6 years	Capsule (mixed beads)	Oral (whole or sprinkled)	IR 50%; ER 50%	Mixed salts of d- and l-AMP (ratio of 3:1)
ADZENYS ER	≥6 years	Liquid oral suspension	Oral	IR 50%; ER 50%	Mixed salts of d- and l-AMP (ratio of 3:1)
ADZENYS XR-ODT	≥6 years	Orally disintegrating tablet	Oral (whole)	IR 50%; ER 50%	Mixed salts of d- and l-AMP (ratio of 3:1)
DYANAVEL XR	≥6 years	Liquid oral suspension	Oral	NR	Mixed salts of d- and l-AMP (ratio of 3.2:1)
MYDAYIS	≥13 years	Capsule (mixed beads)	Oral (whole or sprinkled)	NR	Mixed salts of d- and l-AMP (ratio of 3:1)
VYVANSE	≥6 years	Capsule (powder)	Oral (whole or sprinkled)	N/A	d-AMP

While stimulants are generally well tolerated in youth with ADHD, side effects, including decreased appetite, sleep difficulties, rebound hyperactivity or irritability, headache, and gastrointestinal symptoms, can become problematic. A meta-analysis of appetite loss associated with stimulant medications in pediatric patients with ADHD suggests that nearly half of methylphenidate-treated patients will experience appetite loss (compared to approximately 15% of placebo-treated patients); however, “serious” appetite loss occurs in 10.5% of stimulant-treated youth (compared to approximately 2% of placebo-treated youth). Stimulant-induced appetite decreases appear to be dose related. Several strategies have been proposed for the management of stimulant-induced appetite loss, including careful monitoring of appetite, weight, and body mass index, administration of medication after breakfast, and the use of calorically dense snacks (or fourth meals) later in the day or early evening.

There has been considerable debate about the management of cardiovascular side effects of stimulant medications, and, at times, conflicting recommendations have been provided. Stimulants have been

associated with elevations in mean blood pressure (<5 mm Hg) and heart rate (<10 beats/min). A subset of individuals (5% to 10%) may have an even greater increase in heart rate or blood pressure. Although there are limited prospective data related to the relationship between cardiac risk factors and outcomes in stimulant-treated youth, prudent recommendations from the American Heart Association and the American Academy of Pediatrics recommend obtaining a thorough history to identify high-risk youth with potential cardiac abnormalities or pre-existing cardiac disease prior to initiation of stimulant pharmacotherapy. Routine screening electrocardiography is *not* indicated in the absence of other cardiac risk factors.

NOREPINEPHRINE REUPTAKE INHIBITORS (NRIS). The NRI atomoxetine has demonstrated efficacy in multiple controlled trials, although its efficacy is less than that of the stimulants. One meta-analysis reported atomoxetine's effect size as 0.62, while the stimulants were from 0.91 (immediate release) to 0.95 (sustained release). However, atomoxetine exposure varies substantially (30-fold) across individuals, and part of this variability is explained by CYP2D6 activity. Dosing recommendations are available for atomoxetine when the CYP2D6 genotype/phenotype is known.

The second NRI to be approved for children and adolescents with ADHD is viloxazine which also has *in vitro*, antagonistic activity at 5-HT2B and agonistic activity at 5-HT2C receptors (and has high receptor occupancy at clinical doses).

α-AGONISTS. Multiple RCTs support the efficacy of extended-release preparations of clonidine and guanfacine as monotherapy in children and adolescents with ADHD. Typically, extended-release clonidine is administered BID, and the extended-release guanfacine is given either qHS or qAM with equal efficacy throughout the day. Extended-release α-agonists are FDA approved as monotherapy as well as in combination with stimulants. Moreover, in youth who have a partial response to stimulants, α-agonists may boost ADHD response. Immediate-release formulations of clonidine and guanfacine are also used off-label in the treatment of youth with ADHD.

Selected Studies

MULTIMODAL TREATMENT STUDY OF CHILDREN WITH ADHD (MTA). In MTA, children were randomized to one of four groups: medication treatment alone (with a structured algorithm-based approach), psychosocial treatment alone, algorithm-driven medication management, psychosocial treatment, or “community treatment.” The treatment algorithm involved monthly appointments with a physician during which the stimulant was titrated based on parent and teacher ratings. Treatment-related improvements were observed across all groups (at 14 months relative to baseline). However, algorithm-driven medication management was superior to intensive behavioral treatment alone and community treatment. It is noteworthy that the community treatment group had more limited physician follow-up, and, in this group, the average daily stimulant dose was significantly lower than in the algorithmic medication management group. Finally, approximately a quarter of youth who were randomized to behavioral management treatment required pharmacologic treatment secondary to a lack of effectiveness of the behavioral treatment. This finding highlights the role of pharmacotherapy in the management of many pediatric patients with ADHD.

PRESCHOOL ADHD TREATMENT STUDY (PATS). The Preschool ADHD Treatment Study (PATS) was also a large federally funded 14-month study designed to examine medication efficacy for younger children. All children and their parents first participated in a pre-trial, 10-week behavioral therapy, and training course. Only those children who still demonstrated significantly impairing ADHD symptoms were then randomized to receive immediate-release methylphenidate or placebo. Methylphenidate was significantly more effective than placebo at treating preschoolers with ADHD. However, at lower weight-adjusted, smaller effect sizes compared with school-aged children. In this regard, the mean optimal dose of methylphenidate was 14 mg/day (0.7 mg/kg/day), which is lower than the mean optimal dose of 1 mg/kg/day in the MTA study. In terms of tolerability, spontaneously reported moderate to severe adverse effects were present in approximately one in three preschoolers, including emotional outbursts, initial insomnia, repetitive behaviors/thoughts, decreased appetite, and irritability. Moreover, one in ten children discontinued treatment because of intolerable methylphenidate adverse effects (vs. <1% of school-age children in the MTA study).

Clinical Implications and the Role of Pharmacotherapy. Pharmacotherapy is a fundamental component of ADHD treatment in children and adolescents and is superior to behavioral therapy alone. Stimulant medications are among the most effective pharmacotherapies, although they vary considerably in release properties and duration of action. Additionally, in patients who have an incomplete or partial response to stimulants, adjunctive atomoxetine, guanfacine, and clonidine may boost response.

AUTISM SPECTRUM DISORDERS (ASD)

Pharmacotherapy for Autistic Spectrum Disorders (ASD)

ASDs, including autistic disorder, are characterized by impaired socialization, communication, and behavioral problems, frequently presenting with anxiety, irritability, aggression, and inattention/impulsivity-related symptoms. Psychosocial interventions include social skills training and applied behavioral analysis for youth with ASDs, while the role of psychopharmacologic interventions is frequently focused on target symptoms (e.g., irritability, disruptive and aggressive behaviors, impulsivity). Risperidone and aripiprazole have been approved by the FDA for the treatment of irritability associated with autistic disorder in children and adolescents.

Mixed Dopamine Serotonin Receptor Antagonists. Both risperidone and aripiprazole are FDA approved for the treatment of irritability associated with an autism spectrum disorder. In addition, quetiapine, olanzapine, ziprasidone, and paliperidone are commonly used clinically to manage irritability and aggressive behavior in youths with ASD; however. Meta-analyses of pediatric patients with autism (higher functioning) demonstrated improvement in behavioral symptoms associated with mixed dopamine serotonin receptor antagonists but confirmed the significant metabolic liability (e.g., weight gain) associated with this class of medications.

Additionally, first-generation antipsychotic medications (i.e., dopamine receptor antagonists) have been used to manage irritability and aggression in children with ASD. However, comparative data suggest that the mixed dopamine serotonin receptor antagonists are potentially more effective and may have fewer extrapyramidal side effects. More recently,

there have been several observational studies examining long-acting injectable forms of the mixed dopamine SSRIs, and these may be particularly helpful when children struggle with swallowing tablets and adherence.

Clinical Implications and the Role of Pharmacotherapy

SSRIs are modestly effective in improving global functioning and specifically improve repetitive behaviors, anxiety, irritability, and hyperactivity in children with ASD. Mixed dopamine serotonin receptor antagonists are commonly used for affective dysregulation, including irritability, aggression, and self-injurious behaviors. The mixed dopamine serotonin receptor antagonists may improve both the affective symptoms as well as—in some samples—ritualistic behaviors. For ADHD, as well as symptoms of inattention and distractability, stimulants are commonly used; however, the degree of stimulant-related improvement for these target symptoms is less than that which is associated with idiopathic ADHD.

SLEEP-RELATED DISORDERS

Insomnia is common in the general pediatric population and is certainly more common in youth with psychiatric disorders due to the disorders themselves as well as a sequela of the medications prescribed to treat the primary disorder. Pharmacologic treatment may be indicated if children do not show significant improvement following behavioral intervention. However, excluding other primary causes of dyssomnia (e.g., obstructive sleep apnea, iron deficiency anemia) is critical prior to pursuing pharmacotherapy, as pharmacotherapy could mask an underlying disorder.

Insomnia

Insomnia is common in the general pediatric population and is certainly more common in youth with psychiatric disorders due to the disorders themselves as well as a sequela of the medications prescribed to treat the primary disorder. Pharmacologic treatment may be indicated if children do not show significant improvement following behavioral intervention. However, excluding other primary causes of dyssomnia (e.g., obstructive sleep apnea, iron deficiency anemia) is critical prior to pursuing

pharmacotherapy, as pharmacotherapy could mask an underlying disorder.

Pharmacotherapy for Insomnia. There are no FDA-approved sleep agents for children. After aggressive sleep hygiene and education, controlled trials have demonstrated improved sleep latency outcomes with melatonin. Data regarding other agents used chronically are largely derived from expert opinion or case series, including benzodiazepines, clonidine, mirtazapine, imipramine, trazodone, and, less frequently, sedating atypical antipsychotics.

The primary regulator of the sleep–wake cycle is melatonin, an endogenous hormone produced by the pineal gland in response to changes in retinal light perception. Exogenous melatonin supplementation may be the preferred initial pharmacotherapy for sleep-onset insomnia due to its chronobiotic properties. In clinical studies of children and adolescents, both immediate- and extended-release melatonin reduced sleep onset latency and increased total sleep duration in pediatric patients, although the increase in total duration of sleep is greater with extended-release preparations. Additionally, melatonin may have a particularly important role in circadian rhythm sleep disorders. In this regard, low-dose melatonin (0.5 mg), when timed relative to the endogenous dim light melatonin onset, is more effective in shifting the sleep phase than higher doses, suggesting that timing may have a greater impact than dosage. Data regarding melatonin administration suggest that the optimal timing for melatonin administration is 4 to 6 hours prior to a child's preferred bedtime, and doses of 0.5 to 1 mg have been effective when given in this window. Variation across studies has contributed to a lack of consensus regarding pediatric melatonin dosing. For example, 0.05 mg/kg may be a minimal effective dose when given 1 to 2 hours prior to bedtime. Finally, studies of selective GABAergic modulators and benzodiazepines have not produced positive results in prospective trials of youth with insomnia.

Clinical Implications and the Role of Pharmacotherapy. Pharmacotherapy should be considered only after a thorough assessment of the etiology of the sleep disruption (e.g., sleep hygiene, potential iatrogenic causes, sleep apnea, insomnia as a sequela of a psychiatric disorder). Evidence-based pharmacotherapy for insomnia is largely limited to melatonin-related agents in the pediatric age range. For

pharmacologically induced sleep disruption, consider alternative preparations, classes of medication, or medication discontinuation.

Enuresis

While a specific etiology for enuresis is not commonly identified, a careful assessment is necessary for consideration of potential urologic, developmental, psychosocial, and/or sleep-related causes. If the history, physical examination, and urinalysis are unremarkable and do not suggest a specific etiology, supportive approaches combined with conditioning are considered the first-line treatment. Supportive interventions include education as well as recommendations against punishing the child for enuretic episodes. Behavioral conditioning methods with portable battery-operated alarms have been repeatedly demonstrated to be highly effective.

Pharmacotherapy for Enuresis. In addition to imipramine, two medications have demonstrated efficacy in the treatment of enuresis, desmopressin (DDAVP), and oxybutynin. As a synthetic analog of vasopressin, desmopressin decreases urine production. It is generally given orally or intranasally, dosed initially at 0.2 mg at bedtime, and titrated up to 0.4 to 0.6 mg as needed. Success rates of 10% to 65% have been reported. If successful, a course of treatment is recommended for 3 to 6 months. Additionally, oxybutynin, in combination with imipramine, has demonstrated superiority relative to placebo and imipramine.

Imipramine is FDA approved for enuresis and has been used for decades despite an unknown mechanism of action, with several studies demonstrating 40% to 60% effectiveness. It is given in a single bedtime dose of 1 to 2.5 mg/kg/day. Additionally, RCTs suggest that amitriptyline and desipramine have efficacy in decreasing pediatric enuresis, although they lack FDA approval for this indication. When effective, TCAs should be continued for 4 to 6 months. However, given the risk of arrhythmias with tricyclic antidepressants, an ECG can be considered prior to treatment and periodically during treatment.

Clinical Implications and the Role of Pharmacotherapy. If supportive approaches and behavioral conditioning with a urine-responsive alarm (i.e., “bell and pad”) are ineffective, medication may be considered as a treatment option. Additionally, medication may also be useful intermittently

to allow youth to attend overnight activities such as camp or sleepovers without embarrassment.

Tic DISORDERS

Tic disorders are common in youth, occurring in 15% of the general population, and are more common in youth with other psychiatric disorders. In general, when tic disorders do not affect function, pharmacologic intervention is not recommended. However, when tics interfere with function, as is frequently the case with Tourette syndrome, pharmacotherapy may be indicated. Currently, there are three medications with FDA approval for tic suppression in Tourette's, and these include haloperidol (age >12 years), pimozide (>12 years of age), and aripiprazole (>6 years of age). However, secondary to the risks associated with dopamine antagonists and mixed dopamine serotonin receptor antagonists, α_2-agonists (e.g., clonidine and guanfacine) are generally used as the first-line pharmacologic interventions. Additional trials are underway with VMAT2 inhibitors (e.g., tetrabenazine), which deplete vesicular dopamine and have been used in other hyperkinetic disorders.

Psychotropic medications play a critical role in treating many psychiatric disorders in children and adolescents. However, using these medications effectively and appropriately requires an understanding of pediatric pharmacokinetics and pharmacodynamics, in addition to the nuances of response that are revealed by numerous double-blind, placebo-controlled trials. In this chapter, we review the developmental pharmacology that is relevant to psychotropic medication use in pediatric populations and the evidence for multiple psychotropics across internalizing and externalizing disorders.

CONCLUSIONS

There is substantial evidence for pharmacologic treatments for psychiatric disorders in children and adolescents. Pharmacokinetics and pharmacodynamics in children and adolescents differ considerably from adults, and these differences give rise to differences in dosing, differences in response, and differences in tolerability. As such, the safe and effective use of pharmacotherapy requires an understanding of pediatric pharmacokinetics and pharmacodynamics in addition to the nuances of

response that are revealed by numerous double-blind, placebo-controlled trials.

53.6 Inpatient Psychiatric, Partial Hospitalization, and Residential Treatment for Children and Adolescents

Cynthia Wilson, M.D., and Andrés martin, M.D., Ph.D.

The demand for psychiatric inpatient beds rose significantly after the influenza epidemic of the 1920s. This was due to the need for long-term custody of children with mental and behavioral problems post encephalitis. Against this background, it is interesting to consider what may be the long-term effects of the COVID-19 pandemic on mental health care, particularly for children and adolescents. The number of inpatient beds peaked in the 1950s, prior to the deinstitutionalization movement of the 1960s. Deinstitutionalization was propagated by poor conditions in some institutions, as well as changes in treatment approaches and the advent of psychopharmacologic interventions.

The number of inpatient and residential pediatric beds has continued to decrease since then, especially starting in the 1980s. A nationally representative study of community hospitals conducted by Case et al. in 2007 showed that the inpatient lengths of stay continued to decrease through the end of the 20th century, going from a median of 12 days in 1992 to 5 days in 2000, a reduction of 63%. Meagher et al. looked at one inpatient setting in Massachusetts, which also demonstrated a significant decline in the length of stay, ranging from a mean of 45 days in 1991 and 11 days in 2008. Though the mean length of stay is quite different in these studies, they both show a steady decline in the amount of time children spent in the hospital. The latter study also showed a significantly increased number of psychotropic medications at admission and discharge, lower global assessment of functioning at intake, and an increased number of prior hospitalizations between patients admitted in 2008 versus 1991. There has been a concurrent increase in the number of psychiatric inpatient admissions for children and adolescents, as noted in an analysis of National Hospital Discharge Survey data between 1996 and 2007 by Blader et al. Possible explanations may be that outpatient, community-based, and systems-of-care approaches that work for many children and adolescents may not be available in the amount necessary to meet current demands. Alternatively, children and adolescents requiring inpatient hospitalization may be sicker today than those admitted in the 1990s.

The effects of institutions closing their doors, a shift to managed care and other third-party funders, the privatization of Medicaid, and changing paradigms of effective psychiatric treatment options combined to result in a shift in the way in which inpatient psychiatric hospitalization is conceptualized and used, particularly in the United States. Emphasis has

shifted to acute stabilization, diagnostic assessment, implementation of multidisciplinary treatment interventions, and return to the community and its available supports. The focus of inpatient psychiatric hospitalization has shifted more toward assessment and stabilization and less long-term treatment, although there is recognition that for a minority of children, inpatient and highly structured care settings remain the preferred treatment approach.

REASONS FOR HOSPITALIZATION AND TYPICAL REFERRAL SOURCES

Although there are significantly fewer inpatient beds since the onset of deinstitutionalization in the 1960s, inpatient psychiatric treatment continues to be necessary and essential at times. The most common reasons for psychiatric admission in children and adolescents include attempted suicide, suicidal ideation, homicidal ideation, aggression, psychosis, and an inability to care for activities of daily living due to psychiatric pathology. Inpatient hospitalization is mostly deemed necessary when these symptoms cannot be safely managed in the community. It is often the last resort and is only used if there are concerns about safety or grave disability.

Referrals to child and adolescent inpatient beds can come from a variety of sources, but overwhelmingly from emergency departments. Often inpatient units are affiliated with a hospital or academic institution that has an attached psychiatric emergency room. However, they could also be referred from other hospitals, outpatient psychiatrists, community mental health clinics, or juvenile detention centers. There are additionally free-standing psychiatric hospitals that are not affiliated with a hospital system. A larger hospital system may be better suited to address the needs of medically challenging or complicated children or to pursue complex medical workups.

To complicate matters, in the United States, as in many countries, there is a shortage of qualified child and adolescent psychiatrists. There is additionally a national shortage of sufficient outpatient services to keep children out of the hospital. As a temporary measure, some hospitals have adapted to “board” children on general pediatric wards or in the emergency department while they await a psychiatric bed or until they are stabilized. Children who do not meet strict inpatient admission criteria may

be referred to crisis stabilization programs that provide short-term treatment while longer-term outpatient services are arranged.

LEVELS OF CARE

The level of care appropriate for a particular patient is dependent on the current symptom profile, acuity, and availability of outpatient treatment options. Inpatient hospitalization is considered the highest level of care and provides 24/7 observation and medical care. The majority of inpatient units are locked facilities for safety purposes and therefore considered the most restrictive level of psychiatric care. Open or unlocked units typically exclude patients at acute risk of harming themselves. Partial hospital programs (PHPs) and intensive outpatient programs (IOPs) are used when the child is safe enough to remain at home yet has sufficient symptoms to require structured therapeutic day supports. Residential programs provide care for children and adolescents around the clock, typically over a longer period of time (Table 53.6–1). In addition, there are a variety of outpatient services available for children and adolescents, as discussed in other chapters.

Table 53.6–1.
Differences among Levels of Care

Level of Care	Purpose	Length of Stay	Benefits	Example of Reason for Admission
Short-term inpatient	Acute stabilization	Days to weeks	Improvement in symptoms, safety, and functioning	Acute risk of harming self or others
Intermediate-term inpatient	Acute stabilization and arrangement for appropriate placement	Weeks to months	Acute stabilization of refractory symptoms; safe environment; ongoing individual and/or family therapy	Treatment refractory symptoms; may be awaiting residential or other out-of-home placement
Partial hospital program (PHP) or intensive outpatient program (IOP)	Transition from, or prevention of, inpatient hospitalization	Weeks to months	Maintenance at home with structured therapeutic and school day programs; PHPs typically include a school component, whereas IOPs provide after-school care	Difficulty attending school or normal functioning due to mental health symptoms; step down from inpatient stay
Residential	Long-term treatment	Months to years	Long-term, consistent, safe therapeutic environment	Unable to maintain safe behavior at home, often after extensive community-based services have been tried and exhausted

Inpatient Psychiatric Care

As discussed, the inpatient level of care for children and adolescents is often a last resort and is only used if there are concerns about safety or grave disability. Insurance companies will typically deny payment for inpatient admission if certain stringent criteria are not met. Typical admission criteria include (1) a psychiatric condition that places the child

or adolescent at imminent risk of harm to self or others; (2) a psychiatric illness that poses significant medical complications such as anorexia or catatonia; or (3) loss of judgment or impulse control that results in dangerous, threatening, or disorganized behavior leading to grave disability or impairment.

Inpatient psychiatric care for children and adolescents is used for stabilization, most often with the goal of returning to the community with enhanced supports. The first step in this process is to conduct a thorough psychiatric assessment to inform the inpatient treatment plan as well as to make recommendations for treatment following the hospitalization, commonly referred to as aftercare planning. In order to best do so, it is necessary to consider multiple domains of the child's life, including the individual patient, the family, and the system of care. Given the developmental complexities of childhood and adolescence, all of this has to be done with special consideration of a developmental framework. This assesses the successful completion of prevailing or stalled developmental tasks with the eventual goal of a healthy transition to the next childhood developmental phase and, eventually, adulthood. These tasks are different for children, adolescents, and young adults and can have some individual variability.

In considering the individual issues related to the child or adolescent, it is most helpful to consider a biopsychosocial formulation. Approximately 75% of serious psychiatric disorders have an onset prior to the age of 25, and the clinician must be astute to how these disorders can present in childhood and adolescence as opposed to the typical adult presentation. On an individual biologic level, it is necessary to consider hereditary factors, substance use, intrauterine exposure to toxins, any medical conditions that may be contributing, substance use, and the role of puberty. Medication management is often a key component of inpatient hospitalization, although it should not be the sole component. Children and adolescents, at times, are suffering from a psychiatric illness to the extent that medications and interventions typically reserved for adults may be necessary, such as the use of lithium, clozapine, or interventional psychiatry procedures. Electroconvulsive therapy (ECT) and ketamine treatments can be considered for refractory depression in children and adolescents. ECT is sometimes also used for the treatment of refractory psychosis or catatonia. It is necessary on the individual level to have a thorough assessment and formulation to determine the best overall

treatment plan. Medication may not always be indicated, and the treatment plan will also likely include various psychological therapeutic techniques. It is helpful to consider from a psychological perspective the various cognitive processes and coping skills of the child and adolescent to drive the psychological treatment both inside and outside of the hospital. For example, a child who is very anxious and displays frequent catastrophic thinking may benefit from the use of cognitive behavioral therapy (CBT). Likewise, a child who is self-harming and engaging in impulsive behaviors may benefit more from dialectical behavioral therapy (DBT).

It is crucial to consider the family system of the child and the adolescent. It is important to keep in mind that the family system may not be two biologic parents and can be complex. Examples of possible family constellations could include one biologic parent, stepparents, extended biologic family, adoptive parents, or child protective services. It is important to discuss with the child and adolescent whom they consider to be their family and support system. Impaired family functioning may be contributing to the psychiatric illness of the child, and likewise, the mental illness of the child may be impacting family functioning. Frequently, family conflict precipitates the crisis leading to psychiatric hospitalization for children and adolescents. Family meetings focused on targeted interventions can help to defuse the acute crisis as well as foster better family functioning when the child or adolescent returns home. It can be a safe space for children and adolescents, as well as parents, to have difficult conversations and then independently process without immediately having to return home together. It is additionally common for children and adolescents to reveal previously undisclosed information during a psychiatric hospitalization, such as a sexual assault or their use of substances. Parents can be both devastated and yet appreciative of learning this information. Such disclosures to parents can lead to a better understanding of their child's mental health struggles. Parents should be strongly encouraged to discuss with their child or adolescent any new rules or guidelines that will be implemented at home, such as restrictions around the use of social media or increased levels of supervision to avoid an acute emotional crisis once the child is discharged and returns home. Such an emotional crisis could lead to readmission to an inpatient unit. Family strengths should also be highlighted and praised. Additional concepts to consider within the family domain are expressed emotion,

which is known to exacerbate symptoms of mental illness, and intergenerational trauma. Often, families could benefit from ongoing family therapy outside of the hospital, and this should be included as a recommendation if indicated. This may be in the form of family therapy with an individual therapist or an in-home therapy team, such as intensive in-home child and adolescent psychiatric services (IICAPS). There are additionally in-home models of care focused on problematic substance use and behavioral concerns: multisystemic therapy (MST) and multidimensional family therapy (MDFT).

There is truth in the African proverb and later book title by Hillary Clinton “it takes a village to raise a child.” Children and adolescents are raised in and by the community and the various entities involved in their lives. The needs of emotionally disturbed children cannot be addressed by the mental health system alone. In addition to the mental health care system, it is also important to consider the various other elements of the system of care influencing the social, emotional, and physical health of children and adolescents. This often includes many community agencies such as faith-based organizations, recreational activities, job and skills training, and mentoring. The school system plays an integral role in the life of both children and adolescents. Section 504 of the Rehabilitation Act of 1973 ensures the federal civil rights of those with disabilities, including children and adolescents with mental health diagnoses that may be impacting their academic performance. Under this act, these youth are entitled to a school plan or an individualized educational plan (IEP) until the age of 18. Parents are often unaware of this legal right and, subsequently, need assistance in requesting and giving recommendations for appropriate accommodations. Schools often welcome assessments and recommendations for appropriate accommodations provided by inpatient treating psychiatrists. For many children and adolescents, the system of care can also include government agencies such as child protective services and the juvenile justice system. It is important to consider in a formulation how these interlocking systems may impact the youth’s mental health. It is also important to make recommendations to bolster the mental health of children through increased in-school support, mentors, prosocial activities, improved friendships, and, when necessary, involvement in child protective services.

Milieu Management. The schedule in a child and adolescent inpatient unit is often similar to a typical school day schedule. The therapeutic day includes schoolwork, recreation groups, group therapy, supervised free time, and time for individual and family meetings. One also has to consider the developmental levels of the majority of the patients and how to make the milieu programming developmentally appropriate as well as useful. Among the unique features of inpatient, partial hospital, and residential care is the role of milieu-based, group-wide activities. As part of these activities, children benefit and learn from (and are routinely challenged by) the presence and demands of their peers and staff members. Their interactions and reactions in groups can provide helpful information for a biopsychosocial assessment as well as for appropriate aftercare planning.

The physical layout of a psychiatric unit is generally different from that of a medical inpatient unit. Most often, there is a multipurpose common room, similar to a living room, which can be used for a variety of therapeutic and recreational activities. Some units have a secure outside playground, providing another important outlet for physical expression and exercise. Bedrooms typically have beds for one to three children, and time spent in the community room is encouraged. Inpatient units are designed with attention to safety considerations to minimize the possible risk of harm to oneself or anyone else.

The management of a number of children or adolescents in one enclosed space can be challenging at times. Given their mental health concerns, special attention is often needed to minimize aggression as well as self-harming or suicidal behaviors. Aggression is one of the most common reasons for inpatient hospitalization in children. As such, inpatient units are charged with safe ways of de-escalation and stabilization of aggression and violence. Seclusion into contained spaces, physical holds, and mechanical restraints have been some historical means of dealing with acute violence and the imminent risk of injury to self and others. Following reports of deaths due to asphyxiation during restraints and physical holds in the early 1990s, there have been concerted and federally supported efforts to reduce the use of such restrictive interventions. As a result of these efforts, the use of restraints has decreased dramatically in many settings, although they continue to occur regularly in others.

Every effort should be made for de-escalation and proactive treatment planning. Physical interventions should only be used when all others have failed, and there is an imminent risk of harm to a patient or staff. Following any episode of seclusion or restraint, there should be a debriefing with all staff involved to determine any possible warning signs as well as contributing factors and how this could be prevented in the future. Questions about race and culture and whether or not this contributed to the restraint process should be routinely considered: several entities have reported racial disparities in the utilization of seclusion and restraints. It is clear that this needs to be taken into serious consideration as well as further studied to develop a better understanding of systemic racism in child and adolescent units and the unique challenges of and ways to engage minority youth. There is evidence that behavior modification in an inpatient unit can make a large difference in terms of decreasing inpatient aggression. There is additionally evidence for the use of collaborative problem solving as a milieu management strategy and in the reduction of the need for restraints and seclusion.

A number of additional challenges in the management of the milieu can arise. One such challenging behavior is attempted romantic interludes between peers. Although romantic interest is often developmentally appropriate, it is not conducive to the clinical work of an inpatient setting, and physical contact between peers can be problematic. Another potential behavior is the use of hate speech, either between peers or toward staff. This is best addressed preemptively and with clearly communicated reminders that this will not be tolerated. If such words are used, it should be addressed by staff immediately, and follow-up is needed with the patients involved, as well as with the treatment team, staff members, and particularly with the community of patients, who need to be ensured of their safety and of the antiracist principles governing the inpatient setting.

A further consideration in child and adolescent units is policies around transgender and gender-fluid youth. Children and adolescents should all be asked their preferred names and pronouns, and these preferences are adhered to by staff and in introductions to peers. This can, at times, cause conflict with parents who may not be accepting of the nonbinary or fluid status of their child or adolescent. In addition, questions can arise about rooming assignments, and a clear policy should be put into place that protects confidentiality and is gender affirming.

Multidisciplinary Approach. Inpatient child and adolescent psychiatric units are multidisciplinary by nature. They often include a variety of disciplines, including nurses, milieu counselors, recreational therapists, occupational therapists, social workers, chaplains, dieticians, teachers, pharmacists, psychologists, psychiatrists, and other licensed independent practitioners. In academic settings, there may additionally be residents, fellows, medical students, and other learners. Each staff person's assessment and observations of the child are important and valued. Inpatient mental health services for children require especially high staff-to-patient ratios and 24-hour per-day observation of the child's behavior. Nurses and milieu counselors are specially positioned to observe unit behaviors and peer interactions. Multidisciplinary team rounds typically occur daily, during which representatives from each discipline come together to discuss each patient's progress and treatment planning. Handover of information between shifts provides staff with the framework to improve communication across different staff members and disciplines and is critical to the smooth functioning of an inpatient unit.

Legal Considerations. There are many legal considerations in the inpatient mental health treatment of children and adolescents. Even within the United States, there is significant variation by state regarding at which ages parents may legally hospitalize their children against their will, children are able to voluntarily admit or discharge themselves, children may provide their own consent for outpatient mental health treatment, consent for psychotropic medications, and children and adolescents may seek independent treatment for sexual health. Therefore, it is crucial to know the laws specific to each country, state, or territory. There may be times when a child or adolescent may be hospitalized either against their or their parent's wishes due to safety concerns. These processes also differ by state but typically involve evaluation by one or more physicians and an avenue for a hearing with a judge. There are additional considerations of privacy and how much information can and should be legally shared with parents. Confidentiality and its limits should be openly discussed with children and adolescents at the beginning of their admission. Children and adolescents may additionally disclose that they have been the victims of abusive or assaultive behavior in the community, which would need to be reported to child protective services. Laws regarding what is reportable and what is considered abuse also vary by

locality and are essential knowledge for all mental health providers specific to where they practice. It is not uncommon for parents, especially those who are divorced or separated, to disagree on the treatment plan for the child or adolescent, and it is then necessary to know who has legal decision-making abilities. It is often helpful to ask for a divorce decree or custody documents when having to ascertain these distinctions.

Treatment and Discharge Planning. Treating the child in the least restrictive environment should be a guiding principle of any level of care. Short inpatient stays provide a safe, containing environment for a child who is acutely at risk of harm to self or others. At the time of admission, outpatient support services necessary for discharge should start to be explored. Inpatient care should not be viewed as an endpoint but rather as a site for stabilization and a launching point for longer-term community treatment options or residential placement. Because one of the rules of inpatient hospitalization is to protect children from harming themselves or others due to dangerousness or aggression, it follows that at discharge, a child no longer poses such an acute risk or is no longer gravely disabled due to mental illness. There may be times at which suicidal ideation, self-harm, or aggression are chronic, and therefore the goal may be to minimize rather than altogether eliminate this risk and to enhance safety planning.

The inpatient admission assessment often includes the input of multiple disciplines, as well as parents and other collateral sources. Information regarding the child's past treatments may be evaluated by obtaining prior records or speaking with the child's outpatient providers and parents. Pediatricians can be a very valuable resource as they have often known the child and family for many years and have unique insight into both developments as well as family dynamics. Observation of the child and adolescent in groups and interacting with peers is a particularly helpful aspect of inpatient hospitalization and can provide clues to the social and emotional strengths and challenges that they experience in the community. Inpatient treatment interventions are individualized and should focus on maximizing strengths as well as addressing any vulnerabilities. Several different modalities of treatment are potentially implemented during the inpatient stay, including psychoeducation, individual therapy, psychopharmacology, and family work. Collateral information from families and outpatient providers aids in understanding the progression of the

child's decompensation and resultant admission. It additionally provides information regarding previously tried medication as well as therapy techniques. Details of the dosing of medication, duration of treatment, adherence, and reason for discontinuation are all important to obtain. Typically, the child will be returned to the prior providers, and therefore, collaboration about treatment is essential for continuity after discharge.

Communication of facts about the treatment and time to effect is crucial. Detailed conversations with children and parents about possible side effects and expectations can strongly enhance engagement and adherence. And although in many localities, children and adolescents may not be legally required to provide consent, it is helpful for them to understand the risks and benefits of medication and provide assent. Families and children often have anxiety about taking psychotropic medications, which can be driven by misinformation and misconceptions. Open communication between the treatment team and the family about these beliefs can increase understanding and long-term adherence. It is also important to keep in mind that many children and adolescents are medication naive and to be mindful that their first experience with psychopharmacology in the inpatient setting may determine their perception of psychiatric medications as a whole, as well as their lifelong views on psychiatric treatment. Appropriate lab tests should be obtained prior to starting medications. In addition, the risks and benefits must be weighed for each treatment, and the reality of adherence to the treatment must be considered. For families in which medication adherence is problematic, the use of visiting nurse services may be a consideration. A large and arguably most important part of an inpatient stay is implementing support services in the community. This may be a variety of different types of outpatient treatment options and may include recommendations for education or further testing by the child's school.

Transitional Age Youth. With advances in research on brain development over the past two decades, the traditional view of adolescence ending at age 18 has been debunked, and the term transitional age youth has started to be used for adolescents between age 15 and young adults up to age 25. There has been an increasing voice that this age group deserves special attention and has a unique set of developmental challenges. Some hospitals have started to implement transitional-age youth units for young adults and older adolescents. It is

important to consider developmentally the best ways to aid in transitioning children and adolescents successfully into young adulthood. The groundwork for this should begin as early as possible and can be an important topic of milieu programming, as well as family work.

Partial hospital and Intensive Outpatient Programs

The structure of PHPs and IOPs is loosely based on inpatient programs. Programs can include a school component (typically called a PHP) or maybe an after-school program (often referred to as an IOP). There can also be differences in the number of days a week and hours a day of programming. Most programs have a staff structure similar to an inpatient unit, and many PHPs and IOPs are an extension of an inpatient program, with many of the children “stepping down” into this less restrictive level of care after their initial inpatient stabilization. The daily routine of a PHP differs from an inpatient unit in that the child wakes up and gets ready at home, and is then transported to the facility. The child then goes home in the late afternoon to return the following day again. It can be particularly helpful that the child can implement learned coping skills in the evenings and then be able to return to the program the following day to process any conflicts or challenges in the home environment. Children and adolescents are typically admitted to PHP/IOP programs due to difficulties at school or home due to mental health problems that have not been responsive to less intense outpatient treatment efforts or as a step down from an inpatient unit. Typically, these children are not currently at acute risk of harming themselves or others. For such patients, once-weekly visits to their outpatient clinicians may not suffice, given the severity of their symptoms, but inpatient admission may not be warranted either. PHPs and IOPs often last for several weeks to months. Assessment and treatment are similar to those in inpatient programs, including contact with outside providers and school personnel, as well as a biopsychosocial developmentally informed assessment. Discharge from a PHP or IOP program depends on symptom improvement and preparation of the child or family to be able to continue care at home with adequate outpatient services. A step down from PHP/IOP may include traditional weekly or biweekly outpatient therapy with medication support by a psychiatrist or include an in-home therapy service such as IICAPS, MST, or MDFT.

Residential Treatment Centers

“Residential” can have a variety of meanings, from residential placement of a child with no other home option to a voluntary placement sought by families to provide 24-hour care, housing youth in the juvenile justice system, or providing therapeutic treatment with the goal of returning to the community. The history of identifying residential stays as treatment began with the establishment of the American Association of Children’s Residential Centers in 1954. Even at that time, there was variation in the definition of residential treatment, though most centered around a psychodynamic orientation, requiring isolation of the child from the environment as a necessary form of treatment. This trend continued through the 1960s and 1970s until the beginning of deinstitutionalization. In the 1980s, with the advent of managed care, intensive outpatient treatment became more economically efficient as compared to residential treatment. Residential treatment also declined due to improvements in psychopharmacology and advocacy for community-based, wraparound, family-centered outpatient care, partly due to the more current philosophy that children are better assessed in the context of the environment in which maladaptive behaviors occur.

Despite best efforts, some children still require residential placement, whether temporary or longer term, although there are increasingly fewer placement options. Children in need of residential treatment tend to have either severe psychiatric and/or developmental disorders, preventing them from being managed through community and family supports alone, or have such circumstances that prevent them from living either at home or in therapeutic foster care. Residential treatment center staffing differs from inpatient and PHP/IOP settings. For example, the psychiatrist on staff often serves in a consultant role, thereby lessening the psychiatrist’s involvement in treatment. There are also fewer nurses per child, but the number of day-to-day residential staff is increased. Lengths of stay have decreased significantly since the 1950s, with further evidence since the 2000s of 3- to 6-month lengths of stay being efficacious. The use of cognitive behavioral and dialectical behavioral approaches has generally replaced psychodynamic approaches. Reduction in seclusion and restraint has also occurred in the residential setting. Residential programming focuses on individual coping skills, relationship building, and basic living skills, including self-care. There is a routine schedule as in inpatient units but with more individualized free time. Parent training and

family therapy are integral aspects of residential treatment and prepare the child and family for the child's return home.

CHALLENGES RELATED TO THE COVID-19 PANDEMIC

There have recently been unique challenges in all levels of care for the child and adolescent psychiatric services. As it has with most things, the COVID-19 pandemic has resulted in major modifications to many policies and procedures. For example, in many inpatient units, it was necessary for all children to be tested for COVID-19, as well as to wear masks, implement physical distancing, and increase emphasis on hand hygiene. In addition, on many inpatient units, visitation was either canceled or significantly reduced, including for parents. This led to family meetings often occurring via electronic platforms such as Zoom. However, there have also been some unexpected advantages to these changes. For example, kids who typically do not receive visitors are not comparing themselves as much to their peers who have regular visitors. Further, family meetings between divorced or separated parents can, at times, be more comfortable and productive via Zoom, and family meetings are more convenient and less volatile when parents do not have to be physically present. The same is true for residential treatment settings. Many PHPs and IOPs have transitioned from in-person to entirely electronic platforms. The majority of outpatient services have also transitioned to electronic platforms, with many providers not taking new patients, thus making inpatient and PHP/IOP discharge planning more difficult due to even greater limitations on available outpatient services. It is too soon at the time of this writing to know how clinical care will shape up post pandemic. But it is certain that the "good old days" will not be back in the same way: synchronous means of electronic communication such as Zoom, tired as we may be of them by now, have opened new venues for care and eased much of the logistic burden of in-person meetings and visits, particularly during working hours. The pandemic, dreadful as it has been, will leave some positive changes in its overdue wake.

GLOBAL PERSPECTIVE

There is significant worldwide variability in terms of the availability of inpatient, PHP/IOP, and residential treatment centers for children and adolescents. There are additional variabilities in the criteria for admission, as well as available community treatment options. This chapter was written from the perspective of services in the United States, and even as the same guiding principles may apply, there are country-, cultural- and region-specific variations we have not examined in this chapter. However, it is true worldwide that children and adolescents suffer from psychiatric disorders, and providing safe and adequate mental health care needs to remain a worldwide priority.

FUTURE DIRECTIONS

Advances in psychiatric treatment options, the availability of a range of community services, and a general shift in philosophy have gradually changed the conceptualization of psychiatric inpatient hospitalizations for children and adolescents from one of longer-term treatment to one of multidisciplinary diagnostic needs assessment and acute stabilization. Although there have been many changes over the past decades, the basic dynamics of staff, patients, and family remain unchanged. Adequate assessment of a child or adolescent cannot occur without a thorough assessment of the individual, family, and system of care through a biopsychosocial and developmentally informed lens. It is also necessary to remember that this is often the first encounter with psychiatric services for patients and families and that these early experiences can set the stage for lifelong views of psychiatric treatment and adherence. PHPs and in-home services are valuable services and contribute to the capability for children to have shorter inpatient stays and home reunification after inpatient or residential stays.

ACKNOWLEDGMENTS

This chapter represents an update and revision of previous chapters in this series, most recently by Dana Kober, MD from the last edition. We are indebted to Dr. Kober for her work and retain much of her prose in this current edition.

53.7 Community-Based Treatment

ANDRÉS J. PUMARIEGA, M.D.

Community-based treatment for children and adolescents has undergone significant transformation over the past 30 years. The traditional community mental health model has largely yielded to the community-systems-of-care philosophy and model. This model is based on an individualized, intensive, and flexible approach to service delivery for children and families within the context of their homes and communities as an alternative to treatment in out-of-home settings. This model also focuses on systems issues that affect care, including interagency coordination, service access and utilization, financing, and clinical and cost-effectiveness of mental health and support services provided to children and their families. Psychiatry, which was central in the traditional model, has only recently re-engaged itself as a participant in this new model. However, as the community systems of care model has been scaled up at regional and statewide levels, inadequate fidelity and resource allocation continue to result in a lack of access to community-based services and excessive utilization of residential services, many of lower quality and therapeutic value. More recently, in response to the shortages in child psychiatrists and requests by pediatric primary care physicians for greater access to child mental health services, collaborative and integrated behavioral health models have begun to emerge to form more effective alliances with this important sector of care. Psychiatrists are meeting the challenge of reaffirming their unique value in these models and in integrating their developing clinical and scientific knowledge and skills base.

The increasing need for and utilization of child mental health services in the United States has spurred their rapid growth. Recent studies suggest that approximately 20% of children and adolescents have a diagnosable mental, emotional, or behavioral disorder, with 5% having a serious mental illness and emotional disturbance. A number of morbidities have been associated with childhood emotional disturbance and mental illness, including suicide, homicide, substance abuse, child abuse, teenage pregnancy, school dropout, youth crime, and associated institutionalization and incarceration. However, less than 1% of children in the United States receive mental health treatment in a hospital or residential setting, with another 5% receiving treatment in outpatient or community-based settings; greater than two-thirds of children in need still receive insufficient or no mental health services whatsoever. There is evidence that the recent COVID-19 pandemic has significantly increased levels of mental health needs and rates of morbidity, as well as rates of mental health utilization among children and youth, aggravating these gaps in services even more.

In contrast, funds dedicated to the financing of public mental health services for children have grown significantly since the 1970s. Medicaid, the public insurance program for the poor and disabled, funds a significant proportion of child mental health services in the United States. In January 2020, over 32 million children were enrolled in Medicaid, and another 6 million were enrolled in Children's Health Insurance Program (CHIP). Mental health and substance abuse services are more than 45% of the over 600 billion dollars of overall Medicaid costs. The federal government contributes from 50% to 75% of costs, depending upon the state. The total public costs of behavioral health disorders among children and youth come to $247 billion annually, including services costs, lost productivity, and the cost of criminal activity. During the 2009 to 2011 period, an average annual total of $10.9 billion (in 2011 dollars) was spent on the treatment of mental health disorders among children aged 5 to 17 years, with 44.0% of expenditures for prescription medicines ($4.8 billion) and 34.9% were for ambulatory visits ($3.8 billion). The mean annual expenditure per child aged 5 to 17 years for the treatment of mental health disorders (among those with expenses for mental health) averaged $2,192 during 2009 to 2011, with mean expenses per child for ambulatory visits of $999 and $1,246 for prescription medications.

The main cost-containment approach to reduce these expenditures has been to control inpatient expenditures, which has more recently led to a major shortage of child and adolescent acute inpatient beds in the United States. A disproportionate level of these expenditures is still dedicated to residential treatment, which is viewed with increasing skepticism, given their relatively high cost, as well as limited documentation of outcome. In addition, there has been increasing documentation of poor practices and abuses in residential treatment as a result of underfunding and decreasing standards and quality of care. As a result of the growth in expenditures, the resources available to fund community-based child mental health and human services are increasingly limited.

BIPOC (Black, Indigenous, and people of color) children and their families have been traditionally served by public community-based mental health and human services. Children from these populations experience higher levels of stressors, such as poverty, discrimination, immigration, acculturation stress, and exposure to violence and trauma, and they are likely to have higher levels of need for services. It has become clearer that these populations suffer from major disparities in access to care as well as access to quality and effective care, particularly African American and Latino youth. A growing awareness and recent reckoning with the long-term impact of racism and discrimination in the United States has pointed to inherent structural racism in societal institutions, including mental health, health, education, and social services, which are now recognized as resulting in such disparities and the lack of cultural competence of such services. The cost of effectively serving BIPOC children and adolescents is in stark contrast to the much higher cost of psychosocial morbidities of racial/ethnic disparities, including lost human potential and the costs of welfare dependency and institutionalization. The United States continues to have the highest youth incarceration rates in the world, the highest levels of out-of-home or community residential placement for youth, and a high rate of children in state custody. Due to lack of funding for effective community-based mental health services, health and human service agencies (schools, social welfare agencies, child protective agencies, juvenile justice, and public health) have shouldered the increasing burden of psychosocial morbidity experienced by these children and youth. These agencies typically address pieces of the service system puzzle, with little to no coordination with other agencies serving the same youth resulting in increasing care fragmentation.

These trends have increased pressures on public child mental health and social service agencies to demonstrate improved clinical and cost-effectiveness, increasingly turning to managed care approaches to finance and organize mental health and social services. The majority of children covered by Medicaid are under managed care plans, including for behavioral health services. However, most managed care approaches were developed with private sector populations in mind, relying on a priori benefit restrictions based on actuarial data on middle-class populations with adequate social supports, who are traditionally lower users of services. When applied to public child mental health services, these approaches deprive children at high risk of effective intervention and preventive services. They also contribute to fragmentation of care and burden shifting to other child-serving agencies and systems, significantly increasing morbidity and acute need. Some Medicaid entities have successfully implemented community-systems-of-care approaches and integrated them with managed care methods, but many have had difficulty integrating them. Over the last 20 years, there has been an exponential growth of class action lawsuits against state Medicaid, educational, child welfare, and juvenile justice agencies failing to meet federally required service mandates, particularly around their high representation of children with significant mental health needs. The most egregious of such lawsuits involve the practice of parents having to give up custody of their children to obtain necessary mental health services.

HISTORY

From its earliest origins, children's mental health services have emphasized a community orientation. In the United States, these services began in the 1890s in response to the perceived need for counseling juvenile offenders rather than incarcerating them with adults. At that time, much like today, the United States was undergoing rapid sociocultural changes due to immigration, industrialization, and urbanization, and these social strains contributed to marked increases in juvenile crime and status offenses. The earliest juvenile courts in Chicago and Boston established clinics that comprised the first child mental health services in the nation. Their success led the Commonwealth Foundation to commission a study in the 1920s that recommended the development of child guidance clinics throughout the United States staffed with interdisciplinary teams of

professionals that could serve children and their families. They provided low-cost services oriented to the needs of the child and the family, with treatment modalities evolving to include individual psychodynamic psychotherapy, family therapy, crisis intervention, and even day treatment programs. They served as models for the community mental health centers that, with some alterations, emerged in the 1960s, and many have survived to this day.

The “medicalization” of psychiatry, starting in the late 1970s, served to move child and adolescent psychiatry toward the more hospital-based, tertiary care model. This left the child guidance clinics, and the community mental health centers that followed them, without significant psychiatric input. Many of the children previously receiving psychiatric services in these clinics were then served in free-standing psychiatric hospitals, residential facilities, or detention facilities, often in the custody of child welfare or juvenile justice agencies.

The modern era of community-based systems of care for children was ushered in by the publication of Jane Knitzer’s groundbreaking book *Unclaimed Children*, which exposed the aforementioned consequences of neglecting the provision of community-based mental health services for children and their families. Her advocacy and that of others led to the development of the Child and Adolescent Service System Program (CASSP), which assisted all 50 states in the development of an infrastructure for publicly funded, community-based services. The CASSP initiative was supported by the conceptual work of Stroul and Friedman, who coined the term “community-based system of care for seriously emotionally disturbed children” and enunciated the principles behind such systems of care. Stroul and Friedman’s work spurred the development of many innovative community-based treatment modalities, as well as a number of model demonstration programs in different parts of the United States that embody the use of these modalities within the context of an organized interagency system of care. In the early 1990s, the Robert Woods Johnson Foundation established eight pilot demonstration community-systems-of-care programs in different parts of the country, which demonstrated the viability of the systems-of-care approach and demonstrated cost savings, as well as less restrictive levels of care. Starting in 1994, the Center for Mental Health Services (CMHS) of the Substance Abuse and Mental Health Services Administration established the Comprehensive Community Mental Health Services for Children and

their Families Program. This program has funded 173 community-systems-of-care sites throughout the nation in widely diverse communities. The *Surgeon General's Report on Mental Health*, published in 1999, focused its recommendations for children's mental health around the systems-of-care model and its benefits for service system reform and individualized care. More recently, given the focus on school violence and the threat of terrorism in the United States, there has been additional focus by the federal government on these two aspects of community children's mental health. The Safe Schools Health Students program has funded 240 schools and communities to develop school-based preventive and clinical programs oriented at decreasing school violence and substance abuse, and the National Child Traumatic Stress Initiative funded many sites to adapt, implement, and evaluate promising intervention approaches addressing child traumatic stress in communities. Additional federal funding for children's mental health services was allocated in the 2010s in response to the continued occurrence of school shootings in various communities, as a result of the Affordable Care Act, and more recently in response to the mental health impact of the COVID pandemic in 2020 and 2021.

THEORETICAL ISSUES

The CASSP initiative set forth the principles inherent in community-based systems of care. The key principles include access to a comprehensive array of services, treatment individualized to the child's needs, treatment in the least restrictive environment possible (with full utilization of the resources of the family and the community), full participation of families as partners in services planning and delivery, interagency coordination, the use of case management for services coordination, no ejection or rejection from services due to lack of "treatability" or "cooperation" with interventions, early identification and intervention, smooth transition of youth into the adult service system, effective advocacy efforts, and nondiscriminating, culturally sensitive services.

The wraparound approach is also critical for systems-of-care interventions and services. This approach is based on the principle of individualization of services and proposes that an individualized service plan be "wrapped around" the child, including clinical, support, and nontraditional interventions. A wraparound approach is greatly facilitated

by the use of noncategorical and flexible funding for services, which enables a case manager and family to purchase whatever services the child and family needs at that time (including living needs, educational, social support, and even staff security services). Wraparound plans can build a level of service intensity rivaling that of inpatient or residential settings without removing a child from their home, especially using systematic wraparound protocols that have measured fidelity.

Cultural competence is an integral element of community-based systems of care. It implies that practitioners in systems of care develop the necessary attitudes, skill, and knowledge base to serve minority and culturally diverse children and families in their communities, as well as having service systems that develop policies and practices to remove barriers for access to services and make these more responsive to the needs and values of diverse communities. The community-based systems-of-care approach is congruent with the cultural values of ethnic minority populations, which emphasize strong extended family involvement in the life and upbringing of children and the use of natural community resources first in dealing with the emotional and physical problems of family members. These factors have been shown to be protective from some of the morbidities associated with emotional disturbance, such as substance abuse and suicidality. National guidelines for cultural competence for managed Medicaid services have been published by the CMHS, and the Practice Parameter adopted by the American Academy of Child and Adolescent Psychiatry (AACAP) operationalizes elements of cultural competence at both the clinical and systems levels. Building on this work, more recent efforts by various professional organizations and researchers on children's mental health have focused on the impact of structural racism on racial/ethnic disparities, such as the rising prevalence of psychiatric morbidities such as suicide in BIPOC children and the barriers to access to effective mental health and social services.

Another important principle inherent in this approach is the prioritization of services to "seriously emotionally disturbed children." This designation includes the presence of an Axis I diagnosis under the criteria of the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association but places equal emphasis on the child's inability to function in at least one of their domains (e.g., school, home, socially with peers). This reflects the difficulty many children and their families

have in accessing necessary services when the diagnosis was not "severe enough," particularly when the child was diagnosed with a disruptive disorder (although many children with disruptive behavioral disorders have comorbid serious mental illness when evaluated systematically). These problems are more pronounced in the diagnostic assessment of ethnic minority youth with serious emotional disturbance (SED), with serious underestimation of comorbid affective and substance abuse disorders by clinicians. Other studies indicate that the level of care received by children is only partially accounted for by their clinical diagnosis, whereas the level of function and psychosocial stressors are stronger predictors. It is also important to note that racial/ethnic disparities around diagnosis result in underidentification of BIPOC children and youth with significant mental health needs.

The movement to managed care has resulted in the application of community-based systems-of-care principles to these approaches. In fact, these principles embody a more clinically based managed-care philosophy. That is, active care management becomes the primary modality for utilization management rather than arbitrary benefits restriction. In combination with the principles of care in the least restrictive environment, systems of care result in children actually receiving higher-quality services with fewer disruptions in their lives and development at a lower cost than with more restrictive, higher levels of care. The AACAP has developed guidelines for states using managed care for children's behavioral health services funded by Medicaid, integrating community-based systems-of-care principles into their contracts with private managed care providers or into their policies and procedures for public managed services. It also has developed (in conjunction with the American Association of Community Psychiatry) an evidence-based level of care determination tool, the Child and Adolescent Level of Care Utilization System/Child and Adolescent Service Intensity Instrument (CALOCUS-CASII). It uses the level of function and contextual variables as the main variables for level-of-care determination, with recommended levels of care based on treatment intensity using systems-of-care and wraparound approaches. The CALOCUS-CASII has demonstrated significant interrater reliability and validity with mental health, child welfare, and juvenile justice populations and has contributed to significant systems-of-care reform in many states, including the state of Hawaii from 2003 to the present.

More recently, the federal Affordable Care Act that has promoted health care reform has promoted the establishment of Medical Homes, where individuals (including children and youth) receive their primary care and also the coordination of specialty care. This has facilitated a movement in both general and child-and-adolescent psychiatry toward collaborative and integrated behavioral health models, to enhance collaboration with pediatric primary care physicians in Medical Homes, and to enhance access to entry-level community child psychiatric services. The full implementation of these models calls for systematic screening of behavioral health needs served by Medical Homes and a stepped model of care, where either (a) the primary care physician directly delivers psychiatric care in collaboration with a care manager, (b) the primary care physician refers the child for stabilization by the child mental health service or specialist and receives the child back once stabilized, or (c) the primary care physician and child mental health service collaborate longitudinally in the child's care. The primary care physician is trained and/or supported by child psychiatric and mental health consultation in screening, assessment, and entry-level behavioral health services as delivered within the primary care setting. There is both ready access to child psychiatric consultation (direct and indirect) and case management support to enable the primary care physician to deliver these services within the medical home and assist with specialty referrals and continuity tracking of the child's course of treatment and outcomes. In integrated models, there is embedded case management and therapist support in the Medical Home, as well as access to regular child psychiatric consultation on the panel of patients served by the Medical Home.

TECHNIQUES

A community-based treatment approach to services begins with access to services facilitated through multiple portals of entry, including direct referral or referral through child service agencies (such as the school or juvenile justice, child welfare, or public health agencies). A triage system should direct children and families to services and providers appropriate to their special needs. A full interdisciplinary team, including a child and adolescent psychiatrist, should be involved in the development of triage procedures and protocols. Comprehensive mental health assessments should be made by licensed providers who are credentialed and trained to

evaluate children and families in consultation with a child and adolescent psychiatrist. Such assessments should include clinical/diagnostic, functional, developmental, family, and cultural/community evaluations of the needs *and* strengths of the child and family. Whenever possible, standardized measures should be used that are reliable, valid, clinically useful, culturally competent to the population being served, and useful for programmatic evaluation.

Children and families who require time-limited, less intensive services should have an initial care plan developed by a licensed mental health professional in consultation with a child and adolescent psychiatrist. The initial care plan for children requiring more extensive treatment should be developed by an interdisciplinary team, including all relevant child mental health and child service professionals. The parent(s), other relevant family members, and the child, if appropriate, should be members of this team. The care plan should identify problem areas and strengths that are relevant to the child and family's functioning, as well as community-based interventions to address these needs. The patient and their family should be equal participants with the clinical team in the development and implementation of the plan of care. In some programs, special "child and family teams" that are composed primarily of the child, family, and other natural supports in the community develop the outlines of care plans, and these are then negotiated by case managers with interdisciplinary teams of professionals and agencies. Plans of care should be individualized to the needs of the child and family, including attention to cultural issues, and should follow the child continuously throughout all levels of care, being amended as needed. The plan of care should promote continuous coordination and integration of all applicable services and agencies that have responsibilities for providing services to the child and family (such as primary health care, juvenile justice, schools, and social services).

Treatment and other services should be specific to the unique needs of the child and their family and use approaches that maintain or reintegrate the child into the family and community. Child and adolescent psychiatrists, psychologists, social workers, psychiatric nurses, and other members of the team should participate in the development of service protocols to ensure that the special developmental, physical, mental, and emotional needs of the child are addressed. The system should have as many diverse therapeutic modalities with children and families as possible, particularly those modalities that have demonstrated

effectiveness with seriously emotionally disturbed children. These include Medical Homes, traditional and intensive outpatient services, nonresidential community-based interventions (including home-based, day treatment, and school-based services), flexible support services, community-based residential services (such as therapeutic foster homes and group homes), and brief, acute inpatient services when needed. These interventions are aided by the increasing effectiveness of cognitive, behavioral, family-based, and psychopharmacologic therapies, which should be integrated into all community-based interventions and levels of care.

Case management services are essential in community-based treatment, including assessment of problem areas, measurement of functioning level, determination of needs, linkage with necessary resources, care coordination, advocacy, and monitoring of services provided and their outcomes. The child and family should be assigned a case manager who has the necessary skills to ensure seamless coordination of care across all levels, different providers, and the full-time course of illness/disturbance. The frequency and intensity of case management services are proportional to the clinical and psychosocial needs of the child and family. The patient/family should be participants in the case management process, with shared responsibility with case managers for using and coordinating services. Case management protocols should facilitate the coordination of multiagency, multisystem interventions, integrating services from the various providers and agencies (including primary care and health providers), and the development of wraparound plans that are truly individualized for the child and family's needs. These protocols should include access to flexible noncategorical funds to enable the purchase of flexible services needed for an effective wraparound plan.

ROLES AND FUNCTIONS OF PSYCHIATRISTS

Given the complexity of these new systems of care, the skills and roles that psychiatrists must display go far beyond the circumscribed clinical roles to which they are usually limited. These roles include serving as a front-line clinician, clinical consultant and collaborator to other professionals, clinical team leader, administrative leader in delivery organization/system, quality assurance/improvement consultant,

consultant to interagency teams, and outcome evaluator/researcher in systems of care. Child and adolescent psychiatrists, given their broad biopsychosocial and developmental perspectives, should be best able to integrate and coordinate community-based treatment delivered by multiple professionals with diverse skills. However, given the emphasis on tertiary care models in the training of many child and adolescent psychiatrists, they often have not developed all the skills needed to serve as effective members and leaders of these new systems. Three publications from AACAP, *Guidelines for Training Child and Adolescent Psychiatrists in Community-Based Systems of Care*, the *Practice Parameters for Child Mental Health in Systems of Care*, and *Best Principles for Integration of Child Psychiatry into the Pediatric Health Home* provide guidance on the skills, knowledge, attitudes, training experiences, and practices that psychiatrists need to function effectively within community-based systems of care.

CLINICAL ISSUES

Indications

Community-based treatment approaches are indicated for the treatment of the majority of children with moderate to serious emotional disturbance or mental illness, which is often associated with comorbidities and multiple psychosocial stressors and needs. It is most indicated for the prevention of out-of-home placement of such children and for the treatment of children served by multiple agencies with limited family resources. It can be contraindicated when the child's family is too fragmented or inaccessible. It often has to be modified with more intensive and restrictive treatment elements when the child faces imminent danger from whatever source (suicide, homicide, abuse, victimization, severe substance abuse), dangerous symptomatology, or serious decrease in function (such as acute psychotic symptoms or delirium). However, community-based treatment can be delivered in these instances as long as staff and physical security and safety needs are addressed through more intensive wraparound services (such as one-to-one staffing or on-site medical services). These services can be de-escalated when such symptoms or conditions are resolved (usually after brief stabilization) or the family is able to function again to an extent to which it can safely and effectively participate in the child's care.

Limitations

The community-based treatment approach can suffer from limitations when there is a lack of appropriately trained child mental health professionals who are conversant in evidence-based psychotherapies with children and youth and when there is a lack of an adequate and accessible continuum of care with sufficient options for an appropriate level of care intensity to meet the child and family's clinical and functional needs. In addition, a lack of adequate services coordination and integration can lead to significant care fragmentation. This can occur when psychiatric and nonpsychiatric services are segmented, and there is a lack of timely care coordination services, leaving children for inadequate periods of time in inappropriate levels of care intensity (either too low when they are developing more acute needs or too high after no longer needed).

Complications

The misapplication of the community-based treatment approach can lead to children and youth, and their families being underserved. This can result from a lack of access to necessary clinical and support services, lack of access to more intensive services, excessive pharmacologic treatment to compensate for lack of evidence-based psychotherapy services, and lack of timely care management services.

Contraindications

Community-based treatment services are contraindicated for children who suffer from acute symptomatology. These include acute suicidality with imminent danger to self, psychosis or mania leading to risk to self or others or inability to be adequately protected/cared for, or substance abuse that leads to risk to self or others. In addition, the child who is at risk of victimization in their home or community environment requires out-of-home placement. In all these instances, the community-based treatment approach calls for continued coordination with services in the home community and all possible efforts to return the child back to their family or to a normalized community setting with adequate support.

Shaniquah was a 14-year-old African American youth who lived with her Caucasian adoptive mother and adoptive siblings in a mid-sized Southern town. She presented with significant isolation and withdrawal, lack of motivation, irritability, and problems with aggression and fighting with her adoptive mother and siblings at home and with peers and teachers at school. She was expelled from school after the latest of such fights, in spite of her good academic standing, and this resulted in her making suicidal statements with thoughts of means and intent to die. She was taken by the local mobile crisis services to the local child and adolescent psychiatric unit, where she had been admitted twice before over the past year for suicidality and aggression and there was diagnosed with disruptive mood dysregulation disorder and attention deficit hyperactivity disorder, the latter established since age 7 and for which she had received outpatient services from her pediatrician and the local community mental health center. Her adoptive mother felt unable to care for her at home and had been asking for residential services, but the inpatient team referred them to the new Child and Adolescent Action Team (CAAT), an intensive community-based system of care program being established in different areas of her state. Within the team, she had a masters level therapist who worked with her and her family, a female mentor who worked to connect with her informally and motivate her to engage in prosocial activities, a case manager who worked to coordinate care with the school and identify community resources and activities she would engage with, and a child and adolescent psychiatrist. During her intake and child psychiatric evaluation, it was established that she also suffered symptoms of post-traumatic stress disorder (PTSD), and she began to reveal a past history of sexual abuse by her adoptive mother's former boyfriend, exacerbated by conflicts with her adoptive mother's current boyfriend as well as triggers by male peers at school. The therapist and child psychiatrist worked closely to address Shaniquah's PTSD symptoms with both trauma-focused cognitive behavioral therapy (CBT) as well as appropriate pharmacotherapy. The therapist also identified and began to address significant conflicts between the adoptive mother and Shaniquah, with the former minimizing the impact of trauma on Shaniquah as well as the cultural divide between them (seeking to treat her "the same" as her other stepsiblings of different races/ethnicities). This involved much

intensive family therapy, which at times was difficult for both but was quite productive. The CAAT Team female mentor also established a close relationship with Shaniquah, serving both as a role model as well as helping to engage her in prosocial activities of interest that validated her Black identity. The case manager on the team worked from early on to improve communication with Shaniquah's school, helping school staff recognize the impact that male peers had on her and engaging her school counselor and teachers in providing more academic and emotional support as well as support for appropriate social activities. This multiprong approach gradually helped the adoptive mother to better support Shaniquah at home and abandon plans for residential placement, instead now supporting her aspirations to enter a special magnet program at school. Shaniquah herself learned to use psychotherapy and mindfulness techniques to reduce her reactivity, developed a stronger bond with her adoptive mother, and re-engaged in academic and social pursuits.

Goals of Treatment

The goals of community-based treatment usually include the following: (1) to restore the child's function within the family, at school, with peers, and in the community; (2) to maintain or reintegrate the child within the family and community and avert separation or disruption of the community tenure; (3) to individualize interventions to the unique clinical and psychosocial needs of the child and family; and (4) maximally to use the strengths and resources of the family and the community on behalf of the child.

ETHICAL ISSUES

Ethical issues can arise in community-based treatment when the child experiences serious symptomatology in the face of family disorganization or risk of harm within the family and home. The ethical conflict arises from the inherent tension between the child's and family's needs for safety and stability and the goals of retaining the child within their family or community and helping both achieve change within their natural environment, avoiding restrictive care and disconnection from the child's relationships and natural supports. A home in which there is a high level

of conflict or abuse can be more restrictive for a child than some out-of-home programs due to the degree to which the child's function and activities are constrained. Also, the child may require a more structured or restrictive environment than the family can provide, such as when the child is experiencing suicidal, violent, or severe runaway behaviors. On the other hand, residential placement has been known to result only in temporary respite, with relapse of the child's emotional and behavioral symptoms once they return home since the structure, dynamics, and resources of the home environment have not changed during their absence. Interdisciplinary teams are usually well equipped to face such ethical dilemmas, given their representation of multiple stakeholders; chief among these are the voices of the family and the child and their advocates.

Another inherent clinical ethical dilemma arises when considering whether to place a child on a pharmacologic regimen versus intensive community-based or psychosocial interventions for disruptive or dangerous behaviors or symptoms. In these instances, the tension is between the biases toward less "medicalized" psychosocial interventions over pharmacologic interventions. The short- and long-term risks versus benefits (and evidence base) of any psychopharmacologic intervention for a child should be carefully weighed. However, many community-based interventions can be adjunctively aided by targeted pharmacologic interventions and vice versa, which can further aid in the reduction of restrictiveness, reduce needed doses of medications, and facilitate better integration into the community. The role of the psychiatrist in addressing these ethical dilemmas is critical.

The utilization of limited community-based treatments exclusively to reduce costs without considering the needs of the child and/or family can be another serious ethical breach in the pursuit of community-based treatment. Unfortunately, the financial incentives to provide less intensive care inherent in most managed care approaches can contribute to such dilemmas, potentially endangering the child if they place the child in greater danger or risk. Community-based approaches need to be pursued within organizational and financial structures that do not have arbitrary benefit limits, allow for wraparound approaches, and use on-site case management to avoid such situations.

RESEARCH AND EVALUATION

Research in child mental health services has particularly focused on the effectiveness of community-based treatment. Research in this area has included the evaluation of community-based residential approaches, nonresidential intensive community-based approaches, and the clinical, functional, and cost outcomes of community-based systems of care, as well as factors affecting the need and utilization of mental health services in different populations of children.

Community-Based Interventions

The Surgeon General reports on mental health and on youth violence point to research evidence supporting the effectiveness of a number of community-based interventions for children and youth, such as intensive case management, therapeutic foster care, partial hospitalization, and intensive in-home wraparound interventions (particularly multisystemic therapy [MST]). Other community-based interventions that show promise include school-based interventions, mentoring programs, family support, and education programs, wilderness programs, crisis mobile outreach teams, partial hospitalization, time-limited hospitalization with coordinated community services, and family support services. Studies involving these modalities have demonstrated significantly better outcomes than traditional outpatient or residential services. These include reduced levels of externalizing and internalizing symptoms, improved family functioning, reduced utilization of more restrictive services, diversion from juvenile justice involvement or detention, and improved cost-effectiveness. In addition, a number of in-home preventive parent–child interventions with infants and young children have demonstrated long-term effectiveness in reducing child abuse, as well as adverse behavioral and academic outcomes (such as the Elmira Project by Olds and coworkers in upstate New York and the child abuse prevention projects in New Orleans by Boris Zeanah and colleagues). On the other hand, there is a lack of research evidence or actual lack of effectiveness for a number of more restrictive interventions, such as inpatient hospitalization in isolation of community services, long-term residential treatment, therapeutic group homes, and boot camps.

The wraparound model of care embodies this approach toward multimodal community-based interventions. This model emphasizes aggressive outreach, the use of least restrictive treatment options, and individualized, flexible, and unconditional child- and family-centered

services for children imminently at risk or already in out-of-home placements. A number of studies of wraparound programs in different communities across the nation with diverse populations of at-risk children and families have reported positive outcomes in terms of reduction of externalizing behavioral problems, level of function, reduction in out-of-home placement, improved family management skills and function, and consumer/family satisfaction. MST combines home-based, wraparound, and cognitive behavioral interventions within a systemic context. It has been evaluated with youth at risk of detention/incarceration and at risk of psychiatric or substance abuse hospitalization, with significant results in reducing out-of-home placement, externalizing problem behaviors, rates of recidivism, and costs of treatment. A more recent community-based intervention—cognitive behavioral intervention for traumatic stress—has demonstrated effectiveness in addressing traumatic stress among children of diverse cultural backgrounds in school settings.

Community Systems Evaluations

Outcome data on early system-of-care demonstration projects in Vermont, New York, Ventura County, California, and the eight Robert Woods Johnson pilot sites demonstrated reduced hospitalization rates and days, decreased out-of-home placement, and less restrictive placements, significantly lower incidence of negative behaviors placing the child at risk for out-of-home placement, and significantly lower rates of overall problem behaviors. The Robert Woods Johnson pilot sites also demonstrated significantly lower costs using a managed subcapitation approach for funding flexible services for children with SEDs. Studies of the Civilian Health and Medical Program of the Uniformed Services (CHAMPUS)-funded Fort Bragg Demonstration Project and the Stark County CMHS system-of-care site compared their outcomes to those of usual service sites. These programs achieved significantly lower restrictiveness of care, higher family and consumer satisfaction, increased access to services, and greater funding spent on less restrictive services. However, clinical and functional outcomes and costs were not significantly different overall. Critics of these studies point to their short-term nature, and more recent studies have supported that significant clinical and functional outcomes from system-of-care programs are found on longitudinal evaluation.

The Substance Abuse and Mental Health Services Administration (SAMHSA) has sustained a major initiative, the Comprehensive

Community Mental Health Services for Children and their Families, to promote the development and expansion of community-based systems of care. This initiative, also known as the Children's Mental Health Initiative (CMHI), was authorized by Public Law 102–321 to provide funds to public entities for the purpose of delivering comprehensive community mental health services to children and youth who have an SED and their families. From 1993 to 2015, it funded 173 demonstration grants and cooperative agreements in states, territories, counties, and federally recognized tribal entities to create local systems of care that serve children and youth with serious mental health conditions and their families. It has included both a centrally designed evaluation, with required systematic data collection on all children served, and locally administered evaluations. Two main designs have been used: a longitudinal design with multiple assessment baselines at program entry and every 6 months until 36 months (and after program exit in newer sites), and two sets of comparison studies of system of care demonstration and control community sites. Data collected from grantees show that children and youth who received system of care services experienced positive behavioral and emotional health (as measured by the Child Behavior Check List (CBCL) total, internalizing, and externalizing scales), significant reductions in suicidal ideation and attempts, and improved educational outcomes such as reductions in expulsions and improvement in attendance. The average number of psychiatric hospital days was reduced from 0.98 to 0.63 days at 6 to 12 months in grantee sites, and total costs per child involved in juvenile justice went from $ 2,204 at intake to $ 936 between 6 and 12 months, achieving cost savings for all children served when all child service sector services are included. Grantees also made overall gains in applying systems of care principles to transform service delivery systems. Building on the success of these systems of care outcomes, SAMHSA began awarding 1-year *Expansion Planning grants* in Fiscal Year (FY) 2011 and 4-year Expansion and Sustainability grants in FY 2012 in order to stimulate the wide-scale adoption of the systems of care approach that is part of SAMHSA's Theory of Change. As of FY 2015, SAMHSA has awarded a total of 50 1-year *Expansion Planning grants* and 53 4-year Expansion and Sustainability grants.

In addition, some of the current and past CMHS-funded sites have begun to evaluate the added effect of the integration of evidence-based psychotherapeutic interventions within the system-of-care model. Some

system-of-care programs have begun to integrate evidence-based manualized therapies (such as parent–child interactive therapy) and community-based interventions (such as MST), demonstrating enhanced clinical outcomes. The Hawaii children's system of care has pursued the most ambitious integration of evidence-based interventions, creating a menu and an algorithm for the application of such interventions, with significantly improved functional and clinical outcomes and decreased level of care intensity of services over time. However, there are major challenges in integrating evidence-based interventions into a community system of care, including maintenance of fidelity, the need for added training resources, attitudinal changes by clinicians, and the overall complexity of the enterprise.

Services for Underserved and BIPOC Children and Youth

Services research literature with underserved minority youth has been sparse and initially focused on documenting racial differences in services provided. African American children tend to remain in foster care for longer periods of time and to have more foster care placements than White children. Studies have shown culturally diverse children to be underrepresented in mental health institutions and overrepresented in child welfare and juvenile justice settings and placements compared to nonminority youth, even when they are equally psychiatrically impaired. Ethnic and racial differences in the diagnoses of culturally diverse adolescents have been identified by some investigators, including overdiagnosis of conduct disorder and psychoses and underdiagnosis of affective, personality, and substance abuse disorders. Significantly lower rates for overall services utilization persist over a number of years, and specifically for the treatment of depression among African Americans and Latinos have been documented. Some studies have found a significant relationship between race and the service needs of racial and ethnic minorities. Studies have also shown higher retention in the treatment of minority youth if the clinician is of a similar ethnic/racial background. These findings have been replicated over the years in spite of the development of much evidence-based psychotherapy and community treatment programs that are effective in serving BIPOC children and families. Significant among them, the SAMHSA Comprehensive Community Mental Health Services for Children and their Families initiative has demonstrated not only significantly improved access by

BIPOC children and families but also equivalent outcomes that are correlated to cultural competence program measures.

Collaborative and Integrated Behavioral Health in Primary Care

Most of the research evaluations so far for collaborative and integrated behavioral health models have focused on their application to adult populations. There are a number of pilot collaborative care programs that have been developed, which have demonstrated significant successes. For example, Massachusetts has successfully demonstrated the Massachusetts Child Psychiatry Access Project (MCPAP), a program that provides timely telephonic psychiatric and clinical guidance to primary care providers (PCPs) treating children with mental health problems. The program allows enrolled primary care physicians to get assistance for any child in their care. The program has enrolled most primary care practices, representing an estimated 95% of all youth in the state, and has high rates of PCP participation, with over 5,000 patients served from 2008 to 2009. Primary care physicians who use the program have reported significantly higher ratings of their ability to serve children with mental health problems. Similar statewide programs have been developed in New York State and Washington State, with similar results. Studies have begun to demonstrate the effectiveness of collaborative and integrated care models. For example, Kolko et al. studied children and caregivers who participated from eight pediatric practices and were cluster-randomized to Doctors Office Collaborative Care (DOCC; n = 160) or enhanced usual care (EUC; n = 161). In DOCC, a care manager delivered a personalized, evidence-based intervention. DOCC was associated with significantly higher rates of treatment initiation (99.4% vs. 54.2%) and completion (76.6% vs. 11.6%), improvement in behavioral problems and parental stress ($p < .05$ to $p < .001$), remission in behavior and internalizing problems, treatment response, consumer satisfaction, and greater perceived practice change and efficacy. Grimes et al. examined mental health service use outcomes for children receiving integrated care via a collaborative practice model (CPM) and examined the impact on access disparities. They studied 228 children referred by pediatricians, 32 referred to a CPM intervention, and 196 youths to usual care (control group). Holding all else constant, children receiving the CPM intervention had four times higher odds of accessing psychiatric evaluations than children in the usual care control group (adjusted odds ratio [AOR] = 4.16,

$p < .01$), with seven times odds for engagement in follow-up for CPM youth over those in the control group (AOR = 7.54, $p < .01$).

FUTURE RESEARCH NEEDS

There are still many areas of significant deficit in the evidence base for children's mental health services and systems of care. Areas in which further research is needed include the effectiveness of culturally competent services and culturally specific interventions, the effectiveness of school mental health services, the effectiveness of mental health services integrated within the juvenile justice and child welfare systems, the effect of different cost containment and reimbursement mechanisms, the effectiveness of a systems-of-care approach in combination with evidence-based interventions (both psychological and pharmacologic), and the integration of child mental health and primary care services. The application of population health and mental health services research findings in service system policy and planning is the ultimate objective and value of such research.

53.8 The Treatment of Adolescents

Khadijah Booth Watkins, M.D., M.P.H., Steven C. Schlozman, M.D., and Eugene V. Beresin, M.D., M.A.

The treatment of adolescents must begin with a definition and developmental understanding of adolescence. Although most developmental theorists view adolescence as roughly coinciding with the onset of puberty, it is important to note that the criteria for both the onset and the conclusion of adolescent development are complex and multidetermined. Biologic, psychological, social, cognitive, and cultural paradigms, all play a role in the conceptualization of what exactly constitutes adolescent development.

From a biologic perspective, adolescence begins with the onset of puberty. It is important to note that puberty is not limited to the development of secondary sexual characteristics. In addition,

neurodevelopment research suggests that during puberty, the brain undergoes a number of important changes. These changes are most likely necessary for the emerging adolescent to move away from what Piaget characterized as a relatively rule-bound and concrete understanding of the world toward an increasing capacity for abstract thought. Neuron migration, changes in myelination, pruning of gray matter, and increases in white matter, all lead to changes in frontal lobe activity and have been implicated as playing major roles in long-observed cognitive changes. However, there is also growing evidence for incomplete frontal lobe myelination leading to decreased capacities for complicated problem-solving activities in the presence of hotly affective environments. Thus, despite substantial development of brain regions responsible for executive function, the relatively poor myelination of these regions explains some of the classically observed lapses in judgment and some of the impulsivity that characterizes adolescent behavior. In this fashion, Piaget's observations have been validated and also challenged by a growing understanding of adolescent neurobiology. During the ages of 14 to 26, cerebral cells die, a process known as apoptosis. Also, during this time period, myelination of neurons from lower centers, such as the amygdala, cingulate gyrus, hippocampus to the cortex, and the orbitofrontal cortex, takes place. This important neurobiologic task helps the developing adolescent move from their behavior being driven by impulse and emotion, to behavior which is based more on complex, rational decision making, reflection, and problem-solving processes.

Psychologically, adolescence has typically been viewed as a period of separation and individuation coupled with an increasing desire to form a coherent and consistent sense of self. These tasks, roughly characterized as identity formation by theorists such as Erik Erikson, Anna Freud, and Peter Blos, are central to the experience of the adolescent as they continue along the developmental trajectory. According to Erikson's epigenetic model, adolescence is determined by the quest for identity formation at the risk of role diffusion. The onset of important advances such as the development of sexual and romantic attractions, the formation of political and ethical opinions, and the willingness to differ in opinion from both peers and adult caregivers are all key elements of these psychological changes.

In addition, G. Noam and others have proposed that during early adolescence, group identity and cohesion plays a much more important

role than individual identity formation. Noting that belonging to a group and conforming to the norms of that group are important aspects of the early adolescent years, these scholars theorize that adolescents first experiment with separation and individuation by embracing the rules and regulations of their peer group. In “Eriksonian terms,” this developmental challenge could be coined *inclusion at the risk of exclusion.* To this end, as they mature, healthy adolescents move away from all of the rules of any one peer group and instead choose those aspects of many different groups that best suit their developing sense of self. The normal early-adolescent emphasis on popularity thus grows to also include the later emphasis on being comfortable that one can maintain a coherent identity without relying on the restrictions and rules of any single peer group.

Social norms and pressures contribute to adolescent development in many ways. Ideals of beauty, power, success, masculinity, and femininity are, to a large extent, socially determined. In modern industrial Western society, the adolescent’s individual and group identities are significantly influenced by mobility and the increasing role of media as a means of information, entertainment, and communication. New technologies such as cellular telephones, broadband connections, and the internet have expanded the adolescent’s circle of relationships and generated instant access to groups of individuals, movies, music, news broadcasts, streaming videos, and advertisements. Although group norms and role models previously were confined to relationships in real time, adolescents today are barraged with detailed and graphic information about the intimate lives of celebrities and other public figures in the news. Current events, often dramatic and traumatic events, are instantly available to the adolescent. The rapid transmission of information plays a major role in both defining the world for the adolescent and providing a constant stream of data through which the adolescent may become immersed and influenced in powerful ways.

Although the media is no substitute for life experience in real time, the power of the media to create a social milieu with figures for identification, imitation, and role modeling has grown exponentially in recent years. For example, studies have demonstrated that the media has a powerful effect on adolescent body image and self-esteem and has complex manifestations across various ethnic, racial, and cultural groups. Also, in the context of increased media use and exposure, there has been a dramatic increase in loneliness in Gen Z and millennials. The BBC, Pew,

and Cigna studies, all suggest consideration be given to the increase in social media use as a significant factor, albeit, not the sole source of the upward trend in loneliness. In the Cigna report from January 2020, Gen Z was found to have the highest loneliness score. Also in the Cigna report as well as other studies, it was shown that loneliness is linked to anxiety and depression and it was found that there were significant reductions in loneliness, depression, and anxiety over time with decrease social media usage. All of these factors have complicated the tasks of separation and identity formation in many ways that are only beginning to be understood, and these social changes have led to worries regarding addictive internet use, which seems to start most commonly during adolescence. These issues are addressed later in this section.

Finally, as for all developmental stages, adolescence exists within a specific cultural milieu. Although virtually every culture embraces rituals intended to recognize both the onset of adolescence and the transition to adulthood, the conceptualization of what characterizes adolescence varies in terms of cultural norms. What one culture might consider a normal development is often somewhat startling taken out of cultural context. As the world becomes increasingly multicultural, these considerations are especially important. For example, the Asian youth who begins to question his parents' values is often viewed very differently in Western versus Eastern contexts. Although someone with a Western outlook might view this as a healthy and normal emotional development, the youth's parents might see it as particularly pathologic and dangerous. Cultural differences such as this are obviously generalizations, but keeping these potential differences in mind is extremely important to any clinical consideration of adolescent populations.

CONTROVERSIES IN CONCEPTUALIZING NORMALITY AND PATHOLOGY IN ADOLESCENCE

The period of adolescents has been redefined and conceptualized over time to include young adults, many of whom have not yet assumed adult roles, up to age 24 years. There is a subset of adolescents that "fail to launch." They experience significant challenges with transitioning from high school to college: they have work and career problems, family conflict, challenges in friendships and romantic relationships, and limited independence. Also contributing to the prolongation of adolescence is

increase in the number of youths seeking post–high school education, which is now required for success resulting in a delayed earning potential. With that, coupled with the lack of job opportunities and the increased costs of education, the ability to live and thrive independently has been delayed.

The adolescent's quests for identity and separation have led both clinicians and popular culture to view adolescence as a normally tumultuous period. Although most adolescents navigate the transition from childhood to adulthood without serious incident, there are times of upheaval that are experienced as real crises. These periods may be obvious sources of concern to significant figures in the teenager's life, such as parents, siblings, teachers, or other adults, or they may be concealed and go unnoticed. For most adolescents, the movement from complete dependence on family to independence is at once exhilarating and terrifying, and at other times, it is filled with profound despair. Highly charged affect is quite typical of adolescents and is often intense and labile. In the separation process, the adolescent must in one way or another reject their parents and at other times seek parental approval and nurturing—even babying. It is not unusual, for example, to see an adolescent girl's bed covered with stuffed animals, and at the same time to overhear her talking about moving out of the house or fantasizing about sexual intrigues.

Although the normal adolescent is capable of understanding the consequences of their actions, teenagers typically live "in the moment" and are occasionally blind to risky behavior. Because normal myelination proceeds in a caudal-to-rostral pattern, emotionally charged moments may not enjoy efficient use of the more sophisticated regions of the brain until individuals are in their mid-20s. These neurobiologic processes are compounded by cultural norms that create a sense of grandiosity and invulnerability. However, at other times, the adolescent's omnipotence evaporates as the teenager fears a multitude of potential dangers, from physical illness to kidnapping. Finally, the quest for identity carries with it substantial self-consciousness, characterized by fear of public exposure and shame. These fears may result in reluctance to share feelings or discuss issues that are potentially humiliating.

In addition, all adolescent behavior is influenced by personal traits, such as temperament, and by the environment, including relationships with peers, siblings, and parents and the community in which the teenager

lives. Consequently, there is a great deal of heterogeneity in adolescent behavior. To further complicate matters, developmental advances are never linear. Progress is punctuated by periods of regression to earlier stages. It takes considerable clinical acumen or a great deal of familiarity with a particular teenager to understand what is normal for one adolescent or pathologic for another.

Some researchers feel that viewing adolescence as a tumultuous period creates a setting in which adolescent tribulations and "out-of-control" behavior are viewed as normative and therefore not deserving of clinical attention. Researchers such as Offer have instead suggested that whereas most adolescents are in fact well adjusted and not psychologically troubled, the tendency to view adolescence as "normally difficult" potentially risks missing the population of youth who are legitimately suffering. In fact, research suggests that approximately 20% of the adolescent population in Western settings is seriously in need of clinical intervention. Some of this attention is needed for managing particularly charged crisis points in normal development for youth at risk, whereas other attention is required to treat the onset of many psychiatric disorders that achieve greater prevalence during adolescence. Among these are mood and anxiety disorders, schizophrenia, eating disorders, and substance use disorders. The suicide rate increases tremendously throughout adolescence: Data from the Centers for Disease Control and Prevention (CDC) show that the suicide is the second leading cause of death in youth aged 10 to 24 years. In addition, data from the Youth Risk Behavior Survey (YRBS) published by the CDC show that 18.8% of teens "seriously considered" suicide during the 12-month period during 2019. Prevalence estimates were highest among females (24.1%); White non-Hispanic students (19.1%); students who reported having sex with persons of the same sex or with both sexes (54.2%); and students who identified as lesbian, gay, or bisexual (46.8%).

Although the overall rates of suicide had decreased compared to the rates in 2018, there is growing concern about the increase in the rates of suicide among Black adolescents. Thus, the psychiatric treatment of adolescents has significant public health repercussions.

Much of these challenges are driven by the paradoxical lack of careful thought among adolescents, who nevertheless clearly have the capacity to embrace rational and abstract problem-solving approaches. In short, often the overall judgment and risk assessment of adolescent thinking is

markedly different from that of adults. For example, whereas adults would rarely accept a challenge to drive recklessly on the freeway, such a scenario is not unheard of in late adolescent populations in spite of their growing capacity for sound judgment and abstract reasoning. Some researchers have suggested that the affectively charged environment of the adolescent leads to an increased willingness to take risks, sometimes called a “hot cognition” in the cognitive developmental literature. Again, this is best understood in the setting of the incomplete neurodevelopment outlined earlier. Thus, whereas adolescents might appear adultlike in their thinking during calmer moments, affectively volatile environments can pose a particular risk to their well-being. These observations serve to accentuate the need to view adolescent behavior as potentially in need of clinical attention.

Another area of controversy involves the interplay of media and popular culture in affecting adolescent behavior. Many researchers have suggested that violent or disturbing media increases the likelihood of psychosocial problems within adolescent populations. These studies have led to policy statements by a number of professional organizations, including the American Academy of Pediatrics and the American Psychological Association, in which suggestions for curtailing media impact are made clear. Other researchers have noted the potential use of the media in both understanding adolescent thinking and in allowing adolescents to explore difficult issues through displacement and projection. From a clinical perspective, therefore, the issue of media effects on adolescence is extremely important, and any discussion of the psychiatric treatment of adolescence must take into account this key controversy.

Among the major concerns surrounding digital media use in adolescence is the ways cell phones and social media are handled: Nearly 95% of all teens own a smartphone and 45% are online on a near-constant basis. Fifty-one percent log onto social media more than once a day and 97% use social media such as TikTok, Twitter, Snapchat, YouTube, Instagram, or Facebook. There are considerable dangers of social media use in adolescents.

Though most teens think peers are nice, 88% witnessed others being cruel or mean. Considerable attention has been given to the serious impact of cyberbullying among adolescents. The 2019 cyberbullying data from the Cyberbullying Research Center found that approximately 37% of

the students reported experiencing cyberbullying in their lifetimes and 15% admitted to cyberbullying others at some point in their lifetime. Female students, LGBTQ students, and students not sure of their sexual identity were found to have the highest prevalence.

Cyberbullying increases dramatically from grade school through high school and may have significant psychiatric consequences, including depression, suicidal thoughts and behavior, anxiety and post-traumatic stress disorder, social isolation, low self-esteem, poor academic performance, and alcohol and substance use. Furthermore, bullying has been shown to have lifelong psychiatric consequences, particularly anxiety and mood disorders.

Many teens reference their sexual behavior, substance use, and/or violence through digital media. Sexting is a particularly worrisome problem in teens. Sexting is the use of text messaging or other means to post sexually explicit photos. Up to 20% of teens are found to engage in sexting, and while studies vary widely, probably 15% have sent an image, and as many as 27% have received images.

Nonconsensual sexting is extremely common with approximately 1 in 8 youths forwarding explicit images or messages without the permission of the original sender, and about 1 in 12 youths have a sext forwarded without their consent. A 2018 meta-analysis found that one in 5 youths under 18 are exposed to unwanted sexual material online.

The reasons for sexting are highly variable but usually involve the desire to maintain or seek a relationship, peer pressure, boredom, joking around, or showing off. While most teens feel the recipient would want to receive the photo and keep it to themselves, forwarding photos is a significant problem. Most teens are unaware that digital media affords recipients making a photo “go viral” and expand to a very wide audience. The consequences of such exposure may be profound and serious. Many teens who engage in sexting are deeply shamed, anxious, and depressed and few are aware that there could be potential legal problems including a risk of being charged with disseminating child pornography and placement on a sex offenders registry if convicted.

Teen drivers have a higher rate of fatal accidents which can be attributed to their immaturity, lack of skills, and lack of experience and distracted driving can make it difficult to react during a potential crash. Distracted driving is defined as any activity that takes the driver’s attention away from focusing on the road and driving which can include talking to

peer passengers, talking or texting on a cell phone, changing the radio, eating, or applying makeup.

Specifically, the impulsive use of the cell phone while driving, which occurs all too often, can lead to injury or death. In fact, motor vehicle accidents are a leading cause of death and nonfatal injury among U.S. adolescents.

The data from the 2019 CDC's Youth Risk Behavior Surveillance System (YRBSS) survey showed that 39% of high school students who drove in the past 30 days texted or emailed while driving on at least one of those days. Also of note, students who engaged in distracted driving were also more likely to not always wear a seat belt, they were more likely to ride with a driver who had been drinking alcohol and more likely to drive after drinking alcohol.

There can be serious repercussions of social media such as exposure to harmful or inappropriate content, exposure to dangerous people, the oversharing of personal information, privacy concerns including data collection and identity theft, and interference with sleep. Of note, one such danger of social media is the suicide contagion or copycat phenomenon. There have been numerous studies of copycat suicides that have been well documented and the copycat phenomenon is a significant issue for adolescents, replicating celebrity or fictional portrayals of suicide. It's imperative that parents are aware of what they have seen or read and discuss their reactions. When teens hear of celebrities, or even fictional characters in the media dying by suicide, there is a 2-week window in which they are vulnerable to attempt suicide. The CDC and American Foundation for Suicide Prevention set guidelines for journalists on how to report on deaths by suicide that does not sensationalize, report details of the means, and instead, focus on the survivors. Mention of the method of suicide in reporting has been linked to suicide contagion, or "copycat suicide."

While there may be dangerous consequences of social media, there are potential benefits. For many teens, the immediate contact affords nurturing social relationships and connection, which is particularly true for teens with high-functioning autism spectrum disorder and shy teens.

Connection and social relationships are key components to building resilience.

Teens are able to stay connected to friends, meet new friends that share similar interest, share artwork and music, and express themselves.

Social media can foster separation from parents and increased autonomy, helping shy or anxious teenagers develop social interactions, and providing forums for discussing moral, social, or religious issues in concert with the adolescent's increased cognitive capacity. However, given the potential serious risks, it is imperative that clinicians know the media use of their patients. Media literacy is a critical and uncharted aspect of the care of adolescents, and one that should not be neglected. Media literacy on the part of parents, pediatricians, and allied health professionals will serve an integral role in providing the important and necessary supervision as well as guidance for the adolescent.

There continues to be concern regarding addiction as it relates to the internet and gaming. The World Health Organization, in their 11th edition in 2019, included gaming disorder, to be considered an "addiction," much like gambling addiction. The American Psychiatric Association, however, does not currently include internet gaming addiction in the DSM-5, although it has been noted that these behaviors are worthy of future study in the context of internet gaming disorder.

Proponents of these concerns note that many people become enamored of internet activity during adolescence at the expense of normal functioning. These adolescents are said to ignore more normal social behavior and spend increasing time engaged in internet activity. Clinicians who are more skeptical of the concept of internet addiction point to the lack of good prospective studies, confounding issues such as different uses of the internet among those who display worrisome internet behavior, and poor understanding of molecular mechanisms such as dopamine reward systems that have been postulated in other addictive problems. In addition, what is considered socially normal increasingly involves the internet. Thus, fundamental questions, such as how much time on the internet is too much or whether activities such as internet gaming and gambling hold the same risks as internet pornography, need to be better explored.

Finally, in considering media effects on adolescents, one must consider the ongoing debate regarding massively increased use of video game activity among teens. Because many of these games adhere to increasingly realistic and complex narrative themes, there is concern that especially violent video games will desensitize adolescents to aggressive behavior. In addition, there is also the risk of internet safety and engaging with strangers. However, there are investigations that suggest that video

games offer opportunities for virtual displacement of aggression that might otherwise be acted out in the “real world” as well as opportunities to connect with peers and escape into fantasy as ways of coping. As with research concerning internet use, data regarding video games are quite mixed, and much study is needed for a better understanding of the nuances of these activities.

WHEN DOES AN ADOLESCENT REQUIRE TREATMENT?

Psychiatric treatment is indicated for any individual when there is a disturbance in thought, affect, or behavior that affects normal functioning. For adolescents, this would include impairments in a teenager’s biologic functions, such as eating, sleeping, and other daily personal routines, as well as problems with relationships with family and peers, problems in school, and problems in occupational and recreational activities. Although it is true, as noted earlier, that normal adolescence involves a certain degree of emotional and/or behavioral volatility, most adolescents overall have a rather smooth course, punctuated by crisis points that usually resolve quickly.

The major issue for parents, caretakers, and clinicians is making the discrimination between a normative developmental crisis that will eventually self-correct and a behavioral change that indicates a deeper problem worthy of clinical attention. This distinction may not be easy for a number of reasons. First, there are often discrepancies between the way an adolescent looks and how they feel. For example, an adolescent with a depressive disorder who is contemplating suicide may appear no different than before the episode, somewhat quiet and contemplative, or mildly irritable. On the other hand, teenagers with profound insecurity and social phobia may present as arrogant and seemingly fearless. Second, although many adolescents are capable of effective communication, there is often a reluctance to share deeply troubling thoughts or feelings with friends, parents, or other adults. This may be due to developmental lags in expression, but more commonly, it is due to the deep self-consciousness and feelings of vulnerability that are typical of normal adolescence. Consequently, many adolescents are misunderstood by parents and peers, which only compounds a sense of aloneness and personal distress. Third, there may be cultural taboos, stigma, or a sense of

betraying family expectations that obstruct a teenager from expressing emotional or psychological problems. Despite these obstacles, there are important questions clinicians should keep in mind in determining whether an adolescent is in need of treatment:

- Has there been a developmental lapse, for example, a falloff from the trajectory with respect to functioning in school, home, friends, and recreational activities?
- What is the level of emotional distress?
- What is the meaning of the problem to the adolescent? Although a problem may seem minor for an adult, it may carry tremendous weight for the adolescent.
- How vulnerable is the adolescent to stress? Is there a range of effective coping skills, or is the adolescent limited in managing stress?
- What supports does the adolescent have with other adults at home or in the community?
- Does there appear to be a recent onset of a psychiatric disorder? Is there a past history of psychiatric disorder and/or treatment? Is there a positive family history of such disorders?
- How impulsive is the adolescent?
- Is there family psychopathology, such as mood disorders, substance use disorders, or severe conflict?
- Are there major changes in the family, such as divorce, unemployment, and so on, that might seriously disturb the adolescent?
- Are there concerns about physical or sexual abuse or neglect?
- Have there been recent losses in the family or in peer relationships, such as loss of a friend, romantic relationship, failure to make an athletic team, and so on? How vulnerable is the adolescent to loss?
- How capable is the adolescent in managing affect, such as anger or sadness?
- Are there other acute or chronic medical conditions in the adolescent or in the family?
- Are there cognitive limitations, such as mental retardation?
- Have there been any major media events, such as suicides, school shootings, terrorism, or copycat phenomena, that have had a strong effect on the adolescent?
- Has there been a significant trauma to the adolescent outside of the family, for example, date rape, sexual harassment, bullying, scapegoating, and so on?

Answering these questions requires gathering data from multiple sources, including the adolescent, family members, teachers, pediatrician, medical records, or other members of the community. The research literature demonstrates that in children and adolescents, there is a poor correlation between self-report and reports from others regarding behavioral symptoms. Hence, data collection must include more than one informant.

MODALITY OF PSYCHIATRIC TREATMENT

The psychiatric treatment of adolescents can occur on a number of fronts. Treatment may focus on individual or group settings and may encompass interventions from pharmacologic, psychosocial, and environmental perspectives. Thus, the treatment of adolescents encompasses considerations of individual need, family and community resources, clinical impressions, and biologic history. Furthermore, treatment often brings together multiple aspects of the adolescent's world. Legal, academic, medical, and psychological issues, all play potential roles in any clinical intervention.

Biologic Interventions

Biologic treatments primarily involve medication interventions. Agents such as antidepressants, conventional mood stabilizers, typical and atypical antipsychotics, anxiolytics, and psychostimulants, all are used in adolescent populations.

There are other biologic treatments used in the treatment of adolescents such as electroconvulsive therapy (ECT), transcranial magnetic stimulation (TMS), and ketamine treatment; either intravenous infusion or nasal spray.

Adolescent depression can result in significant disability and is potentially lethal. All three modalities are used in the treatment of refractory depression. ECT is currently the most effective modality for major depression that fails to respond to other treatments. Ketamine is also used in the treatment of refractory depression, and if a teen responds to ketamine, it can rapidly reduce suicidality and relieve other serious symptoms of depression. TMS, while shown to be effective in treating adults who did not respond to pharmacologic interventions, it has not demonstrated the same efficacy in adolescents.

Obviously, choosing a pharmacologic regimen is based on clinical and diagnostic impression, as well as the family's and the adolescent's willingness to embrace medication treatment. Furthermore, as for all medication treatments, both the patient and the family must have a sound understanding of the risks, benefits, and potential limitations of this particular modality as well as potential adverse effects, side effects, and alternatives to the proposed treatment. Finally, any consideration of medication treatment in the child population should include an understanding that randomized and controlled trials of specific medications are not always available and that many of the most commonly prescribed medications have not been approved by the U.S. Food and Drug Administration (FDA) for use in children. Nonetheless, the last 10 years have seen a dramatic increase in clinical investigation into the efficacy of pediatric psychopharmacology, and clinicians should understand that keeping abreast of these rapid developments is paramount in pursuing medication options for adolescents. In addition, the FDA black box warnings associated with the increased risk for suicide in antidepressant use in children and adolescents need to be taken into consideration when prescribing these agents. Families must be told of the FDA warnings and helped to understand the risks and benefits of these medications despite these concerns. The American Academy of Child and Adolescent Psychiatry website has instructions for how to discuss these complex issues with parents and teens. The risk posed by having these warnings includes the documented decline in the overall willingness to diagnose and treat psychiatric conditions in young people. Finally, as with pharmacologic treatment of adults, treatment of adolescents may be most efficacious when medications are combined with psychosocial therapies.

A 15-year-old boy was noted by his parents to have a difficult time leaving his computer in the morning. Although the problem was initially relatively well managed with gentle reminders that he was going to be late to school, over time, the boy showed a constant tendency to check his standing on an internet social networking site. This behavior resulted in frequent school tardiness, eventual school refusal, and increasingly poor hygiene. He was referred by his pediatrician for treatment with a psychiatrist, with whom he endorsed concerns that if he did not constantly update his website, his “social score” would decrease and that this decrease would translate into worsening social standing at school. He did not enjoy the constant maintenance of his website but felt powerless to stop and was ashamed of his behavior. He was started on fluoxetine and received a course of cognitive behavioral therapy (CBT) for obsessive-compulsive disorder. Over the next few months, his behavior gradually improved, with decreased anxiety and greater social engagement.

Group Therapy

Group therapy is a useful modality in the treatment of adolescents. It’s a form of psychotherapy with multiple patients led by one or more therapists. Typically groups are comprised of teens of similar ages and with different personalities. Group therapy uses this dynamic and interaction between peers to increase understanding of mental illness and improve social skills. Group therapy facilitates communication among peers in a way in which their feelings and experiences are normalized. As a result of the interaction and engagement, teens participating in group therapy are able to learn about themselves and the impact their behavior has on others and are able to receive feedback from peers. There are many different types of group therapies (e.g., psychodynamic, social skills, substance abuse, multifamily, parent support, etc.), and group therapy is often incorporated into the various therapy modalities such as CBT and DBT.

Psychosocial Interventions

Individual and group interventions include psychoanalytic therapy, psychodynamic therapy, CBT, and interpersonal therapy (IPT)

approaches. All of these modalities, for both individual and group treatments, have been found to be effective for the treatment of a wide range of adolescent problems, including adolescent depression, anxiety disorders, substance abuse, and suicidality.

Psychoanalytic and Psychodynamic Therapies. Psychoanalytic and psychodynamic treatments seek to help the adolescent to come to terms with and thus better understand unconscious conflicts and maladaptive defense mechanisms. In addition, they may be useful in facilitating more adaptive coping skills. These goals are accomplished by a close relationship between therapist and patient and the use of unconscious processes such as transference, countertransference, and resistance. The best candidates for psychodynamic and psychoanalytic psychotherapy are adolescents who have adequate cognitive and language functions to use insight, self-reflection, and the ability to communicate effectively with the therapist. They also must have sufficient ego strength to tolerate clarification, confrontation, and interpretation. Because psychodynamic therapy may precipitate some regression and will, at times, be stressful in uncovering conflicts, the adolescent should be able to tolerate affect and have sufficient impulse control to thwart acting out. Commonly used psychodynamic therapies include classical psychoanalytic psychotherapy, supportive psychotherapy, and psychodynamic psychotherapies based on ego psychology, object relations theory, and self-psychology. As in the treatment of most adolescent disorders, psychodynamic psychotherapy is often conducted in conjunction with other modalities, such as pharmacotherapy, family therapy, and/or other psychosocial therapies. Although these forms of psychotherapeutic treatments are probably the most commonly applied interventions in the treatment of adolescents, the open-ended nature of these modalities has made randomized trials difficult. Many clinicians, however, feel strongly that skilled psychodynamic treatment is immensely beneficial to suffering adolescents.

A 14-year-old girl gymnast began increasing her daily exercise and restricting her diet. She had never achieved menses due to her low weight. She became fixated on the size of her thighs and belly and lost so much weight that her coach and pediatrician did not allow her to participate in athletics. She became increasingly terrified of getting fat, and she secretly exercised any chance she could. She was a perfectionist in academics, as well as in gymnastics. Because of excessive weight loss, she was hospitalized, and the diagnosis of anorexia nervosa, restricting type, was established without comorbid disorders. Following hospitalization with modest weight gain, an outpatient plan was initiated, including regular meetings with her pediatrician for monitoring of vital signs, weekly meetings with a nutritionist, weekly family therapy, and individual psychodynamic psychotherapy. In her psychotherapy, over the course of 2 years, she was able to understand that her perfectionism was a defense against low self-esteem, that she was very angry with her mother, who lived vicariously through her gymnastics and did not validate who she really was, and that she was, as an only child, the focus in her family, holding her parents' marriage together. Over time, she was able to understand the function of her anorexia as a way to avoid her maturation as a woman, as a dysfunctional means of developing some kind of identity, and as a passive-aggressive attack on her parents. With time, her weight increased, she was able to resume her athletics, and she developed close friends.

New research has focused on the process of mentalization and the theory of mind in the psychodynamic treatment of adolescents. Roughly speaking, mentalization can be considered the process by which individuals come to understand the thinking and emotional states of others. In a sense, the recursive thinking that becomes possible in adolescence is directly tied to this therapeutic skill. Thus, one attempts to build on the adolescent's capacity for empathy as their brain matures to the point at which empathy is more readily accessible.

Cognitive Behavioral Therapy. CBT has gained increasing popularity in recent years, and there are a number of studies suggesting its efficacy for problems such as adolescent depression, eating disorders, anxiety

disorders, suicidality, and obsessive-compulsive disorder. CBT aims to help the adolescent to recognize cognitive distortions that lead to faulty interpretations and maladaptive behavior. CBT draws the connection between thoughts, feelings, behaviors, and body sensations and teaches that changing one can alter others. Techniques such as relaxation and contingency reinforcement are used to help the teenager to tolerate affectively charged environments. Treatment is often manual driven, with a specific number of sessions and homework assignments between appointments. This form of treatment does not focus on aspects of unconscious motivations and conflicts. Instead, it focuses on correcting distorted cognitions by modifying information processing.

A 13-year-old boy was noted by his parents to be extremely worried about contracting germs from his surroundings. He insisted on washing his hands more than 25 times a day and would often spend more than 1 hour a day making sure that his body and hands were clean and “free of contamination.” After evaluation, the diagnosis of obsessive-compulsive disorder was made, and the boy and his parents opted for CBT. The therapist started by helping the boy to rank his fears on a scale of 1 to 10, with 10 assigned to objects that he felt were most germ laden and 1 assigned to those objects that were of little or no concern. The boy was then taught both relaxation techniques and how to engage in thought interruption, and he used these techniques in a stepwise fashion to overcome first the more benign elements on his list, then the most severe. Eventually, he was able to modify his behavior by combining his understanding of what worried him most with his capacity to master and eventually overcome his fears.

Behavioral Therapy. Behavioral therapy has been used for years in the treatment of adolescent anxiety disorders, such as simple phobias, panic disorder, separation anxiety, and school refusal, as well as disorders of conduct and oppositionality. This modality is based on principles of operant conditioning and reinforcement and often uses important techniques such as systematic desensitization and contingency management. Behavioral therapy differs from CBT by focusing on

behavior modification and not on issues such as faulty cognitions and distortions.

Interpersonal Therapy. IPT was first developed in 1984 by Gerald Klerman and colleagues in an effort to provide a short, psychodynamically informed treatment for depressed adults. IPT is based on the central premise that depression occurs in the setting of interpersonal conflict and that therapy should focus in a time-limited fashion on specific interpersonal issues as a means of ameliorating depressed mood. Like CBT, IPT is manual driven and often includes homework between sessions. Although it has not been studied in the treatment of adolescents as much as CBT, IPT has been shown to be effective in the treatment of nonsuicidal, nonpsychotic adolescent patients.

Dialectical Behavioral Therapy. Dialectical behavioral therapy (DBT) was developed by Marcia Linehan, given the realization that patients with affective dysregulation, suicidal, and other self-destructive behavior did not respond adequately to CBT or psychodynamic psychotherapy. Her model involves replacing ineffective, maladaptive behavior in response to internal or external stimuli with skillful, adaptive behavior. In DBT, maladaptive responses are viewed as learned responses to painful affect. DBT for adolescents was developed by Drs. Alec Miller, Jill Rathus, and Marcia Linehan. It involves learning emotional regulation skills, developing strategies for distress tolerance, enhancing interpersonal communication, and walking the middle path, and it combines these modalities with mindfulness techniques. DBT teaches that two opposites can be true at the same time, creating a new way of viewing the situation.

Typically, DBT involves the utilization of an individual therapist and participation in a multifamily skills-based group, requiring that parents meet in groups, sometimes with their adolescents. In the groups, parents will learn the skills to increase desirable behaviors and decrease undesirable behaviors of their teens, improve the quality of their relationships with their teens, effectively problem solve and negotiate, and manage unhelpful thoughts and emotions in response to teens.

One aspect of this form of therapy is the availability of parent skills coaching and adolescent skills coaching calls to help the adolescent “in the moment” to learn to utilize skills for mastery in real time and to help the parent support their teen using skills at the moment they are needed.

DBT has been shown to be effective for adolescents with borderline personality disorder, suicidal ideation and comorbid depression, bipolar disorder, eating disorders, and adolescent with impulsive and aggressive disorders.

Mindful Meditation. Mindful meditation has become increasingly used as a treatment for a number of psychiatric and medical conditions in adolescents. While more research is needed, there is evidence for its efficacy in treating anxiety, depression, and pain syndromes and its use in modulating affective dysregulation, impulsivity, and aggression. It is often a standard component of DBT for adolescents. Research has demonstrated that meditative techniques are helpful for general well-being and stress management.

Grouping psychosocial interventions into categories such as psychodynamic therapy, CBT, IPT, and DBT formats potentially creates the false impression that practitioners practice distinct forms of each modality. Although most clinicians are most comfortable focusing on one or two of these therapeutic formats, almost all who treat children and adolescents use particular aspects of multiple treatments. Psychodynamic therapies can be aided by contingency management, and effective CBT is made possible with a strong and, in some cases, unconsciously motivated relationship. Indeed, Ablon and colleagues showed that the best indicator of success in all forms of treatment is less related to the therapeutic modality use than to universally important features, such as the trust that the patient places in the clinician and the relationship that the clinician has with the patient.

Environmental and Systemic Treatments

In addition to psychotherapeutic and biologic interventions, the treatment of adolescents often includes therapeutic involvement in the adolescent's environment. *Family therapies*, for example, aim to help the adolescent to negotiate their changing role in the family dynamic. Because adolescence is characterized by a movement away from the family of origin, many families become potentially distressed and volatile as the adolescent asserts their opinions within the family environment. Family interventions help to clarify family responsibilities and responses as these changes take place.

Similarly, *school interventions* seek to help an adolescent's teachers and school to better understand the specific dynamics between an adolescent's behavior and the school's response to that behavior. School consultants can make huge changes in a teenager's ability to continue along the social and academic trajectory by helping teachers to better understand the adolescent's behavior, by recommending and, in some cases, providing outpatient evaluation, and by suggesting behavioral techniques within the classroom. Sometimes relatively small but psychologically informed interventions such as simply changing classrooms can be immensely beneficial for a troubled teenager.

Finally, there is a growing appreciation of the importance of bringing interventions to the environments in which adolescents are most troubled. *Multisystemic therapy (MST)* has gained increasing popularity for the treatment of conduct disorders among adolescent populations. MST is based on the premise that conduct-disordered teens need interventions in schools, at home, in the office, and in the neighborhood. These interventions must be integrated and coordinated, and current studies document the efficacy of this multifaceted approach in reducing adolescent transgressions of conduct.

All forms of adolescent treatment are complicated by issues particular to adolescent development. Because much of the adolescent patient population is younger than 18 years old, parents must legally and ethically provide informed consent before allowing their children to be treated either with medications or psychotherapy. However, given the emphasis that healthy adolescents place on separation and autonomy, it is clinically paramount that this population understands the risks and benefits of psychiatric interventions and be willing participants in their treatment. Only in extremely rare circumstances, such as severe psychotic states or in the presence of dangerous suicidality, is it clinically useful to prescribe psychiatric medications and other treatments against an adolescent's will. In addition, adolescents may feel differently about their treatment when they are given the opportunity to discuss their feelings without their parents present. For example, side effects such as sexual dysfunction characteristic of many psychotropic agents need to be discussed with appropriate patients in the absence of their parents. In general, clinicians need to treat adolescents as much as possible like the adults they are striving to become while at the same time keeping in mind all of the legal

and ethical considerations that are paramount in the treatment of any underage patient.

Hospital and Residential Treatment

Most adolescents can be treated in the outpatient setting. However, at times, inpatient, residential, or day hospital care might be required. In recent years, largely due to third-party payers and the advent of managed care, access to these more restrictive environments has been quite limited. The primary indication for inpatient settings is typically danger to self or others. Adolescents might be admitted to short-term residential or day hospital programs, many of which are in unlocked settings if there is an acute deterioration in behavior with an inability to function in the home and school environments. The most common diagnostic categories requiring hospitalization include severe depression, suicidal behavior, bipolar disorder, obsessive-compulsive disorder, psychosis, eating disorders, substance abuse, post-traumatic stress disorder, and conduct disorder. Inpatient, residential, and day hospitalizations offer the adolescent a therapeutic milieu for observation and multimodal treatment. The adolescent and family may use these services for medication management, behavioral containment, and the acquisition of better problem-solving skills. In many health care systems, a continuum of services has been established, with initial inpatient care leading to step-down units, such as unlocked residential or day hospital programs that offer a less restrictive environment and gradual re-entry into the community. A primary function of hospital-based care is to develop a comprehensive after-care program with coordination between outpatient services and utilization of school-based programs and other community services.

RESILIENCE AND WELL-BEING

Resilience can be defined as the process of adapting well and maintaining personal and social stability in the face of adversity, such as trauma, tragedy, threats, family and relationship problems, serious health problems, financial stressors, or other significant sources of stress. While there are many components to resiliency, the key elements are connection, awareness, wellness, healthy thinking, and meaning.

Resilience, while it may appear to come naturally for some, resilience is learned and must be cultivated and mastered. It is a set of skills that allow flexibility, innovation, and protection. It's an important skill to master as without it, one is easily overwhelmed and distressed and resorts to maladaptive coping skills and strategies.

Well-being integrates mental and physical health and is a dimension of wellness, which has several dimensions, including emotional well-being (coping effectively with life and creating satisfying relationships) and physical well-being (recognizing the need for physical activity, healthy foods, and sleep). According to the CDC, well-being is considered to be the presence of positive emotions and moods, the absence of negative emotions, satisfaction with life, fulfillment, and positive functioning. Higher levels of well-being are associated with decreased risk of disease, illness, and injury; better immune functioning; speedier recovery; and increased longevity. Adolescent well-being depends on both the adolescent and their environment, with family, school, and romantic relationships being decisive environmental factors.

EFFECTIVE ADOLESCENT THERAPY

The treatment of adolescent patients is quite different from the treatment of latency-age or adult patients. Adolescents can seem both extremely childish and surprisingly mature. In addition, the same adolescent population may undergo rapid and unnerving developmental changes in a relatively short amount of time. These issues substantially complicate the clinician's task. Forming an effective alliance with an adolescent patient requires special attention to already important clinical considerations such as confidentiality and safety. For example, the patient who admits to using illegal drugs may not want their parents to know but may acknowledge a desire for help in understanding this growing drug problem. Although patient safety is always the most important clinical consideration, clinicians must view each situation on a case-by-case basis. Often, adolescents come to their treaters for guidance on issues that they are not able to discuss at length with their parents. A friendly, honest, flexible, and available clinician is absolutely essential for the adolescent to feel comfortable in coming forward with important and pressing issues.

Clinicians also need to be curious about their adolescent patients' worlds. Adolescents will express themselves wonderfully in displacement,

finding voices in the music they listen to, in the television they watch, and in the stories and movies they embrace. Although it is neither reasonable nor possible for a clinician to stay abreast of the pantheon of popular culture, inviting adolescent patients to discuss aspects of their culture that excite them is a valuable means of building trust and of gaining insight.

FUTURE DIRECTIONS

The psychiatric treatment of adolescents is, by definition, a complex endeavor. Because adolescent behavior manifests as a function of biologic, developmental, psychological, and cultural phenomena, the clinician must be prepared to take into account all aspects of the adolescent's world to effect change. We cannot underestimate the impact of social events and political movements on adolescent development, such as climate change, gun control, sexual assault and harassment, discrimination, racism, injustice, and social justice reform. We need to consider the long-term impacts of COVID-19 as well as the impact of environmental and social events on adolescent development.

Furthermore, no clear hierarchy exists among the various determinants of adolescent difficulties. The same behavioral problems among different adolescents can have strikingly different determinants. One irritable teen might have a biologic predisposition to depression, whereas another might suffer primarily from a chaotic home life. A tendency to address only one aspect of an adolescent's presentation risks oversimplifying the extent to which adolescents suffer and misses a valuable opportunity to be maximally effective. Indeed, it is this very complexity that makes the treatment of adolescents so rewarding and fulfilling.

Child Psychiatry: Special Areas of Interest

54.1 Adoption and Foster Care

Dale Aaron Peeples, M.D., and Sandra B. Sexson, M.D.

Adoption and foster care are social institutions that provide substitute care for children and adolescents who are unable to be cared for by their biologic parents in their own homes. Foster care represents a temporary solution to out-of-home care, whereas adoption is aimed at a permanent assumption of parental responsibilities by parents other than the biologic parent(s). Recent data suggest that approximately 424,000 children are in formal foster care in the United States in a given year, with more than 673,000 being served by child welfare systems each year and close to 251,000 entering the system, and slightly fewer exiting the system annually. All of these numbers reflect a slight increase followed by a plateau over the past decade. Informal fostering also occurs outside of the public system, likely doubling the number of children and adolescents affected. Statistics for adoption are more opaque because adoptions are only formally tracked in the public child welfare system, not in the private system. It is estimated that approximately 2.5% to 3.5% of

the U.S. population is adopted. Child welfare data suggest that more than 66,000 children are adopted annually from the child welfare system. Almost half of the adoptions occur through various private arrangements (stepparents, nonbiologic parents who conceived via reproductive assistance, private agencies, or Indigenous Tribes). Public adoptions have grown over the past decade, while international adoptions have seen a significant decrease due to changes in international relationships and shifts in source countries for adoptees. Child welfare statistics show a growing number of children in foster care awaiting adoption over the past decade with most recent estimates at 122,000.

The staggering statistics regarding foster care and adoption demand that psychiatrists and other mental health professionals address the complex needs of this vulnerable population of children and adolescents in the United States. Children in foster care frequently experience multiple placements, and many of those who are reunified with their families of origin are subsequently placed into care again. Children who are adopted are less likely to have another disruption in placement. Currently, parental neglect and the inability to provide adequate care are the most common reasons that children are removed from their homes. Fifty years ago, causes for separation typically revolved around incapacitating parental illness or death or unstable financial situations. Today, the reasons for parental incapacitation are heavily influenced by parental alcohol and drug abuse and all the iterations of poverty. Other, less common, reasons include physical abuse, abandonment, and sexual abuse. Although many children show resilience in the face of all of these stresses, the risk for mental and physical health problems in children in foster care and, to a lesser and somewhat more controversial extent, children in adoptive settings is much greater than that of the general population. Although it appears that many children enter placement situations with vulnerabilities in these areas, the consensus among professionals is that multiple disruptions in placements over time add to this vulnerability, increasing the risk for serious and prolonged mental health problems. This section reviews the history of adoption and foster care in the United States; identifies trends in the

management of out-of-home placement, both foster and adoption, over recent years; and reviews the limited literature on outcomes in an effort to inform the practicing psychiatrist on how best to approach the care of this very vulnerable population.

FOSTER CARE

History of Foster Care

History is replete with examples of out-of-home care for children. For centuries, parents have abandoned children because of unwillingness or inability to care for them. History suggests that over the centuries, religious entities took over this responsibility, typically forcing children into child labor situations. Children from cities, seen as dangerous, were sent to farm families as a source of cheap labor, not only leading to mistreatment but also removing them from their families of origin and community systems permanently because of the distances involved. Group care for these children was developed in the 19th century when orphanages were found to be less costly for the state. Pejorative attitudes continued to paint them as coming from bad families with high risk for bad outcomes. Family reunification remained a possibility although, at the beginning of the 19th century, it required mothers to pay a fine and reimburse the state for costs incurred by the state for the child's care. By the early 20th century, such temporary out-of-home placement was common, leading to the first White House Conference on Care of Dependent Children, which formally endorsed foster care over the institutional model.

Although most of the law on foster care comes at the state level, federal law sets the tone and direction for the states. In a chronologic review of federal legislation on child welfare, several themes emerge, including funding programs to improve child safety and well-being, permanency of placement, and improving outcomes of youth in the child welfare system. The first federal funding of children's services came about with Title IV of the Social Security Act of 1935, which helped set national standards for child welfare. It provided

funds to help support children in single-parent homes but excluded minority families until the Civil Rights Movement. The Child Abuse Prevention and Treatment Act (passed in 1974 and updated in 2010) provides funds to states to prevent, assess, investigate, prosecute, and treat child maltreatment, as well as providing funds for both data collection and child welfare research. Focus on the emotional and developmental needs of children increased with the Adoption Assistance and Child Welfare Act of 1980. This act was aimed at preventing unnecessary separation of children from their families by providing more services for the prevention of removal, as well as efforts toward reunification. It also sought to address the problem of the unstable and continuous cycle of children being in multiple foster homes over extended periods of time. It established mandated 6-month reviews of each child in foster care. Permanency planning was emphasized, with reunification as the primary goal and adoption as the alternative. Over the years, this act was expanded to provide adoption support for special needs children. Under Title XIX of the Social Security Act, foster care children generally receive health care through Medicaid. The Multiethnic Placement Act of 1994 also took steps to improve permanency, particularly for minority children. The law increased efforts to recruit a diverse representation of foster and adoptive families to reflect the backgrounds of those in the child welfare system. It also eliminated discrimination based on race, color, or national origin.

Many children who were removed from their homes were eventually returned to families of origin (up to 75% in earlier studies, with around 57% as recent as 2016). A significant number of those reunited subsequently return to foster placement. The Adoption and Safe Families Act of 1997 sought to provide safeguards to protect children from neglect and abuse while promoting timely permanency plans and holding the child welfare system more accountable. Concerns that prolonged efforts toward reunification had been unsuccessful led to more stringent guidelines regarding permanency planning. States were required to move toward freeing a child for adoption when a child had been in foster care for 15 of the prior 22 months, with permanency hearings within 12 months after the child

went into foster care. Kinship care in the form of permanent placement with a family member became a more popular option in lieu of reunification. The limitations on the aggregate time in foster care also discouraged the prior practice of moving children from foster care back to the family of origin and then back into foster care again over and over, delaying decisions on other, more permanent options.

More recently child welfare legislation has attempted to address those foster children who “age out” of the system, that is, those who remain in the foster care system until transition into adulthood. Initial steps began in 1986 with the addition of an amendment to Title IV-E of the Social Security Act—the Independent Living Initiative. This provided states with funds for preparation for independent living as youth aged out of foster care. This was replaced in 1999 by the Foster Care Independence Act which increased funding to states to help with transition to independent living and provided the option for states to extend Medicaid coverage to the age of 20. All youth aging out of foster care are eligible for Medicaid coverage until the age of 26 because of the Affordable Care Act of 2010. In addition to targeting access to health care, the federal government has also recognized the need of coordinating other services as children age out of foster care. The Fostering Connections to Success and Increasing Adoptions Act of 2008 requires the development of a transition plan at least 90 days prior to a youth aging out of foster care. Ideally, this will help address housing issues, health insurance, education, mentoring, and employment services, as young adults exiting foster care have little or no “family-type” support. Each year, more than 20,000 adolescents “age out” of foster care with limited connections or support systems. In 2018, the Family First Prevention Services Act was signed into law, and continued a trend of working toward maintaining families, and minimizing restrictive placements. It allowed states to use Title IV funds to offer treatment services to the families of youth at risk of entering foster care and continued to develop kinship care and reunification programs. Standards for residential treatment programs servicing foster children were

increased, independent living services were extended to the age of 23, and educational vouchers to the age of 26.

Who Is in Foster Care?

In the United States, there are currently more than 423,000 children in foster care. Although child abuse and neglect occur across all racial and ethnic groups, as a percentage, children of color are over-represented in the foster care system compared to the general population. Multiracial children account for 8% of the foster care population while making up 3% of the population. Black and Indigenous children have a relative risk twice that of the general population. Not only are there more Black and Indigenous children in foster care proportionately, but those in foster care are more likely to remain there for longer periods of time and are less likely to experience permanent reunification or adoption.

There are some positive trends seen over the past decade regarding ethnicity and foster care. Although Black children remain over-represented in the foster care system, they have experienced the greatest reduction as a group of children receiving services, by 25%. Otherwise, the total number of children by ethnicity entering foster care has remained relatively stable. The one exception to this is multiracial children, which increased by a third during that time.

Another group of over-represented youth in foster care is sexual and gender minorities. Often, issues around sexuality and gender identity fuel conflict in the home, resulting in high numbers of runaway and homeless youth who identify as a sexual or gender minority. Overall, they are more likely to experience placement instability, group home placement, and age out of the foster care system. Qualitative studies suggest that these youth frequently experience discrimination in the foster system with care providers rejecting their identity, and caseworkers often assuming reunification may be impossible due to the biologic family's initial rejection of the youth.

Over the past two decades, the number of unaccompanied minors crossing into the United States from the southern border has

dramatically grown, with unstable circumstances in Central America, and U.S. immigration policy both influencing this change. Historically, about 6,700 unaccompanied children entered the United States annually, but over the past decade, those numbers climbed to over 72,000 in 2019. This drastic surge strained resources available to these children, leading to extended delays in detainment facilities. In 2018, this problem was exacerbated when a “zero tolerance” immigration policy temporarily went into effect, separated children from their parents, and reclassified them as unaccompanied minors. Most of these children are males over the age of 14, primarily fleeing Guatemala, El Salvador, and Honduras. They often face desperate circumstances such as violent criminal gangs, poverty, and natural disasters. At a bare minimum, unaccompanied refugee minors experience the stress of adjusting to a new culture and separation from family. In addition, many have been exposed to war, rape, torture, and severe deprivation prompting their immigration to the United States. Subsequently, post-traumatic stress disorder (PTSD), depression, and anxiety are common issues among refugee children. In 2002, Congress transferred the care of unaccompanied children from the Immigration and Naturalization service to the Department of Health and Human Services (HSS) to move away from an adult-oriented detention model to a child welfare-based model. Unaccompanied children are individuals under the age of 18 who have no lawful immigration status and who are without a parent or legal guardian. Initially, these youth are apprehended by Immigration and Customs Enforcement. Those that have an asylum claim are managed by the Office of Refugee Resettlement in HSS, who then assist in arranging placement. Temporary shelters are located in 23 states and house youth while they await a more permanent placement, either sponsorship by a relative, community foster care, or a group home. The average length of stay in a shelter grew from 34 days in 2016 to 93 days in 2018. Benefits for these children as they enter foster care are the same as those for children born in the United States. State child welfare systems monitor their care while in the child welfare system. Additionally, foster parents

receive training in cultural sensitivity to help with the children's adjustment to life in a new country.

There are 574 federally recognized Indigenous tribes with a varying capacity for management of their own child welfare programs. Consequently, some Indigenous children are managed by state protective services. In the state system, they are over-represented relative to their portion of the population and are disproportionally placed into group home and institutional settings. Estimates about the number of children served by tribal organizations are unavailable, and therefore not included in national statistics. In 1978, the Indian Child Welfare Act was passed which reaffirmed and empowered Indigenous tribes to manage child welfare issues. It was put forth in response to the high rates of Indigenous children in foster care, and the fact that they were often placed in boarding schools and group homes away from their reservation, community, language, and culture. Specific plans for services vary from tribe to tribe. In addition to the challenge of operating many different models, services to children on reservations are also challenged by the rural nature of the setting, limited funding, and frequent turnover in local government, which can impact policy. Federal services are available to help Indigenous communities implement culturally sensitive practice model improvement projects.

Children of all ages are in foster care. Estimates in 2019 suggested that 7% of those in care are less than 1 year of age, 35% are between 1 and 5 years of age, 23% are between 6 and 10 years of age, 21% are between 11 and 15 years of age, 11% are between 16 and 18 years of age, and close to 2% are older than 19 years of age. Many of the older children entered foster care younger than 1 year of age. Infants stay in care longer and are less likely to be reunited with their parents. Males continue to represent slightly over half of children in foster care at 52%.

As a group, children entering foster care comprise a high-risk population for both physical and mental health problems. Studies suggest that one-third of children in foster care have at least one chronic medical problem or disability and over 80% will have mental health problems during their lifetime. Estimates suggest that as

many as 80% of children in foster care were exposed to drugs or alcohol in utero and 40% had low–birth-weight either from prematurity or in-utero growth failure; both factors that increase the risk for many medical problems and developmental and mental health problems. It is not surprising that studies suggest that from 50% to 90% (compared to 10% to 20% in the general population and 35% or so in children living below the poverty level) of children who are placed in foster care have significant mental health problems necessitating interventions. In addition, children involved in the child welfare system are at much higher risk for mental health problems than their socioeconomically matched counterparts. Of interest, those entering the foster care system are more likely to get mental health care than those who remain in their homes, regardless of clinical need, leading some to suggest that foster care is a gateway to mental health services for many children. Significant nonclinical predictors of the use of mental health services for children in foster care include older age and being White. In addition, children who have been sexually abused are more likely to access mental health services, as are children living in nonrelative foster care placements versus those in kinship care. Those placed for reasons of physical neglect are less likely to receive mental health services.

There is a growing body of literature illustrating the physiologic changes children in foster care may experience due to early exposure to abuse and neglect. Neurodevelopmental impairment also results from early neglect. In addition to general growth delays, head circumference is decreased in children coming from institutional placements. The Bucharest Early Intervention Project (BEIP) is a longitudinal randomized-controlled trial following children exposed to institutional care and comparing their growth and development to those who were able to find placement in foster care and a community control sample. In this study, when children were followed up at multiple points (ages 5, 8, 12, and 16), electroencephalography patterns consistent with attention deficit/hyperactivity disorder (ADHD) were present more often in institutionalized children than their peers, reflecting immature cortical development. The presence of consistent changes at follow-up

illustrates the potential long-term impact brought on by early neglect. In other adoption studies, both magnetic resonance imaging and diffusion tensor imaging reveal decreased total brain volume in both white and gray matter. For children who found placement in foster care as opposed to an ongoing institutional setting, there was an increase in white matter volume suggesting some neural plasticity and the potential for some catch-up once living arrangements improve. With respect to specific brain regions, studies are mixed regarding both the amygdala and the hippocampus, with some finding increased volume and others reporting decreased volume.

Despite similar experiences in terms of neglect and deprivation, outcomes for children do vary, suggesting that some individuals might inherit resistances to these stressors, while others might be more vulnerable to negative environmental effects. Polymorphisms in genetic sequences may offer some explanation for these different outcomes. Variation in the serotonin reuptake transporter gene (5HTT) is associated with moderating the influence of early adverse experiences and the development of anxiety and depression. Studies in adopted children comparing groups adopted before and after the age of 6 months found that variation in the 5HTT allele did impact the development of emotional problems in children adopted after the age of 6 months. In the English and Romanian Adoptees study, variation in dopamine reuptake receptors (DAT/DRD4) was associated with ongoing ADHD symptoms at the ages of 11 and 15, suggesting that children with the high-risk haplotype did not outgrow ADHD symptoms as rapidly as their peers. In the BEIP study, allele variation in the dopamine reuptake catechol-O-methyltransferase gene resulted in significantly lower rate of depressive symptoms in children with one of the variations.

Reviews of the literature consistently demonstrate that minority children, particularly Black children, are less likely to receive services than their White counterparts, despite both having high behavior dysfunction scores on screening instruments. This disparity suggests that caregiver, child welfare, and court officials' attitudes regarding mental health service needs may be culturally biased, influencing which children in need get mental health services. Psychotropic

medication prescribing practice in the foster care population is another area of major concern, with an over-reliance on medication in place of psychosocial interventions. Given that the foster care population is very much at risk of mental health problems, it may not be surprising that this population receives psychotropic medications at rates of two to eight times that of their peers. The concern is whether evidence-based psychosocial interventions, which are often difficult to manage in unstable living environments or in homes with multiple foster children, are being employed when indicated. Certainly, foster children are at higher risk for prenatal exposure to substances, malnutrition, and family history of mental illness, all of which could necessitate a pharmacologic intervention. However, psychological factors such as grief, adjusting to a new environment, and attachment issues may manifest as internalizing and externalizing symptoms causing a psychiatrist to rush to medicate when a psychosocial intervention is in order. This is a particular risk when the history is frequently obtained from sources that only know a portion of the child's history.

Reasons Youth Enter Foster Care

The reasons that children and adolescents require placement outside their families of origin are complex, involving problems with the parents, child factors that contribute to failure of the nuclear family, and societal or environmental conditions. Biologic parents' problems may place their children at risk of neglect or abuse. Substance abuse, mental illness, intellectual disability, domestic violence, and lack of social support systems (low socioeconomic status and being a single parent) all negatively affect the parents' ability to provide adequate care for their children. The child may also bring factors, such as temperament, into the situation that increases the risk of parental failure. Children with difficult temperaments and those with the inability to self-regulate effectively make parenting more difficult. However, even the child with an easy temperament may be at increased risk of neglect in a chaotic and demanding family. Children with cognitive and physical disabilities also may be

more difficult to parent. Children who have temper tantrums and oppositional behavior bring more stress to the already vulnerable parent–child interaction. The more needs a child has, the more difficult it is for parents to provide care that is adequate. Finally, adverse environmental conditions may contribute to the failure of capable parenting. Examples that increase stress in families include poverty, unemployment, decreased or absent social supports, and poor nutritional resources. Effective interventions to prevent the need for foster placement, as well as interventions aimed at providing substitute care, must address all of these components if they are to be successful. Too frequently, the child is moved to foster care, but many of the issues involved in the ongoing lack of fit for the child in the family are not aggressively addressed.

Not all children who encounter child protective services (CPS) end up in foster care. After a report of neglect or abuse is received, the caseworker determines if there is enough information to open a case. If there appears to be a safety risk, a case opens, and an investigation commences to determine if the allegations are "substantiated" or "unsubstantiated." Depending on these findings, a number of options are available. A case could be closed, the family could accept voluntary services, or a referral could be made to the court. For those families that go to court and are separated, a permanency plan is developed focusing on the child's eventual exit from the foster system. Sometimes a guardian ad litem is appointed by the court to represent the best interests of the child. If the termination of parental rights is considered, the court seeks clear and convincing evidence that the parent is unfit.

The prior description of CPS procedure focuses on formal steps with court supervision. However, families can accept voluntary recommendations which remove them from court oversight. Typically, this scenario comes about when a family voluntarily accepts to move a child to a kinship placement at the beginning of a CPS investigation. States are not required to track this type of arrangement, but estimations suggest this "hidden" or voluntary kinship foster system is similar in size to the formal foster care system. Criticisms of this approach are that the procedure is

coercive toward families (with the threat that they will lose their child if they do not accept the safety plan), that the process lacks judicial oversight, that a clear reunification plan is often lacking, and that kinship care providers don't receive funds and services they would qualify for if CPS went through the formal placement process. Benefits include minimal disruption to the child, flexible visitation with parents, and reduced demand for state resources. Increasingly, additional funding is allotted to support these types of arrangements, but it still remains less than a family would receive if the kinship placement went through the court.

Outcomes

Outcomes for children and adolescents placed in foster care are hard to assess, but The National Youth in Transition Database has monitored youth transitioning out of foster care at 17, 19, and 21. The survey looks at financial self-sufficiency, education, social support, homelessness, and high-risk behaviors (substance use, incarceration, pregnancy). By the age of 21, 86% have part-time or full-time employment. Sixty-nine percent have achieved a high school diploma or GED, with 7% having obtained further vocational training or an advanced degree, and 24% report they are still engaged in some form of education. At 17, 94% report having a supportive adult in their life, but by 21 this number drops to 87%. High-risk behaviors are elevated at all points of the survey. At age 17, 27% report a history of substance use treatment, and 11% report treatment in the past 2 years at age 21. Thirty-three percent note incarceration by the age of 17, with 20% having experienced incarceration in the past 2 years at 21. Childbirth numbers gradually increase with age, and 22% report having had a child by 21. Homelessness was experienced by 27% of 21-year-olds. In this data, four subgroups of young adults transitioning out of foster care can be identified. Forty-five percent appear resilient, having obtained educational skills and employment, while avoiding most negative outcomes. The second largest group is "parents on public assistance," individuals who typically made gains in education, but

had children early and subsequently have limited workforce involvement and are more likely to receive public assistance. Unsurprisingly, this group is three-quarters female. The “troubled and struggling” group comprises about 18%, and has high rates of homelessness, educational and employment deficits, and higher rates of substance use and incarceration. The last group is the incarcerated (15%) who have the highest rate of arrest and substance use, high rates of homelessness, and are over three-quarters male. It can be argued that youth who remain in foster care at 17 may not be representative of all youth who encountered the foster care system, such as those who quickly reunited with family. Still, these statistics show the significant challenges faced by these young adults and the need they have for continued social support during this transitional phase of life. The average young adult is not financially independent until the age of 26, these young adults could broadly benefit from ongoing mental health and substance use services, post-high school educational support, housing and job access, and childcare programs.

Outcomes during foster care look at issues related to the disruption of care, given that improving placement stability is perceived as a major goal in foster care placement. Over a 12-month period, as many as 50% of children in placement experience a disruption, resulting in movement to another home or a more restrictive environment. Child characteristics thought to increase the risk of placement disruption include older age, general health problems, a mental health diagnosis, family history of mental health issues, sexual and gender minority identification, and presence of behavior problems, especially those related to conduct disorders. Studies assessing the impact of gender are mixed, but recent reviews suggest females may now be at greater risk of disruption. Children removed for physical and sexual abuse are also more likely to have trouble with a placement compared to those removed for neglect. In addition, the experience of stress in the foster family in 6 months prior to the child’s placement has been associated with increased rates of disruption, while foster parents that are trained to deal with special needs are more likely to continue caring for

challenging children. Emerging data that links the number of behavior problems reported by the foster parent per day with increased disruption of placement suggest the need to focus interventions on reducing the child's behavior problems and increasing the foster parents' ability to deal with them. Children in kinship placements seem less likely to be disruptive than those in nonkinship foster care. Reasons for this are unclear. Typically, there are fewer children in kinship placements, which may affect a family's ability to manage a given child's behavioral problems. In addition, attachments in kinship placements may be easier to foster. Disruptions appear to be less likely when foster parents are warm and child-centered and when foster children are open to fostering. There are well-established, evidence-based interventions focused primarily on teaching parents to intervene appropriately with the children in their care. However, few of these have been implemented with foster parents on a wide-scale basis. Policy and systems also play a role in placement stability for children. There are times when the state may mandate a move for a child to reunite siblings, switch to a long-term placement, or merely try to deal with the reality of funding issues. When children have a high level of turnover in caseworkers, they are at greater risk of changing placements. Subsidies for guardianship and adoption placement, as well as hiring graduate-level social work staff, are associated with improved outcomes in placement. Without a doubt, multiple disruptions lead to increased problems for the child and for the caregivers.

Since the 1980s, child welfare systems have focused more on reunification with the family of origin as a permanent placement option. However, over time, some leaders in child welfare have questioned whether this goal is always appropriate because many children who are reunited go back into foster care. Lower rates of reunification occur when the child is very young, an adolescent, or Black. When the child is removed because of neglect there is a lower likelihood for successful reunification. Family variables that decrease the rates of reunification include poverty and failure to visit when children are in foster care. Longer time in foster care, as well as kinship placement, also lowers the reunification rates. Still, over the

years, child welfare has assumed that reunification is the best outcome for children in foster care based on the need for continued contact with the biologic family and the fact that extended periods in foster care usually lead to less stability. However, recent data has accumulated suggesting that reunification may not always be the best option. Reunited children in several studies have had more behavioral problems, engaged in more risky behaviors, and had poorer life-course outcomes. Better outcomes for those who were not reunited included higher scores on intelligence testing, increased general well-being, and fewer problems with repeated criminal arrests. Some of the major parental issues that lead to foster placement—specifically substance abuse—are not easily remedied in the parent, limiting the likelihood of successful reunification. Intensive interventions to support families with mental illness, substance abuse, homelessness, and severe poverty are not readily available in most settings. Reunification in the right situation is still a laudable goal, but child welfare agencies should openly confront the pros and cons in each situation in an attempt to make a permanent decision in a timely manner that is best for the individual child.

Since the 1990s, kinship care has become more popular as a formalized placement alternative to traditional foster care options. Federal laws such as the Personal Responsibility and Work Opportunity Reconciliation Act of 1996, the Adoption and Safe Families Act of 1997, and the Fostering Connections to Success and Increasing Adoptions Act of 2008 have given preference for child placement to kinship arrangements. Most states have options for reimbursing kinship care, although frequently at lower levels than nonkinship foster care. Theoretical advantages to kinship care include the preservation of the child's sense of family and cultural identity; increased access to relatives other than the kinship provider; greater stability in placement; maintenance of religious, ethnic, and racial values; and, potentially, the existence of previously established relationships with the children that may facilitate attachment relationships. Kinship care provides a way for the child's family to be preserved even when reunification with the family of origin is not possible. Children in kinship placements as compared to

those in foster care also show greater mental health stability and fewer behavioral issues. However, there are numerous concerns about kinship care. As a group, kinship caregivers are more likely to be single, older, with more health concerns, less education, higher rate of unemployment, and from lower socioeconomic status. Frequently, kinship caregivers are grandmothers who parented the foster child's parent, which causes some concern among child welfare agencies. Child welfare workers report having more difficulty supervising kinship placements, citing that kinship caregivers frequently do not adhere to parental visitation restrictions. Some of these negative differences may be alleviated with more equitable resources and support services and increased supervision commensurate with that provided to nonkinship foster parents. Continued research on kinship care is necessary to provide child welfare agencies with reliable data on the long-term outcomes of children reared in either kinship or nonkinship foster placements to inform future decisions.

Additionally, it is being recognized that the majority of kinship arrangements are informal, meaning the court and the public child welfare system have not helped broker the arrangement between the birth parent and the caregiver. Approximately 1.76 million children are in this type of living arrangement, six times as many when compared to families that have formalized the agreement. Unfortunately, this creates obstacles for both the caregiver and the child. Without proof of legal rights, obtaining services ranging from health care to school enrollment may be impossible without assistance. Grandparents find themselves most commonly serving in the role of the informal kinship caregiver. Often they are reluctant to seek out legal action to terminate birthparents' legal rights. They retain hope that the social circumstances (often substance use) that led to the current living arrangement will correct itself, and the child will be able to live with the birth parent once more. Although this arrangement is often prompted out of compassion for the biologic parent, it limits a child's access to social services, and places a child at risk in terms of permanency of placement, as they can be removed from the home at the whim of the birth parent. Policies vary

from state to state, but informal kinship caregivers have options beyond adoption that allow them to seek services for children. Unfortunately, these generally require some out-of-pocket expense for legal fees, which may be an obstacle to some families. Seeking guardianship will allow a caregiver to access services for a child, but in some states, it would also require the termination of parental rights. Legal custody, as opposed to guardianship, is appointed by the family court instead of probate court, but otherwise, quite similar in that it often requires the proposed custodian to provide proof of the birthparents' inadequacy, and in some instances, parental rights will be terminated. Some states offer a *de facto* custody option. This is also managed by the family court and requires that the care provider prove that they provided for the child's needs for a period of time (often 6 months to a year) without the involvement of the birth parent. Biologic parental rights are not terminated, and no concerns about the birthparents' inability to raise the child need to be discussed in court. However, once the ruling is made the birth parent is not allowed to remove the child from the de facto custodian without court approval.

Treatment Foster Care

Treatment foster care (TFC) is a well-researched, evidence-based approach that refers to interventions focusing on at-risk children who are unlikely to otherwise be managed in the community and would thus find themselves in an institutional placement such as a mental health facility, juvenile corrections, or a secure residential facility. These are children who have experienced significant trauma, abuse, and neglect which have begun to manifest as major mental illness or budding antisocial behavior. TFC interventions are similar to a number of older services, such as "specialized foster care," "wraparound" foster care, and multidimensional TFC. All try to help at-risk children by developing strong community links, therapeutic training for foster parents, providing treatment directly in the home, limiting the number of children in the home, providing crisis intervention services, and treating the foster parent as a professional

as well as providing additional payment to the foster family. Children show an improvement in social skills, a reduction in problem behaviors, and an increase in placement permanency. Such interventions may help reduce antisocial behavior, and subsequent incarcerations for youth in foster care. Additionally, children receiving such services have also shown improvements in school attendance, homework, and employment.

Mental Health Problems

Children in foster care struggle with many psychological issues because the reasons that they enter foster care have almost universally potential negative effects on psychological development and emotional adjustment. The events leading to the need for placement are adverse, often involving abuse, neglect, exposure to violence, and inconsistent parenting. Despite the fact that the foster placement may be a safer environment, it carries with it the loss of familiar surroundings and familiar caretakers, caretakers to whom the child usually has some attachment despite the abusive or neglectful relationship. In addition, foster placements typically are not planned but occur abruptly with little opportunity for preparation. How children handle these major stresses depends on the reasons for placement, the age and/or developmental level of the child, the old and new home environments, and the support systems available for the transitions. Each separation emphasizes the rejection and feelings of abandonment, compromising the ability of the child to develop effective emotional attachments. Younger children are particularly vulnerable to attachment problems, which may affect their ability to relate effectively in the future. Their inability to trust their caregivers to provide them with consistent predictable care leads them to mistrust future relationships and exhibit behaviors of avoidance, anger, and/or oppositionality. These behaviors in turn make it hard for even the most nurturing of adults to continue to offer the child much-needed nurturance. Attachment to foster parents may also be complicated by complex and ambivalent feelings of being unfaithful to the biologic parents when children open up to a

relationship with a new caregiver. Typically, children removed from their birth parents blame themselves, perceive themselves as unlovable, and feel guilty about the separation. When children cannot trust their caretakers, their psychological development is complicated by the use of primitive defense mechanisms, and they are at risk of developing pathologic narcissism, which may lead to an inability to express empathy. Sometimes children have experienced care in their families of origin or in deprived placements that are so pathologic that they may develop reactive attachment disorder or disinhibited social engagement disorder, which requires immediate and intensive intervention to avoid catastrophic outcomes.

Children who have experienced pathologic care during their younger years also have difficulties regulating their behaviors, leading to problems with modulation of their emotions, aggression, and even attention and activity levels. Self-regulation is learned through a protective process with a predictable caretaker, an experience many foster children lack. In addition to the pathologic care, there may be other risk factors for regulatory problems, including prematurity, low birth weight, and exposure to drugs and/or alcohol in utero. The world of the abused and/or neglected child is one of extreme unpredictability, which leads to high levels of anxiety and fear. They are unable to sleep, a problem that contributes even further to a pervasive inability to regulate behavior.

Not only have young children in foster care experienced loss of their primary caretakers, who, in many cases, were unpredictable and pathologic in their caregiving, but many have also been traumatized overtly by physical and sexual abuse, as well as exposure to violence. Some may meet full criteria for acute or PTSDs, but many will have subthreshold symptoms that need to be addressed. The stress systems in the brain may be activated in such a way as to keep the child in a chronic state of arousal, an issue that more recent research suggests may impair the child’s ability to manage stress in the future. Early and intensive interventions may remediate these problems at a neurobiologic level.

Children in foster care also have much higher risks for developmental disabilities than children who are not in foster care.

Risk factors that lead to foster care may affect development. These include such negative influences as direct effects of maltreatment (brain injury, spinal cord injury, burns), as well as prenatal exposure to toxins such as alcohol and other drugs. Parental incapacities may have genetic components that affect the child as well, including intellectual impairments and language delays. Developmental disabilities also increase the risk that children will go into foster care and stay in out-of-home care longer, that foster placement will be less stable, and that other problems either within the child or the families involved will be exacerbated.

What about the Foster Parents?

Foster parents are asked to provide a nurturing and accepting environment for children who have had numerous negative and unpredictable experiences with adults in their environment, who come to a “temporary” relationship with ambivalence and difficulties with trust and attachment, and who then frequently test in numerous ways the foster parents’ acceptance of them within their families. Foster families have to deal with frequent, occasionally less than helpful, intrusions into their lives by caseworkers and other supervisors of foster care while sometimes getting little if any support for this challenging and difficult task. Furthermore, they have to do this knowing that their attachment to the child is likely to be disrupted, often under situations that they do not support, such as sending a child back to parents who have a history of being abusive. Foster parents experience grief and loss as children enter and leave their care. They experience rejection and opposition from children under major stressful conditions. Although most placement agencies provide some education to prepare parents for the challenges of foster care, ongoing training specific to the individual child’s needs and support systems to help the foster parent deal with their sense of loss and grief while continuing to provide nurturing support may improve outcomes for both the foster families and the children placed in their care. Professionals working with foster children and foster parents must address these important issues to facilitate

optimum outcomes. The development of rituals for entering and leaving families and careful documentation through scrapbooks and photo albums may provide continuity in the life of the child moving across placements, as well as a historical record for the foster family.

The Psychiatrist's Role

The child and adolescent psychiatrist, along with the entire team of mental health professionals, is in a unique position to advocate for and provide effective interventions for the highly vulnerable population of foster children in the United States. In 2015, the American Academy of Child and Adolescent Psychiatry issued an updated guide outlining best practices in caring for children in foster care. Recent trends have led to increased use of psychotropic medications for children in foster care, relative to other youth with Medicaid coverage. Due to a combination of legitimate concern for safety issues surrounding these medications and state budgetary concerns, increasing attention is paid to prescribing practices of physicians treating children in child welfare services. Subsequently, before considering a medication, it is imperative to conduct a comprehensive mental health assessment (including, whenever possible, reaching out to biologic parents for history), and to identify any medical or developmental issues. Immediate intensive interventions are needed that address the breadth of the problem—not just prescribing medications, but also offering intensive parent training to foster parents specific to the child they must parent and implementing other psychosocial treatments along with psychopharmacologic treatments that are evidence-based for the disorders identified. Unfortunately, evidence-based nonpharmacologic interventions are frequently unavailable or poorly reimbursed, including intensive parent training. Child and adolescent psychiatrists often struggle with little continuity of information about the child's functioning, therefore limiting appropriate decision making as well as few available resources for consistency in evidence-based psychosocial interventions.

When medication is indicated, educating all parties involved in the child's welfare is essential, including obtaining assent from the child. Estimates of the number of children in foster care using these medications are two to eight times that of age-matched peers. When it is determined that a child will benefit from a pharmacologic intervention, consider a conservative approach. Avoid starting multiple medications or making multiple changes at once. Follow-up with the patient in a timely manner when changes are made—ideally 2 weeks after an initial visit. If a medication does not appear beneficial, confirm that the dose and duration are appropriate, and then remove the medication by a gradual taper if it truly poses no benefit. Monitor for side effects, including checking vital signs and weight regularly. When possible, use FDA-approved options and discuss "off-label" use with all parties when such an approach is necessary. When polypharmacy is necessary, clearly explain the role of all medications to the child and the caregivers. Try to avoid using medications of the same therapeutic class together for extended periods, try to avoid using doses above the maximum suggested recommendation, and try to avoid the "as needed" use of medications. In preschool-aged children, be very judicious about medication use. The Texas Department of Family and Protective Services and The University of Texas at Austin College of Pharmacy developed a comprehensive guide for prescribing psychotropic medications to foster children, which clinicians can use for further guidance.

It is necessary to keep the best interests of the individual child always at the forefront in assessment and intervention strategies and advocate for the child for permanency planning that considers the child's attachments, predictability, nurturance, support, and safety. Insisting that foster parents and families are involved in the treatment is also mandatory, avoiding the all-to-frequent custom of having a caseworker (or even a "transport" person with no information) brings the child to the psychiatric appointment without the involvement of the caregiver. Custody assignments should foster the child's sense of belonging within a system and should avoid disruption of strong psychological ties unless physical or emotional well-being is

compromised. Psychiatrists are uniquely qualified to evaluate these attachments and support systems and recommend and/or implement treatment interventions that are evidence-based. In addition, as care providers, psychiatrists must advocate for the availability of effective services, which, while never readily available, may become even more limited as an effect of the expanding influence of Medicaid and managed care. Almost all children in the foster care system have Medicaid coverage. The number of psychiatrists accepting Medicaid continues to drop, and presently, only about a third of practitioners are willing to take on new patients with this coverage. In the context of the national shortage of child and adolescent psychiatrists, this misfit between payer source and provider means many foster children do not have access to care.

Looking to the Future

Although progress in understanding the problems and needs of children whose families of origin cannot successfully care for them continues, the field of foster care faces unanswered questions. Maltreatment and neglect have established negative effects on the growing child. Multiple placements with failure to provide consistent care over time lead to negative outcomes. Nonetheless, many questions as to how best to intervene are often controversial and, more often, difficult to implement (even when evidence indicates an appropriate intervention) because of limited resources. Children and adolescents in foster care must have physical and mental health assessments and interventions beyond medication management from the very beginning of care. Foster parents need to be involved in these interventions. Agencies need to provide more education and individualized support to foster families who are providing care for these challenging youth. Further research is needed to assess the viability of family preservation, early determination of the need for out-of-home permanency planning, and the advantages and disadvantages of kinship care over nonkinship care. As services shift away from institutional and group home settings, interventions are needed for youth with severe behavioral issues and developmental

needs. Implementing more organized support for adolescents who “age out” of foster care is a continuing challenge.

ADOPTION

History of Adoption

Adoption is a practice through which children whose parents are unable to provide for their care are supplied parents, often providing the adoptive parent(s) much-desired children. The practice is ancient and documented throughout history. Prior editions of this volume have summarized the history from ancient Babylonian times through today’s practices. It was not until the 1850s that adoption was first recognized legally in the United States. Previously, informal adoptions often resulted in indentured servitude and child labor. In 1851, Massachusetts passed a law on adoption that integrated concepts that are still important. The law required judicial approval, biologic parent or guardian consent, and the determination that the adoptive family was able to care for the child. Under these new laws, children were accorded legal membership in the family, although sometimes without access to the inheritance. Children’s needs became an established priority.

Historically, adoption records, when available, were not confidential. Typically, the birth certificate was not changed. In the early 20th century, social workers implemented the concept of *closed adoption*, establishing secrecy among the triad of the adoptee, birth family, and adoptive family. Social workers tried to match adoptees with adoptive parents based on race, religion, and physical and intellectual attributions. These efforts at secrecy were felt to protect the privacy of all involved, enhance permanency, and help the child avoid the social stigma of illegitimacy. Sometimes adoptees were not even told that they were adopted. Obviously, many children were then, and still are, considered unadoptable. The practice of secrecy is controversial. Historically, concerns for all parties in the adoption process were made to argue in favor of secrecy. First, among these was the idea that the adopted child might experience confusion

about their identity development and who their “real parents” were. Second, the adoptive parents might feel that they did not have the right to act as the child’s “full parents.” Finally, there was concern that the birth mother might not be able to move on from the loss of giving her child up for adoption due to the ongoing contact, thus prolonging her grieving process. Initial studies went on to refute such concerns. Additionally, as the face of adoption shifted in the United States, openness became unavoidable in many cases. Children adopted later in life through foster care are obviously aware of the family of origin. Similarly, children cared for by extended kin are often encouraged to maintain a relationship with their biologic parents.

Open adoptions, in which records are open and adoptive children may actually have contact with biologic parents, have become more common. The degree of openness varies from family to family, ranging from a one-time meeting between the biologic mother and the adoptive parents to ongoing regular contact with the biologic family. Although research is limited, recent studies eliciting feedback from adoptive parents have suggested that contact between the family of origin and the parents undertaking the adoption results in a higher comfort level with the adoption process for the adopting family, as well as instilling greater empathy in them toward the birth family. Adoptive parents have indicated that they are able to control boundaries with birth families and generally note that they also feel they have a good level over control of communication. As this contact improved empathy toward the family of origin, it also may lead to more positive perceptions about the adopted child’s behavior. Having an agreed-upon and predictable structure for future contact is also seen as a positive to families. As contact continues, adoptive parents note fewer concerns that the biologic parents may seek reunification, as trust between the two parties grows. Contact also reduces fears that adopted children have about their biologic parents. They report less stress and worry about the safety and well-being of their family of origin. Similarly, it is felt that some connection and openness can help them to better deal with mental health issues that the biologic parent may be experiencing. This preliminary data are limited because the responses are almost totally from the

adoptive parents, studies are small and nonstandardized, generally recruitment of subjects is through convenience samples, and most are focused on the adoption of White infants. Still, the data offer some newer insights into the management of openness in adoption.

With societal changes, such as increased use of birth control, legalization of abortion, and the decreased stigma of single parenthood, the latter third of the 20th century saw fewer infants available for adoption, and both older children in foster care and children from other countries became potential adoptees for families in the United States. The goal for adoption of older children shifted from historical beginnings, when the benefit was for service to the adoptive family, to the psychological benefit of the child. Children from other countries began to be adopted in the United States after World War II and again after the Korean War, raising the controversy over transracial or transcultural adoptions, one that is not resolved. Recently international adoptions have been in global decline due to shifts in cultural attitudes and regulatory processes, but the United States remains the largest destination country for international adoptions. Previously Russia and Guatemala were a source for many international adoptions, but now China, Columbia, India, South Korea, Bulgaria, and Haiti have the most children placed in the United States annually. In many cases, both with international adoptions and to a lesser extent with adoptions from foster care, the physical appearances of the child and the parent are obviously different, leading to the designation of “visible” adoptions.

Epidemiology of Adoption

Adoption is a well-established institution involving huge numbers of children and adults over the years. Although relevant statistics have not been routinely compiled, estimates suggest that between 2.5 and 3.5% of children in the United States are adopted, with more than 2% in nonrelative adoptive placements and another 1.5% in relative adoptions, including stepparents, who account for a significant number of “relative” adoptions. Foster care adoptions, have gradually increased with the push toward permanency planning, and

now represent about 40% of adoptions. Approximately 120,000 to 130,000 children are adopted each year, but this number has varied widely, with only about 50,000 annually in the 1940s and highs of 175,000 in the late 1960s and early 1970s.

Children are adopted in a number of different ways. Infants may be relinquished by their biologic parents and adopted through private agencies or through attorneys, physicians, or clergy. These children are placed in adoptive homes either from the hospital or after a few weeks in “private” foster care. More and more of these adoptions are “open,” allowing initial contact with biologic parents, particularly mothers, and in some cases, ongoing contact between the adoptive and biologic parent(s). Although statistics on this group are not being collected, it is estimated that approximately 50,000 children per year are adopted in this manner. A second group comprises international adoption—the practice of adopting children from outside the United States. This group continued to increase over much of the last two decades, often averaging close to 20,000 adoptions annually, until recent declines due to geopolitics. In 2019, there were just under 3,000 international adoptions. These adoptions typically are arranged through agencies, and a total average of over $30,000 and take anywhere from 3 months to 3 years to complete depending on the source country. The average age of adoption has gradually increased, and it is now relatively rare to have an international adoption completed under 1 year of age. A little under half of the international adoptions are completed before a child is five. These children may have had less than optimal care in orphanages prior to adoption. They were removed from their countries of origin and had little or no information about their biologic families. Finally, children may be adopted from the foster care system. As many as 66,000 children or adolescents are adopted annually through the child welfare system. However, over a quarter of children in foster care are waiting on adoption. These children typically have been in temporary placements, sometimes for a number of years. These adoptees are more likely to be from a racial or ethnic minority, and more than half are 6 years of age or older and may have

experienced abuse and neglect, as well as multiple foster care placements.

Legislation continues to head in a progressive direction, gradually removing some of the barriers to adoption and opening the door for nontraditional adoptions, including single-parent, sexual minority, and transracial possibilities. The 2015 Supreme Court ruling of Obergefell v. Hodges recognized the right of same-sex couples to marry. One factor necessitating this equal protection was the protection of family well-being, and subsequent rulings have extended this decision to protect the rights of same-sex couples to adopt. Some states have attempted to prevent sexual and gender minorities from adopting by contracting private religious organizations to assist with adoption placement, who then use decline services on the grounds of “religious freedom.” Gay and lesbian couples are more likely to adopt through the foster care system than heterosexual couples, and overall adoption rates are higher in states that have policies in place that are friendly to sexual minorities. Consequently, these families do a great service to many children remaining in foster care and are generally also more willing to adopt transracial children. As openly gay families having the ability to adopt children is a relatively new phenomenon, longitudinal studies are just beginning to provide some outcome data. In early childhood, there appears to be no difference in internalizing or externalizing behavior by parent and teacher reports in children raised in gay, lesbian, or heterosexual families. Further, there are no differences in gender role behavior in these children. Play preferences in young children appear less gender stereotyped in children reared by homosexual parents, particularly by lesbian mothers. Studies have also found that reduced parental stress is associated with better child adjustment. Consequently, state and federal policies that minimize discrimination against gay and lesbian parents can benefit their children as well. The topic of adoption by transgender parents is a relatively new issue, and there are no specific legal barriers to this group, but in reality, they often face discriminatory attitudes, and many lawyers advise disclosing gender status early to avoid last-minute disruptions to the adoption process.

Approximately, 40% of all adoptions are transracial or transcultural, meaning that the race, ethnic, or cultural origin of the child is different from that of one or both of the adoptive parents. This is most common in international adoptions, where 84% are transracial, but also seen in private adoptions (21%) and domestic adoptions (28%). Transracial adoptions in the United States initially involved only overseas adoptions, but in the 1960s, some transracial domestic adoptions began to occur. Parents were initially encouraged to de-emphasize the importance of racial differences to facilitate the child's integration into the new family. More recently, parents are encouraged to discuss race and focus on the positives of cultural diversity, as well as acknowledge to their children that they are living in a racialized world to help validate any experiences with microaggression or overt racism that may be directed at the child. Recently, many studies have begun to focus on two issues—how to promote the development of a racial/ethnic/cultural identity for a child and how to promote a child's awareness and ability to cope with racism. Contact with members of the child's racial community is helpful but infrequently occurs in transracial adoption. Having such connections may help children cope better with experiences of racism. Also of importance in the United States are the experiences of Black children adopted into White families compared to Black children adopted into Black families. Researchers have described more identity issues in these populations, with Black children reared in Black families identifying themselves as Black much more frequently than those reared in transracial settings. Findings are complicated because multiracial children were included in the "Black" population. Although highly contentious, both politically and socially, review articles conclude that transracial adoption leads to a majority of satisfactory outcomes, similar to other samples of adopted children after infancy.

Obviously, adoptees enter the adoptive family with different life experiences. Those who are adopted as newborns experience family life and development much like children reared in biologic families. However, the majority of others come from preadoption experiences

of severe deprivation, traumatic life experiences, and multiple disruptions in caregivers before adoption.

Developmental Issues in Adoptive Families

Although most adopted children seem to progress along typical developmental trajectories, often even demonstrating developmental catch-up after adoption, there are some developmental challenges encountered in the adoptive family that are peculiar to the realities of the situation. Numerous authors suggest that there is an element of loss, embodied in the process of relinquishment, in the psychological development of most adoptees, and that loss, particularly loss of the biologic child that the adoptive parents were not able to have, may be an important psychological issue for the adoptive parents as well. These losses may affect the attachments of the child to the parents and vice versa, attachments that are necessary for typical development to progress. Benoit, Nickman, and Rosenfeld grouped these losses into three categories: *Overt* losses of environmental stability, including relationships; *covert* losses, which embody how the children think about the reasons for adoption and the effects that being "given up" may have on developing self-esteem; and finally *status* loss, which arises from feeling stigmatized by the fact of the adoption, a loss experienced generally but more commonly in transracial or international adoptees. These elements of loss may contribute to difficulties that the child may have in establishing strong attachments to the adoptive family. The parents may also have ambivalence regarding the adopted child, sometimes having failed to mourn the loss of their own fertility. This ambivalence, along with extended-family attitudes that may be unsupportive of adoption, can impair the adoptive parents' ability to attach wholeheartedly to the adopted child. Delays in the finalization of the adoption may also cause adopted parents to have some reservations regarding attachment for fear of further disappointment and loss. Thus, one of the first major developmental tasks for the adoptive family is the facilitation of successful attachment. Attachment difficulties are more complicated when adoptions occur after multiple disruptions in care

over extended periods of time or after prolonged periods of institutional care. In these cases, immediate psychological interventions are imperative.

Adoptive parents have the additional responsibility of telling their adoptive children about the adoption and what they might know about the family of origin. Although in the past, secrecy was frequently attempted; most professionals today recommend early disclosure and ongoing processing of the fact of adoption throughout the developmental years. Many feel that early disclosure, even before children can fully comprehend the information, is recommended. Addressing the reality of the adoption early and in an integrated manner allows children to develop healthy identities as adoptees as they progress developmentally, both cognitively and emotionally, over time and keeps the topic open as something easily talked about within the family. This may become very important when adopted children begin to wonder about their families of origin and begin to ask questions that the adoptive parents must answer as honestly and openly as possible. Anxieties about rejection may spill over into the adoptive family, causing children to worry about being removed from their adoptive homes. These issues are often heightened during adolescence when children are normally struggling with issues of identity and separation from the nuclear family. Increased curiosity about families of origin may be difficult for adoptive families to address. Adolescents' typical desire to know more about their biologic families, even to meet them, may feel like rejection to the adoptive families. When there is adolescent turmoil within families, adolescents may idealize biologic families as a way to exert independence within their adoptive families. It is unclear how more "open" adoptions, particularly those that foster open relationships with biologic families, may affect these issues common in closed adoptions.

Over the developmental spectrum, adoptive parents may find parenting challenges not experienced by biologic parents. Frequently the adoptive parents enter the relationship with unresolved grief regarding their infertility, making them potentially less emotionally available to adopted children. Because of genetic differences as well

as early experiences, the goodness of fit temperamentally and psychologically may not be optimal, making it more difficult for the adoptive parents to understand and respond empathically to the adopted children. Any problems the children have, any differences they may manifest, often tend to be viewed through the eyes of the adoption rather than as being normal variants within human development. Support for the adoption from extended families tends to decrease the effectiveness of some of these challenges.

Risk for Mental Health Problems

It has long been established that adopted children are over-represented in both outpatient and inpatient mental health settings. Some of these findings predated the recent increase in the number of children adopted from settings in which they had been neglected or abused prior to adoption. Some of this over-representation may result from the evidence that suggests that adoptees are referred for problems of less severity than nonadoptees, leading researchers to hypothesize that adoptive families were more likely to seek interventions than nonadoptive families. Consistently, adoptees demonstrate more risk, however low, for externalizing behaviors, including substance abuse, conduct symptoms, aggression, and possible suicidal behavior, behaviors that are more distressing to parents and the community and more likely to lead to mental health referrals. Nonetheless, analyses controlling for the severity of the mental health problems demonstrated an increased risk in adoptees over than in nonadoptees. Researchers postulate that the reasons for this over-representation in clinical populations are complex and may represent an actual increase in risk for problems in this population along with a referral bias among parents who, for a multitude of reasons, including higher educational and socioeconomic levels, may be more willing to access mental health interventions for their children. Many of the studies suggesting increased risk fail to differentiate clinical from nonclinical samples, the age of children when adopted, and the type of comparison group. Some suggest that the over-representation statistics in clinical

populations may be colored by a small group of very serious cases. Large nonclinical studies have yet to be completed, but the ones that have been done continue to show risk factors for the adopted population, albeit at lower levels. Drug use, antisocial behavior, and school adjustment are compromised, although adopted adolescents have fewer problems with withdrawn behavior and have increased prosocial behavior compared to nonadoptees.

Over the years, it has been assumed that the older the child at the time of adoption, the higher the risk for mental health problems. Studies in the 1990s suggested, however, that although those children adopted as infants statistically demonstrated fewer behavioral and psychiatric problems, about 25% of them did have problems. Having a nonadopted sibling seemed to be a risk factor in these cases. In addition, studies have shown that deprivation in early childhood and later adoption resulted in the highest level of maladjustment. Yet, among these children, more than one-fourth of them demonstrated no serious problems as adolescents. Other studies have suggested few problems in those children adopted as infants, and all tend to show increased difficulties in adjustment relative to the age of adoption, with infants showing the least problems and children adopted after the age of 10 years showing the most problems when compared to matched controls.

Comparison groups in adoption outcome research have been problematic as well. If the comparison group is that of nonadopted children from intact families, adopted children show more problems with adjustment. However, adopted children seem to have better adjustment than those raised in foster care or institutions and even those returning from temporary care to families where there is a history of and potentially ongoing impaired parenting. The complex nature of evaluating outcomes demands addressing these issues, identifying risk factors that children bring to adoption, as well as risks within the adoptive family, and developing early interventions to help adoptive families and adoptees address these risk factors early and intensively so as to improve outcomes across the population.

Adopted children are frequently the source for research evaluating genetic versus environmental contributions to the development of

mental illness. Researchers looking at schizophrenia have demonstrated that adoptees at high genetic risk for schizophrenia may be protected in optimal adoptive environments, whereas those who experience disordered parenting situations are more likely to develop schizophrenia, suggesting complex interactions between genetic and environmental contributions to the manifestation of the disorder.

International Adoptions

The practice of international adoptions experienced a gradual decline over the past 15 years. A recent high was in 2004 when 23,000 children were brought to the United States, while 2019 saw under 3,000 adoptions finalized. Geopolitics plays a strong role in the viability of international adoption. The Hague Convention on the Protection of Children and Co-operation in Respect of Intercountry Adoption (Hague Convention) was established in 1993 with the goal of setting international expectations for the regulation of cross-border adoptions. The Hague Convention set forth international standards for adoption, which increased the amount of oversight some countries had in place. The goal was to put safeguards in place so families have informed consent about the adoption process and, whenever possible, to keep children connected to their community. The United States signed on in 1994, but full implementation waited until 2008. There is disagreement over how much The Hague Convention directly reduced international adoption relative to changes in specific countries' adoption policies. For instance, Russia was a major source of international adoptions until nationalistic pressure led to a ban on U.S. adoptions in 2013. China's growing middle class and reversal of the one-child policy have dramatically reduced the number of children available for international adoption and shifted gender ratios toward parity. Families adopting from overseas also need to be aware that the adoption does not automatically grant citizenship. Although Congress has taken steps to streamline the process, it is estimated that over 15,000 individuals

in the United States were adopted internationally but never had their citizenship established.

The serious deprivation in the early lives of many of these children has focused attention on the importance of early childhood experiences. Developmental problems, particularly motor delays, as well as a broad spectrum of medical problems, are commonly identified in children adopted internationally, particularly in those reared in orphanages. Approximately 12% of all adoptees have at least one chronic disability, twice the rate among all children in the same age range. Overall rates are similar among international and domestic adoptees. However, international adoptees who immigrated to the United States later in life and consequently experienced longer periods of deprivation prior to adoption have higher rates of impairment. The country of origin also influences disability status, as rates from children of Russian or Eastern European origin are much higher than those children hailing from China and Korea. This is likely due to a greater reliance on institutional care in Eastern Europe as well as alcohol consumption rates that are twice as high in Russia as they are in China. All international adoptees should be given a full medical and developmental evaluation within the first two weeks after arrival in the United States, with interventions instituted immediately for infections, lack of immunizations, and early intervention for growth and developmental delays. Repeated meta-analyses suggest that international adoptees have increased mental health problems, particularly externalizing behaviors. Preadoption conditions appear to be more predictive than the age of adoption. The longer the child is in a deprived early environment, the greater the risk for attachment difficulties. Interventions that foster attachment in these high-risk children should be implemented. Evidence suggests that children who are able to establish secure attachments with their adoptive mothers attain better developmental recovery, both cognitive and social, in middle childhood. Most studies show good outcomes for internationally adopted children. Factors that may increase the risk for developing mental health problems include male gender, older age at placement, preadoption care in an orphanage, and placement

with a single parent or in a white-collar family. The story of international adoption over the last several decades highlights the effect of extreme early deprivation and the possible recovery in developmentally supportive families. It has become apparent that adoptions after 24 months of age in these severely emotionally deprived children complicate recovery. Longer deprivation leads to more significant developmental delays and less complete recovery. In addition, recovery, when it occurs, typically does so within the first 2 years after placement. The final chapter on long-term outcomes is yet to be written, but the evolving literature suggests that children severely deprived for long periods of time may continue to have problems with oppositional behaviors, attachment difficulties, odd or bizarre behaviors, including social behaviors, and language delays. It is obvious that adoption improves the outcomes in many of these severely deprived children, many of whom are beginning to tell stories of the confusing move from their countries of origin, being placed frequently in families who do not speak a language they have ever heard, along with the abrupt discontinuation of any exposure to their language of origin. Those who have age-appropriate competence in their language of origin typically have better outcomes. Examination of the typical developmental process through which these young children adjust to English as a second language warns clinicians against diagnosing selective mutism in these children who are adjusting to a world totally dominated by a new language. Nonetheless, retrospectively these international adoptees seem to balance these confusing circumstances and benefit greatly from the more empathic and developmentally appropriate care in their adoptive families.

The Role of the Psychiatrist

Many child and adolescent psychiatrists work intensively in outpatient, inpatient, and residential treatment settings. Some are involved early in the adoption of high-risk children through consultation with schools, child welfare agencies, and juvenile court settings. Although there is little research in the area, case reports

identify the need for empathy for both the adoptive parents and the adoptee. Psychiatrists working with adoptive families need to explore their countertransference issues related to adoption, including issues related to abandonment and rescue, which may impair their abilities to work with the dyadic issues in a balanced, empathic, and objective manner. It is imperative that psychiatrists educate themselves regarding the complicated research regarding outcomes to avoid presuming that adopted adolescents will have problems, a practice that may lead to self-fulfilling prophecies. Embarking on a psychotherapeutic process with an adoptee must fully include the parents to increase open communication within the family. At times, adoptive parents harbor fears regarding the child's heredity, which may lead to the expectation of negative outcomes. Although without empirical evidence, group interventions for both adopted children and for their families may have the potential as effective treatment methodologies. Issues that commonly arise in psychotherapy with adoptees involve problems with self-esteem and fears of additional losses or rejection. However, recent studies have demonstrated the development of good self-esteem in most adoptees. Issues related to curiosity about biologic families are common concerns, sometimes leading to the opening of birth records without the consent of the birth parent. Another area of increasing focus relates to the common concern about treatment for attachment problems, which may be too frequently presumed in adoptive situations of early deprivation, causing clinicians to miss other treatable diagnoses. Controversial techniques such as holding therapy and rebirthing pose a significant physical risk of asphyxiation and should be discouraged. Newer interventions to foster attachment involving group educational programs on sensitive parenting coupled with focused feedback on the interactions between the parent and the child led to better infant outcomes, as well as enhanced parent–child attachments. Although the reality of adoption must enter into the psychotherapeutic equation, psychiatrists are cautioned to integrate issues related to adoption with an overall individualized assessment of the child in the family, avoiding the tendency to ascribe all psychopathology to issues related to adoption. Psychiatrists are obviously more likely to

work with adoptive situations in which the children and families are not doing well. It is important to remember that, whereas adoptive status may influence the situation and negative experiences prior to the adoption exert great effect on the outcomes, each family needs to be evaluated thoroughly, and targeted interventions must be implemented in an effort to preserve the family because adoption disruptions in older adoptions are higher compared to adoptions in infancy. Data are difficult to come by regarding disruptions, but overall rates are around 10%.

Another consideration regarding treatment is that adolescence is the most challenging time for adopted children for both behavioral and emotional problems, regardless of the stage in life at which the child was adopted. This is partially due to the universal challenges of adolescence, but heightened due to the loss and trauma many adopted children experienced early in life. These experiences resurface during adolescence and can catch the adoptive parent off guard. Many adoptive parents envisioned a “happily ever after” scenario and believed that their love would be enough to help a child process issues related to grief, identity, and early childhood stressors. Consequently, adoptive families are four times as likely to seek counseling services and seven times as likely to seek residential treatment when compared to birth families. Problems may become so severe that a youth is at risk of re-entering foster care or the adoption is legally dissolved. From the limited data available, these outcomes are rare with approximately 10% of children who are adopted through the child welfare system finding themselves placed back into foster care. Of that 10%, approximately one-third may have the adoption terminated. Another 10% have extended disruptions to their living situation such as running away, living with another family member, or having an extended placement in a residential treatment facility or a juvenile corrections facility. As federal policy only began to encourage adoption from foster care in the 1980s and 1990s, postadoption services to families with special needs children are relatively new. Services are becoming more widespread with the recognized need to avoid disruption in placement. However, they tend to vary significantly from state to state and it can prove a

challenge to locate all services for families in need. Encouraging families to seek out services that improve their knowledge and skills is vital, as is reminding them that this is a sign of family strength, not parental inadequacy, as so many may believe. Education is where intervention begins and a discussion of the adopted child in light of the impact that early abuse and deprivation can cause will provide a greater understanding of the child, increase empathy, and help them look for ways to provide support and build on a child's strengths to promote resilience. It is also helpful to discuss realistic expectations of a child and to encourage parents to take care of their own well-being to promote better interactions with the child.

Psychiatrists may also work with the biologic parents and families of children who have been given up for adoption or whose children have been removed because of abuse and neglect. These persons often have pre-existing psychopathology, which might become more complicated because of the removal of their children. In addition, for those whose children are in foster care and for whom reunification is a goal, intensive psychiatric interventions, and support may be the most significant influence on the ultimate outcome.

Future Directions

It is clear that for many children and families, adoption meets a special need and facilitates a positive psychological outcome. For a minority, psychological adjustment is more challenging. Identifying, more specifically, the risk factors for less-than-optimum outcomes and developing evidence-based interventions to address critical issues like attachment, externalizing behaviors, and increasing empathic responses of adoptive families to high-risk children is the challenge for the future. Few current interventions take into account the complex nature of repeated trauma, attachment, and identity issues faced by adopted children. Policies that facilitate adoptions earlier when there is little hope for family reunification are imperative to interrupt the prolongation of temporary placements, which increases the risk of compromised adoption outcomes. Additional work is also needed to provide adoptive families with postadoption

support to address the needs of the child as they are identified. Egregious policies that remain law in some states, which require adoptive parents to formally “abandon” children in order to obtain residential treatment, call for immediate correction. More needs to be learned about birth parents and optimal management of open adoptions or late reunions, which are becoming more frequent but about which very little is known. Finally, continued efforts are needed consistently to keep the best interests of the child at the forefront in all decisions regarding permanency planning, whether it is related to reunification, long-term foster care, or adoption.

54.2 Child Maltreatment

HEATHER WILLIAMS, M.D., AND BRADLEY FREEMAN, M.D.

Child maltreatment is a grossly underrecognized problem that is pervasive across all socioeconomic classes, races, ethnic groups, and religions. Although the federal government and every state have programs to investigate allegations of abuse, prevent abuse, and educate caregivers, the cases that are reported and substantiated are just the tip of the iceberg of the true prevalence of child maltreatment. For centuries, the recognition of child maltreatment has been compromised by pervasive denial and systemic constraints related to the recognition, reporting, investigation, and intervention of abuse and neglect. The physical and mental health impacts of child maltreatment can be severe and long-lasting, with the potential for the psychological effects to endure long after any physical or sexual injury has healed.

A diverse group of professionals—including child and adolescent psychiatrists, psychologists, social workers, law enforcement, school personnel, pediatricians, dentists, emergency department workers, and other mental health professionals, are mandated to report suspected child maltreatment. Additional professionals such as pathologists, radiologists, and attorneys, for example, often participate in the identification, evaluation, and substantiation of child maltreatment. There are many roles for child and adolescent psychiatrists and psychologists, social workers, and other mental health professionals in these cases. The above clinicians may

provide treatment to children who experience significant symptoms due to trauma, such as behavioral and emotional problems because of abuse. Mental health professionals may evaluate and treat perpetrators of abuse, many of whom may have been victims of abuse themselves earlier in their lives. Clinicians may provide evaluations of children and adolescents suspected of having been maltreated for forensic or legal purposes. A forensic evaluation may assist the court in determining specific details and the chronology of maltreatment in a child or adolescent. Child psychiatrists may be asked to evaluate the credibility of children's and adolescents' reports of maltreatment and the competency of the youth to testify. In civil lawsuits pertaining to child maltreatment, psychiatrists and other mental health professionals may testify about the nature, extent, and cause of the child's psychological injuries. Finally, mental health professionals may address the problem of child maltreatment on the level of public policy by providing education to legislators, judicial officers, and attorneys about the psychiatric aspects of abuse and the developmental needs of children.

DEFINITIONS

DSM-5-TR

The somewhat terse classification system provided by the Diagnostic And Statistical Manual Of Mental Disorders, Fifth Edition, Text Revision (DSM-5-TR) lists *child physical abuse*, *child sexual abuse*, *child neglect, and child psychological abuse*. The four conditions appear in the chapter "Other Conditions That May Be a Focus of Clinical Attention" and in the section "Abuse and Neglect." These categories should be used when the focus of clinical attention is the severe mistreatment of one individual by another. The coding system of DSM-5-TR allows the evaluator to distinguish each type of maltreatment: confirmed abuse from suspected abuse; an initial encounter from a subsequent encounter; parental abuse from nonparental abuse; whether the abuse previously occurred during

the person's childhood; and whether the mental health services are for the perpetrator of parental or nonparental abuse.

Federal Law

The Child Abuse Prevention and Treatment Act (CAPTA) was passed in 1974 and has been amended several times, most recently in January 2019, by the Victims of Child Abuse Act Reauthorization Act of 2018. In federal law, *child abuse and neglect* mean, as a minimum, any recent act or failure to act on the part of a parent or caretaker which results in death, serious physical or emotional harm, sexual abuse or exploitation, or an act or failure to act which presents an imminent risk of serious harm. In federal law, *sexual abuse* means the employment, use, persuasion, inducement, enticement, or coercion of any child to engage in or to assist any other person to engage in any sexually explicit conduct or simulation of such conduct for the purpose of producing a visual depiction of such conduct. CAPTA further expands the legal definition of child sexual abuse to include the following terms: rape (and in cases of caretaker or familial relationships, statutory rape), molestation, incest, and prostitution. CAPTA was also most recently amended to include other forms of sexual exploitation of children and victims of sex trafficking.

State Law

A large mass of legal definitions and statutes exist at the state level. The legal definitions of terms related to the maltreatment of children vary from one jurisdiction to another, so clinicians should be aware of their state statutes, with a special focus on mandatory reporting laws, corporal punishment laws, and legal age of consent.

Medical Diagnoses

Child maltreatment is a unique area of medicine where the medical diagnosis and legal findings overlap. For this reason, the diagnoses listed below are informed by legal definitions and statutes. However, the diagnosis of child maltreatment in the clinical setting is

independent of the investigative process dictated by these laws and is determined based on the medical provider's level of concern for maltreatment. There are also variations in terminology used between the medical and legal fields.

Child Neglect

The most prevalent form of child maltreatment, *child neglect,* is a failure to provide or supervise and can be committed through acts of commission or omission. Neglect can fall into several categories, including the following:

- Physical neglect, such as abandonment
- Nutritional neglect
- Medical neglect
- Inadequate supervision
- Emotional neglect
- Educational neglect

Neglect may also be chronic, where an individual incident of neglect may not appear harmful, but multiple incidents over time create a negative impact on the child.

Child Physical Abuse

As described above, the minimum definition of *child physical abuse* involves an act on the part of a child's caretaker, which results in death, serious physical harm, or imminent risk of serious harm. In the clinical setting, child physical abuse may present with a wide range of symptoms, from subtle bruising on a nonmobile infant to abusive head trauma resulting in long-term disability or death. Determining the level of concern for child physical abuse in the clinical setting depends on several factors, including the constellation of symptoms and injuries, the history provided to explain these injuries, and the developmental capabilities of the child. If there is no history provided to explain the injuries, if the history provided is implausible to explain them, if the child is developmentally incapable of causing the injuries, or if abuse is disclosed, witnessed, or

confessed this should raise concerns for child physical abuse, warranting a report to local child protective services and consideration of additional medical evaluation.

Corporal punishment, or physical discipline, includes acts such as spanking or paddling. Each state differs in its laws regarding the use of corporal punishment in the home and at school. Regardless of state law regarding the use of corporal punishment, if the discipline resulted in serious physical harm or imminent risk of physical harm, it should be considered child physical abuse and reported as such.

Abusive head trauma is a specific type of child physical abuse with potentially long-lasting neurocognitive and mental health impacts related to the intracranial injuries and abuse. Medical providers are strongly discouraged from using the term “shaken baby syndrome,” as this inappropriately focuses on one specific possible mechanism of injury instead of the abuse itself.

Child Psychological Abuse

Child psychological abuse is a pattern of intentional verbal or behavioral actions or lack of actions that conveys to a child that they are worthless, flawed, unloved, unwanted, or endangered. Child psychological abuse is divided into the following categories: spurning, rejection or degradation, terrorizing, exploiting or corrupting, denying emotional responsiveness, and isolation. The severity of psychological abuse depends on (1) whether the perpetrator intends to inflict harm on the child and (2) whether the abusive behaviors are likely to cause harm to the child. In contentious divorces, one of the parents may indoctrinate the child to fear or dislike the other parent, thus causing parental alienation between the child and the rejected parent. Depending on the circumstances, parental alienation may be identified by one or more of these DSM-5 terms: child psychological abuse, parent–child relational problem, or child affected by parental relationship distress.

Child Sexual Abuse

Child sexual abuse is defined by the American Academy of Pediatrics as occurring when a child is engaged in sexual activities that they cannot comprehend, for which they are developmentally unprepared and cannot give consent, and/or that violate the law or social taboos of society. Recent definitions and laws have expanded to include children who are victims of human trafficking and internet crimes against children, such as child pornography. State laws vary greatly regarding age of consent, definitions of terms such as penetration, and timing for evidence collection related to an acute sexual assault. Inappropriate sexual contact with a child can include kissing, fondling, digital–genital, oro–genital, genital–genital, and anogenital contact. The vast majority of child sexual abuse is perpetrated in the home by a close household family member.

Children commonly engage in sexualized behaviors with themselves or with other children, described as “sexual play” that is spontaneous, intermittent, mutual, and noncoercive. Normal sexualized behaviors typically include acts such as self-stimulation and voyeurism. It is important to recognize that these behaviors may be distressing to caregivers but are not an indication that child sexual abuse has occurred. Reassurance and education regarding these behaviors are frequently all that is needed when they present. Sexualized behaviors become problematic when they cross socially unacceptable boundaries, become coercive or aggressive, or represent an early onset of adult sexual activity. When the behaviors become problematic, further interventions to extinguish the behaviors and evaluation for possible child maltreatment may be indicated.

HISTORY OF CHILD MALTREATMENT

Historical and literary sources have documented child maltreatment for thousands of years in cultures from all parts of the world. Although some forms of abuse were considered deviant or prohibited in particular cultures, most often the abusive practices were accepted or even encouraged by the societies in which they occurred. The long-term trend in European and American history has

been to move from blatant, socially acceptable child abuse to strong societal disapproval.

Since the latter half of the 20th century, child abuse became the subject of widespread clinical and governmental concern. Abusive practices were actively identified, rather than ignored and denied. Modern recognition of child abuse was signaled in 1946 by a pediatrician and radiologist, John Caffey, who noticed a syndrome of children with multiple skeletal injuries and chronic subdural hematomas. Until the 1960s, physical abuse of children was considered rare, partly because physical discipline of children was generally more acceptable and partly because of societal denial concerning violence toward children. In 1962, Henry Kempe and his colleagues brought child maltreatment to the attention of physicians and legislators in a historic article, “The Battered-Child Syndrome.” Within 5 years, child abuse reporting laws were adopted by every state.

It took a separate societal realization during the 1970s to acknowledge the extent of sexual abuse. Child sexual abuse perpetrated by their caregivers, previously referred to as incest, was known to occur, but most people believed that it was unusual and happened primarily among deviant families. It is now known that sexual abuse perpetrated by family members and other forms of sexual abuse are not rare. The term “incest” is no longer preferred in the clinical domain as it does not necessarily pertain to children and it suggests a degree of consent.

In 1974, the federal government passed the CAPTA, which established uniform national standards for the identification and management of child abuse cases. Child abuse legislation, originally directed toward case discovery and perpetrator punishment, now focuses on prevention, rehabilitation, and family reunification. Individual states independently define maltreatment, formulate investigative procedures, collect data, and organize service delivery systems.

Research in the field of child maltreatment has continued to grow, and there are now teams of maltreatment providers in hospitals across the United States and internationally whose purpose is to

assess children with concerns for maltreatment and collaborate with community partners to ensure the safety of these children. Maltreatment providers with specialized certification and training exist at most major academic children's hospitals and offer a range of services including consultations and assessments of patients presenting with concerns for child physical abuse, child sexual abuse, and neglect. They typically work closely with their social work colleagues to liaise with local investigative agencies and provide expert testimony in court when needed.

COMPARATIVE NOSOLOGY

The first edition of the DSM (DSM-I) (1952) and the second edition of the DSM (DSM-II) (1968) made no mention of child maltreatment. The Group for the Advancement of Psychiatry (1974) mentioned child maltreatment among the pathogenic factors of childhood mental disorders: "The deleterious effects … of open rejection or neglect, occasionally involving willful injury or inadequate feeding, are well documented." However, the Group for the Advancement of Psychiatry did not include child maltreatment in their proposed system of classification.

When the third edition of the DSM (DSM-III) (1980) was published, the American Psychiatric Association Task Force on Nomenclature and Statistics introduced a chapter called "V Codes for Conditions Not Attributable to a Mental Disorder That Are a Focus of Attention or Treatment." The V Codes, which were modeled on the practice in the ninth edition, clinical modification of the *International Classification of Diseases* (ICD-9-CM), did not include specific categories for child maltreatment. However, it was intended that child abuse would be coded as a *parent–child problem*, the category used "when a focus of attention or treatment is a parent–child problem that is apparently not due to a mental disorder of the individual (parent or child) who is being evaluated." The DSM-III specifically stated that "an example (of parent–child problem) is child abuse not attributable to a mental disorder of the parent." The emphasis on *parent–child*

problem was apparently on identifying perpetrators of abuse, not the child victims of abuse.

The revised third edition of the DSM (DSM-III-R) (1987) provided a similar definition for *parent–child problem*: “This category can be used for either a parent or a child when the focus of attention or treatment is a parent–child problem that is apparently not due to a mental disorder of the person who is being evaluated.” However, the example involving child abuse was replaced by “conflict between a mentally healthy adolescent and her parents about her choice of friends.”

In the fourth edition of the DSM (DSM-IV) (1994), the title of the chapter changed to “Other Conditions That May Be a Focus of Clinical Attention.” In addition, a specific section was introduced, “Problems Related to Abuse or Neglect,” which included terms related to child maltreatment. The editors noted that this category was “included because of the clinical and public health significance of these conditions.” For the first time, it was possible to diagnose clearly *physical abuse of child*, *sexual abuse of child*, and *neglect of child*. Furthermore, the DSM-IV made it possible to distinguish whether the person being evaluated was the perpetrator of abuse or the victim of abuse. The terminology regarding child maltreatment in the DSM-IV-TR (2000) was the same as that in the DSM-IV.

The fifth edition of the DSM (DSM-5) (2013) and the text revision (DSM-5-TR) (2022) include child maltreatment in the same chapter as in the previous edition, “Other Conditions That May Be a Focus of Clinical Attention.” A new section was included titled “Abuse and Neglect.” This section encompasses abuse of all persons, young and old. Diagnosing abuse with the current DSM nomenclature has become more specific. The child can be diagnosed as being a victim of *child physical abuse, child sexual abuse, child neglect*, and *child psychological abuse*. It remains possible to differentiate whether the clinical service was for the victim or the perpetrator of abuse. For adults, the provider can indicate if the abuse or neglect is from the individual’s childhood history.

Additionally, the diagnoses of parent–child relational problems and child affected by parental relationship distress are also included in

the same chapter but under the section titled “Relational Problems.” That section includes the language, “In the extreme, these close relationships can be associated with maltreatment or neglect, which has significant medical and psychological consequences for the affected individual.” The description of parent–child relational problem in DSM-5 indicates the child is affected in either the behavioral, cognitive, or affective domain.

The tenth edition of the ICD (ICD-10, Version 2007) has a slightly different way of organizing child maltreatment diagnoses. The ICD-10 has a chapter titled “Injury, Poisoning and Certain Other Consequences of External Causes” and a section titled “Other and Unspecified Effects of External Causes.” Within that section is a heading for “Maltreatment Syndrome,” which includes the following diagnoses: neglect or abandonment; physical abuse; sexual abuse; psychological abuse; other maltreatment syndromes; and maltreatment syndrome, unspecified. The ICD-10-CM (Clinical Modification) includes codes that enhance the specificity of the abuse or neglect diagnosis. For example, the abuse can be coded as either *suspected* or *confirmed* and the type of encounter can be denoted as either *initial* or *subsequent*.

The eleventh edition of the ICD (ICD-11, Version 2019) has a chapter entitled “External causes of morbidity or mortality.” Maltreatment is a subsection in this chapter and encompasses physical, sexual, psychological, specified, and unspecified categories. This version of the ICD no longer includes the section “Maltreatment Syndrome.” There are extension codes that are provided to add detail to defined categories. Abandonment and neglect are included in the list of codes. Under the “Factors influencing health status or contact with health services” chapter, there is coding for personal history of physical, sexual, and psychological abuse, and neglect in addition to unspecified and specified history of maltreatment.

EPIDEMIOLOGY

Each year, the Children's Bureau, an agency within the Department of Health and Human Services, collects data on child maltreatment. The results are published in an annual document called *Child Maltreatment*. The agency estimated that, in 2018, approximately 4.3 million reports with concern for abuse or neglect were made to child protective services involving 7.8 million children. Of those reports, 678,000 reports were substantiated within each individual state's statutes defining abuse and neglect, 1.3 million received postresponse services, and over 200,000 children were placed into foster care. The substantiated cases were distributed as follows: 61% neglect, 11% physical abuse, 7% sexual abuse, and 15.5% two or more types of abuse and neglect. The Children's Bureau estimated 1,770 children died as a result of maltreatment in 2018, over an 11% increase from the 2014 estimate. Approximately 47% of these deaths were children younger than 1 year of age and boys (2.87 per 100,000) had a higher fatality rates than girls (2.19 per 100,000).

The data were analyzed for patterns of maltreatment by the sex, age, and race or ethnicity of victims. With regard to the age distribution of victims, the age group from 0 to 1 years of age had the highest victimization rate (26.7 per 1,000 children) with the rate of victimization decreasing with increasing age of the victim. The majority of identified child victims were either White (44.5%), Hispanic (22.6%), or African-American (20.6%). American-Indian or Alaska Native children had the highest rate at 15.2 per 1,000 children, and African-American children had the second higher rate at 14.0 per 1,000.

All of these figures are approximations because the actual amount of abuse is unclear. The reporting of abuse and the annual victimization rate increased during the 1980s and reached a high in 1993 (when the victimization rate was 15.2 per 1,000 children in the population). This increase is thought to have resulted from greater public awareness and willingness to report child abuse, improvement in data collection techniques by individual states, and local economic conditions that placed a larger number of families under stress. The victimization rate fell after 1993 and reached a low of 9.2 per 1,000

children in 2012. Much as it is difficult to definitively state why the rate increased in the 80s and 90s, it is also difficult to state why the rates have decreased in recent years. This decrease may be the result of a true decrease in child maltreatment related to prevention programs but may also reflect differences in reporting, data collection, and state laws. Regardless of the reason for fluctuations in the number of reports per year, these numbers likely reflect a significant underestimate of the true extent of maltreatment.

RISK FACTORS

Characteristics of a child that may be risk factors for maltreatment include age less than 4 years old, prematurity, emotional/behavioral difficulties, physical disabilities, and unplanned or unwanted pregnancy. Risk factors associated with caregiver and family characteristics include substance abuse, parental mental illness, lack of understanding of child's needs or developmental capabilities, caregiver history of child abuse or neglect, and young parental age. Additional family characteristics that are often associated with child maltreatment are low caregiver educational achievement, low caregiver socioeconomic status, single parenthood, large number of children in the home, nonbiologic caregivers, and domestic violence in the home. Community and societal risk factors include community violence, concentrated neighborhood disadvantages, poverty, and social isolation. These factors may be difficult to identify and assess. It is also important to be aware of the unconscious bias identification of these risk factors may create, as their presence does not mean abuse or neglect had to have occurred nor does their absence mean abuse or neglect did not occur. These factors must be considered in the overall context of the individual case. Community and societal factors that may be protective for a child are a strong extended family and social support system.

DIAGNOSIS AND CLINICAL FEATURES

Abused children manifest a variety of emotional, behavioral, and somatic reactions. These psychological symptoms are neither specific nor pathognomonic: the same symptoms may occur without a history of abuse. The psychological symptoms manifested by abused children and the behaviors of abusive parents can be organized into clinical patterns. Although it may be helpful to note whether a particular case falls into one of these patterns, that in itself is not diagnostic of child abuse.

Physically Abused Children

Abused children display behaviors that should arouse the suspicions of the health professional. For example, these children may be unusually fearful, docile, distrustful, and guarded. However, they may be disruptive and aggressive. They may be wary of physical contact and show no expectation of being comforted by adults, they may be on the alert for danger and continually size up the environment, and they may be afraid to go home.

The literature regarding the psychological consequences of physical abuse and neglect indicates a wide range of effects: affect dysregulation, insecure and atypical attachment patterns, impaired peer relationships involving increased aggression or social withdrawal, and academic underachievement. Physically abused children exhibit a range of psychopathology, including depression, conduct disorder, attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder (ODD), dissociation, and post-traumatic stress disorder (PTSD).

Carol, 4 years of age, had a change in her behavior at preschool approximately 3 months after the birth of her sister. Her teacher saw Carol push other children and hit a classmate with a wooden block, causing a laceration of the child's lip. When Carol's teacher took her aside to talk about her behavior, she noticed what seemed to be belt marks on Carol's abdomen and forehead. The teacher reported possible child abuse to protective services. In addition, the family was referred for psychiatric evaluation.

Carol's baby sister was colicky and slept only for short periods of time throughout the day and night. She stopped crying only when her mother held her. Her mother, therefore, had little time for Carol, and Carol's father took over her care on evenings after daycare and on weekends. He began to drink more than usual and became increasingly irritable. The parents argued over the mother's attention to the infant and the requirement that the father takes care of Carol. Carol, who was a bright, curious, and talkative child, constantly asked questions and often asked to carry the baby. When refused, she would lie on the floor and have a tantrum. She also began to have difficulty falling asleep and awoke repeatedly during the night. Carol's father was unable to cope with her requests for attention and often told her to "shut up" and slapped her when she continued her demands. On many occasions, he responded to her tantrums or repeated questions by hitting her with his belt.

While protective services monitored the situation, Carol and her parents began a family therapy program that included parenting training and behavioral therapy for Carol, which was coordinated with the preschool. Carol's father attended Alcoholics Anonymous (AA) meetings and stopped drinking. He was able to control his anger at his daughter. Six months later, Carol's aggressive behavior ceased. She was doing well with peers, was sleeping through the night, and stopped having temper tantrums.

Sexually Abused Children

A variety of symptoms, behavioral changes, and diagnoses sometimes occur in sexually abused children: anxiety symptoms, dissociative reactions and hysterical symptoms, depression, disturbances in sexual behaviors, and somatic complaints.

Anxiety Symptoms. Anxiety symptoms include fearfulness, phobias, insomnia, nightmares that directly portray the abuse, somatic complaints, and PTSD.

Dissociative Reactions and Hysterical Symptoms. The child may exhibit periods of amnesia, daydreaming, trance-like states, hysterical seizures, and symptoms of dissociative identity disorder.

Depression. Depression may be manifested by low self-esteem and suicidal and self-mutilative behaviors.

Disturbances in Sexual Behaviors. Sexualized behaviors in children toward other children or adults are particularly suggestive of sexual abuse. Behaviors exhibited by young children such as repeated masturbating, imitating intercourse, or inserting objects into the vagina or anus are suggestive of sexual abuse. Sexually abused children may display sexually aggressive behavior toward others. Other sexual behaviors are less specific, such as showing genitals to other children. A young child who experienced sexual abuse may manifest age-inappropriate sexual knowledge. In contrast to these overly sexualized behaviors, a child who has been sexually abused may avoid sexual stimuli as they grow and develop.

Somatic Complaints. Somatic signs suggestive of possible sexual abuse include enuresis, encopresis, anal and vaginal itching, and nonspecific somatic complaints such as frequent headaches, and stomachaches.

The above symptoms are not pathognomonic of maltreatment. Nonabused children with anxiety disorders, and other psychiatric disorders may also exhibit some of the symptoms and behaviors. For

example, normal, nonabused children commonly exhibit sexual behaviors such as masturbating, displaying their genitals, and trying to look at people who are undressing.

Approximately one-third of identified sexually abused children may not exhibit observable symptoms. Most adults who were abused as children have no obvious significant abuse-related symptoms. However, the following factors tend to be associated with more severe symptoms in the victims of sexual abuse: greater frequency and duration of abuse, sexual abuse that involved force or penetration, and sexual abuse perpetrated by the child's father or stepfather. Other factors associated with poorer prognosis are the child's perception of being less believed, family dysfunction, and lack of maternal support. In addition, multiple investigatory interviews appear to increase symptoms.

Child Sexual Abuse Perpetrators

Child sexual abuse that occurs over a period of time may be characterized by a particular pattern or sequence of steps. Victims of sexual abuse recount a gradual progression of boundary violations by the perpetrator, starting with tiny invasions and escalating to serious, overwhelming intrusions. Healthy, self-confident children may rebuff the intrusions directly (via temper tantrums and verbal disagreements) or indirectly (through silence and distancing maneuvers), or by adopting a strategy that causes the offender to refrain.

Sexual abuse that occurs over a period of time typically involves a close household contact of the child and may evolve through phases. There may be a period of engagement or "grooming" where the perpetrator gains the child's trust or the trust of their caregivers in order to gain access to the child prior to engaging in inappropriate sexual contact. The sexual contact may be ongoing and escalate over time. Sexual abuse includes any form of inappropriate sexual contact with a child, including but not limited to kissing, digital–genital contact, oro–genital contact, anogenital contact, and genital–genital contact. The child may not disclose the abuse for an

extended period of time due to fear, shame, or not feeling like they will be believed or supported, and the perpetrator may engage in threatening ways to keep the inappropriate sexual contact a secret. Sometimes the sexual abuse is discovered accidentally without a disclosure. If the child does not feel safe, supported, or believed, it is not uncommon for the victim to recant, deny, or minimize the abuse.

Extrafamilial perpetrators of sexual abuse against children usually have regular access to the child. Children may be repeatedly abused by trusted adults, such as teachers, counselors, family friends, and clergy. In this scenario, the pedophilic perpetrator grooms the child over a period of time. They gain the friendship of children through enjoyable activities and gifts, introduce sexual activities that may seem innocent and even pleasurable, and progress to more intrusive activities.

A financially comfortable couple lived in a pleasant, clean house in a nice neighborhood, but they had no friends. Their four teenagers never had visitors. One day, the oldest girl, 17 years of age, went to the police and told them she had a baby at home and her father was the baby's father. The girl said her father had been having sexual relations with her for more than 4 years and he was now doing the same with her younger sisters. The mother admitted knowing about the situation for years, but she had not reported it to the authorities for fear of losing her husband.

Long-Term Consequences of Maltreatment

Many adults who were abused as children have no easily identifiable significant abuse-related symptoms. However, epidemiologic studies —such as the Adverse Childhood Experiences (ACE) Study—have shown a link between childhood adversity and adult psychopathology in diverse populations. It is likely this vulnerability is mediated by persistent physical consequences of the maltreatment on the child's developing brain.

Neurobiologic Aspects of Child Maltreatment

Genetics. Research has described the interaction between genetics and environmental factors (referred to as G × E interactions). Although G × E interactions have been studied for nearly a century in biology and general medicine, the mapping of the human genome has made it possible to study complex interactions among specific genes and between genes and the environment. For example, a G × E interaction appears to play an important role in the neurobiologic response to childhood maltreatment. In several studies, maltreated male children with a genotype conferring high levels of monoamine oxidase A (MAOA) expression were less likely to develop antisocial behavior as adults. In other studies examining the role of genetics in modulating the response to stress, a functional polymorphism in the promoter region of the serotonin transporter gene (known as 5-HTTLPR and *SLC6A4*, respectively) was found to affect the likelihood of developing depression and suicidality in response to stressful experiences. Individuals with one or two copies of the "short allele" were more likely to develop depressive symptoms than individuals with two "long alleles."

Neuroimaging. Childhood maltreatment exposure increases the person's risk of major depression, substance abuse, anxiety disorders, and PTSD, and maltreated individuals with those disorders tend to have an earlier age of onset, greater symptom severity, more comorbidity, a greater risk of suicide, and poorer treatment response than nonmaltreated individuals with the same conditions. It is noteworthy that imaging findings associated with these disorders—such as reduced hippocampal volume and amygdala hyper-reactivity—are observed more consistently in individuals with a history of child maltreatment. Trauma victims who develop PTSD have changes in brain activation that are consistent with the individual's experienced symptoms. For example, individuals with PTSD who report reliving their traumatic events in the form of flashbacks have reduced activation in the medial prefrontal cortex and anterior cingulate cortex (observed on functional magnetic

resonance imaging [fMRI]), which is consistent with less regulatory control over affective arousal states. However, individuals with PTSD who experience dissociation when exposed to trauma memories have increased activation in the medial prefrontal cortex and anterior cingulate cortex, which is consistent with robust inhibition of affective arousal states.

Chronic physical abuse and repeated sexual abuse cause changes in the child's developing brain that persist into adulthood. Chronic severe abuse can lead to a syndrome known as complex PTSD or disorder of extreme stress not otherwise specified (DESNOS). This disorder, which was evaluated but rejected by the Post-Traumatic and Dissociative Disorders Sub-Work Group for DSM-5, is characterized by alterations in the following: ability to modulate emotions; attention or consciousness; somatization; self-perception; perception of the perpetrator; relations with others; and systems of meaning. The core of this disorder is a breakdown in the ability to regulate internal states. Trauma exposure changes the way in which children perceive environmental stimuli, especially their perception of threats, and how they organize and process information. Specifically, individuals with a history of trauma are more vulnerable to reacting with subcortically initiated responses that are irrelevant or even harmful in the present situation.

EVALUATION PROCESS

The evaluation of a child or an adolescent who may have been physically or sexually abused depends on its circumstances and context. Practitioners must consider whether they are conducting a forensic evaluation, which has legal implications and may ultimately be used in court, or a clinical evaluation, which is done for a therapeutic purpose. A forensic evaluation emphasizes collecting accurate and complete data to determine the level of concern for abuse. The data collected in a forensic evaluation must be preserved in an audio and video-recorded format. The results of the forensic evaluation are organized into a report that is read by attorneys, a judge, and others. However, the emphasis in a therapeutic

evaluation is to assess psychological strengths and weaknesses, make a clinical diagnosis, develop a treatment plan, and lay the foundation for continuing psychotherapy. The clinician may also be interested in determining what happened to the child, but it is not so essential to distinguish facts from fantasies. Compared with the forensic evaluation, the psychotherapist does not need to keep such detailed records and ordinarily does not prepare a report for court.

In addition to distinguishing a forensic examination from a therapy meeting, a number of factors may affect the evaluation of a child who was abused or may have been abused: whether one is a pediatrician in an emergency department or a child psychiatrist in an office, whether a parent or another person is suspected of the abuse, the severity of the abuse and the victim's relationship to the perpetrator, whether physical signs of abuse are obvious or absent, the age and gender of the child, and the degree of anxiety, defensiveness, anger, or mental disorganization the child exhibits. Often, the examiner must be creative and persistent.

From the psychiatric perspective, the interview is usually the primary source of information and the physical examination is secondary. In practice, children who present with concerns about child maltreatment typically receive a physical exam in close proximity in time to the history being obtained by medical providers or social workers.

Parent Interviews

The evaluator obtains a history from the parents (separately, in most cases) and other pertinent informants, as well as from the child, if verbal. The emphasis of the interview depends on the circumstances.

Suspected Physical Abuse. The examiner should obtain a history from caregivers regarding the cause of the patient's injuries and pertinent past medical history. It is always a consideration that the caregivers are not telling the truth, so it is essential to document the history that is provided by the caregivers and compare it to the

objective clinical findings of the patient to determine a level of concern for maltreatment

When the child is brought to the emergency room, a detailed and spontaneous account of the injury should be obtained promptly from parents or other caregivers. The interviewer should allow the caregiver to explain, expound, derail, or detour the storyline. Caregivers often provide histories that are implausible for the injuries noted on the child, such as multiple broken bones from rolling off of the couch, or provide no history at all to explain the injuries, such as stating that the patient went to sleep without injuries and woke-up covered in bruises.

A 30-day-old girl was transferred from a rural hospital to a university medical center because of supposed near-sudden infant death syndrome (SIDS). The child was unresponsive and required mechanical ventilation. A brain scan revealed bilateral subdural hematomas, subarachnoid hemorrhage, and hemorrhage in the parenchyma of the brain. A skeletal survey showed two posterior rib fractures. An ophthalmologist observed extensive retinal hemorrhages. After the child was admitted to the Pediatric Intensive Care Unit, the child abuse consultant interviewed the parents separately. The mother, 28 years of age, said that she had recently started a new job. The baby had been perfectly fine when she had left her in the care of her live-in boyfriend, the child's biologic father. The father, 24 years of age, said that when he checked on the baby, he found her to be not breathing, blue, and unresponsive. He ran to report this to a neighbor and then called 911. The child abuse consultant told the father the child must have been injured in some way and asked whether he had any explanation for this injury. The father said, "I shook the baby after I found her not breathing." The consultant's assessment was that the patient's injuries were most consistent with child physical abuse and notified child protective services and the local police department so they could initiate and coordinate their investigation.

Suspected Sexual Abuse. As with physical abuse cases, caregivers involved in child sexual abuse cases may not be telling the truth. This is especially true when there are concerns for child sexual abuse in the home, and the adult caregiver does not believe or support the patient or the caregiver is the possible perpetrator of the abuse. Parents may also fabricate concerns for child sexual abuse during custody disputes. It is important to remember that it is rare for a child to fabricate a report of sexual abuse.

The examiner should determine how the allegation originally arose and what subsequent statements were made; determine the

emotional tone of the first disclosure (e.g., whether the disclosure arose in the context of a high level of suspicion of abuse); determine the sequence of previous examinations, the techniques used, and what was reported; try to determine whether the previous interviews were likely to have distorted the child's recollections; review, if possible, transcripts, audiotapes, and videotapes of earlier interviews; seek a history of overstimulation, prior abuse, or other traumas; and consider other stressors that could account for the child's symptoms. The examiner should also ask about exposure to other possible male and female perpetrators.

In Either Case. Whether physical or sexual abuse is involved, a pertinent psychosocial history should be collected and organized, including the following:

1. Symptoms and behavioral changes that sometimes occur in abused children.
2. Confounding variables, such as psychiatric disorders or cognitive impairment, may need to be considered.
3. Family attitude toward discipline, sex, and modesty.
4. Developmental history from birth through periods of possible trauma to the present.
5. Family history, such as earlier abuse of the parents, substance abuse by the parents, spouse abuse, and psychiatric disorder in the parents.
6. Underlying motivation and possible psychopathology of adults involved.

Collateral Information

The evaluator should consider requesting collateral information from the following, after obtaining authorizations: protective services, school personnel, other caregivers (e.g., babysitters), other family members (e.g., siblings), the pediatrician, and police reports.

Child Interview

Several structured and semistructured interview protocols have been introduced that were designed to maximize the amount of accurate information and minimize mistaken or false information provided by children. These approaches include the cognitive interview, which encourages witnesses to search their memories in various ways, such as recalling events forward and then backward. The Step-Wise Interview is a funnel approach that starts with open-ended questions and, if necessary, moves to more specific questions. The interview protocol developed at the National Institute of Child Health and Human Development (NICHD) includes a series of phases and uses detailed interview scripts. The Cornerhouse Forensic Interview Protocol is another semistructured, nondirective interview method for alleged victims of child sexual abuse.

Although these protocols may be particularly important in a forensic context, experienced clinicians endorse flexibility and consistent good-hearted behavior by the interviewer. As when seeing any patient, the evaluator must size up the situation and use techniques that are likely to help the youngster become comfortable and communicative. One victim might need a favorite object (e.g., a teddy bear or a toy truck); another might need to have a particular person included in the interview. Some children are comfortable talking; others prefer to draw pictures. An unrelated joke, a shared cookie, or the picture on the evaluator's wall may lead to a disclosure of abuse. Important comments might be made while chatting during the break time instead of during the structured interviews.

Interview Process. The interviewer of the child who may have been abused should remember the following principles:

1. Audio and video record the interview.
2. Use a minimum number of interviews (perhaps two or three), because multiple interviews may encourage confabulation.
3. Avoid repetitive questions, either–or questions, and multiple questions, and try to avoid leading and suggestive questions.
4. Use restatement, that is, repeat the child's account back to the child (which allows the interviewer to see whether the child is

consistent and ensures that the interviewer understands the child's report).
5. Conduct the examination without the parent present (if the child is young, consider having a family member in the room).
6. Use an examination technique that is appropriate to the child's age and developmental level.
7. Determine the child's terms for body parts and sexual acts; do not educate or provide/introduce new terms.

Interview Content. The interview should not take the form of an interrogation. The interviewer should note the child's affect while discussing these topics and be tactful in helping the child manage anxiety. Young children may not be able to report all of the relevant information. The examiner should explore the following:

1. Whether the child was told to report or not to report anything.
2. Who was the alleged perpetrator.
3. What the alleged perpetrator did.
4. Location of the incident.
5. When it started and when it ended.
6. Number of times the abuse occurred.
7. How the child was initially engaged, and how the abuse progressed over time.
8. How the alleged perpetrator induced the child to maintain secrecy.
9. Whether the child is aware of specific injuries or physical symptoms associated with the abuse.
10. Whether photography or videotaping took place.

The Investigative Interview Protocol. The usual clinical interview may need some modification for evaluating a child who may have been abused. The Investigative Interview Protocol, which was developed at the NICHD, consists of the following components: introduction, rapport building, training in episodic memory, transition to substantive issues, investigating the incidents, eliciting information that has not been mentioned by the child, collecting information

about the disclosure, closing the interview, and concluding with a neutral topic.

INTRODUCTION. The interviewer introduces himself or herself and explains in general terms the purpose of the meeting. The interviewer explains the importance of telling the truth. The child can say, “I don’t understand your question” or “I don’t know.” The child can correct the interviewer if the interviewer makes a mistake.

RAPPORT BUILDING. The interviewer encourages the child to talk about the child’s activities and interests but avoids focusing on television, videos, and fantasy.

TRAINING IN EPISODIC MEMORY. Asking the child to describe two specific past events assesses the child’s memory and models the form of the interview for the child. Using nonleading, open-ended questions, the interviewer asks the child to tell everything that happened on two specific days. The interviewer trains the child to give a free narrative account, which is the pattern through the rest of the interview.

MAKING THE TRANSITION TO SUBSTANTIVE ISSUES. The interviewer asks the child to focus on the reason for the interview by making a nonleading statement such as, “I understand that something may have happened to you. Tell me everything that happened from the beginning to the end.”

INVESTIGATING THE INCIDENTS. The interviewer starts with open-ended questions, such as “Tell me everything about what happened.” If the child describes a specific incident, elicit additional information in a nonleading manner by saying, for example, “You mentioned (a particular activity). Tell me everything about that.” After posing open-ended questions, the interviewer proceeds with focused questions that relate to information already mentioned by the child. For example, “You mentioned a friend was there. What was her name? What was she doing”? This process of investigating the incidents is

repeated, which are typically “the last time,” “the first time,” and “another time that you remember well.”

ELICITING INFORMATION THAT WAS NOT MENTIONED BY THE CHILD. The interviewer may proceed with direct questions only if they have tried other approaches and forensically important information is missing. For example, “When you told me about the time in the kitchen, you mentioned the man took off his pants. Did something happen to your clothes? Tell me all about that.” The interviewer may need to formulate a direct question by making use of outside information. For example, “I heard you told your mother that something happened at school. Tell me everything about that.”

OBTAINING INFORMATION ABOUT THE DISCLOSURE. The interviewer wants to know how the child came to disclose the alleged abuse. Using nonleading questions, the interviewer may say, “Tell me what happened after (the last incident)” and “Does anybody else know what happened”?

CONCLUDING THE INTERVIEW. At the end of the interview, the interviewer says, “You have told me lots of things today, and I want to thank you for helping me.” The interviewer may also say, “Is there anything else you think I should know”? and “Are there any questions you want to ask me”? The interviewer should not compliment the child with comments such as, “You were very brave to talk about those things that happened.” The interviewer may conclude with a discussion of a neutral topic, such as, “What are you going to do today after you leave here”?

Extended Forensic Interview. In typical child abuse investigations, a single-session forensic interview model is widely recommended by Child Advocacy Centers across the United States. Interview protocols, which try to define the ideal single-session interview, assume the child is a willing and able participant who can provide a significant account of the alleged abuse. If the single interview results in an equivocal account of abuse, the interview is

flawed, or the details need further clarification, another interview following the same protocol may be required. These single-session interviews may not suffice for children who have difficulty relating to a stranger about emotional, traumatic information. Such children may benefit from a multisession interview process.

An extended forensic interview (EFI) model was investigated by the National Child Advocacy Center to help determine if such a protocol would be superior to the single-session model for certain children. It was investigated for use in children who either (1) did not disclose but there was other compelling evidence for abuse such as medical findings, (2) the child was unable to provide a full disclosure during the single interview, and (3) the allegations remain unresolved (founded or unfounded) after the single interview. It was determined through field trials at multiple sites that a six-session EFI was the most efficient model. The results from the field testing showed the EFI had utility and had an equal rate of court outcomes as the single interview model. Thus, for single-session forensic interviews that may have initially been unfounded, the EFI helped to resolve the ambiguity surrounding the allegation in almost two-thirds of cases. Like other interviews, the EFI should be recorded.

PHYSICAL EXAMINATION OF SUSPECTED CHILD MALTREATMENT

A comprehensive medical examination should be performed promptly by a medical professional, preferably one with special expertise in child abuse. The assessment should include a head-to-toe examination of all areas of the body including the anogenital region. Any findings should be objectively documented in the medical record and photo-documented when possible. The medical assessment should also include a comprehensive review of systems, past medical history, birth history, and family history to determine concern for underlying medical or inherited conditions that could contribute to the child's clinical presentation.

Just as there is no single psychological characteristic that is diagnostic of abuse, no single physical injury is diagnostic of abuse when considered in isolation. A medical provider must consider the overall constellation of injuries in the context of the history provided to explain them and the developmental capabilities of the patient. The following is a list of injuries that suggest child physical abuse:

- Any injury to a preambulatory infant, including bruising, oropharyngeal injuries, fractures, intracranial injuries, and abdominal injuries
- Multiorgan system injuries
- Injuries in different stages of healing
- Patterned injuries
- Injuries to areas of the body typically protected from accidental injuries, such as the nonbony locations of the torso, ears, face, neck, and upper arms
- Significant injuries that are unexplained

These injuries may range in severity from minor cutaneous injuries to life-threatening intracranial injuries. The younger the patient, the more at risk they are for severe or fatal injuries. Physical abuse also tends to be repetitive and escalate over time, so it is essential to intervene on behalf of the patient even when the injuries appear to be minor to prevent risk of future harm. These seemingly minor injuries noted on infants are called sentinel injuries, and a thorough medical evaluation is needed promptly to assess for occult injuries or those injuries that are not apparent on physical exam.

A 3-month-old female presents with a lingual frenulum tear. The patient's father reports that he was feeding the patient a bottle earlier that morning and noticed the blood coming from her mouth. He denies knowledge of any accidental injuries that could explain the torn frenulum. The patient is discharged home without further evaluation or report to child protective services. The patient returns 2 weeks later in full cardiopulmonary arrest. Head computed tomography (CT) reveals large bilateral subdural hemorrhages and extensive cerebral edema. A full nonaccidental trauma evaluation is completed at that time revealing multiple fractures in different stages of healing and extensive retinal hemorrhages. The patient dies 2 days later as a result of the intracranial injuries. A report to child protective services and law enforcement is made to investigate the case and to ensure the safety of the other children in the home. Upon interview with investigators, the patient's father admits that the initial oral injury was the result of force-feeding when he became frustrated with the patient refusing the bottle. He also confesses that over the following 2 weeks, he had started shaking the baby out of frustration, including on the morning of presentation when the patient presented in cardiopulmonary arrest.

Physical Findings of Sexual Abuse

The vast majority of victims of child sexual abuse will have no signs of anogenital injury, especially in the nonacute setting, which represents the largest portion of sexual abuse exams due to the well-known delay in reporting sexual abuse and resiliency of the anogenital region. It is of the utmost importance for medical providers to recognize an absence of injury does not invalidate the child's report of abuse. A number of anogenital exam findings have been described in child abuse literature. These physical findings are carefully categorized by Adams et al. with regard to their association with sexual abuse. Findings strongly suggestive of sexual abuse include certain signs of acute anogenital trauma and residual

(healing) injuries. Other signs of sexual abuse include sexually transmitted infections (STI) (e.g., Neisseria gonorrhea, chlamydia trachomatis, syphilis, human immunodeficiency virus [HIV]), semen identified in forensic specimens from a child's body, and pregnancy.

SPECIAL TESTS AND LABORATORY EXAMINATION

Child Physical Abuse Evaluation

It is essential that medical providers have a standard approach to the evaluation of suspected child physical abuse in order to identify and treat all injuries as promptly as possible and to reduce provider biases regarding which patients should undergo the evaluation. The American Academy of Pediatrics provides evidence-based recommendations regarding this evaluation based on the patient's age and clinical presentation. All young infants and older patients with concern for neurotrauma should receive a head CT to assess for intracranial injury. Advanced neuroimaging via MRI of the brain and spine and dilated fundoscopic exam to assess for retinal hemorrhages are indicated for patients whose initial head imaging or exam is concerning for intracranial injury. All children under the age of 2 years or young children with developmental disabilities or neurologic compromise should receive a skeletal survey to assess for occult skeletal trauma. All children up to the age of 5 years should have labs obtained to assess for occult abdominal trauma with a follow-up abdominal CT for elevations in these labs or those children with concerns on physical exam for abdominal trauma. A follow-up skeletal survey approximately 2 weeks after the initial study is typically recommended to assess for occult skeletal trauma not identified in the initial study, and siblings of children with concern for child physical abuse should undergo an assessment for injuries due to the inherent risks associated with their sibling's injury.

Child Sexual Abuse Evaluation

State laws vary regarding the timing of evidence collection following acute sexual assault and range from 24 hours to 120 hours with special consideration to the age of victim and their disclosures. The acute sexual assault evaluation should be performed by a trained medical professional, including sexual assault nurse examiners (SANE nurses). The acute sexual assault evaluation includes a thorough head-to-toe examination of the victim and anogenital exam with photo-documentation, typically assisted by medical equipment such as a colposcope. Evidence collection kits vary depending on the state, and they typically include several swabs designated for specific areas of the body. Chain of custody must be maintained during and following the evidence collection process. Depending on the age of the victim and type of contact disclosed by the victim, STI, HIV, and pregnancy testing and prophylaxis may be indicated. In prepubertal patients, the anogenital exam should be external. Anesthesia should only be used if there is concern for internal injuries that cannot be visualized on external exam and may need surgical intervention. If a patient is noncooperative with an exam, the patient should be allowed to refuse the exam with accommodations made to collect as much evidence and information as possible to the extent of the individual patient's comfort level, as the intent is not to retraumatize a victim with the process intended to protect them. When a patient presents with concerns for sexual abuse outside of the acute timeframe established by their state laws, a forensic medical exam should be performed as promptly as possible and includes a head-to-toe exam, including anogenital exam with photo documentation, and any appropriate STI testing indicated by disclosures of sexual contact made by the victim. Most victims will have no findings on exam. If an injury or STI is identified, follow-up exam and testing may be indicated to assess for healing and cure of disease. Should the patient need HIV postexposure prophylaxis, follow-up with infectious disease experts is commonly indicated, as the regimen is prolonged and monitoring for side effects and compliance is needed.

DIFFERENTIAL DIAGNOSIS

Physical Findings

Pediatricians who examine children who may have been abused must consider a wide range of congenital, infectious, toxic, and traumatic conditions in their differential diagnoses. Most importantly, accidental trauma must be considered as a cause for the patient's clinical presentation, emphasizing the importance of a thorough history to determine if a plausible accidental mechanism of injury has been provided to explain the patient's presentation. For bony injuries, congenital and metabolic bone diseases must be considered, such as rickets and osteogenesis imperfecta. For intracranial bleeds and bruising, underlying coagulopathies, such as von Willebrand and hemophilia, must be considered. Testing for rare underlying genetic conditions such as GA1 (Glutaric Aciduria Type 1) may also be considered. These exceedingly rare conditions are far less likely to explain the patient's clinical presentation than trauma but are important to exclude, especially when considering the legal implications of the diagnosis of child physical abuse and abusive head trauma. Medical providers must also recognize mimics of child maltreatment. Most commonly, cutaneous findings such as slate grey nevi, formerly known as Mongolian spots, may be confused for bruising, or conditions such as staph scalded skin syndrome may be confused for inflicted thermal burns. This emphasizes the importance of a thorough exam, medical history, and broad differential diagnosis when evaluating patients with concerns about child maltreatment.

Psychiatric Considerations

The psychiatric evaluation of youngsters who may have been abused may involve assessing the patient's credibility. Although children generally tell the truth when they talk about abuse, sometimes children make false denials (saying that they were not abused, when actually they were) or false allegations (saying they were abused, when actually they were not).

Possible Explanations of Denials of Abuse. A false denial or retraction may occur for several reasons. The child may have been pressured by the perpetrator or family members to recant the allegation. The pressure may consist of bribery, mockery, or threats of injury. The child may be protecting a parent or other family member, even without external coercion (i.e., the child takes on this responsibility through role reversal). The child might be frightened or distressed by the investigation and may decide to withdraw participation. For instance, an interviewer could induce a false denial by asking overly challenging questions. A child may be inhibited by shame or guilt; the child may mistakenly assume responsibility for what happened. Finally, the child may have accommodated the abuse, consciously or unconsciously, instead of objecting to it.

Possible Explanations of Allegations of Abuse. A false allegation of abuse, although rare, may occur for several reasons.

ALLEGATIONS ORIGINATING WITH ADULTS. Sometimes a false allegation arises in the mind of a parent or another adult and is imposed on the child.

Parental Misinterpretation and Suggestion. The parent may have misinterpreted an innocent remark, a neutral piece of behavior, or a benign physical condition as evidence of abuse and may have induced the child to endorse this interpretation. This happens in child custody disputes, as well as in other settings.

Parental Delusion. The parent and child may share a *folie à deux*, or the child may simply give in and agree with a delusional parent.

Parental Indoctrination. A parent may have fabricated the story and may have induced the child to collude in presenting it to the authorities.

Interviewer Suggestion. Previous interviewers may have asked leading or suggestive questions. An interviewer who believes abuse

occurred may unwittingly shape a child's responses until the child validates the interviewer's assumptions.

Group Contagion. In epidemic hysteria, people modify what they have heard to meet their emotional needs. Thus, rumors may become more convincing as they are retold.

UNCONSCIOUS OR NONPURPOSEFUL MENTAL MECHANISMS IN THE CHILD

Fantasy. A younger child may confuse fantasy with reality.

Delusion. Although rare, older children and adolescents may experience delusions about sexual activities in the context of a psychotic illness.

Misinterpretation. Sometimes children misunderstand what happened and later report it inaccurately.

Miscommunication. The child may misunderstand an adult's question, and the adult may later misinterpret or take the child's statement out of context.

Confabulation. Children fill gaps in their memory with whatever information makes sense to them and others at the time.

CONSCIOUS OR PURPOSEFUL MENTAL MECHANISMS IN THE CHILD

Pathologic Lying. Also called *pseudologia fantastica*, this refers to children who tell stories with such zeal that they may become convinced of their truth.

Innocent Lying. Children may make false statements because that seems to be the best way to handle the situation. Developmentally, this is more likely to happen with younger children.

Deliberate Lying. Children may choose to avoid or distort the truth for some personal advantage. This happens more with older children

and adolescents.

PERPETRATOR SUBSTITUTION. The child may have been sexually abused and may exhibit symptoms consistent with abuse but may identify the wrong person as the perpetrator, resulting in a false allegation. The child may do this to protect the actual offender, or the child may displace the memories and accompanying affects onto another individual.

The parents of a 9-year-old boy were divorced, and he spent the summers visiting his father. When he returned from visitation, the mother noticed injuries: A healing cut on the boy's right ear and a collection of superficial, vertical scratches from his umbilicus to his pubis. She had the boy disrobe and took digital images of his abdomen. Several days later, the mother took the boy and the images to the boy's regular psychotherapy appointment. She told the therapist that she was concerned the boy had been physically and sexually abused. The therapist interviewed the boy individually, who explained in a matter-of-fact manner his ear was cut accidentally when he had his hair cut and his abdomen was scratched when he went body surfing at a beach. The therapist concluded the boy had not been abused and reassured the mother. The therapist did not notify child protective services.

SPECIAL ISSUES

Neonatal Abstinence Syndrome

Neonatal abstinence syndrome (NAS) is another example of the potential maltreatment of a fetus. Newborns who have been exposed to maternal drug use can undergo withdrawal after their birth. This can be due to illicit substance use by the mother or iatrogenic addiction (e.g., maternal treatment of a pain condition with opioid medication). The newborn's symptoms are reflected by the type of substance exposure. Symptoms of NAS encompass high-pitched

crying, jitteriness, tremors, convulsions, sweating, fever, mottling, excessive sucking/rooting, poor feeding, vomiting, and diarrhea. A toxicology workup can be done in addition to thorough history taking, although the mother may be reluctant to disclose substance use. It is estimated that 3% of the 4.1 million women of childbearing age who abuse drugs will continue to use drugs during their pregnancy. From 2000 to 2009, the rate of infants born with NAS rose from 1.2 to 3.4 per 1,000 hospital births per year. Maternal substance use has both medical and developmental concerns for the newborn as well as legal, health, and economic impact for the mother.

Medical Child Abuse

Medical child abuse, or factitious disorder imposed on another, was formerly known as Munchausen Syndrome by Proxy. This occurs when a child receives unnecessary and harmful or potentially harmful medical care at the instigation of a caretaker. The perpetrator is usually the mother and often has a narcissistic, histrionic, or borderline personality disorder and thrives on the center-stage position they assume. Medical child abuse is perpetrated by fabrication (falsifying or lying about symptoms) or induction (an act that induces or causes illness, such as poisoning). Frequently, this form of maltreatment has been ongoing for an extended period of time before it is recognized by medical providers. In families in which medical child abuse is found, more than one child may be involved consecutively or simultaneously. In extreme cases, children can be killed, seriously injured, terrorized, and experience severe adverse effects from medications or other treatments.

A 12-year-old boy was referred for psychiatric evaluation because of oppositional behavior. The psychiatrist interviewed the youngster and his mother and learned they had an enmeshed relationship and their affect toward each other ranged from loving to embittered. An older brother had finished school and worked full-time but still lived at home. The patient's medical history was unusual, in that the mother claimed the boy had a long history of fainting spells that defied diagnosis. The mother, but no medical professional, had witnessed these spells. The mother was a secretary in a medical practice consisting of neurologists and neurosurgeons, and she had induced her employers to repeatedly work up the child with physical examinations, laboratory testing, and electroencephalograms (EEGs). In fact, one of the neurosurgeons did burr holes to place EEG electrodes directly on the surface of the child's brain. No neurologic diagnosis was made, and factitious disorder by proxy was suspected. The child's neurologist said that no further testing would be done and encouraged psychiatric treatment. The psychiatrist helped the patient and his mother achieve age-appropriate psychological separation, and there were no more fainting spells.

Sex Trafficking

Human trafficking is referred to as modern-day slavery. When specifically addressing sex trafficking of minors, it is called commercial sexual exploitation of children (CSEC). CSEC includes a large number of crimes against minors, including prostitution, survival sex, internet-based exploitation, and child pornography. While trafficking may involve the physical transfer and movement of the child, these crimes also frequently occur in or close to the home. LGBTQ youth are especially vulnerable to human trafficking related to survival sex. It is estimated that almost 300,000 American youth are at risk of becoming victims of the commercial sex trade. The

average age at which children enter the trade is between 12 and 14 years for girls and 11 and 13 years for boys.

The use of violence, drugs, coercion, and other methods of manipulation are commonplace among the traffickers. If a youth in the sex trade becomes addicted to drugs, the trafficker can use the addiction as a means of control. The National Center for Missing and Exploited Children created the Child Sex Trafficking Team in 2001 due to the need for specialized services in this area. Training of police officers, detectives, and emergency room staff can help to identify youth involved in trafficking.

Cultural Variations

Parenting practices in United States society vary widely. They are partly determined by the cultural heritage of the family, and the cultural context of the alleged act should be considered in evaluating suspected neglect and abuse, including assessing whether the discipline of a child is abusive. Some unusual bruises result from cultural healing practices. Coining or cupping—techniques used in many European and Asian countries—are used to draw toxins from the skin surface and to remove feverish mucus from the system. In coining, a coin is heated in hot oil and massaged against the skin. In cupping, a heated glass cup is used to create suction against the skin. Skin scraping and moxibustion may also mimic physical abuse.

Female Genital Mutilation

Commonly called *female circumcision*, female genital mutilation is performed on an estimated 2 million girls worldwide each year. It is practiced across diverse socioeconomic classes and different ethnic, cultural, and religious groups. Commonly, girls are circumcised between 4 and 10 years of age, but the procedure may be performed on infants, may be postponed until just before marriage, or may be done after the birth of the first child. In some cultures, it is considered part of a ceremonial induction into adult society. Female circumcision, in the mildest form, consists of clitoridectomy—the anatomical equivalent of penile amputation. In its most severe form,

total infibulation involves the removal of the clitoris and labia minora plus an incision of the labia majora to create raw surfaces that are then stitched together. This practice has been widely criticized, including opposition by the World Health Organization (WHO) and other major healthcare groups. In the United States, female circumcision is generally considered child abuse. Efforts have been made to educate immigrant communities on the health risks and legal liabilities of the practice.

Male circumcision is not usually considered child abuse, but it does have its critics. Although this simple procedure is one of the most common operations performed worldwide, complications may result, such as hemorrhage and infection. Advocates of male circumcision cite research that it is somewhat protective against HIV infection, other sexually transmitted diseases (STDs), and penile cancer.

Religious Practices

Certain religious practices may be construed as forms of abuse if they are likely to harm children. For example, adherents of Christian Science believe illness should be treated with prayer instead of medical care. As a result, children may sustain chronic illness, disability, or death. This is an area of flux: some state laws and some courts have allowed parental discretion to withhold conventional medical treatment for legitimate religious reasons, whereas others have not.

Teamwork

Child maltreatment cases require a multidisciplinary team (MDT) of medical providers, mental health professionals, law enforcement, and child protective services. Team participation provides consultation, professional support, collaboration, and coordination for continued safety, health, hope, and positive social interactions within the grim realities of case discovery.

In cases of suspected child abuse and neglect, the physician should make an assessment based on a history, a physical

examination, and indicated medical studies; should request appropriate surgical, medical, and psychiatric consultations; should diagnose the suspected maltreatment; and should report these concerns promptly to their local child protective services and investigative agencies. Child protective services will determine the safety plan for the patient, which can range from periodic monitoring to out-of-home foster care placement. Members of the MDT may also refer the patient to appropriate mental health services and other medical or developmental therapies that are needed. These activities, taken together, should be a coordinated team effort.

REPORTING LAWS AND PRACTICES

In every state, the District of Columbia, and all areas controlled by the federal government (e.g., military bases), physicians are required to report child abuse to the police or the appropriate child protection agency. The typical statute says a physician who has “reason to believe” or “reason to suspect” child abuse is required to report it, and as long as the physician is “acting in good faith,” they are protected from criminal or civil litigation related to their report. In most states, other designated individuals, such as nurses, psychologists, school officials, police officers, district attorneys, and providers of child daycare and foster care, are also required to report child abuse.

Under-Reporting

A significant factor in reporting errors is the failure of clinicians and other mandated reporters to consider child maltreatment in the differential diagnosis of child injuries. Frequently, mandated reporters fail to pursue the diagnosis of child maltreatment because of diverse cultural and socioeconomic factors. Lack of experience or education in dealing with the issues and the judicial quagmire that result when reporting many child maltreatment cases are also important deterrents. Under-reporting of abuse also occurs when well-meaning but misguided therapists attempt to monitor and treat their abusive

clients without involving the proper authorities. Some therapists think they are above the law; others simply have no idea what the law says about reporting child abuse. The most obvious negative consequence of under-reporting is the abused child and siblings are left in dangerous circumstances and are vulnerable to further abuse.

TREATMENT

Child

The first part of the treatment of child abuse and neglect is ensuring the child's safety and well-being. The child may need to be removed from an abusive or neglectful family to ensure protection but emotionally may feel even more vulnerable in an unfamiliar setting. Because of the high risk of psychiatric symptoms in abused and neglected children, a psychiatric evaluation is in order. Along with providing specific treatments for any mental disorders present, the therapist may have to deal with the immediate situation and the long-term implications of the abuse or neglect. Psychotherapeutic issues to be addressed with an abused child include dealing with the child's fears, anxieties, and self-esteem; building a trusting relationship with the therapist in which the child is not exploited or betrayed; and gaining a perspective, over time, of the factors that contributed to the child's victimization. These issues may be addressed in individual or group psychotherapy or both.

The intensity and duration of treatment depend on the severity of the symptoms. If an abused child has no post-trauma symptoms, it probably is adequate to provide a few counseling sessions that include psychoeducation and anticipatory strategies for recognizing problems in the future. For a child who has been minimally assaulted (e.g., a relatively innocuous single episode of fondling by a stranger), it may be adaptive for the child to forget the incident and move on.

Abused children who have mild to moderate psychological symptoms have been treated with a form of cognitive-behavioral treatment that has four components: psychoeducation, anxiety management, exposure, and cognitive therapy. *Psychoeducation*

includes teaching the child and the caregivers about the nature of maltreatment, offenders, and strategies to avoid future abuse. *Anxiety management* includes teaching children how to use relaxation and other coping strategies to reduce fearful responses to memories and reminders of abuse. *Exposure* refers to talking, drawing, or writing about the abuse experiences. It is usually helpful to have the child share the painful, ugly details of the abusive experiences with the therapist. This may take time and may require therapeutic creativity and flexibility. Although some children may be able to relate the bad things that happened through ordinary conversation, other children may need a variety of play, artistic, or other projective techniques. Some children avoid painful memories through conscious (suppression) and unconscious (repression) mechanisms. *Cognitive therapy* techniques are used to help the child replace cognitive distortions about the event or negative feelings about himself or herself.

Abused children and adolescents with very severe symptoms (such as complex PTSD or DESNOS) require extensive treatment. These victims of abuse have been treated with a multimodal approach, including specific psychotherapies such as dialectical behavioral treatment (DBT), psychotropic medication, and perhaps hospitalization or residential treatment.

Parents

Developing an intervention plan for an abused or neglected child requires assessing the parents' behavior and functioning in several respects. The psychopathology and the prognosis for achieving adequate parenting skills for the abusive parent and the one who allowed the abuse to occur should be assessed. The evaluator should determine whether the parent's dysfunction is confined to this child or involves other children and whether the dysfunction is short-term or long-term (reflecting a lifelong pattern). The evaluator should assess the parent's willingness to participate in the intervention plan and the availability of personnel and physical resources to implement

the various intervention strategies. One must consider the risk of additional physical or sexual abuse if the child remains in the home.

On the basis of the information obtained, several options can be selected to improve the parent's functioning: (1) eliminating or diminishing the social or environmental stresses; (2) lessening the adverse psychological effects of the social factors on the parents; (3) reducing the demands on the parent to a level that is within their capacity through day care utilization or provision of a housekeeper or babysitter; (4) providing emotional support, encouragement, sympathy, stimulation, instruction in parental care, and training in planning for, assessing, and meeting the needs of the child (supportive casework); and (5) resolving or diminishing the parent's inner psychic conflicts (psychotherapy). Some clinics provide group counseling for nonoffending parents.

Intrafamilial Child Sexual Abuse

The first step in the treatment of child sexual abuse perpetrated by a family member is its disclosure, which means overcoming the denial and collusion of the family members and fear and blame felt by the victim. The perpetrator may leave the home, or the child may be removed by protective services, so the inappropriate sexual contact is not likely to recur. In those circumstances in which it is possible for the family to reunite or cases where the perpetrator never left the home, family therapy is useful to re-establish the group as a functioning unit and to develop healthier role definitions for each member. Specific individuals may need therapy regarding unique aspects of their involvement. If the child victim does not feel heard/validated, they can develop a defensive posture and become reclusive, distrusting, and feel unloved in addition to a host of other negative psychological sequelae. The nonoffending caregiver may also develop a sense of guilt that erodes their self-confidence and interferes with family relationships. They may feel unworthy of being a parent which could result in further parenting deficits or overcompensation for perceived faults. When the participants experience severe psychopathology, treatment must be directed

toward the underlying illness. While the perpetrators of abuse are learning to develop internal restraints and appropriate ways to gratify their needs, the external control provided by therapy helps to prevent further abusive behavior. At times, legal agencies are involved to help enforce external controls.

PREVENTION

Primary Prevention

Measures that reduce the occurrence of child abuse—*primary prevention*—can be classified on the basis of their audience or intended recipient. *Universal interventions targeted to the general public* include such strategies as a poster campaign admonishing parents not to shake their babies, required videos about the dangers of shaking babies in newborn nurseries, warnings about consuming alcohol and drugs during pregnancy, and raising public awareness through the media, civic associations, church groups, and parent–teacher organizations. To some extent, children can be taught to avoid or resist being abused. However, ultimately, the adults in a community must create safety and security for their children. *Selective interventions are targeted to populations at high risk of child abuse*. In general, for example, there should be less child abuse in a community with fewer single parents (use of birth control and greater involvement of fathers in families) and greater financial security (local jobs and social support systems). In-home programs aimed at primary prevention of child maltreatment have proven effective, but they are expensive and time intensive. These programs typically involve in-home intervention throughout pregnancy and the first 2 to 3 years after birth to provide education regarding child development and childcare to at-risk mothers. Governmental regulations may be helpful, such as the licensing of daycare centers and regulations concerning the operation of residential programs for children. Finally, one can sometimes *intervene with specific persons or families that are at high risk*. Counseling and parenting classes may deter parents from being abusive, although this has not been

substantiated. Treatment of parents who abuse substances and services for families with a history of spouse abuse may be helpful. Individuals can help friends and relatives who appear stressed and who are struggling with their parenting responsibilities.

Secondary Prevention

Early detection and prompt intervention, when child abuse occurs, comprise secondary prevention. Education of the medical profession, members of allied health fields, and all who come in contact with children aid early detection. Emergency department personnel, pediatricians, teachers, and counselors have many opportunities to identify abused children. It is hard to know how best to use the limited resources available to child protection agencies. Some critics think too much effort is put into assessing the millions of referred cases, with relatively little attention given to interventions. For instance, an agency might put many hours into collecting information, might arrive at a decision about whether a case is founded, and might engage in expensive legal measures but might offer little or no aid to help a marginal family function better. In general, child abuse and neglect prevention and treatment programs should try (1) to prevent the separation of parents and children if possible, (2) to prevent the placement of children in institutions, (3) to help the parents attain self-care status, and (4) to help the family become self-sufficient. As a last resort, to prevent further abuse and neglect, children may have to be removed from families who are unwilling or unable to profit from the treatment program.

FUTURE DIRECTIONS

When “The Battered Child Syndrome” was published in 1962, the concept of child maltreatment had a rather narrow scope, that is, child physical abuse. During the half-century since that landmark event, the understanding of child maltreatment has grown to include medical, educational, and other forms of neglect; child sexual abuse and the exploitation of children in child pornography; verbal or

psychological abuse; observing family violence; the neglect of children in orphanages; and the abuse of adolescents in institutional settings such as residential treatment centers. In the future, the scope of child maltreatment will continue to enlarge and there will be descriptive research regarding less common forms of child abuse, such as medical child abuse; parental alienation, in which a child of divorced parents loses their relationship with one of the parents; and abusive corporal punishment in schools. The phenomenon and consequences of psychological abuse will be studied more thoroughly. The sequelae of child maltreatment have been studied through retrospective and limited prospective research. The study of psychological abuse will be of particular interest to mental health professionals, especially since both *child psychological abuse* and *spouse or partner psychological abuse* were added to DSM-5. The definitions of these mental conditions refer to "nonaccidental verbal or symbolic acts … that result, or have reasonable potential to result, in significant psychological harm." The research project that addressed ACEs took child psychological abuse into consideration, in that two of the ACEs directly reflected child psychological abuse: verbal abuse by a parent or other adult in the household and feeling threatened with physical injury. The ACE researchers found that an emotionally abusive family environment accentuated negative outcomes later in life. Authors from many countries have noted that causing parental alienation in a child—inducing the child to fear or hate a parent, resulting in psychological parentectomy—is a particularly pernicious contemporary form of child psychological abuse.

In the future, there will be systematic studies from an international perspective of child maltreatment, providing information on, for example, child soldiers in Africa, child suicide bombers in the Middle East, child labor in Asia, the trafficking of children and adolescents for prostitution, and the deaths of large numbers of children due to lack of food and medical care.

A major focus of research in the next few years will pertain to resilience. This research will address the question of why some maltreated children manifest very serious psychological and

behavioral symptoms, whereas other abused children are free of symptoms both in the short and the long term. At least part of the answer to this question will involve genetic predispositions, specific life experiences, and the interaction between genetic and environmental factors.

In the more distant future, there will be a greater understanding of the chain of events by which trauma damages young victims, starting with specific genetic and other congenital vulnerabilities and predispositions that interact with maltreatment and other forms of adverse childhood experiences. These predispositions and experiences lead to changes in cognitive and affective pathways in the brain, which will be observed through neuroimaging. Alterations in the brain will be shown to cause changes in behavioral and emotional functioning, which result in dysfunctional relationships and additional symptoms and disorders. Although society's goal is the primary prevention of child maltreatment, that objective will not be fully achieved. The research outlined here will inform the secondary prevention of the consequences of child abuse, as well as the biopsychosocial treatment of abused children.

54.3 Children's Reaction to Illness and Hospitalization

SUSAN BECKWITT TURKEL, M.D., JULIENNE JACOBSON, M.D., AND MARYLAND PAO, M.D.

HISTORY

Hospitalization of young children was a rare event before the mid-19th century, as most children were cared for at home, and hospitals were considered unsafe for them. When young children were admitted to early general hospitals, their mothers typically remained with them to assist in providing their care. This was routine and met with little opposition. Some hospitals would only admit children on the condition their mothers were present. From the 1850s through the 1880s, hospitals encouraged regular visits from parents and siblings. These visits were viewed as important for the well-being of the sick children. Outbreaks of infectious diseases might temporarily restrict visits, but they were reinstated as soon as possible. Any restrictions on visits would be lifted for seriously ill or dying children. The goal was to create, at least in part, a "homeliness" where children could feel safe and comfortable.

The transformation of the hospital into a headquarters for scientific medicine started in the period before the First World War and had profound implications on medical care, research, and education. The exclusion of parents from the hospital began in the late 19th century. Hospitals gradually restricted parental access and removed toys, pictures, and pets from the wards. These changes reflected changing ideas about the spread of infectious diseases, the growing professionalism of nursing, the development of the specialty of pediatrics, and funding changes for healthcare. Visitors, including parents and siblings, were restricted or excluded from the children's wards because of the belief that the emotional upset the visits created would be detrimental to the child's recovery. Fear of infection led to banning personal contact between parents and their children, and glass panels were provided so parents could see their children on the ward. The practice of enabling mothers to remain with their hospitalized children never completely disappeared, but mainstream practitioners during this period were unconvinced of the importance of having the mother in the hospital with her sick child.

Nursing was highly regimented during this period, and children and parents often perceived the staff as uncaring. Pediatric doctors and nurses cared about their patients' emotional well-being but were taught to be disciplined, professional, and scientific and not to show affection or emotion. Consequently, hospitalized children were traumatized by their illness, by separation from their parents and families, and by the lack of warmth in the care they received.

Little changed until after the Second World War. By that time, the prevailing practices were in conflict with emerging psychoanalytic and developmental theories of the social and emotional growth of children and new thinking about the child's need for parental interaction and emotional care. John Bowlby, deputy director of the Tavistock Clinic in England, established a separation research unit in 1948, which led to his formulation of attachment theory. Bowlby warned that maternal deprivation or separation or denial of a warm, intimate, continuous relationship with the mother, or mother substitute could have far-reaching effects on the child's character and mental development. Other psychoanalytic studies used hospitalization as an example of the first early separation from home. Psychoanalysts were aware of the lack of integration between the practice of child guidance, psychoanalysis, and pediatrics. Observation of the profound emotional reactions of children to physical illness and the likelihood that mothers might be unable to make objective observations when they were emotionally upset by the stresses of their child's condition was noted. The need to prevent the negative psychological impact of hospitalization on children was soon accepted by most psychiatrists and some pediatricians, but this did not yet change hospital practice.

James Robertson, a student working with John Bowlby, translated Bowlby's theories into film, starting with "A 2-year-old Goes to Hospital" in 1953. This film emphasized the detrimental effects of an

admission that separated a young child from his family, friends, and mother's care. It demonstrated the phases of protest, despair, and detachment (or denial) through which small children pass when isolated from their mothers for a length of time and illustrated how children who had been left in the hospital exhibited greater behavioral problems when they returned home. His film was widely shown to both professional and lay groups and was instrumental in accelerating change in hospital practice.

Following the efforts of Robertson and others, public outcry led to formation of a British parliamentary committee, chaired by Sir Harry Platt, which investigated the hospital care of children. The committee found that children were expected to conform to ward routines, lie quietly in their cots, and were not allowed to play; their parents were allowed to visit only during restricted visiting hours. The committee's report, "The Welfare of Sick Children in Hospital", published in Britain in 1959, led to the revolution in pediatric hospital care in Britain and other western countries. The Platt Report recommended unrestricted visiting and accommodation for parents, especially for children less than 5 years old. The committee sought to minimize potential damage caused by the separation of children and mothers, and to encourage appropriate stimulation for the child in the hospital.

The recommendations of the Platt report took time to be implemented. Gradually the views of pediatricians and pediatric nurses changed from those prevailing since before the Second World War and became less discordant with the views of child psychiatrists. Pediatricians and child psychiatrists now agree about the significant impact of separation, illness, and hospitalization on children and their families.

The length of hospitalization and the reasons children and adolescents require hospitalization had changed considerably. Children used to be admitted to the hospital for much longer periods than they are today. Changes in morbidity and treatment modalities, along with alternatives to inpatient care such as day surgery, home intravenous antibiotics, ventilators, and advances to maintain technology-dependent children at home, have led to shorter and less frequent hospitalizations. The average length of stay has been reduced by almost half and same-day discharges have almost tripled in the past 25 years. The leading causes of hospitalization recently have been asthma, gastrointestinal disorders, pneumonia, and seizures; inpatient surgeries have declined as outpatient procedures have increased. Hospitalizations lasting more than 7 days now are likely to be for psychiatric reasons, chemotherapy, and treatment of malignancies, or to address complications of procedures or prior treatment.

As survival rates have increased, at least 90% of children with chronic conditions now live to young adulthood. Inpatient hospitalization for children with more common conditions has shifted to outpatient care, leaving proportionally more complicated, chronically ill children in inpatient settings.

Hospitalized children now are significantly medically complex, often with comorbid psychiatric disorders. This small proportion of children accounts for most health care expenditures: 20% of children with complex chronic illness and children with special health care needs account for 80% of costs. The prototypical medically complex child has a multisystem disorder, is probably technologically dependent, has frequent inpatient admissions, require multiple medications, multiple subspecialists, and optimal care coordination across inpatient and outpatient settings. Care is usually provided at tertiary care centers. These children have three times longer lengths of stay, over 10 times greater billing charges, significantly higher gastrostomy and tracheostomy placements, intensive resource use, and 15 times inpatient mortality. Seriously and chronically ill children are "growing up in the hospital," and the lives of these children and their families may differ considerably from their peers.

CONTEMPORARY PEDIATRIC HOSPITALS

Contemporary pediatric hospitals and wards are staffed and structured differently than adult units, and children's hospitals typically include features not found in most adult settings. The physical layout of a children's hospital or pediatric ward is usually designed to facilitate the child's primary caregiver staying with the child. Sleeping arrangements, showers, laundry, and other facilities are made available to increase individual patient and parent comfort and facilitate extended stays with children. Private rooms or conference rooms exist to allow doctors and parents to confer in privacy.

Accommodations are now made to encourage visits even from large or extended families, placing the experiences of children and their families at the heart of pediatric healthcare. To decrease stress in waiting areas, toys and activities are available in brightly colored, child-friendly spaces. In an effort to

provide maximum continuity of care, every child may be assigned a primary nurse who will continue to be the child's primary nurse in subsequent hospitalizations. While most large medical centers have hotels nearby for family members, children's hospitals often provide additional settings such as Ronald MacDonald House, where entire families may stay in small, subsidized apartments. Social workers, parent advocates, groups for parents and for siblings, and educational groups provide support to families. Disease-specific summer camps for patients and siblings and other recreational group activities for sick children are characteristically managed through children's hospitals or disease-specific charitable organizations. Parents, initially focused on potentially life-threatening physical concerns, often express deep gratitude for these services later and are grateful for additional support for their child's psychosocial development. Psychosocial standards have been developed for children with cancer and their families to ensure many of the services described below are integrated routinely into care.

Child life programs have become standard at children's hospitals. These developmental specialists are available in most pediatric inpatient units and in some outpatient pediatric settings to help minimize disruption in a child's development by hospitalization, surgery, or other potentially frightening or distressing medical experiences. Child life specialists provide recreational activities, often in designated places where children can engage in therapeutic play. Child life specialists help provide information and preparation, and can rehearse useful coping strategies for medical procedures with children. Preoperative surgical preparation programs have been shown to be effective in reducing anxiety and improve children's abilities to cope with the stress of a surgical procedure more effectively. The goal is to help children understand their feelings about their experiences in the hospital and facilitate better adjustment.

Emphasis has been placed on minimizing physically painful experiences. Regular assessment of pain in children using age-appropriate measures has been widely implemented, and the use of nonpharmacologic and pharmacologic techniques adapted for young patients are more standardized and better utilized. These changes have been important in further decreasing the stress of hospitalization for children and adolescents.

Education is a major part of each child's life, and hospital schools and teachers are present in most pediatric settings. Some children's hospitals have arrangements with the local school system to provide teachers, and others employ their own. Either way, collaboration with the child's school is important in helping maintain academic progress as much as possible.

Principles of behavior management are typically incorporated into the culture of pediatric units, where staff can play an important role in modeling and encouraging age-appropriate behavioral management by parents. The absence of limits and consequences for misbehavior can be harmful for children, leading to acting out and difficulties in regulation of emotion and behavior. Although mental health professionals have limited opportunities to monitor behavior directly and cannot substitute for parents and staff on the unit, frequent consultation with psychologists, social workers, and child psychiatrists can be helpful to the care team, to patients, and to families.

Helping children, adolescents, and their families adapt to hospitalization should involve the child, parents, family, and hospital staff. In current family-focused models of care, a child's care is planned around the whole family with parents considered integral to the treatment process. Family-centered care has proven to be valuable in helping families and children cope with the stress, fear, and altered parenting roles that accompany a child's illness and hospitalization. While the creation of a nurturing and developmentally sensitive hospital environment is primarily the responsibility of staff, the assistance of family members is essential in establishing structure and maintaining stability for sick children. "Anticipatory guidance" about parenting struggles in and out of the hospital can be helpful. Parents of children with life-threatening illnesses often feel guilty and need support to maintain usual parenting practices. Parents of chronically ill children should be included in discussions with hospital staff about realistic rules; this leads to increased adherence to daily schedules and consistent behavioral expectations.

Inpatient pediatric care requires constant review by nursing and medical staff as well as by patients and families to remain relevant and effective. While past initiatives have created the current environment of pediatric inpatient care, hospital staff should remain open to adopting additional practices as further studies identify better alternatives.

COLLABORATIVE CARE, INTEGRATED CARE, AND THE MEDICAL HOME

Psychiatric participation in pediatric care has been extended from the hospital to the outpatient setting, and pediatric primary care has become an important site for providing mental health services. Approximately one in four U.S. children suffer from a chronic health problem, and one in five from a psychiatric disorder. Integrating psychiatric into pediatric care can improve overall medical outcomes, increase healthcare utilization, and decrease healthcare costs for medically ill children and adolescents by shortening hospital length of stay, reducing rates of readmission, and improving adherence. Integration of child psychiatric services in pediatric primary care assists in addressing structural and attitudinal barriers, shortages of behavioral health specialists, and geographical difficulties in locating and participating in psychiatric care.

Outpatient integrated care systems are intended to expand psychiatric access. They range from care coordination and collaborative care to colocation to embedded child psychiatric services to fully integrated medical-psychiatric practices, which can make it much easier for families by providing early psychiatric referral, increasing access to care, and improving their engagement in mental health services.

The medical home concept originated in the American Academy of Pediatrics (AAP) in 1968 to provide for children with special health care needs. The AAP defines the medical home model of care as comprehensive, high-quality care that is accessible, family-oriented, coordinated, continuous, compassionate, and culturally effective, with the goal of coordinating medical and mental health care. About half of U.S. children receive health care in a medical home setting.

The integration of behavioral health interventions into pediatric medical care has been a national priority. The 2010 Affordable Care Act promoted the medical home as an efficient way of providing accessible, continuous, comprehensive, family-centered, coordinated care to children and adolescents. School-based health centers are another way a medical home can be structured to provide the same services in settings that are easiest for students and families to access. Most models of integrated and collaborative care have relied on state-level initiatives or additional funding sources to establish them, usually in large public or academic health care systems, which may be difficult to sustain. The use of telehealth technology can extend service delivery and has become an essential tool in increasing the number and variety of services.

The wrap-around service delivery model refers to coordination between multiple agencies providing mental health, child welfare, juvenile justice, developmental support, addiction, and primary health care required for children and adolescents with complex needs.

IMPACT OF ILLNESS AND HOSPITALIZATION ON CHILDREN

Sick children are not a homogeneous group. They come to the hospital having very different life experiences, irrespective of their medical condition. The presence of an acute, life-threatening, or chronic physical illness by itself is insufficient to produce psychiatric problems, but it may make the child more vulnerable to emotional difficulties and may exacerbate any pre-existing psychiatric illness or behavior problems. How a child will react to illness and hospitalization is more a reflection of their age and understanding of their situation, their parents' response, and the nature of the illness, and its treatment rather than the greater severity of the medical condition itself.

Preschool children are hospitalized more than older children, and those younger than 7 years are at greater risk for more frequent and potentially lasting emotional and behavioral problems after hospitalization than older children. The risk of later aggressive and hyperactive behaviors can usually be predicted by the mother's emotional state and the child's premorbid behavior. Baseline internalizing or externalizing behaviors may be the best predictor of increased behavior problems 3 to 6 months after hospitalization, and medically ill children with greater premorbid emotional and behavioral problems have more psychiatric disorders following their illness. When illness is experienced as an insurmountable obstacle or the cause of rejection by loved ones, the child may react with extreme emotional distress, and suicidal ideation and behavior may occur. Overall, 20% of children with chronic conditions have behavioral and emotional symptoms, double the rate of the general population.

Conditions that are less visible, have a remitting-relapsing course, or uncertain prognosis may be associated with greater emotional problems. Males with chronic conditions appear to have more emotional sequelae than females. Children with brain damage have poorer overall adaptation to illness. Adopted children and their parents also seem to have more problems with hospitalization. On the other hand, the personality characteristics of sociability, flexibility, and physical attractiveness appear to be protective, and may mitigate against more severe emotional problems. Children from families with clear boundaries, the capacity to balance competing family needs, the ability to maintain flexibility, and the tendency to ascribe positive meanings to life events, fare best.

Chronic and serious physical illnesses involve recurrent separations and frequently upsetting events, which can be distressing to both parents and children. Surgery, medical procedures, adverse medication side effects, and diagnostic tests can be frightening, confusing, unscheduled, disruptive to sleep, and painful. The burdens of chronic illness are pervasive and may produce chronically stressful situations, resulting in maladaptive behavior, emotional symptoms, and added financial burdens, all contributing to conflict, guilt, and anxiety in the family.

Medical illness and hospitalization can pose serious threats to the developmental process and impact the physical and emotional environment, disciplinary context, schooling, family life, and neurobiology of the chronically ill child, and thus profoundly affect cognitive, emotional, social, and sexual developmental trajectories. Invasive procedures; separation from family, friends, and school, lost opportunities to develop interests, and a diminished sense of self-mastery further complicate development. Environmental restrictions, such as isolation for infection control and limited activities available in the hospital, lead to fewer opportunities to discover personal strengths and weaknesses. Chronically ill children often have difficulty finding something to be “good at” and have trouble feeling confident and competent. Delayed growth and puberty are common in chronically ill children and adolescents, especially when malnutrition, prolonged corticosteroid treatment, or chronic inflammatory processes are prominent. These growth delays typically have additional negative psychological implications.

One week after discharge from the hospital, a child often demonstrates increased anxiety about separation, may experience sleep problems, and may be more aggressive. These behavioral changes should quickly resolve as the child adjusts to the return home, but this may not always happen. Repeated admissions of children coming from dysfunctional or disadvantaged families are very likely to be associated with emotional and behavioral problems following hospitalization, but all children may be at risk. The most difficult period of adjustment to a hospitalization may be near the beginning, when new and painful experiences and separation are most distressing. Prolonged periods of hospitalization bring the risk of developing maladaptive behaviors. In a meta-analysis of studies of children’s behavior after hospitalization, children hospitalized for 2 to 3 days showed more behavioral problems than those hospitalized for longer or shorter periods, and overall, briefer hospitalizations of older children were the least likely to have detrimental effects.

Post-traumatic stress disorder (PTSD) has been described following critical illness and surgery. Serious accidents and hospitalizations following acute physical trauma may be associated with PTSD, while the risk of PTSD in children and parents after simple planned surgery is almost nonexistent. Children and parents after newly diagnosed cancer and children and parents following solid organ transplantation may also be at risk for PTSD. Parental distress and characteristics of the family environment are more correlated with the development of PTSD symptoms in sick children than family composition, course of hospitalization, or the extent of a child’s accidental injuries. In contrast, commitment, help, support, and the open expression of feelings in the family can facilitate a child’s better adjustment to newly diagnosed cancer and associated intensive medical treatment. Sometimes the treatment of life-threatening medical illness may be experienced as repeated trauma, which might not impact during or immediately after treatment, but rather appear as long-term effects on affect modulation and interpersonal relationships.

Attempts have been made to mitigate the negative consequences of hospitalization, not only in the way hospitals are structured and function but also in the provision of preventative educational or behavioral interventions. In a meta-analysis of a variety of interventions, psychoeducation was generally not effective with younger children, and any benefits from the experimental interventions disappeared by 4 weeks after discharge. Other programs which focus on increasing parents’ knowledge and understanding of the range of behaviors and emotions that young children typically display during and

after hospitalization and that support direct parent participation in their child's physical and emotional care are more effective and help reduce the mother's emotional stress, depression, and anxiety, reduce the child's negative behavioral symptoms and increase the child's adaptability up to 12 months after hospitalization.

When psychiatric and behavioral symptoms are severe or persistent, a thorough psychiatric assessment, based on multiple brief examinations of the child and information gathered from parents, other family members, hospital staff, and teachers, is needed. A child's biologic vulnerability to depression and anxiety may be inferred from a history of previous psychiatric symptoms or psychiatric treatment, or from a family history of a mood, anxiety disorder, or other psychiatric disorder. Psychiatric syndromes of adjustment disorder, major depression, anxiety, delirium, and psychosis can be diagnosed in medically ill children, and require appropriate intervention.

Behavioral and cognitive approaches, such as distraction, guided imagery, and relaxation for reducing procedural distress, are well-established in the pediatric hospital setting. Supportive individual and family therapy and cognitive behavioral and family therapy may be useful in reducing anxiety and in providing patients and families with adaptive strategies to use in coping with illness and its treatment. Psychopharmacotherapy may be indicated based on the severity and duration of psychiatric symptoms.

IMPACT OF CHILD'S ILLNESS ON FAMILIES

The family of a seriously or chronically ill child is as affected by the illness and frequent hospitalizations as is the child, and the social impact of the illness is felt throughout the family system. Family systems are dynamic and can be sources of risk or protection for a child with a serious medical problem. Chronic conditions present the entire family with an additional set of tasks, responsibilities, and worries. There is personal impact on a parent, financial impact on the family, and implications for family and social relationships. Parents must deal with the day-to-day management of the illness, with the increased financial burden associated with medical bills and time lost from work, and with the uncertainty about treatment and their child's prognosis. This can place additional strain on a marriage and can significantly affect the parents' relationships with other children. Relatives, teachers, and friends may be available to provide support, but they also may be negatively impacted by the child's illness. Social activities usually become limited, decreasing opportunities for interpersonal support.

When illness presents early in the child's life, parents face additional challenges and feel uncertain and helpless. They must make difficult treatment choices, confront the risk of premature death, and come to terms with their lost expectations, fearing the loss of the child's functional abilities and independence.

Family cohesion, open communication, and the ability to adapt to conflict are indicative of healthy family function and psychological adjustment in families with chronically ill children. Nine aspects of a resilient family process have been identified: (1) balancing the chronic condition with other family needs, (2) maintaining clear family boundaries, (3) developing communication competence, (4) attributing positive meanings to the situation, (5) maintaining family flexibility, (6) maintaining a commitment to the family as a unit, (7) engaging in active coping efforts, (8) maintaining social integration, and (9) developing collaborative relationships with professionals.

Parental temperament and coping skills strongly influence how their child copes. Children take their cues for coping and adaptation to illness primarily from their parents, especially their mothers. Parents who are able to isolate their own fears and anxieties during crises are better able to enhance their child's understanding of the illness and facilitate self-care and independence in their child. Parental anxiety can have a negative effect, and children with very anxious mothers often have less distress during procedures when their mothers are not present.

Parents tend to remain at the hospital during the initial diagnosis and early therapeutic interventions, and usually return when symptoms worsen or complications arise during hospitalization. Once the first crisis passes, the mother is most likely to take on the day-to-day care of the child. She is often the parent who remains in the hospital with the child, accompanies the child to physician visits, provides support for procedures, and acts as advocate for the child with health care team. Research on fathers' reactions is consistent with studies on mothers, although fathers are less well-studied. Fathers traditionally take on additional financial burdens associated with a child's illness and endure separation

from their spouse and ill child during hospitalizations. Mothers also work and lose pay when off work with their sick child, adding to the economic impact on the family. Men often seek to be more involved in caring for their sick child. Fathers give direct care to the sick child, take turns staying in the hospital, and take on the primary care for the other children remaining at home. Although fathers may not be as constant a parental presence at the hospital as mothers, treatment teams must remember to include fathers who also struggle to adjust and cope with challenging issues of their child's condition and care.

Parents may respond differently to different conditions. For example, with traumatic brain injury in their children, fathers are more likely to use denial and report greater injury-related distress, while mothers are more likely to demonstrate acceptance and emotion-focused coping. Mothers may also be better able to adjust over time, while fathers' adjustment and marital satisfaction may not improve.

Parents need to deal with feelings of helplessness due to their inability to protect their child from harm. Differences in coping style may contribute to emerging family dysfunction. While at risk for maladjustment, there is considerable individual variation, and many do well. Some parents experience marital distress and impaired sexual relationships, but other parents of children with cancer report their marriages are satisfactory and their partners are supportive, and higher divorce rates have not been found. While marital discord is associated with increased psychological problems in chronically ill children, a mutually supportive marriage can benefit the family's ability to cope with stress. Feeling uncertain about the outcome is to be expected, but it can lead to a fragile sense of optimism and hope. Parental hope may be a coping strategy, and parents may avoid information and people that threaten their hope. Open, empathetic communication and a sense of connectedness strengthen the relationship, while physical and emotional distance is the most common challenge.

Siblings of a seriously, chronically ill child are in a very difficult position. They often are asked to take increasingly adult roles to "help out" while receiving less attention and support from their parents, adapting to personal and family changes while dealing with their own strong emotions. The sibling may love and worry about their sick brother or sister and, at the same time, resent them, leading to feelings of guilt. Sibling rivalry and jealousy increase when the focus of both parents and the family's resources are directed toward the ill child with less time and attention for the healthy siblings. Siblings of chronically or severely ill children often feel isolated, and their family life is interrupted. They are more likely to develop depression, anxiety, and a negative self-image and have fewer quality peer activities. Younger siblings may be more resilient, and life-threatening illnesses may exacerbate the siblings' risk.

Sibling adjustment typically parallels the family's adjustment and finding ways to help the mother feel confident in managing her child's illness is integral to her ability to provide the optimal home environment for both the sick child and the healthy siblings. Parents of sick children rate the siblings' quality of life better than the siblings themselves do, so sibling adjustment needs to be assessed individually.

Siblings may be asked to donate hematopoietic stem cells for transplantation. Donor siblings often feel they "had no choice" about donating. Both donors and recipients may have post-traumatic stress symptoms following the transplant, and nondonor siblings may report more anxiety and lower self-esteem. Teachers have observed donors to have both more adaptive coping and more school problems and attention-seeking behaviors than nondonor siblings. Donors themselves report the psychological aspects of donating outweigh any physical consequences, whether their sibling lives or dies. If the recipient dies, the donor sibling frequently feels guilty, and may use spirituality and religion as primary coping strategies. Siblings want to be included in decisions, be provided information, be given choices, have help sharing their feelings, be provided opportunities to meet with peers, and experience a supportive hospital environment when they visit.

Siblings of a dying child benefit from preparation and support as the time of anticipated death nears. They should be included in discussions of what changes to expect and estimates of survival, and again be asked about their own fears and experiences. Increased anxiety and persistent feelings of regret related to a sibling's death have been described in surviving siblings who were not present during the illness or at the time of death. Bereaved siblings who received support from clinicians and were present and involved at the time of their sibling's illness and death often report positive memories, and most perceived physicians and staff as warm, kind, and honest. Surviving siblings who were involved in the process describe their sibling's strong willpower, good mood, and stamina in the face of adversity, enhanced family cohesion and strengthening of family bonds, and feelings of personal growth. A

minority of surviving siblings describe negative experiences, and report increased awareness of vulnerability, feeling emptiness and loneliness, unacknowledged and personally stagnant, and see increased family conflict. Families who actively seek information and services, work to solve problems, express their feelings, and are able to balance personal, family, and illness needs show better adaptation to a child's illness and hospitalization.

Maintaining supportive relationships with people in the community can also be an important protective factor. Informal support networks provide emotional and informational support and sometimes tangible aid. Illness-specific resources and formal support groups should be made available to families. When coping difficulties are recognized or psychological symptoms develop, mental health services may be needed and referrals made.

When families are given a new devastating diagnosis, such as childhood cancer, optimally, the family views the illness as a challenge that is controllable and changeable, making long-term difficulties in psychological adjustment less likely. Alternatively, the family may respond as though the event is a matter of chance beyond their control, and exhibit denial, detachment, intellectualization, or substance abuse instead.

Health care providers are very influential and play a powerful role in the lives of families with a sick child. Parents look to them for essential medical information and guidance. Pediatricians need to be aware that anything said by physicians, whether well-reasoned or not, can have an enormous impact on parents and children, and effects may be immediate or long-lasting. When families of pediatric cancer patients were surveyed about information they received from medical teams about what to expect from the effects of cancer and its treatment on a child's psychological health, 86% of parents and 71% of siblings reported they did not receive enough or any information. They felt unable to ask professionals about current and future psychosocial issues and related topics. Half the parents and a quarter of the siblings later wished they had communicated their feelings more to other members of the family, noting limited communication in their own family. Reports of family communication differ and family members may have different requirements, necessitating assessment of the need for support and information for each member.

Medical communication delivered in a clear, thoughtful, and sensitive manner can promote competent family functioning and resilience, despite the presence of a life-threatening illness in a child. However, when health information is not thought through or clearly given, it may be misconstrued, misinterpreted, or misunderstood, and may lead to a constellation of abnormal behaviors and altered parent-child interactions that are referred to as the vulnerable child syndrome (VCS), first described by Green and Solnit in 1964.

The cardinal features of VCS include:

1. pathologic separation difficulties, such as poor sleep in infants, recurrent unexplained abdominal pain, or school phobia in older children
2. infantilization with overprotective, overly indulgent, and overly solicitous parent, and an overly dependent, disobedient, irritable, argumentative, and uncooperative child
3. bodily over concerns, when the child has many physical complaints and the parent (usually the mother) has difficulty differentiating between the child's discomfort and their own distress, and cannot distinguish mild, self-limited symptoms from potentially serious illness
4. Separation anxiety, delaying starting school, and school underachievement.

Predisposing factors to VCS include a history of infertility, miscarriage, illness during pregnancy; prematurity; a life-threatening illness; or a child with a chronic medical illness, especially if there was hospitalization during the first year of life. VCS is linked to more frequent emergency room visits and inpatient hospitalizations. Depending on how their parents perceive the event, even older children seen in an emergency department for minor head trauma or hospitalized for gastroenteritis or asthma may be at risk for VCS.

The prevalence of VCS in a community sample was estimated at 10% in 1995 but may be higher today with improved survival of premature children and children with serious chronic illnesses. The degree of parental perception of vulnerability does not necessarily correlate with the severity of neonatal problems, birth weight, or current health. Rather, higher levels of maternal anxiety at neonatal discharge

better predict parental perception of child's vulnerability and are associated with worse developmental outcomes. Affected parents often have difficulty with setting age-appropriate limits, and demonstrate permissiveness alternating with excessive attempts to control their child's activities. They are also likely to seek higher levels of medical service and have more dissatisfaction with the medical care provided.

A child's perception of their own vulnerability does not necessarily correlate with their parents' perception. When children rate themselves as vulnerable, most parents agree; when parents rate their children as vulnerable, only about half the children agree.

Effective communication is at the heart of the preventing and managing VCS. If the child stays healthy and communication between parents and pediatricians is effective, VCS does not necessarily persist into school age. Persistent parental fear that a child remains vulnerable can be elicited by asking parents, "has your child ever been seriously ill"? VCS should be suspected when parents then respond by relating traumatic accounts of their child's perceived near-death experiences. The physician can decrease the risk of unintentionally exacerbating parental anxiety and any belief in their child's vulnerability when discussing diagnosis, prognosis, and anticipated treatment with a parent with excessive anxiety or guilt by being aware of the parents' and their own state of mind. The parents' frightening experience should be acknowledged, parents provided a more accurate assessment of their child's health, and informed when time-limited medical problems are resolved and will not recur. The importance of encouraging appropriate autonomy in the child should be emphasized with discussion of potential adverse effects of excessive parental concern on a child's development and behavior. Reassurance and regular follow-up help to distinguish normal development and behavior from problems needing psychiatric consultation.

A CHILD'S RESPONSE TO ILLNESS AND HOSPITALIZATION AT DIFFERENT AGES

A child's behavioral response and concept of illness and its causes follow a sequence of developmental stages related to their perceptual ability and cognitive development (Table 54.3–1). This section is limited to a description of a child's response to illness and hospitalization at different ages. For a complete description of child development, see the chapters on Child Development and Adolescent Development.

Infants (Birth to 18 Months)

Serious illness and hospitalization separate infants from their parents and set them in a strange, frightening, unpredictable environment. This can provoke anxiety and confusion putting them at risk for disruption in the development of basic trust. Infants younger than 7 months rarely protest separation from their mothers and seem to accept substitute caretakers in the hospital. They may then appear briefly but dramatically upset upon return home. Infants older than 7 months protest initially, appear uncooperative and subdued in the hospital, and then require a readjustment period upon return home. The more infants are provided with contact and comfort from parents when distressed by illness or hospitalization, the better basic trust can be protected. Infants subjected to unexpected medical procedures may have difficulty forming attachments and become anxious. Repeated exposure to pain and the absence of social stimulation in neonates may affect later pain sensitivity, brain volume, neuroendocrine functioning, behavior, and cognition. If parents are unable to hold and soothe their babies because of the nature of an injury or medical care, the babies are at risk for apathy and withdrawal, the attachment process may be disrupted, and separation anxiety may develop. Infants may then refuse to interact with parents, or become clingy, demanding, and difficult to soothe.

It is important to maintain consistent nursing staff and infant routines, preferably with parents or familiar caregivers in the baby's room. If they cannot stay, attempts should focus on maintaining regular times for parental visits. Parents should be encouraged not to leave only after infants are asleep as this adds to an infant's anxiety and distrust. Normal stranger and separation anxiety may become exacerbated by frequent staff changes, so attention to providing familiar affectionate staff on a regular schedule may be helpful. Both parents and babies benefit from staff support, and parents may need staff to model appropriate interactions and interventions with their baby.

Table 54.3–1.
Summary of Impact of Illness and Hospitalization

Age	Child's Response	Possible Effects of Hospitalization	Possible Effects of Chronic Illness
Infancy 0–18 months	▶ Unable to understand ▶ Fear abandonment ▶ Perceive pain	▶ Anxiety and confusion with separation	▶ Decrease access to the environment ▶ Parents' guilt, anger, and grief may interfere with attachment ▶ Difficult to establish trust ▶ Greater helplessness
Toddler 18 months to 3 years	▶ Fear abandonment ▶ Little capacity for reasoning or understanding experience	▶ Regression ▶ Negativism ▶ Restricted activities ▶ Important to maintain routines ▶ Transitional objects help	▶ Delay motor and language development ▶ Parental reluctance to set limits ▶ Problems with bladder and bowel function
Preschool 3–5 years	▶ Fear mutilation ▶ Magical thinking ▶ Attribute illness and pain to punishment for bad behavior	▶ Fear abandonment ▶ Fear mutilation ▶ Hospital play beneficial	▶ Parental overprotection ▶ Regression ▶ Limited initiative ▶ Compromised social function
School Age 6–12 years	▶ Illness is punishment for bad behavior or due to own ideas of cause ▶ Understand simple bodily structure and function ▶ Understand the purpose of treatment	▶ Fear pain ▶ Benefit from clear expectations and concrete explanations ▶ Important maintain roles and rules	▶ Alienation from peers ▶ Fewer social interactions ▶ Limited activities ▶ Parental overprotection
Adolescent 13–18 years	▶ Abstract thinking ▶ Understand body processes and implications of illness ▶ Understand cause and effect ▶ Hypothetical reasoning ▶ Comprehend mind–body issues	▶ Fear alienation from peers ▶ Value privacy ▶ Appearance important ▶ Want to participate in treatment decisions	▶ Concerned about appearing different from peers ▶ Concerned about medication side effects ▶ Show risk-taking behavior ▶ Treatment nonadherence ▶ Immaturity and overly dependent on parents

Toddlers (18 Months to 3 Years)

Toddlers' primary developmental goal is to establish early autonomy and separation-individuation from their parents. These tasks require a secure base. They are difficult to accomplish without having first established basic trust, which may not have occurred effectively if the toddler was ill or hospitalized as an infant. Toddlers fear abandonment when separated from their parents or primary caregivers. Like infants, they benefit from maintenance of routines and stable relationships, which support early independence and efforts at developing competency. Transitional objects may be particularly helpful in this age group, so bringing toys, blankets, or other familiar objects from home to the hospital or doctor's office may help calm an anxious toddler.

The requirements of medical care can be infantilizing and carry high risk for regression, increased dependence, and negativism. It is easy for parents to become overly protective or permissive during a toddler's illness and behavior problems may result. If these parenting patterns persist after recovery, tantrums, and oppositional behavior increase, which leads to parental anger and threat of rejection, followed by guilt and more permissiveness, and a vicious cycle of behavior problems can develop. Providing anticipatory guidance to parents during a toddler's hospitalization and follow-up behavioral management and support after discharge can be helpful.

Preschool Age (3 to 5 Years)

Preschool-age children seem to be more upset by hospitalization than older children or infants, but they are the most likely to benefit and respond positively when their environment is supportive. When the child is prepared for hospitalization, parental visits are consistent, and parents participate in their child's care during hospitalization, the potential emotionally traumatic effects of hospitalization need not occur.

The preschool age is the period of "magical thinking" when children typically attribute illness and pain to punishment, and hospitalization and separation to rejection. Limited understanding and concrete thinking contribute to fears and misconceptions, leading to feelings of guilt and distress. Children this age have a very rudimentary concept of the body and its parts. They fear mutilation, and all parts of the body are considered equally essential. This limited understanding may cause procedures such as phlebotomy and surgery to be especially terrifying. Children are often unable to articulate their fears. They may not understand adult attempts to describe bodily structures and functions, illness effects, or treatment plans. Children of this age often benefit from preparation for procedures through medical play. When the material is presented in a manner congruent with their cognitive function, comprehension is improved, and fear is reduced.

School Age Children (6 to 12 Years)

School-age children are typically active and focused. Developmentally, they are working to become secure in their own abilities and accomplishments. During this period, they acquire academic and social skills and begin to internalize parental and societal values. School-age children, like younger children, often believe that their illness is a punishment for misbehavior. Their strong respect for authority and rules often leads school-age children to feel illness or injury is the consequence of not following rules properly. Because their understanding of anatomy and physiology is more complete, children this age have less fear of mutilation than younger children. However, because their thinking remains concrete, they cannot comprehend hypothetical possibilities or complicated explanations. Adult attempts to explain illness, injury, or anticipated medical procedures may be confusing, especially when explanations are complex or abstract. Medical explanations can be easily misunderstood or misinterpreted, leading to confusion and increased fear, which the child may be reluctant or unable to disclose. Drawings, photographs, and clear explanations at an appropriate cognitive level will better help children understand and master their experiences. It is important to minimize physical pain as much as possible. Difficulty coping with pain, and anxiety about pain, may compromise a child's ability to understand and participate in care. Potentially painful or frightening experiences may be less stressful with adequate preparation and explanation. School-age children should be encouraged to express their fears, ask questions, and talk about their feelings to engage them in the process and help increase their sense of mastery of their illness.

It is important to maintain routines and relationships for school-age children during illness or hospitalization. Children should be supported to meet their responsibilities for school, maintain

connections with peers, and participate in as many of their usual activities as possible. These older children have an increasing awareness of the personal significance and implications of their illness. The ability to adapt to new, challenging experiences increases with age and expanding cognitive function. Coping with illness and hospitalization may increase children's resilience and teach skills useful in other settings.

Adolescents (13 to 18 Years)

Adolescence is a complex process of transition from childhood to adulthood and is a challenging time for most. Adolescent's ability to understand their illness, their body and its functions, and the causes, nature, and treatment of their illness expands as cognitive skills increase. They are more skeptical of simplistic explanations or superficial reassurance. As formal operations develop in individuals of normal intelligence, adolescents become able to hypothesize cause and effect, understand hypothetical suppositions and multifactorial explanations, and participate in decision-making and assent/consent for treatment.

Adolescents are usually aware of the implications of their illness. They may be concerned about its effects on their relationships, fertility and sexuality, and vocational possibilities. They fear the loss of independence and control, and of their sense of physical well-being and integrity. Younger adolescents especially do not want to be different from their peers. They are exquisitely sensitive to changes in their appearance and dread permanent disfigurement. They understand the permanence of death and fear it. Issues of puberty, autonomy, personal identity, sexuality, education, and vocational choice are challenging to adolescents. They are more difficult for an adolescent who is also coping with an acute or chronic illness. Illness can be associated with medical setbacks, impaired physical or mental abilities, forced dependence, and a perceived poor prognosis. When an illness is severe or disfiguring, an adolescent's identity, self-image, and ego development can be negatively affected. Identity formation is especially challenging in the hospital setting, and adolescents may come to rely on their illness or disability as their identity, rather than setting goals or aspirations beyond the hospital environment. Biologic, psychologic, and social development are highly interrelated. Delays in one area, such as body image or sexual development, lead to consequences in other domains. Delayed puberty in boys may lead to low self-esteem and apparent immaturity, which in turn can foster dependence on the family and eventual reduced educational qualifications and increased underemployment or unemployment.

Adolescents with a chronic illness are generally well-adjusted and perceive their illness as less severe than their physicians assume they do. Many who live with chronic illness or disabilities are well-adjusted socially and emotionally. When adolescents perceive their illness to be severe or untreatable, they are more likely to have symptoms of depression and low self-esteem. Those adolescents with the greatest uncertainty of their outcome often have more difficulty accepting and discussing their condition and may avoid disclosure to peers. In a study of chronically ill adolescents with a variety of disorders compared to matched controls, there were no differences in levels of anxiety or self-esteem between the two groups, and both held a similarly positive outlook on life. This finding may be related to the ability of adolescents to deny the worst aspects and consequences of their illness in order to function effectively, or it may be related to their experience coping with multiple minor stresses resulting in greater resilience and more successful coping strategies than their healthy peers. Adherence to treatment, rules, and authority may be problematic for some medically ill adolescents, and they may be more likely to demonstrate risky behaviors than their healthy peers. Medically ill adolescents require the same anticipatory guidance and close supportive follow-up as any adolescent at risk.

It is important that adolescents participate in their own care and treatment decisions, although in most cases, diagnosis and treatment information is still directed to the parents. Adolescents highly value their privacy and confidentiality. Hospitalized adolescents prefer to have medical information provided directly to them by health care professionals, but often still chose to have their parents present for support. Adolescents would like to have discussions of diagnosis and prognosis as soon as possible after admission, even when their condition may be terminal. Adolescents often recognize the imminence of their death and want to discuss their feelings. They may request information that the parents are reluctant to disclose to them and may be ready to discontinue treatment when their parents are not. In these situations, it is important that the health care team is ready to support both the adolescent and

parents and to provide help to bridge their differences. Advance care planning is encouraged by the Institute of Medicine and the AAP, and developmentally appropriate tools for discussing end-of-life care are available for adolescents and young adults.

RESPONSE TO SPECIFIC ILLNESSES

Asthma

Asthma, a reversible reactive airway disease triggered by immunologic and nonimmunologic factors, is the most prevalent chronic illness of childhood, affecting more than 1 in 20 school-aged children. While asthma can present at any age, 75% of patients present in the first 3 years of life. The sensation of chest tightness, respiratory distress, and anxiety may be particularly frightening to young children, while adolescents with new-onset asthma seem to adapt more easily than anticipated. There is a high comorbidity in asthma with anxiety and depressive disorders, although this risk may be less when asthma is well-controlled. Anxiety plays a greater role when a child's symptoms are mild, and it is more difficult to quantify symptoms when asthma is severe. Trouble breathing typically triggers anxiety, and proinflammatory cytokine release is found in both asthma and depression. Maximizing the child's ability to perceive symptoms and comply with treatment can reduce the morbidity and mortality of asthma.

Rheumatologic Disorders

Rheumatologic disorders in pediatric patients are typically more severe clinically than the same disorders in adults and may have significant psychiatric and medical consequences. These conditions are treated with potent immunosuppressive medications, steroids, and immune modulators that themselves may be associated with psychiatric side effects. Psychiatric symptoms may also be the result of the autoimmune process or related underlying vasculitis, or the psychiatric disorder may be unrelated and coincident. In determining the long-term effects of psychiatric complications of pediatric rheumatologic disorders, parental functioning may play a role, and parental distress and maternal depression have been associated with greater behavior problems in the child.

Juvenile idiopathic arthritis (JIA) can lead to social isolation, chronic pain, and skeletal deformities, which may lead to depression, anxiety, low self-esteem, and lower quality of life. In studies of children and adolescents with JIA, those with less severe physical disabilities were often more affected psychologically, and more emotional and social problems and pain are noted in children whose parents feel stressed, pessimistic, and guilty.

Systemic lupus erythematosus (SLE) in children and adolescents is associated with anxiety, depression, and cognitive dysfunction. Pain, fatigue, and depression may be related to the effects of the chronic illness, needed medications, or SLE itself. Central nervous system involvement, with both neurologic and psychiatric symptoms, occurs in more than half of children and adolescents with SLE, usually early in the course of the disease. Neurocognitive impairment is common, and complaints of memory and concentration problems are frequent even when not documented on neuropsychologic evaluation.

Cystic Fibrosis

Cystic fibrosis (CF) is a lethal inherited disease caused by mutations in the CF transmembrane conductance regulator (*CFTR*) gene. Survival of patients with CF has been considerably extended by improved therapy of pulmonary infections, improved nutritional management, and an organized system of centralized care with physicians experienced in caring for the complications of CF. The goal of treatment has been slowly shifting from symptomatic management to targeting the underlying CFTR defect to halt disease progression and prevent the occurrence of CF complications.

The psychological and social functioning of patients with CF is similar to that of healthy peers until their disease becomes severe and their physical and social activities become increasingly limited. Patients with CF are at increased risk for psychiatric problems, such as depression, and their ability to cope with their disease and comply with treatment is important for their quality of life. The psychological and social problems associated with CF may be intensified during adolescence, when more problems

with independence, sexuality, relationships, and noncompliance emerge. It is difficult to develop independence when required daily care is complex and may require assistance, and it is difficult to develop self-esteem when chronic productive cough, physical limitations, and peer relationships are disrupted by recurrent hospitalizations. Boys and girls seem to respond differently: girls seem to have a better body image and to be more distressed coughing in public, and for boys, short stature and pubertal delay may have a greater impact on their quality of life than the issue of shortened survival.

CF is a common indication for lung transplantation. Most transplants are living donor lobar transplants and are usually performed in adolescence. The mean survival is greater than ten years post-transplant, which can allow recipients to develop long-term goals and plan for independence.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is also often associated with depression and anxiety. Children with a good knowledge of their illness, an internal locus of control, a healthy family climate, and an open social network do well, and can maintain good mental health functioning despite severe illness. Disease severity appears to be a significant predictor of depressive symptoms in adolescents. The relationship between social support and adjustment observed with other conditions is also noted in children with IBD; those with high levels of social support from both family and peers show significantly better adjustment than those with limited support from either source. On the other hand, parental depression is associated with greater depressive severity in children more than adolescents with IBD. Cognitive behavior therapy and pharmacotherapy, with fluoxetine the most studied, have been shown to be helpful in treating depression in children and adolescents with IBD.

Insulin Dependent Diabetes Mellitus

Type 1 insulin dependent diabetes mellitus (IDDM) affects many aspects of everyday living and requires a high degree of personal responsibility to manage effectively. Poor diabetic control in childhood is associated with a greater risk for long-term complications and may lead to cognitive difficulties, making careful management more critical. Depression and anxiety are common in children and adolescents with IDDM, and risk is higher during the first year after diagnosis in those with pre-existing anxiety and in those whose mothers have psychiatric problems. Adolescence and associated physiologic changes of puberty can lead to increased insulin resistance; at the same time, peer relationships become more complex, and parental supervision may be withdrawn, all leading to greater problems with compliance and glycemic control. There appears to be a direct relationship between the diabetic adolescent's emotional and physical well-being. Adolescent juvenile diabetics, who are considered well-controlled medically, also tend to be well-adjusted at home and with peers, are appropriately independent, and have good self-esteem and an internal sense of control.

Diabetes is associated with an increased risk for eating disorders, which are associated with poorer glycemic control and an increased risk of diabetic comorbidities. Intentional omission of insulin to lose weight or as a form of suicidal behavior may occur with Type 1. Similarly, some patients with Type 2 will intentionally omit oral hypoglycemic drugs to lose weight. Binge eating disorders are also common. Patients tend to deny their manipulation of diet or insulin, but poor glycemic control, missed clinical appointments, and recurrent episodes of diabetic ketoacidosis or hypoglycemia should lead to suspicion of an eating disorder.

Heart Disease

Depression is common in patients with congenital heart disease and can exacerbate the physical consequences of the disorder. Children with congenital heart disease may have more medical fear and fear of the unknown, more physiologic anxiety, more depression, and more delinquent behavior than the general pediatric population. Those with cyanotic malformations may be at higher risk, which can be further exacerbated by maternal anxiety. Pain and separation from parents are more upsetting to younger children, while older children and adolescents are more focused on their physical status and the long-term implications of their condition. Accommodating to complete heart block and the implantation of a cardiac pacemaker often produces emotional distress; those children and adolescents without psychiatric symptoms who undergo the procedure demonstrate intellectualization, identification

with medical personnel, and denial during the medical emergency. Problems in adjustment that occur following cardiac transplantation reflect the patient's previous level of emotional adjustment more than a specific response to the procedure.

Ventricular assist devices (VADs) have become widely used in the management of end-stage heart failure in children, particularly in cardiomyopathy or myocarditis patients. Although overall outcomes are favorable, medical complications are common, especially for children with complex congenital heart defects. VADs are most useful as a bridge to recovery or eventual transplant.

Surgical Procedures

Some surgical procedures may be more disturbing than others, and children usually have more emotional problems after genitourinary surgery than after tonsillectomy. Although early psychoanalytic studies on the effect of tonsillectomy concluded that this operation was a stressful experience for every child, especially those with a history of previous trauma, currently the majority of children do well. Despite mild adverse behavioral changes in some younger children, more than 90% undergo the procedure without negative consequences.

Hemophilia

Hemophilia is an example of an inherited X-linked coagulation defect that serves as an illustration of individual and family response to a chronic and potentially lethal disorder. Most boys and their families adapt well and are able to maintain age-appropriate functions at home and school despite their illnesses. The few who show poor adjustment tend to have overprotective, overanxious, or guilt-ridden mothers, and the sons often respond either with social withdrawal and fear or with inappropriate recklessness.

Cancer

Cancer has been the second leading cause of death for children ages 5 to 14 years and the fourth leading cause of death in adolescents ages 15 to 19 years. Progress in the treatment of pediatric malignancies has led to an increase in the number of children, adolescents, and young adults surviving free of neoplastic disease, but this increased survival has come at a price. Survivors may suffer endocrinopathies, growth abnormalities, intellectual decline, neurocognitive and psychosocial dysfunction, and increased rates of anxiety, depression, dementia, and personality and behavioral disturbances. They also have an increased actuarial risk of developing a second malignant neoplasm. The prevalence rate of psychiatric disorders in children and adolescents with cancer is mixed, ranging from rare to as many as half of the patients with anxiety disorders, PTSD, and depression. Psychological interventions have shown promise in decreasing distress associated with diagnosis and treatment but have not shown an effect on long-term clinical outcomes. Survivors of childhood malignancies may have impaired quality of life, compromised social functioning and emotional well-being, including suicidal ideation, and diminished academic and occupational success as adults.

Covid-19

A pandemic associated with a new coronavirus began in China in December 2019 and quickly spread through person-to-person contact to multiple countries by January 2020. The virus was named severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) by the Coronavirus Study Group, and its related disease named coronavirus disease 2019, or COVID-19, by the World Health Organization. COVID-19 was declared a pandemic by the World Health Organization on March 11, 2020. Transmission is by droplets, spread mainly by coughing and sneezing by symptomatic and asymptomatic individuals.

Children have mainly become infected in family clusters and have had relatively milder illnesses and better outcomes than adults with the original genotype of the virus. The incubation period of COVID-19 ranges from 2 to 14 days, with most patients developing symptoms 3 to 7 days after exposure; children are usually symptomatic 1 to 2 days sooner than adults. Cough, fever, and headache are the most common presenting symptoms. Whether COVID-19 is clinically suspected or patients are asymptomatic, the diagnosis must be confirmed by a positive polymerase chain reaction test. Respiratory involvement

is apparent in about 90% of pediatric patients. Gastrointestinal symptoms of abdominal pain, nausea, vomiting, and diarrhea are occasionally seen. Nonspecific skin findings can range from petechiae to papulovesicular rashes, diffuse urticaria, or chilblain-like lesions. Lymphopenia elevated procalcitonin, and elevated C-reactive protein are noted in laboratory studies. Pre-existing cardiac, hematologic, neurologic, and oncologic illnesses are reported most often in hospitalized children with severe COVID-19. SARS-CoV-2 is neurotropic, directly attacks neurons, is associated with a variety of neurologic symptoms, and precipitates an abnormal immune response in the CNS.

Multisystem inflammatory syndrome in children (MIS-C) in pediatric patients is most often seen in children 6 to 12 years old who present with fever and vomiting. MIS-C patients may become critically ill, requiring intensive care, mechanical ventilation, ionotropic support, and occasionally extracorporeal membrane oxygenation. Gastrointestinal (92%), cardiovascular (80%), hematologic (76%), and respiratory (70%) systems are most often involved in MIS-C.

Neurologic involvement is common in children with MIS-C and is usually transient. Patients with neurologic involvement are more likely to have underlying neurologic disorders, including seizures, neuromuscular disorders, autism, or developmental delay. Approximately one in four patients with neurologic involvement with MIS-C present with altered awareness or confusion of delirium. About 10% of MIS-C patients can develop a persistent disability or life-threatening neurologic conditions. Severe encephalopathy, CNS infection, encephalitis, aseptic meningitis, central demyelination, Guillain–Barré syndrome, acute fulminant cerebral edema, seizures, altered mental status, coma, demyelinating disorders, infarction, cerebellar ataxia, peripheral neuropathy, intracranial hypertension, lethargy, and drowsiness are reported.

Most survivors of COVID-19 can get back to normal soon after their initial illness. But in some, symptoms persist far longer, even after an initially mild illness, which has complicated planning to reopen schools. Patients, mostly girls, are reported to experience fatigue, dyspnea, palpitations, chest pain, muscle weakness, dizziness, difficulty concentrating, gastrointestinal problems, and headaches, symptoms similar to acute illness but without an active infection. Symptoms may last 6 to 8 months and can be very debilitating.

With the onset of the pandemic in 2020, the world essentially went into lockdown in an effort to slow the spread of the virus. Emergency nationwide school closures led to an immediate massive effort by schools and teachers to create online courses and deliver them as quickly as possible via the internet. School closures have been severely disruptive to children and adolescents, resulting in adverse academic and psychological effects. Loneliness from enforced social isolation and lack of usual peer interactions has increased the risk of depression and anxiety during and after the period of isolation, and the length of loneliness could be a predictor of future mental health problems.

Infants and toddlers appear to be more affected by the stresses COVID-19 places on their parents, and prolonged parental stress has been associated with increased behavior problems in the child. Younger children are more likely to become fearful, intolerant of uncertainty, more clingy, and dependent on their parents, while older children become more inattentive and worried about COVID-19 infection, school examinations, and other academic consequences. Anxiety, depression, irritability, mood swings, inattention, and sleep disturbance are fairly common, and depression and anxiety are particularly noted in adolescent cohorts.

Those children with pre-existing chronic medical and psychiatric conditions are at higher risk for regression, tantrums, and conflict with parents and siblings, making it more difficult for parents to handle their behavior and manage any special needs when they are home for long periods instead of in school. Mental health concerns are highly prevalent among youth with physical health problems, which worsened during the COVID-19 pandemic. Pre-existing autistic spectrum disorder (ASD), attention deficit/hyperactivity disorder (ADHD), and disruptive behavior disorders worsened. When speech, physical, and occupational therapies became limited, skills declined due to disruption in ongoing chronic care and supportive services. Children and youth who were previously in residential centers were sent back to their dysfunctional families as centers closed, exacerbating family problems. Children living in poverty suffered the consequences of malnutrition, parental unemployment, and homelessness. Physical exercise, eating habits, and lifestyle change when students are out of school. Becoming more sedentary and less physically active with prolonged school closures and home confinement meant more time in front of screens, more irregular sleep, and increased intake of high-caloric “comfort food,”

resulting in weight gain and loss of cardiovascular fitness. Isolation in adolescence can increase the risk of poor adult health and depression.

Many families lost members to COVID-19, and some children live with a single parent or have parents who worked on the front lines, potentially adding to family distress. Physical abuse increased and the organizations that work with children with abuse or neglect became more restricted and less available. As the pandemic continued, risk increased for parental mental illness, domestic violence, and child maltreatment. More domestic violence and physical and/or sexual abuse at home increases the risk for suicide in children and adolescents, especially in girls, and suicidal ideation has been reported in 20% of junior high students, with 6% reporting suicidal plans, and 5% making suicide attempts.

TRANSITION FROM PEDIATRIC TO ADULT MEDICAL CARE

As children with chronic and severe medical problems are living longer into adulthood, the previously unanticipated problem of transitioning a pediatric patient to adult care has become important to address. Adolescence describes the time from childhood to adulthood when the teen must change from pediatrician to internist and move from shared responsibility with parents to individual responsibility for their own health. At some time, adolescence ends, and adulthood begins, even for patients with special health care needs. The transition from pediatric to adult-oriented care is a process that should take place in stages over the adolescent years. Six core elements of transition have been designated: (1) Transition policy, (2) Transition tracking and monitoring, (3) Transition readiness, (4) Transition planning, (5) Transfer of care, and (6) Completion of transfer. These six elements apply as well to transition from adolescence to adulthood in the medical home.

Adolescence can be a difficult time, especially for those with chronic illness who face unique challenges in developmental tasks. Effective transfer to adult care involves ongoing coordination and good communication with the patient, family, and adult physicians so that the anxieties of all, including the pediatrician, are adequately addressed.

Transition is not the same as transfer of care. Transition is a multifaceted process that addresses the psychosocial, educational, and vocational needs of adolescents as they move from child-oriented to adult-oriented care. It is predicated on effective communication between pediatrician and internist, and between the patient, parents, and providers. Transition implies a guided educational and therapeutic process rather than an administrative event.

There are two different approaches for transfer of adolescents with chronic medical problems to adult medical care. Patients may be directly transferred to internists. This is typical for patients with pediatric-onset of adult disease. Alternatively, patients may be transferred to a specialized center focusing on pediatric disorders in adults, and will be seen in pediatric clinics with separate areas designated for young adults.

Pediatric care is typically family-centered. The pediatrician looks to the parent for information and to provide instructions. In contrast, adults speak for themselves directly to their physicians. It is useful for the adolescent preparing for transition to begin talking to the pediatrician directly, without their parents' assistance, to prepare for their increased responsibility for their own care.

The time of transition of care is a period of vulnerability and potential risk, best accomplished during a period of relative stability. Many young adults regard health care as a low priority compared with education, employment, housing, relationships, and recreation. Young adults who have survived with pediatric care and parental support are at risk of deterioration after they move on to adult providers who are impatient with noncompliance and unfamiliar with the management of rare and often complex chronic childhood conditions. Those with less severe and visible conditions may have greater problems moving from pediatric to adult care, lacking preparation or only minimal or last-minute planning, resulting in poor communication and limited coordination for the effective transfer of care.

It is important that pediatric relationships are appropriately terminated as part of the transition process. The patient's level of developmental maturity and ownership of their own care is the most prominent determinant of transition outcomes. In order for the process of transition to be effective, the patient needs to have demonstrated adequate self-management skills, long-term social support, self-reliance, autonomy, and independence. Nonadherence with treatment is particularly prevalent in

adolescents. Effective physician management requires attention to psychological and social issues as well as medical factors.

A positive sense of the future is associated with a greater sense of control in adolescents, supporting their emotional well-being and growth and increasing the likelihood of a more successful transition (Table 54.3–2). When accomplished effectively, transition can provide the young adult with a sense of the future and of future responsibilities that continued pediatric care fails to reinforce. A carefully planned transition to adult health care should improve self-reliance, enhance autonomy and independence, and support young people in attaining their maximum potential and having meaningful adult lives.

Table 54.3–2.
Recommended Approach to Transition in Adolescence

Period	Task
Early Adolescence Ages 10–13 years 1. Transition Policy	Introduce concept of separate and confidential visits with MD. Straight forward reward-oriented approach. Begin discussion of transfer of care. Need for privacy begins.
Mid Adolescence Ages 14–16 years 2. Track progress 3. Monitor transition readiness 4. Assess skills	Begin discussion of healthy living and risky behaviors in nonjudgmental approach. Expect increased introspection. Begin visits to new setting and meeting new providers.
Late Adolescence Ages 17–21 years 5. Planning and transfer of care 6. Integration into an adult medical care setting	Increased self-responsibility. Transition to adult providers. Future-oriented approach. Progression of personal identity and code of ethics. Physician seen alone. Evolving role of social supports.

For those who are mentally ill, the transfer of their psychiatric care from child-adolescent to adult psychiatrists can be more daunting than medical transition and a potentially more precarious time if preparation is inadequate. The MILESTONE Project (Managing the link and strengthening transition from child to adult mental health care) is intended to address the significant socioeconomic and societal challenges related to the transition process for psychiatric care, which is less structured than the process for medical care. Successful mental health transition requires effective self-management, medication adherence, attendance at medical appointments, understanding of the illness, and coping with mental health crises when they occur.

SOCIAL MEDIA

Any website that allows social interaction is considered a social media site. This includes social networking sites such as Facebook, Twitter, Instagram, and TikTok; gaming sites and virtual worlds such as Neopets, FreeRealms, Minecraft, Webosaurs and video sites such as YouTube, Instagram, TikTok, and various blogs (these examples will almost certainly be dated by publication). These sites offer today's youth a portal for entertainment and communication, and some adolescents log onto their favorite social media sites as often as 10 or more times a day. Just over half of children in the United States have a smartphone by age 11, and 84% of teenagers have their own phones. A significant part of this generation's social and emotional development is now occurring while on the internet and cell phones. Students use the internet to do homework, look up information, collaborate on group projects, and attend school online, especially since the COVID-19 pandemic. Internet and social media sites

provide useful applications and allow the development of user-generated content, blogs, patient experience journals, and video and photo-sharing sites. Children and adolescents, particularly those with chronic conditions, seek out social media and other online sources to acquire health information, connect with others affected by similar conditions, and play a more active role in their healthcare decisions. Many patients and families can develop large support networks by sharing and disseminating information about their child's illness on specialized sites, including hospital-sponsored sites such as CaringBridge or CarePages. Internet support groups and interactive peer video games can decrease some of the isolation patients, and families feel with rare or unknown conditions or with necessary hospital medical isolation practices. Applications that monitor and track symptoms (e.g., adherence, mood, nutritional intake, chemotherapy side effects, blood cell count) may be useful, and applications that facilitate delivery of stress management and relaxation techniques (e.g., biofeedback, breathing exercises, mindfulness, imagery) are available but less widely disseminated. These tools are helpful but are not a substitute for clear in-person communication, clinical psychological and psychiatric assessment, and psychotherapy.

Practitioners, patients, and families need to consider threats to confidentiality and privacy and professional and therapeutic boundaries when communicating via social media. The risks to adolescents when using social media can be more than most adults appreciate. Cyberbullying and online harassment are common, which can have profound consequences and precipitate aggressive and suicidal behavior in response. Sexting, or sending sexually explicit messages, photographs, or images via cell phone, computer, or other digital devices, can lead to school suspension for perpetrators and emotional distress for victims. "Facebook Depression" develops when teens and preteens spend excessive time on social media, risking social isolation and involvement with sites that may promote substance abuse or unsafe sexual or other behaviors. The Children's Online Privacy Protection Act (COPPA) prohibits sites from collecting information on children younger than 13 years without parental permission, and sites should mirror COPPA regulations, setting 13 as the minimum age to sign onto sites such as Facebook and Instagram. Parental supervision of social media, online sites, and other digital activities is essential, especially as there is minimal legal protection for minors between 13 and 17 years from the hazards of cell phones and computers.

54.4 Psychiatric Sequel of HIV and AIDS

MARK DEANTONIO, M.D.

In June 1981, the first cases of what was later called acquired immunodeficiency syndrome (AIDS) in the United States were reported in *Morbidity and Mortality Weekly Report*. Since that time, this syndrome has become one of the greatest public health challenges. In 2019, an estimated 38.0 million people were living with human immunodeficiency virus (HIV) worldwide. HIV continues disproportionately to affect certain geographic regions (e.g., sub-Saharan Africa and the Caribbean) and subpopulations (e.g., women in sub-Saharan Africa, men who have sex with men, injection-drug users, and sex workers). There have been significant changes in the understanding, epidemiology, and treatment of this disease in children and adolescents, modifying psychiatric sequelae. In the United States, the prevention of vertical transmission and the surveillance of blood make it rare for a child or adolescent younger than 15 years of age to become infected with HIV. However, adolescent sexual behavior and drug use, especially when combined with psychiatric disturbance, put individuals at increased risk of HIV infection in adolescence and young adulthood. Psychiatrists in the United States might never encounter an HIV-infected child but have a great opportunity to decrease the risk of infection when psychiatrically treating adolescents who are at risk. Gaining an understanding of the

psychiatric sequelae of HIV and AIDS and the dynamics of adolescent risk behavior will allow the physician to craft effective interventions to prevent transmission in youth.

EPIDEMIOLOGY

In the United States at the year-end of 2018, approximately 1.2 million people were living with HIV, including 1,012,100 with diagnosed HIV and 161,800 with undiagnosed HIV. The number of people with HIV (diagnosed or undiagnosed) in the United States has steadily increased as the number of new infections per year has outpaced the number of people dying from HIV. Key 2018 HIV prevalence data in the United States include 58% of persons with HIV had male-to-male sex as their transmission category, Blacks/African-Americans accounted for approximately 41% of all people with HIV, and 58% of persons with HIV were 45 years of age or older. Among the 37,515 persons who were diagnosed with HIV in 2018 in the United States, 66% acquired HIV via male-to-male sex, 43% were Black/African American, and 46% resided in the South at the time of the diagnosis. The HIV incidence (estimated new HIV infections) in the United States has declined slightly between 2014 and 2018, with an estimated 36,400 new infections in 2018. However, the highest number of persons newly diagnosed with HIV in 2018 was between 20 and 35 years of age. Using back-calculation methods, the CDC estimated the proportion of persons with HIV in the United States who are unaware of their HIV status decreased from 25% in 2003 to 13.8% in 2018; however, among persons aged 13 to 24 years with HIV, 45% are undiagnosed. Persons who are aware of their HIV status can benefit from HIV treatment and are less likely to transmit the virus to others. The annual number of deaths for persons diagnosed with HIV remained relatively steady between 2014 and 2018. Most of these deaths are due to non-AIDS causes, particularly liver disease, cardiovascular disease, and non-AIDS malignancies. Among persons with diagnosed HIV who died in 2018 in the United States, Blacks/African Americans had the highest number of deaths and highest death rate. Globally, an estimated 38 million people are living with HIV, and 25.6 million (67%) reside in sub-Saharan Africa. Globally, in 2019, an estimated 1.7 million new HIV infections occurred, and an estimated 6,90,000 persons with HIV died. In 2019, an estimated 25.4 million persons with HIV globally were receiving antiretroviral therapy.

The changing United States epidemiology shows relative control of HIV infection in children under 13 but a significant rise in rates of individuals in their 20s. Sexual behavior, specifically male-to-male sexual contact, is the primary cause of infection, with injection drug use and heterosexual contact decreasing as a cause. The behaviors that cause infection in individuals in their 20s often begin in adolescence. These trends highlight the importance of interventions to change sexual behavior in adolescence.

There is another way in which HIV infection affects children and adolescents: When their parents or family members are infected. The number of U.S. youth affected by HIV in a family member is growing because the majority of infected women are mothers; 60% have children younger than 18 years of age, and 45% live with their children. Living with chronically ill parents, often with comorbid substance abuse, has significant consequences for the affected family members, with potential psychiatric and social sequelae.

ETIOLOGY

Psychiatric sequelae of HIV infection in children and adolescents are due to multiple and interacting etiologies. These include direct and indirect effects of HIV infection on the brain, stresses of living in families often affected by substance abuse, psychiatric disorders, chronic illness, and death. Adolescents who contract HIV infection have a high likelihood of pre-existing psychiatric diagnosis, cognitive deficits, histories of sexual or physical abuse, ongoing substance abuse, homelessness, and chaotic family dynamics. The addition of HIV infection to these adolescents adds profound stress and challenge to an already overwhelming existence.

HIV is transmitted through blood-to-blood or semen-to-blood contact. The virus can also be transmitted by penile–vaginal intercourse, especially if other sexually transmitted diseases (STDs) coexist. Receptive anal intercourse and the use of contaminated syringes are the most common causes of HIV infection in the United States. HIV-infected women can transmit the virus during pregnancy, delivery, or through breast milk. It also can be transmitted through untested blood products. There are

four identified types of human retroviruses, which belong to two distinct groups: the transforming human T cell lymphotropic virus (HTLV) types I and II, and cytopathic HIV-1, which is more common in the United States, and HIV-2. HIV-1 is further divided into groups, classes or subtypes, and circulating recombinant forms, all of which indicate geographic origin.

Testing to diagnose HIV infection has evolved to provide quicker, more accurate, and more cost-effective results. Current testing approaches directly detect the virus or demonstrate antibodies to the virus or a component, which appears 2 to 12 weeks after acute infection. A definitive diagnosis among infants younger than 15 months old cannot be made because the antibody crosses the maternal–fetal blood barrier, so all infants of HIV-infected mothers will have maternal HIV antibodies, whether infected or not. Once an individual is diagnosed as infected, the level of plasma HIV RNA (viral load) and the absolute number of peripheral $CD4^+$ T cells are used to monitor clinical status.

In 1985, when HIV testing first became available, the main goal of such testing was to protect the blood supply. At that time, professional opinion was divided regarding the value of HIV testing for individuals and whether HIV testing should be encouraged because no consensus existed regarding whether a positive test predicted transmission of the HIV virus to sex partners or from mother to infant. No effective treatment existed. In 1987, the implications of positive HIV serology became evident. HIV testing and counseling were recommended for all persons in high-risk groups and all persons seeking treatment for STDs. In 1995, after perinatal transmission of HIV was demonstrated to be substantially reduced by the administration of zidovudine to HIV-infected pregnant women and their newborns, it was recommended that all pregnant women be counseled and offered testing for HIV. In 2001, the CDC recommended that all pregnant women should have HIV screening as a part of routine prenatal care. Although the woman needed to be aware of what they were being tested for, it was also felt that the previously recommended pretest counseling was a barrier to testing and should be simplified. At this time, the CDC recommended that HIV testing be offered routinely to all patients in high-HIV-prevalence healthcare settings, despite risk factors. In low-prevalence settings, targeted HIV testing on the basis of risk screening continues to be recommended.

In September 2006, the CDC again revised recommendations for HIV testing of adults, adolescents, and pregnant women. Due to the changes in demographic of the HIV/AIDS epidemic in the United States, increasing proportions of infected persons are younger than 20 years of age, women, members of racial or ethnic minority populations, persons who reside outside metropolitan areas, and heterosexual men and women who frequently are unaware that they are at risk of HIV infection. As a result, the effectiveness of using risk-based testing to identify HIV-infected persons has diminished. In addition, prevention strategies that incorporate universal HIV screening have been highly effective (blood donors and pregnant women). Perinatal transmission rates have been reduced to less than 2% due to prophylactic administration of antiretroviral drugs, scheduled cesarean delivery, and avoidance of breastfeeding. Studies document that the majority of adults who are aware of their HIV infections substantially reduce sexual behaviors that might transmit HIV after they become aware that they are infected. Therefore, to increase the diagnosis of HIV infection, destigmatize the testing process, link clinical care with prevention, and ensure immediate access to clinical care for persons with newly identified HIV infection, the CDC now recommends the adoption of routine HIV testing in all health care settings for individuals from the age of 13 to 64 years. The testing should be undertaken only with the patient's knowledge and understanding that HIV testing is planned. Patients can refuse testing. Persons likely to be at high risk of HIV infection—injection drug users and their sex partners, sex workers, partners of HIV-infected persons, and persons who have had or whose sex partners have had more than one sex partner since their most recent HIV test—all should be tested annually. This significant change in testing recommendations reflects the ever-changing nature and better understanding of HIV/AIDS.

Pre-exposure prophylaxis, or PrEP, is a new tool in HIV prevention. It is a prevention option for individuals who are at high risk of getting HIV. It is a pill with two antiviral medications (tenofovir and emtricitabine), which are taken daily. PrEP has been shown to be safe and efficacious for adults. Recent studies have now documented the safety and efficacy of adolescents using PrEP. However, these studies also highlight the challenge of using PrEP in adolescents, which is that over time, adherence to treatment declines. New treatments of injectable pre-exposure prophylaxis medications, which could address the adherence issue, have not been studied yet in adolescence.

Disclosure of a child's or adolescent's HIV status brings up complex issues requiring careful assessment of an individual's circumstance. Knowledge of one's HIV status is associated with emotional distress and increased rates of depression. The level of distress depends on how the disclosure occurs, under what circumstances, and the reaction of the people involved. Telling a child that they have HIV appears to be influenced by several factors, including older child age, higher child cognitive functioning, recent major life events, and higher family expressiveness. Many clinicians and caregivers are ambivalent about disclosing to children because of fears that the children will inappropriately disclose to the community at large and face stigmatization as a consequence. Current pediatric practice guidelines encourage disclosure by adolescence, but neurocognitive deterioration may complicate timing. Clearly, it is critical that HIV status be disclosed to adolescents before they become sexually active. Simply telling adolescents that they are HIV positive may not reduce risky sexual behavior or disclosure of that status to their sexual partners. This potential lack of disclosure underscores the importance of emphasizing safer sex practices, including condom use, for all adolescents regardless of HIV status.

Neurodevelopmental Sequelae of HIV Infection

HIV is found primarily in microglia and macrophages and not directly in neurons. The virus is thought to have neurotoxic components and induce a variety of inflammatory factors that cause neuronal cell death. The clinical presentation of HIV neurologic involvement can vary from mild neurocognitive impairment to static encephalopathy, progressive encephalopathy, and dementia. There has been more progress in understanding the effects of HIV on the brain in adults than in children, owing to the dramatic decrease in childhood infections. Studies of infected patients 13 to 18 years of age are limited. In the earliest asymptomatic stages, abnormalities may show up in cognitive abilities evaluated during neuropsychiatric testing but not necessarily as impairments in functioning. In children and adolescents, those infected are also likely to have cognitive deficits due to in-utero drug and alcohol exposure, attention-deficit disorder, and learning disabilities, all of which increase maternal HIV infection risk and complicate neuropsychiatric testing. The clinical presentation of HIV central nervous system (CNS) involvement may vary with the age of infection and mode of transmission. In children or adolescents infected through blood transfusion, encephalopathy generally presents later and follows a more indolent course. By contrast, in almost one-fourth of vertically HIV-infected children, encephalopathy can present and contribute significant morality and mortality as an AIDS-defining illness even when the child is not severely immunocompromised. Early progressive encephalopathy is usually seen in young, untreated infants with high-viral loads and rapid clinical deterioration. Vertically HIV-infected children who are labeled "slow progressors"—those with lower viral loads and higher CD4 counts—often exhibit no cognitive deficits throughout childhood and adolescence.

The most common computed tomographic findings associated with encephalopathy are basal ganglia calcifications, brain atrophy with enlarged ventricles, and enlarged cortical sulci. HIV-infected children have a higher incidence of ischemic strokes and cerebral artery aneurysms, which can rupture. Magnetic resonance imaging (MRI) has been recommended for infected children who present with a lack of neurocognitive progression or dysfunction even though they are otherwise asymptomatic.

In adolescents with advanced AIDS, a gradual progression into dementia is seen. It appears as a subcortical dementia process with motor impairment, cognitive disturbance, and a predominance of apathy over depression. Psychotic symptoms may be present. In addition, opportunistic CNS infections such as toxoplasmosis, progressive multifocal leukoencephalopathy, and CNS lymphoma can complicate the CNS clinical picture. There is no specific treatment for HIV involvement in the CNS. When progressive encephalopathy is present in children and adolescents, increased doses of antiviral agents are used, but there have not been studies documenting efficacy in children and adolescents.

CLINICAL FEATURES

Despite more than 30 years of studying HIV/AIDS in children and adolescents, there have been few studies of psychiatric diagnoses in these individuals. Although there is clearly defined neurologic pathology due to HIV infection, psychiatric illness, specifically due to HIV infection, has not been

quantified. Instead, psychiatric diagnoses are related to inheritable psychiatric disorders and reactions to having a chronic illness in the context of often chaotic and traumatic environments.

Early studies of emotional and behavioral disorders in perinatally HIV-infected children showed high rates of anxiety, depression, adjustment problems, and attention-deficit/hyperactivity disorder (ADHD). However, results among studies were inconsistent and failed to use appropriate control groups. Studies of behavioral disorders in HIV-infected children that included uninfected control groups of similar backgrounds generally reported high rates of emotional and behavioral disorders in both groups. One controlled study found elevated rates of ADHD in a sample of prenatally drug-exposed children, with no difference between HIV-infected and uninfected children. Another controlled study found elevated rates of internalizing and externalizing symptoms in HIV-infected children and demographically matched control. However, rates of symptomatology were actually higher in the control group. The Woman and Infant Transmission Study Group Study compared HIV-infected children with uninfected siblings born to HIV-positive mothers. Findings confirmed earlier data, revealing high rates of hyperactivity and impulsivity in both the infected and uninfected children. The Pediatric AIDS Clinic Trials Group reported a higher frequency of psychiatric hospitalization among perinatally infected children than in the general pediatric population and HIV-uninfected members of the cohort. The majority of patients were admitted because of depression, and a minority were due to behavioral disorders. Studies of vertically infected adolescents and psychiatric illness are limited to case reports. The group whose AIDS progresses significantly in adolescence exhibits a dementia process, which may include psychosis and agitation. The group of vertically infected adolescents who are labeled “slow progressors” due to their mild degree of immune suppression appear to present with depression, anxiety, and chronic adjustment disorders related to chronic illness.

Adolescents who become infected due to sexual or injection substance abuse have recently been a focus of study through the Adolescent Trials Network for HIV/AIDS Interventions. There is evidence that having psychiatric illness in adolescence, especially when coupled with substance abuse and cognitive and learning difficulties, increases the high-risk behaviors that can lead to HIV infection. It has been documented that a significant number of HIV-infected adolescents have depressive disorders. Conduct disorder and substance abuse are also present to a significant degree. The majority of these disorders predated their HIV infection. There is evidence in the adult and adolescent literature that having depression while being HIV-infected can alter the function of killer lymphocytes. This causes an increase in activated CD8 T lymphocytes and can increase the viral load. Treatment with selective serotonin reuptake inhibitors (SSRIs) and a decrease in depressive symptoms reverse these changes.

TREATMENT

Psychiatrists play an important role in the treatment of children and adolescents who are HIV-infected. HIV infection has changed over the years to a chronic illness in the United States, which requires multiple layers of care in a variety of settings over many years. Although pediatricians have expertise in managing developmental issues in chronic illness in youth, psychiatrists have a system-oriented approach arising from their work with patients who depend on the support systems provided by family, school, and community. Parents of HIV-infected children and adolescents have a high rate of psychiatric illness, substance abuse, and chaotic and dysfunctional family interactions. Psychiatry brings expertise to the treatment team in crafting interventions to promote family stability and family support of the patient’s medical treatment. Finally, a significant number of children and adolescents who are HIV-infected have a pre-existing psychiatric illness that requires psychiatric expertise to manage. In children and adolescents receiving antiretroviral treatment, lack of almost perfect adherence to daily regimes continues to be the greatest barrier to sustaining a clinically effective response. Lack of adherence can also lead to the development of HIV strains resistant to the available antiretrovirals. Although adherence issues are common with all chronic illnesses in children and adolescents, it is more of an issue in HIV-infected children and adolescents living in situations in which parents may be physically or mentally ill or with children and adolescents in a foster care or residential setting with inadequate supervision. The psychiatrist has a critical role in working with the treatment team, the child or adolescent, and caregivers to problem-solve and intervene around issues of adherence.

The HIV epidemic adds to the challenges of the psychiatric treatment of children and adolescents in inpatient and residential settings. The American Academy of Child and Adolescent Psychiatry has the following recommendations concerning HIV and inpatient psychiatric treatment:

- HIV infection or risk of HIV infection is not a reason to deny a child admission to a psychiatric hospital.
- All patients admitted to a psychiatric hospital should be treated as if they were HIV-infected. Even if all patients were tested on admission for antibodies to HIV, one is still not sure of infection status due to the potential latency period of antibody response documenting infection.
- Universal precautions should be employed for any secretions, including blood from any psychiatric inpatient. There is no need for a change in the management of an HIV-infected child if universal precautions are used for all inpatients.
- HIV-positive or potentially positive patients do not require individual rooms or toilet facilities. HIV-infected or potentially infected patients do not need to be isolated in regard to the milieu or peer groups. Such patients should participate in all aspects of the inpatient treatment program.
- The Academy agrees with the 2006 CDC recommendation of the adoption of routine HIV testing in all healthcare settings from the age of 13 to 64 years. The testing should be undertaken only with the patient's knowledge and understanding that HIV testing is planned. Patients can refuse to test. Persons likely to be at high risk of HIV infection, including injection drug users and their partners, sex workers, partners of HIV-infected persons, and persons who themselves or whose sex partners have had more than one sex partner since their most recent HIV test, all should be tested annually. The child and adolescent psychiatrist should balance the adolescent's request for privacy with the family's wishes. There are specific laws regarding the confidentiality of HIV antibody testing results and who authorizes consent in minors. These laws vary from state to state. Prior to testing, ensure the laws are understood.
- Results of patients' HIV antibody tests will be maintained in a confidential manner. A patient's HIV status should be shared only with those staff who need to know the status to appropriately care for the child while an inpatient. Sharing of HIV status should, of course, be in compliance with applicable state and federal law.

Through the Adolescent Trials Network for HIV/AIDS Interventions, there have finally been published controlled trials of treatment. Interactions between psychotropic and antiretroviral medications are common in HIV-infected children and adolescents. Most medications used in the treatment of psychiatric disorders are metabolized by the cytochrome P450 (CYP) enzymes, especially the subgroups 3A4 and 2D6. Of the antiretrovirals, the protease inhibitors tend to pose the greatest risk of changes in drug levels that are significant in the HIV patient. Ritonavir is the most potent of the protease inhibitors, with the greatest effect on the inhibition of 3A4 and, to a lesser extent, 2D6. Enfuvirtide, a fusion inhibitor, is not an inhibitor of CYP enzymes and does not alter the metabolism of CYP 3A4, 2D6, 2C19, or 2EI substrates. Therefore, it has no significant effect on blood levels of psychiatric medications or other antiretrovirals. Efavirenz has been shown in vivo to induce CYP 3A4. Other compounds that are substrates of CYP 3A4 may have decreased plasma concentrations when coadministered with efavirenz. In vitro studies have demonstrated that efavirenz inhibits 2C9, 2C19, and 3A4 isozymes. Coadministration of efavirenz with drugs primarily metabolized by these isozymes may result in altered plasma concentrations of the coadministered drug. Drugs that induce CYP 3A4 activity would be expected to increase the clearance of efavirenz. Some antiretroviral drugs have been reported to cause psychiatric symptoms in HIV-infected youth, including mania with zidovudine and attention-deficit problems with efavirenz. It is important for psychiatrists to remain in contact with the other medical personnel providing treatment for the HIV-infected child or adolescent, maintain updated lists of all medication, and frequently consult updated web-based information sites regarding drug-drug interactions.
