In terms of the strategy of psychopharmacologic treatment, thoughtfulness is primary. The concern a physician has is that the psychiatric symptoms present are really due to the "organicity" of HIV infection and so should only be treated by maximizing antiretroviral treatment. Although this point of view needs to be considered, one can make psychiatric diagnoses and use psychopharmacology despite a possible underlying organicity caused by HIV. The most common disorders presenting in this population are

ADHD, generalized anxiety disorder, major depressive disorder, bipolar affective disorder, psychotic disorder not otherwise specified, and schizophrenia. One should use the same medications with the same dose titration as one would with an uninfected child or adolescent. The exception would be to start and maintain lower doses of medication in patients with clear demented or encephalopathy. Stimulants, in general, have few drug–drug interactions, and lithium has none because it is excreted renally. In adults, it has been reported that the HIV virus can target the destruction of cells in the basal ganglia, which can sensitize an individual to extrapyramidal side effects when they use an antipsychotic medication. This observation has not been reported in children and adolescents, but because children and adolescents overall are more sensitive to extrapyramidal side effects, this should be of concern. Therefore, one should first use atypical antipsychotics when treating children who have psychosis and adolescents who are HIV-infected.

Recent studies have documented effective treatment for depression in adolescents and young adults with the combination of cognitive behavioral therapy and administration of SSRI. Family and group interventions are an important adjunct to the successful treatment of HIV-infected youth. For infected adolescents, prevention programs emphasize reducing transmission acts, enhancing the quality of life, increasing self-care behaviors, improving medical adherence, coping with medication side effects, dealing with appropriate disclosure of HIV status, and interacting with health care providers. Preventive interventions for youth living with HIV using therapeutic approaches based on cognitive behavioral principles have been studied. One intervention included two primary components: (1) increasing positive health behaviors, particularly around medication adherence, and (2) enhancing altruistic motivation to reduce transmission acts. The intervention emphasized coping with being HIV positive, adopting healthy routines, partaking in health care decisions, reducing substance use and risky sexual behavior by identifying risk triggers, and increasing self-efficacy to use condoms and negotiate safe sex. The intervention sought to build skills and improve emotion regulation. These are similar to the strategies used to enhance psychological functioning for youth in psychiatric care. Adolescents who received the intervention reported more lifestyle changes, improved coping, fewer sexual partners, and a lower percentage of unprotected sexual acts than did youth who did not receive the intervention. Additional sessions emphasized increasing life satisfaction and emotional strength. The additional sessions reduced emotional distress and psychiatric symptoms among the infected youth, including somatization and anxiety. Programs have also been developed to help the adult caregivers of children and adolescents with HIV infection. These programs teach effective parenting skills, parental monitoring of medication adherence, and increasing social support among family members and the community. Some of the more innovative interventions also address the caregivers' mental health and quality of life.

Despite potential long-term intergenerational consequences of HIV illness, few services are available to assist children and adolescents of HIV-infected family members. The few programs with published data have yielded positive effects for affected adolescents. These programs address coping with stigma, dealing with illness-related tasks, dealing with parental disclosure, increasing maternal well-being and social support, developing effective parenting skills, decreasing victimization, custody planning, maintaining positive family routines, and handling emotional reactions to AIDS. Two– and 4-year follow-up studies of intervention effects have been both promising and disappointing. Two years after the intervention, treated adolescents reported significantly fewer conduct problems, less emotional distress, lower levels of family-related stress, and higher self-esteem than adolescents in the control group. Outcomes were comparable for youths who were bereaved and nonbereaved by parental AIDS and across ethnic and gender subgroups. Unfortunately, the positive effects had eroded by the 4-year follow-up, underscoring the need for sustained support and treatment for these families. HIV prevention programs for affected children and adolescents must address intergenerational imitation of HIV risk behaviors and substance abuse and help them to cope with HIV-related psychosocial challenges such as bereavement. Unfortunately, psychosocial interventions for the affected have not been broadly implemented or prioritized.

CONCLUSION

Child and adolescent psychiatry, with its developmental and systems approach, has a unique position from which to manage the mental health sequelae of HIV infection in children and adolescents. Although

this epidemic has created challenges, it has also given opportunities. The epidemic has forced a reevaluation of child and adolescent sexual development and a more comprehensive understanding of the development of sexual orientation. It has prioritized the need for the assessment of sexual and drug-taking behavior as part of an adolescent psychiatric assessment. Finally, the AIDS epidemic demands that psychiatrists constantly monitor high-risk behaviors in adolescent patients and implement strategies to reduce these behaviors. Such interventions will improve the quality of life and prognosis of adolescent psychiatric patients regardless of HIV infection status.

54.5 Adolescent Substance Use Disorders

Sean R. Lenoue, M.D., and Paula D. Riggs, B.A., M.A., M.D.

Adolescent substance use disorders (SUDs) are often multifaceted in their etiology and treatment approach. In the United States, the economic impact of substance misuse approaches $450 billion annually. The overall negative impact of substance use on the lives of youth, individuals, and our communities is incalculable. Given the increasing number of states that have legalized marijuana for medical and recreational use, adolescents are exposed to and use higher potency marijuana products. The opioid epidemic continues to devastate the United States, and total drug overdose deaths peaked at the highest recorded level in 2020. Research advances have increased our understanding of the neurobiology of addiction and behavior change, as well as genetic and environmental contributions to adolescent-onset SUD. These advances have informed the development of more effective substance prevention and treatment interventions. Clinicians working in pediatric mental health settings can play an important role in the prevention, identification of risk factors, and early intervention for youth who are at risk for developing SUD. This chapter focuses on specific aspects of the etiology, psychoeducation, prevention, screening, common comorbidities, and treatment relevant to adolescent-onset SUD.

SUDs and other psychiatric disorders commonly co-occur in part due to similar antecedent environmental risk factors, and both are influenced by adversities during critical developmental periods. Generally speaking, most childhood-onset psychiatric disorders increase the risk of developing an adolescent-onset SUD which complicates the clinical management of preexisting psychiatric disorders and increases the risk of developing new-onset mental health problems. Approximately 80% of people struggling with substance use issues begin using substances as teenagers. The majority of adolescents in the United States experiment with drugs or alcohol before graduating from high school, and the estimated risk of developing a SUD by the age of 18 years are 23.8%. Adolescent-onset SUDs are more likely to persist into adulthood and increase the risk of mood and anxiety disorders as well as antisocial personality disorder. Half of all psychiatric disorders begin before the age of 15, and three-quarters have onset by age 24. Thus, both SUD and non-SUD psychiatric disorders are largely pediatric-onset, and there is a bidirectional relationship between the two. Most childhood-onset psychiatric disorders (particularly attention-deficit/hyperactivity disorder [ADHD], trauma, and oppositionality) increase the risk for adolescent-onset SUDs. Adverse childhood experiences (ACEs), including maltreatment and trauma, also increase the risk of developing mental health problems and adolescent-onset SUD (Douglas et al., 2010; Felitti et al., 1998). The onset of SUD during adolescence complicates the clinical management of preexisting psychiatric disorders and increases the risk of developing new psychiatric symptoms and medical problems. Repeated substance use during adolescence increases the risk of addiction to other drugs tried later and interferes with the rapid brain development that occurs throughout adolescence into young adulthood. After initiation, repeated substance alters the brain in ways that contribute to further drug use. Initially, substances of abuse increase firing in the dopaminergic pathways of the ventral striatum, producing a subjective “high” that promotes further drug use. However, prolonged, repeated

use of the drug gradually diminishes dopaminergic neurotransmission, producing less intense “highs” and greater postuse dysphoria. At this stage, the neural circuitry in the dorsal striatum, rather than the ventral striatum, drives the preoccupation with drugs, decision making, and habitual use, making it much more difficult to consider or achieve abstinence. Thus, prevention, early identification, and intervention are crucial to efforts to prevent the progression to more chronic and severe substance and mental health problems as adults.

At-risk children can often be identified as young as 3 to 5 years of age, often presenting with impulsivity, aggression, hyperactivity, inattention, poor persistence, and emotional lability. This constellation of symptoms, characterized as “behavioral dysregulation,” is highly heritable. Such children often continue to have poor self-control and disruptive behavioral disorders in later childhood and are at high risk for developing SUDs during adolescence. Psychiatrists and other behavioral health clinicians play an important role in the early identification and treatment of childhood trauma/adversities, childhood-onset psychiatric disorders, behavioral and learning/academic problems, and other risk factors to reduce the risk of adolescent-onset SUD. Behavioral health clinicians also play an important role in providing youth and families with research-based psychoeducation and prevention of alcohol, nicotine/tobacco, marijuana, and other SUDs. Excellent psychoeducation resources are found on the NIDA website, and we list some examples in Table 54.5–1.

PREVALENCE OF SUBSTANCE USE

The Monitoring the Future (MTF) survey annually reports substance use trends in a nationally representative sample of more than 11,000 8th-, 10th-, and 12th-grade students from 112 schools. Key takeaways from the most recent MTF report are as follows:

- Vaping: Remains consistent for nicotine and marijuana vaping, elevated overall since 2017 for 8th, 10th, and 12th graders.
- Marijuana: Remains consistent for 8th, 10th, and 12th graders over the past decade, with little change in rates of daily- and past-year use.
- Alcohol: Although adolescent alcohol use and binge drinking have declined over the past decade, alcohol continues to be the most commonly abused substance by adolescents, with more than 50% of high school seniors and more than 40% of 10th graders reporting alcohol use in the past year; 17% and 10%, respectively reporting binge drinking in the past 2 weeks.
- Illicit/Other Drugs: continued decline in adolescent illicit substance use, including heroin and nonmedical use of prescription opioids, with the exception of a slight upward trend in amphetamine, inhalant, and cough medicine misuse among 8th graders between 2019 and 2020.

Nicotine/Cigarette Smoking

While cigarette smoking has reached an all-time low among adolescents, the prevalence of nicotine vaping has risen dramatically in the past 5 years. Research shows that nicotine vaping quadruples the risk of cigarette smoking. Thus it is not yet known whether the increase in nicotine vaping will reverse or slow the downward trend in cigarette smoking in the future (Johnston et al., 2021). The past-year prevalence of nicotine vaping among high school students nearly doubled between 2017 and 2020. The 2020 MTF survey indicates that nearly 35% of high school seniors and 31% of 10th-grade students reporting nicotine vaping in the past year; 8.6% and 5.6%, respectively, reported daily or near-daily nicotine vaping. Recent studies indicate that adolescents who vape nicotine or use e-cigs are three and a half times more likely to use marijuana compared to non-vape/e-cigarette users.

Marijuana

The dramatic increase in nicotine and marijuana vaping (e.g., e-cig; vape devices) since 2017 continues to be an area of significant concern for substance use in youth. Nicotine, cannabis, and stand-alone flavoring are the three primary “vape” products often sought by adolescents. The increased availability and popularity of e-cig and vaping devices and expanding legalized cannabis environment have likely contributed to the rising trend among adolescents, co-use/vaping of nicotine, and marijuana. Results from a recent prospective study of more than 3,000 high school students indicated that nearly 60% of youth who reported vaping were co-using (vaping) both nicotine and marijuana. Only about 23% and 17% were vaping only marijuana and nicotine, respectively. Similar trends have been reported in Colorado and other states that have legalized cannabis for recreational use. Flavorings, preservatives, and carrier components (e.g., vitamin E acetate) of vape products place users at risk for a variety of possible health consequences such as bronchiolitis obliterans or “popcorn lung” and e-cigarette or vaping product use-associated lung injury (EVALI).

Although still early, cannabis legalization has not (yet) been associated with a significant increase in the prevalence of marijuana use among adolescents. However, cannabis legalization has contributed to a dramatic rise in the potency of cannabis products. In commercial cannabis markets, smoked “flower” contains nearly 25% tetrahydrocannabinol (THC) and concentrates (e.g., “dabs,” “wax,” “shatter”) ranging between 70% and 90% THC. The market share of concentrates has risen sharply over the past 5 years and currently represents about one-quarter of cannabis products sold in commercial markets. This has likely contributed to the increasing use of concentrates among teens, especially in marijuana-legalized states. Compared to states that have not legalized marijuana, legalized states report higher rates of adolescent and adult first-time marijuana users and lower perceived risks associated with cannabis use. Colorado and other “early adopter” legalized states have also reported a significant increase in marijuana-related suicides, hospitalizations; emergency department admissions, and poison center calls postlegalization.

Ample research shows that cannabis is addictive; 1 out of 6 adolescents and 1 out of 11 adults who use/experiment will progress to addiction/moderate–severe cannabis use disorder (CUD). Higher THC concentrations are associated with greater addictive potential (abuse liability) and increased psychosis risk, particularly in adolescents. Regular cannabis use in individuals less than 17 years of age increases the risk of psychosis, negatively impacts motivation, drive, and self-efficacy, and is associated with persistent neurocognitive deficits and reductions in adult intelligence quotient (IQ) that may not be fully reversible even with abstinence. There is also a dose-relationship between the frequency of marijuana use before age 17 and poorer academic achievement, greater risk of high school dropout, as well as unemployment or underemployment in adulthood. There is also growing evidence that adolescent cannabis use increases the risk of developing depression, anxiety disorders, and addiction to other drugs in young adulthood. Increasing access to high-potency marijuana through legalization and relaxed regulatory policies, greater social acceptability, and lowered perceived risk are factors that likely contribute to continued and greater interest in marijuana by youth and greater initiation of first-time users. Thus, it is increasingly important that psychiatrists and other clinicians working in pediatric mental health settings have adequate training and research-based knowledge of the risk factors and risks associated with the use of cannabis and other substances during adolescent development.

CLINICAL EVALUATION

Behavioral health clinicians can play an important role in identifying youth who are likely to develop or have substance problems, as well as motivating and encouraging behavior change. This section provides clinicians with information and clinical tools to assist with fulfilling this potential, including discussion of valid substance screening measures, comprehensive clinical and diagnostic evaluation, brief evidence-based interventions, research-based psychoeducation resources for youth and families, and "warm handoff" procedures for referring adolescents to subspecialty substance treatment providers and coordinating care.

Screening

Screening, brief intervention, referral, and treatment (SBIRT) initiatives and programs have been developed and adopted in many states to encourage primary care providers to utilize standardized screening procedures and assessment instruments. Although SBIRT protocols were initially developed for implementation in pediatric primary care settings, over the past decade, SBIRT has been adapted and implemented in a broad range of clinical settings, including outpatient mental health settings. Several brief substance screening and assessment tools have been developed to assist clinicians in identifying high-risk youth and/or those who have started using or abusing substances, including the Brief Screener for Tobacco, Alcohol, and Other Drugs (BSTAD) and Screening to Brief Intervention (S2BI). Both are valid measures designed for self- or clinician administration. The S2BI uses a single stem question, "How many times in the past year have you used"? with four response options (e.g., "never," "once or twice," "monthly," "weekly or more") for nicotine/tobacco, alcohol, marijuana, illicit drugs, inhalants, synthetic drugs (K2, spice), nonmedical use of prescription medications. Both the BSTAD and S2BI may be self- or clinician-administered. In either case, it is important for clinicians to review or administer, interpret, and respond to substance screening results in the context of a confidential clinical evaluation with an adolescent alone (without a parent). If the adolescent reports "no use" → positive reinforcement; "once or twice in the past year" → brief advice using MI; "monthly" → likely to meet DSM-5 criteria for mild SUD → brief intervention or referral; "weekly or more" → likely to meet DSM-5 diagnostic criteria for moderate–severe SUD → referral to subspecialty substance treatment may be clinically indicated if DSM-5 diagnostic criteria for SUD are confirmed.

Brief interventions have been shown to have a modest effect size on reducing substance use and/or preventing progression to more serious SUD when delivered by SBIRT-trained clinicians. Several no-cost or low-cost online resources for training in brief intervention and motivational enhancement approaches can be found on the SAMHSA website (https://store.samhsa.gov/product/TIP-34-Brief-Interventions-and-Brief-Therapies-for-Substance-Abuse/SMA12-3952).

For youth who do not respond to brief interventions, progress to more serious substance involvement, or meet diagnostic criteria for moderate–severe SUD, referral to subspecialty substance treatment may be clinically indicated. It is important to develop "warm handoff" procedures to increase the likelihood that referred youth will engage in substance treatment. "Warm handoff' and coordinated care procedures may be collaboratively developed by partnering with an adolescent substance treatment program or provider offering evidence-based substance treatment. Adolescent engagement in substance treatment may be enhanced by first referring the teen for a brief, confidential expert consultation/evaluation with the subspecialty substance treatment provider as opposed to "referral to treatment." A brief initial consultation/evaluation provides an opportunity to assess the adolescent's "readiness for change" and use motivational enhancement approaches to respectfully address any questions/concerns and further explore and enhance motivation for change. An example of this approach can be heard in the Charting Pediatrics podcast: *When SUD Come to Pediatrics* (S4:E16) (https://www.childrenscolorado.org/health-professionals/professional-resources/charting-pediatrics-podcast/substance-use-disorder/).

Prevention

The Institute of Medicine (IOM) recognizes three categories of prevention interventions: (I) Universal prevention targets the population as a whole); (II) Selective prevention targets high-risk groups of

individuals; and (III) Indicated prevention targets individuals who manifest risk behaviors or early signs and symptoms of the illness. According to the most recent Cochrane review, only the following three interventions were determined to have sufficient evidence to be deemed efficacious or effective: (I) The Unplugged Program (directed toward 12 to 14 year olds); (II) Life Skills Training Program (directed toward 13 to 17 year olds) and (III) Good Behavior Game (directed toward 6 to 7 year olds). All are universal, school-based prevention interventions that are generally adopted school-wide and delivered by teachers trained in the intervention and delivered in the classroom setting. The Cochrane review did not identify any selective or indicated interventions or non–school-based/multicomponent community-based prevention interventions meeting rigorous criteria for effectiveness. However, recent studies not included in the Cochrane review but meeting similarly rigorous criteria support the efficacy of at least one selective school-based prevention intervention known as the Project Toward No Drug Abuse (directed toward 14 to 17 year olds), and one indicated school-based prevention intervention known as the Teen Marijuana Check-Up (TMCU). The National Institute on Drug Abuse (www.drugabuse.gov) has developed a more detailed description of evidence-based substance prevention interventions and programs as well as prevention principles that can be adapted for clinical practice (https://www.drugabuse.gov/publications/preventing-drug-use-among-children-adolescents/prevention-principles) included in the psychoeducation resources section of this chapter.

Treatment

As noted earlier, one of the best treatment strategies is prevention and early identification of risk factors for SUDs. Given mental health disorders and SUDs can often occur together and affect one another, treatment for co-occurring mental health disorders and SUDs needs to be multifaceted as well. There are a host of evidence-based practices to aid providers in most effectively treating their patients. The recently published “Treatment Considerations for Youth and Young Adults with Serious Emotional Disturbances/Serious Mental Illnesses and Co-occurring Substance Use” is an excellent resource for community providers and experts who have clients/patients with co-occurring disorders. This resource guide also includes principles and practical tips that can be adapted and applied in developing coordinated care models. Psychosocial interventions and psychotherapy remain the cornerstone of treatment for co-occurring MH and SUDs. When indicated, medication treatment strategies may also be appropriate. The combined use of therapy and evidence-based medications for the treatment of MH/SUDs may be indicated for moderate-to-severe conditions.

Most psychosocial substance treatment interventions address drug-taking in general. Whereas treatment for withdrawal syndromes or other medications used in substance treatment is generally substance-specific or used to treat co-occurring psychiatric disorders (e.g., ADHD, mood disorders). Compared to numerous studies in adults, relatively few randomized controlled trials have evaluated the safety and efficacy of medications for substance abuse (Table 54.5–2) or co-occurring psychiatric disorders (Table 54.5–3) in adolescents.

Evidence-based psychosocial treatments for adolescents with SUD supported by at least one randomized controlled trial include motivational enhancement therapy (MET)/cognitive behavioral therapy (CBT) (both group and individual format), and family-based interventions including multisystemic therapy (MST), functional family therapy (FFT), multidimensional family therapy (MDFT), brief strategic family therapy (BSFT), adolescent community reinforcement approach (ACRA), MET/CBT, and MET/CBT + contingency management (CM). Each of these treatment modalities has demonstrated efficacy based on the results of at least one randomized controlled trial. Overall, these interventions show comparable but modest treatment effect sizes on reductions in substance use but relatively low rates of abstinence, ranging from <20% (most family-based and group MET/CBT interventions) to 30% (individual MET/CBT). At least two randomized controlled trials have reported that approximately 50% achieve abstinence during the treatment when CM/abstinence-based incentives are added to individual MET/CBT compared to 30% abstinence with MET/CBT alone. This is consistent with the results of numerous studies in adults. Moreover, MET/CBT has most consistently been associated with sustained or increasing post-treatment effect size in both adolescents and adults with SUD, and there is considerable consensus that MET/CBT + CM is currently the most effective treatment for CUDs.

Table 54.5–2.
Medications Used in the Treatment of Substance Use Disorders (SUDs) in Adolescents

Medication	Randomized Controlled Trials	Targeted SUD	Main Outcomes
N-Acetylcysteine (NAC)	Gray et al., 2010	CANNABIS USE DISORDER	Significantly greater reductions in cannabis cravings and cannabis use.
Buprenorphine	Woody et al., 2008	OPIATE USE DISORDER	Randomized 152 opioid-dependent adolescents and young adults in a 12-week study. Randomized participants either received a 2-week detoxification with buprenorphine-naloxone (Bup-Nal) or 9 weeks of Bup-Nal maintenance followed by a 3-week taper. Those maintained on Bup-Nal were significantly more likely to remain in the study at 12 weeks. 70% vs. 21% and had significantly less injection drug use and use of opioids or marijuana. However, the 69- and 212-month follow-up groups were not significantly different in reported opioid use, cannabis use, or injection drug use. Thus, 3 months Bup-Nal did not alter the long-term course, suggesting that even longer-term maintenance may be indicated; additional research is needed. This medication is approved in the United States for the treatment of opioid dependence in those 16 years and older.
Bupropion Nicotine Replacement Therapy (NRT)	Moolchan et al., 2005 Muramoto et al., 2007	TOBACCO USE DISORDER (NICOTINE DEPENDENCE)	Bupropion and NRT alone and in combination have been shown to be well tolerated with a relatively good safety profile in adolescents (Moolchan et al., 2005; Muramoto et al., 2007). There is evidence of efficacy in adolescents for NRT delivered as a patch (Moolchan et al., 2005) and for bupropion at 300 mg/day

dose in at least the short term (Muramoto et al., 2007).

Table 54.5–3.
Medications Treating Co-Occurring Psychiatric Disorders in Adolescents with Substance Use Disorders

Medication	RCT	Targeted Disorder	Main Outcomes
Fluoxetine	Riggs et al., 2007	MDD	Adolescents (*n* = 123) aged 13–19 years were randomized to fluoxetine (20 mg daily dose) or a matching placebo. Participants in both groups received weekly individual MET/CBT as outpatient substance treatment throughout the 16-week trial. Results showed that compared to placebo, subjects treated with fluoxetine had significantly greater reductions in depression severity based on CDRS-R scores (primary depression outcome measure) and higher rates of depression remission (70% vs. 52%). Higher than expected depression remission in both groups suggests that the individual MET/CBT (targeting SUD) received by participants in both groups may have contributed to depression treatment response. Significant reductions in substance use were seen in both groups, but no group difference. Regardless of treatment assignment, participants whose depressions remitted by the end of treatment showed significantly greater reductions in substance use compared to nonremitters, whose substance use did not significantly decline from baseline levels of use despite comparable treatment compliance and completion.
Lithium carbonate	Geller et al., 1998	Bipolar	Lithium treatment was efficacious for both bipolar disorder as well as comorbid substance use disorder in adolescence. Longer-term follow-up study needed.

Pemoline	Riggs et al., 2004	Attention-deficit/hyperactivity disorder (ADHD)	Adolescents (*n* = 69) with ADHD and SUD were recruited from the community and randomized to pemoline titrated to a once daily 37.5-mg dose or matching placebo. Reductions in ADHD symptom severity were significantly greater in the pemoline treatment group compared to placebo on one (Clinician Global Impression- Improvement [CGI-I]) ratings but not both primary outcome measures (ADHD DSM-IV symptom checklist scores, adolescent report). Substance use did not decrease significantly in either group in the absence of specific psychosocial treatment for SUD.
Osmotic-release methylphenidate (OROS-MPH)	Riggs et al., 2011	ADHD	Adolescents (*n* = 303) with ADHD and at least one non-tobacco SUD were randomized to OROS-MPH (titrated to 72 mg daily dose) or a matching placebo. Participants in both groups participated in weekly individual motivational enhancement therapy (MET)/cognitive behavioral therapy (CBT) targeting SUD throughout the 16-week medication trial. Results showed significant reductions in ADHD symptom severity (ADHD-RS scores; primary outcome measure) and days of past 28-day substance use but no difference between groups. OROS-MPH was superior to placebo on some secondary outcome measures: (1) greater improvement in problem-solving and coping skills related to their drug use and (2) greater number of negative urine drug screens. Results suggest that adolescents in

			substance treatment (even if not yet abstinent) may benefit from concurrent treatment of co-occurring ADHD with OROSMPH (which showed a relatively good safety profile and low abuse/diversion liability with regular monitoring in this setting).
Atomoxetine	Thurstone et al., 2010	ADHD	Adolescents (*n* = 70) adolescents referred to outpatient substance treatment and meeting diagnostic criteria for ADHD, and at least one non-tobacco SUD were randomized to atomoxetine or a matching placebo. Participants in both groups concurrently received individual MET/CBT targeting SUD throughout the trial. Results showed significant reductions in ADHD symptom severity (ADHD-RS) and substance use but no difference between groups on primary ADHD or substance outcome measures. Adverse events were consistent with those reported for atomoxetine in non–substance-involved adolescents with ADHD despite nonabstinence in most participants.

An important limitation of existing substance treatment interventions is that none specifically address or integrate, or concurrently treat SUD and co-occurring psychiatric disorders, even though the vast majority of adolescents referred for substance treatment have psychiatric comorbidity. In addition to longstanding systemic and economic barriers, relatively few studies have focused on the development and testing of integrated treatment approaches. Only five randomized controlled trials, enrolling at least 60 subjects (≥30 subjects per group), have evaluated the safety and efficacy of medications for a co-occurring psychiatric disorder in adolescents with SUD. These studies are cited with brief summaries of the main outcomes in Table 54.5–3.

SUMMARY, DISCUSSION, AND CONCLUSION

Over the past decade, the opioid crisis, expanding legalized cannabis environment, and the COVID-19 pandemic underscore the critical role of pediatric primary care providers and mental health clinicians as “front line” first responders with regard to substance abuse prevention, screening, early intervention, and treatment. These events have brought an even sharper focus on the critical shortage of child and adolescent psychiatrists and behavioral health clinicians and the even greater shortage of clinicians with

dual training and experience in treating co-occurring psychiatric disorders and SUDs. Thus, in addition to usual updates on trends in adolescent substance use and current research, this chapter includes a number of clinical tools, psychoeducation, and training resources to further bolster the substance-related clinical skills of clinicians working in these settings. Over the next decade, we can anticipate continued momentum toward greater integration of behavioral healthcare services in schools and primary care medical settings and a continued burgeoning of behavioral health innovations to enhance scalability and access to evidence-based mental health and substance prevention and treatment interventions (e.g., AI-informed mobile apps, online or web-based interventions) and clinical training opportunities to address the clinical workforce shortage. It will be important for today's clinicians to stay abreast and informed of trends driving the evolution of the field and clinical practice.

54.6 Forensic Child and Adolescent Psychiatry

Peter Ash, M.D., and Elissa P. Benedek, M.D.

Forensic psychiatry is a subspecialty of psychiatry that focuses on the interface between psychiatry and the law. It may involve consulting to courts, evaluation of individuals involved in the legal system, working in corrections, having involvement in legal issues related to practice, teaching, and performing research in forensic psychiatry. Psychiatrists seeking board certification in forensic psychiatry are now required to complete a 1-year fellowship in an accredited forensic psychiatry training program. No such specialized training is available for child and adolescent forensic psychiatry, although, increasingly, trainees are getting more exposure to the area in residencies, and many forensic fellowships offer some additional experience in child and adolescent forensic psychiatry. Continued practice in this specialized area may involve certification, recertification, and maintenance of certification.

This chapter will focus on conducting psychiatric evaluations intended to provide evidence to be used in litigation. Forensic evaluations differ from clinical evaluations in that there is no doctor–patient relationship with an implicit duty of care, and confidentiality is limited inasmuch as most reports are being prepared for use in court. Forensic evaluations also differ in that evaluations are focused on answering a specific question. Often the question will have a specific legal test, which may vary from jurisdiction to jurisdiction. For example, while many jurisdictions use a “best interests of the child” test in determining custody in divorce proceedings, in other jurisdictions this test has a specific statutory definition that lists a variety of factors to be considered. It is important for evaluators to be clear on the relevant test in their jurisdictions. The forensic examiner approaches each case with a degree of skepticism beyond that used in most clinical settings. Malingering and secondary gain need to be considered in litigants and criminal defendants. To strive for objectivity, the forensic examiner often seeks out a wide base of collateral information which may include legal, medical, psychiatric, and academic records, interviews with other family members, depositions, police reports, and arrest records. As noted, confidentiality and patient advocacy do not exist in forensic evaluations; thus, guiding ethical principles are not the traditional *primum non nocere*—first do no harm—and beneficence. In fact, were the forensic psychiatrist striving to act in the examinee’s best interests, it would skew objectivity. Appelbaum suggests that, in forensic psychiatry, primacy be given to the value of justice based on the

ethical principles of truth telling and respect for persons. This primacy applies regardless of whether the forensic psychiatrist has been retained by an attorney for one side or is court appointed.

Dr. A was very concerned and sympathetic as she listened to Becky, a 12-year-old girl, discussing the emotional and physical abuse she claimed she had endured while visiting her father during unsupervised visitation. Later, while interviewing Becky's mother, Dr. A listened to a verbatim account of the abuse. It was only upon later reflection that Dr. A recognized that Becky had been coached to parrot a word-for-word version of her mother's story and that, in her sympathy for this allegedly traumatized young girl, she had lost objectivity.

GUIDELINES

Traditionally, child and adolescent forensic psychiatry had focused on issues of child abuse and neglect, custody, and delinquency. Beginning in the early 1980s, many child and adolescent psychiatrists were drawn into civil suits as expert witnesses in cases alleging child sexual abuse. Some experienced role confusion, in which they were trying to serve as both therapist and expert witness, seemingly unaware of this inherent conflict. Added difficulties were created by the lack of clear guidelines as to how one actually assessed children for suspected sexual abuse and the paucity of good research data regarding the long-term effects of child sexual abuse.

The American Academy of Child and Adolescent Psychiatry (AACAP) has issued practice parameters for forensic evaluations which include welcome principles of practice. Anyone undertaking forensic examinations of children or adolescents should become familiar with the American Academy of Psychiatry and the Law's *Ethical Guidelines of Forensic Psychiatry.*

Civil litigation involving children may involve other types of trauma, malpractice, and class action suits against institutions for neglect or abuse. As more youths enter the juvenile justice system, there is a growing need for forensic psychiatrists who are willing to perform evaluations for the court or work within juvenile corrections providing evaluation and treatment for detainees and committed youths. There is a high prevalence of psychiatric disorders in this population, and many youths remain undiagnosed and untreated.

TREATING CLINICIANS TAKING ON A FORENSIC ROLE

Not uncommonly, a treating clinician may be asked to become involved in litigation involving a child or adolescent patient. For example, divorcing parents who have sought treatment for their child to help the child deal with the stress of divorce may ask the treating clinician to provide the court with an opinion as to whom the child should live with, or a child who is in treatment for the effects of an injury or trauma may be suing the person who allegedly caused the injury and the treater is being asked for opinions on the severity of mental injury and prognosis. Treating clinicians who provide opinions to the court are placed in a dual role situation, that of treater and of forensic evaluator, and these roles may conflict (e.g., the confidentiality of the treatment may be lost, which could impair future treatment if the patient becomes less willing to share their thoughts). Requests for the treater to enter a forensic role may be informal or may come as a subpoena. The fact that the parents typically control the release of information, rather than the child patient, adds to the complexity.

Requests for clinicians to take on a forensic role should be dealt with cautiously. In most situations, it is preferable to have the child patient evaluated by a separate forensic evaluator to keep the treatment and forensic roles separate. This is particularly important if the clinician has not formed an opinion on the legal issue and would need to conduct a forensic inquiry which otherwise would not be part of the treatment.

Dr. J was treating 7-year-old Stacy for anxiety arising out of her divorcing parents contesting her custody. Stacy's mother's attorney asked that Dr. J provide an opinion as to how much time Stacy should spend with her father. Dr. J responded that she had not evaluated Stacy with that in mind, did not have an opinion on that issue, and recommended the parents seek a court-ordered evaluation to obtain recommendations for what custodial arrangement would be in Stacy's best interest.

Treating clinicians should also clarify whether they are being asked to be a fact witness or an expert witness. Expert witnesses can testify as to their opinions; fact witnesses cannot. That a clinician wrote in the chart that the patient has major depressive disorder is a fact; whether the patient has major depressive disorder is an opinion. Treating clinicians can be required to answer questions about their treatment, assuming there is an appropriate release, but in most jurisdictions, a clinician cannot be required to provide expert opinions without the clinician's voluntary agreement. Expert witnesses are usually paid for their time; fact witnesses are not. When a treating clinician offers expert opinions, a cross-examining attorney is likely to try to paint the expert as biased in favor of the patient. A treating clinician who is not experienced in forensic issues or practice may wish to obtain consultation as to how to respond to a request to act in a forensic role.

FORENSIC EVALUATIONS

Referrals

Most referrals for forensic evaluations come from attorneys, and some come directly from the court or from child protection agencies or parents. At the outset, it is important to clarify whom the attorney represents, whether the case is civil or criminal, and what the legal issue is. A useful practice is to ask the referring party to put these questions in writing in a cover letter. This also enables the attorneys to think more carefully about exactly what they want to learn from the forensic examination and refreshes the memory of the examiner doing the forensic examination. Conflicts of interest need to be ruled out in taking a case. These might include having treated a relative of the examinee, being on the faculty of a facility being sued, having social ties with an involved party, or having a personal or work relationship with a physician defendant. Forensic psychiatrists need to consider whether they have sufficient expertise in the area in question. A lack of expertise in the topic being litigated does not necessarily preclude involvement as long as one notifies attorneys of this fact. Some attorneys may be willing to provide background materials on issues not often encountered, such as toxic buildings.

Ms. Smith, an attorney, called Dr. W and informed him that she was representing a hospital that was being sued by the parents of a youth who died by suicide in an adolescent inpatient psychiatric unit. She had heard of Dr. W's fine reputation, both as a therapist of adolescents and as an expert witness, and she hoped that he would take the case. Dr. W immediately recognized a conflict of interest in that he did some of his training at this facility and believed that might compromise his objectivity. Furthermore, the defendant's psychiatrist was someone with whom he had a collegial relationship. Finally, inasmuch as his practice was entirely outpatient, he informed Ms. Smith that he did not feel qualified to testify on issues involving the standard of care in an inpatient unit. Dr. W declined to take the case. Dr. J, however, was an unpaid adjunct professor at the same university, had not practiced inpatient psychiatry for years but was not at all reluctant to become involved in the case and did not see a conflict of interest. Needless to say, Dr. J was cross-examined on just these issues.

Other factors to consider when deciding whether to accept a case are the extent of work anticipated; whether the referring attorney is asking just for record review or wants an evaluation as well; whether a written report is expected; the timeline of the case; and whether it is feasible to meet the case's discovery date—the time when attorneys must provide the other side with their expert's name and opinions. Fees should be discussed and a retainer may be obtained up front. It is always unethical to

accept a case on a contingency fee, in that it would compromise objectivity. Plaintiff's lawyers, in contrast, act as advocates for their clients, and so they often work on contingency fees in civil suits.

Informed Consent

Unless a court order requires the evaluee's participation, prior to continuing the interview, informed consent should be obtained. Since, in most cases, minors are deemed legally incompetent to provide informed consent, consent is usually obtained from parents or guardians. However, respect for persons suggests that minors should be given information about the evaluation in a manner suitable for their developmental level, which includes explaining in age-appropriate language who has retained the expert, the purpose of the evaluation, that the evaluator is not there as a treating doctor, the lack of confidentiality, and that the expert may be called to testify. It is important to assist the juvenile in understanding the information presented. Assent to the evaluation should be requested. If the minor does not assent, the clinician needs to consider carefully whether it is appropriate to proceed with the evaluation.

> Dorothy, an intellectually disabled 12 year old, said that she understood that the evaluation would not be confidential but then could not explain what confidential meant. The evaluator then made a further effort to explain the concept in simpler language and asked her again to explain it back.

In some cases in which an examination is court-ordered, informed consent need not be obtained, but the juvenile should still be informed of the nature of the evaluation. If a juvenile refuses to cooperate with a court-ordered examination, they should be informed of the possible legal ramifications of failure to comply with a court order. It is prudent to clarify that the forensic examination is not a treatment relationship, and examinees may need to be reminded of that in the course of the evaluation, particularly if they persist in viewing the examiner as being there to help them. If informed consent is required, a written release should be obtained for dissemination of the written report, and the examinee should be made aware of the limited confidentiality of the evaluation.

Written Report

The written report becomes the backbone of any forensic evaluation. Care needs to be taken to ensure that it addresses the relevant legal issues and contains the foundations for the expert's opinions. A thorough, well-written report often leads to an out-of-court settlement, avoiding the cost and trauma of going to trial. If the case proceeds to trial, the report becomes the basis of the expert's testimony. Reports should be free of any inflammatory or prejudicial statements, and parties should be treated with respect. A good check on one's possible bias is to ask, "How might my report have differed if written for the other side?" The expert must be aware that many people besides the judge may read the report, including plaintiffs, defendants, and their parents.

> Dr. G wrote in a report that the youngster "had the brain of a banana." Needless to say, this was an inappropriate comment.
>
> Dan, an adolescent whose parents were involved in a contentious child custody dispute, was concerned about the possible information that might be contained in the expert's report of his evaluation. He waited by the rural mailbox daily in an attempt to read the report before his parents and was successful in intercepting it. The examiner had made mention of his latent homosexuality. Dan was distressed about this report with just cause.

CUSTODY ISSUES

Child Custody Disputes Between Parents

Custody conflicts most typically arise between divorcing or divorced parents but may also arise between parents who never married and sometimes between parents and others seeking custody or visitation, such as grandparents and surrogate parents. Since the early 1900s, custody decisions have been guided by the concept of the child's best interests, but states vary in how these are defined, with some states specifying particular factors that need to be addressed, so forensic evaluators need to be aware of the specific test in their jurisdiction. In child custody disputes, the child is not a named party in the dispute, and the expert has an advocacy role in speaking for the child's best interests. For this reason, most experts in the field recommend that the evaluator in a custody dispute not be retained by one of the parties but instead be either court-appointed or stipulated to by both parties to avoid any bias that might arise from being retained by one side or the problem of one parent distrusting the evaluator because of suspected bias.

Unlike most forensic evaluations, which focus on an individual, child custody evaluations require assessments of multiple people and their interactions and typically involve individual interviews of each parent, the children, and observations of the child(ren) interacting with each parent and others who live in the proposed custodial environment, in addition to interviews of others who may be involved or have useful collateral information. Unilateral parental evaluations in divorce situations are of very limited utility in that the examiner has only second-hand, and often biased, information about the parent not seen. Furthermore, the examiner cannot make comparisons between the parents if only one parent has been seen.

Child Abuse and Neglect Cases

Forensic evaluations may be requested at any step in the course of litigation involving child abuse and neglect, from the determination of whether abuse and neglect occurred through the assessment of whether the child should be removed from the home to the question of whether a child who has been removed should be returned or whether parental rights should be terminated. All states require physicians to report suspected child abuse and neglect to the state or county protective services agency, and the agency then conducts an investigation. The investigation often includes a forensic interview of the child. While psychiatrists sometimes are asked to conduct these forensic interviews, the trend over the past 30 years has been to have initial forensic interviews conducted by trained personnel in designated centers rather than refer initial evaluations to child and adolescent psychiatrists. In later litigation, either in the juvenile court or in adult criminal court, psychiatrists may be retained to review the initial forensic interview or to reinterview the suspected child victim. Once abuse or neglect is established, a forensic interview may be sought to assist in planning appropriate interventions. If a child is removed from the home, particularly if the removal is occasioned because of neglect by a seriously mentally ill parent, after the parent receives treatment, an evaluation may be sought as to whether the parent has regained sufficient parenting capacity to be reunited with the child.

> Ms. Smith was seen for an evaluation as to whether her parental rights should be terminated with her 5-year-old child after her 1-year-old son was murdered by her live-in boyfriend. Ms. Smith did not believe that her boyfriend had murdered her child as he had not yet been convicted. Her history was replete with past physical and emotional abuse by her boyfriend and others. She was compliant with all evaluation appointments and court-ordered psychiatric counseling until such time as her boyfriend was convicted. Even then, she believed him—she protested his innocence and became less compliant with therapeutic sessions. The evaluator expressed concern about the safety of the 5-year-old child.

Assessments of parental capacity must take into consideration the child's developmental needs, the fit between parent and child, and parental strengths and ability to protect, advocate, discipline, and provide emotional and cognitive support. In addition, the psychiatrist needs to assess the parents' cognitive capacities and social supports, as well as their histories and special issues, such as prior sexual abuse, substance abuse, domestic violence, and mental illness.

Making Recommendations

Recommendations to the court should address the legal issues at hand, be feasible, and be based on the child's developmental needs. Forensic examiners need to remember that the court is the ultimate decision maker and not be offended if their recommendations are not followed. Sometimes this may occur because the court has become aware of new evidence or because of legal issues. However, a report that fails to demonstrate the basis for the expert's reasoning and opinions may also lead to recommendations not being followed.

CIVIL LITIGATION

Torts

A *tort* is a claim of wrong done to another person for which a legal remedy, most often a monetary award for the plaintiff, is sought. The plaintiff must demonstrate by a preponderance of the evidence that there has been a breach of duty owed by the defendant to the plaintiff, as a result of which the plaintiff suffered an injury. Torts may be deliberate, as when an individual sets out to harm someone, or unintentional, as when the act results from negligence (as in malpractice and personal injury cases). The plaintiff may seek compensatory damages for pain and suffering, special damages for medical or psychiatric care, and, in intentional torts, punitive damages. While only a minority of personal injury cases do not settle and actually proceed to trial, in contrast to family law cases, for those cases that do proceed to trial, a jury will typically hear the case, and a long period often elapses before the case goes to trial. The statute of limitations in each state limits the period during which an action may be brought and usually runs from the time when an injury is discovered. However, with juveniles, in most states, the statute does not begin to run until the child reaches the age of majority.

Susan, a 10-year-old girl, was severely bitten by a neighbor's dog and sustained a cosmetic injury to her lower lip. Her father instituted a suit against the neighbor in the role of her best friend. A forensic evaluation revealed that Susan had little concern about her injury. She was doing well in school, had many friends, and had future plans to become a teacher. Her concerns centered on her mentally ill mother, who had been institutionalized and then ran away from the family. Susan wondered about her health and her whereabouts. Susan's father, by contrast, obsessed about her injury.

Post-traumatic Stress Disorder

A common claim is that post-traumatic stress disorder (PTSD) results from the negligent or intentional behavior on the part of a defendant. The forensic psychiatrist may be asked to examine the plaintiff by either side. Sometimes, the forensic psychiatrist's role is limited to record review and critiquing the forensic report of the other side. Evaluating a child or adolescent for alleged PTSD and commenting on issues of causality and future damages is a complex and challenging task. Very young children may have difficulty verbalizing the subjective symptoms of PTSD, and it may manifest itself differently in children than adults. Re-enactment of a trauma may be common, but flashbacks are less likely than with adults. Parents may not be the best observers of their children's behavior and may veer toward minimizing or exaggerating psychopathology. Heightened arousal in PTSD may be confused with attention deficit hyperactivity disorder (ADHD) or coexist with it. Children, especially those living in inner cities or war zones or those exposed to domestic violence, may experience cumulative and chronic PTSD that clouds issues of causality. Prior trauma may sensitize them, thereby heightening their vulnerability to subsequent trauma and the development of PTSD. Age at the time of trauma may affect which symptoms develop but not necessarily symptom severity. The course of PTSD is often affected by parental responses to trauma—hence the need to explore family dynamics and other environmental mediating factors. In addition, the forensic psychiatrist should be aware of studies on the longitudinal course of PTSD in childhood.

Key Points

Key points in the forensic assessment of children involve getting thorough developmental and family histories, including whether the child has experienced prior victimization or witnessed violence or sexuality and, if so, how they have dealt with it. In addition, it is important to note from other sources the exact onset of symptoms. For example, pediatric records may indicate that a child's sleep disturbance and bed-wetting preceded a trauma, contrary to the history given by parents. The forensic psychiatrist should be aware of the salient literature on memory in children and the suggestibility of child witnesses. The child who has been through multiple interrogations may feel that they have not been believed and start to embellish their responses or try to please the interviewer by giving the desired responses. Leading questions and either–or questions that give forced choices can be hazardous.

Questions should be put to the child in an unbiased way that encourages the use of narrative recall. It is important to elicit the child's recall of traumatic events both verbally and through the use of spontaneous play and drawings, which may reveal traumatic themes. The child may evidence behavioral signs of trauma within the interview, such as heightened startle response or, in the case of the sexually abused child, undue familiarity. Although young children are not likely to malinger, statements made by interviewers or parents can readily influence them. Source misattribution, in which children confuse something they have read or been told about with something that actually happened to them, may also lead to erroneous allegations. In research settings, children who were repeatedly urged to think about nonevents eventually came to believe they really happened.

Sylvia, a 4-year-old nursery school child, claimed that she had been repeatedly sexually abused by her nursery schoolteacher. In addition, she reported she had accompanied her classmates to a secret location in a nearby park where there were sacrifices of animals that they were forced to observe. After a transcript of the initial evaluator's interview of Sylvia was obtained, it was possible to conclusively opine that she had been asked leading questions repeatedly and then complimented when she gave the desired answers. In addition, she had been told that other classmates had told the interviewer about their horrific experiences with the nursery schoolteacher.

Pitfalls

Common pitfalls in the forensic evaluation of damages in civil litigation include attributing all of a child's symptoms to the trauma being litigated, failure to get an adequate prior history, a bias that leads to selective interviewing, the failure to pursue disconfirming data, asking numerous leading questions, and the need to give attorneys the opinions they seek. Some examiners immediately equate trauma with PTSD and fail to consider other diagnoses or even whether the trauma in question meets the threshold of trauma necessary to meet the diagnostic criteria of the latest diagnostic manual (DSM-5-TR). Similar problems may be encountered with plaintiffs alleging trauma-related depression or other psychiatric disorders.

Dr. A was called by a defense attorney to review discovery material in a case that alleged permanent harm and suffering in 6-year-old Tony, who was alleged to have been sexually abused at age 3 years in his daycare center. Dr. G, the forensic expert for the plaintiff, had evaluated the child and performed psychological testing on him and concluded that the boy's conduct problems were all related to the alleged abuse, which the child had difficulty recalling. However, his early history of the boy was cursory, and he had little information about the mother, who was a single parent and did not review medical records. In her thorough review of discovery material, Dr. A learned that Tony had witnessed extensive domestic violence and his mother's rape, shown signs of hyperactivity since age 2 years, and exhibited much anxiety related to his mother's safety and several separations from her at times when she was unable to care for him owing to depression. Tony also had delayed language development. Dr. G, at the time of his deposition, was asked why he had not asked about these matters. He said he considered the mother's personal life a private matter and did not see its relevance to the litigation. Dr. A, when deposed, pointed out that many other factors besides the alleged abuse might account for Tony's behavioral problems.

JUVENILE JUSTICE CASES

Overview

The U.S. juvenile justice system, which is more than 100 years old, is in a state of rapid change. The founding premise that wayward youths could be rehabilitated through education, special services, treatment, and redirection has been challenged as more hard-core and violent youths enter a juvenile justice system that lacks sufficient dispositions and funding. Until fairly recently, there have been little data on effective treatments and a paucity of adequate dispositions and funding for this population. In response to the upsurge of adolescent violence, which peaked in the early 1990s, out of a concern for public safety, many states passed mandatory waiver statutes which typically specified that any juvenile over a certain age who was charged with certain specified crimes would automatically be waived to adult jurisdiction. Other forms of waiver to adult court include judicial waiver, in which a juvenile is waived after a hearing, and discretionary waiver, in which the district attorney, by statute, is allowed discretion to prosecute certain classes of juvenile defendants in either juvenile or adult court. Juvenile crime has actually decreased dramatically over the last three decades, and in response, there is a trend to loosen some of the broad waiver statutes. Studies suggest that adolescent defendants waived to adult jurisdiction are more likely to recidivate once released than youths who committed comparable crimes and remained in the juvenile justice system.

The Juvenile Court

The juvenile court remains a civil court in which judges have wide discretion, procedures remain more informal than in adult court, and records may remain sealed. However, in actuality, there are many loopholes and exceptions to the concept of the sealed juvenile record. If a juvenile is waived to the adult court, their records go along. Juvenile records may also be released to insurers, the military, employers, and for purposes of licensing and national security.

It was not until the 1960s that juveniles were afforded clear due process rights. In a seminal 1967 case, *In re Gault,* Justice Fortas charged that “in most juvenile courts, the child receives the worst of both worlds: That he gets neither the protections accorded to adults nor the solicitous care and regenerative treatment postulated for children.” As a result of *Gault* and subsequent cases, juveniles were afforded most of the rights afforded to defendants in adult criminal court, with the notable exceptions of the right to jury trials or transcripts of proceedings. In 1970, *In re Winship* held that the standard of evidence in juvenile hearings must be beyond a reasonable doubt, the same standard used in the adult criminal court.

Preadjudicatory Examinations

Courts often request psychiatrists to perform preadjudication examinations of juveniles. These are designed to help the judge to make appropriate dispositions. These examinations are similar to diagnostic evaluations but go further in that they also consider mitigating factors, risk factors for continued delinquency, and the risk the youth may pose to the community. In addition, an assessment of amenability to rehabilitation and recommendations as to what sort of treatment the youth needs may have a bearing on the type of facility to which the youth is committed.

Waiver Evaluations

Waiver, or *bindover,* as it is known in some jurisdictions, refers to the transfer of a juvenile from the juvenile court to the adult court, in which proceedings are criminal, not civil; and public, not closed; and sentences may be harsher and extend into adulthood. The are no juvenile courts in the federal system, so minors charged with federal crimes have a waiver hearing to determine whether they will be prosecuted as adults in federal district court or transferred to state juvenile court jurisdiction. Most adolescent defendants who now enter the adult criminal system do so as the result of mandatory waivers or as a result of prosecutorial discretion. With judicial waivers, evaluations are used for determining which court should have jurisdiction over the youth, not for disposition as in a preadjudicatory examination. Thus, the focus is on helping the judge weigh factors that have a bearing

on the decision of whether to waive a youth. In addition to developmental and psychosocial history and diagnostic issues, the examiner considers whether the youth has benefited from any interventions, be they therapeutic or within the juvenile justice system, thus far. Amenability to treatment that can be provided within the juvenile system and the ability to contain the youth within the juvenile justice system are also considerations. Special needs that the adult correctional system might not be able to meet need to be identified and consideration also may be given to the age, size, and maturity of the youth. The risk of future violence must be assessed, and short-term prognoses may be made based on known risk factors.

Competency to Stand Trial Examinations

Competency is a term that may be used in reference to many legal issues, such as competency to stand trial, waive *Miranda* rights, plead guilty, and waive the right to counsel. Competency to stand trial in some jurisdictions is called competency to proceed, to more clearly cover issues that arise in a criminal case prior to trial, such as the decision to accept a plea bargain. The court may also request an evaluation in regard to competency to stand trial if waiver seems likely. An adolescent must be competent to stand trial in adult court. Until the mid-1990s, very few states required that a youth be competent to stand trial in juvenile court under the theory that many youths were immature and so incompetent and that the role of the juvenile court was to promote rehabilitation. Since the mid-1990s, an increasing number of states have required that youths be competent to stand trial in juvenile court, as well. Competency examinations focus on the individual's current ability to understand the charges against them and their severity and potential consequences, understand the trial process, be able to work with their attorney in developing a defense, and be able to participate in courtroom proceedings. While in many respects, the evaluation of competency to stand trial of a youth is similar to that of an adult, issues of developmental immaturity are much more likely to render a youth incompetent. Juvenile defendants who are found incompetent to stand trial pose a challenge for the courts in that a major component of restoration is simply to let the minor mature. However, prosecuting and punishing a youth several years after offending who is now in a different developmental stage from how they were when the crime was committed is problematic.

Criminal Responsibility Assessments

In contrast to competency evaluations, which assess the present state of mind, assessments regarding criminal responsibility attempt to reconstruct the defendant's state of mind at the time of the crime. Retrospective assessments of the state of mind are always more difficult and rely on not just the defendant's version of events but also a great deal of discovery material. *Insanity* is a legal term that is used as a defense to relieve defendants of responsibility for the crime. States have different legal definitions of insanity, and several states have no insanity defense. Legal definitions of insanity typically include a cognitive prong that gets at whether the defendant, at the time of the crime, as a result of mental disease or defect, lacked substantial capacity to appreciate the wrongfulness of their conduct. *Substantial* implies serious mental disorders and does not cover Axis II diagnoses or, usually, PTSD. The exact wording of the insanity defense varies from state to state. Some states have an additional volitional prong that refers to the inability of the defendant to restrain themselves as a result of an abnormal state of mind. In addition, the law requires that the defendant possessed a guilty state of mind (*mens rea*)—that is, intention at the time of the crime. Mental abnormalities may affect the ability to form intent or lead to diminished responsibility for the act. Thus, a murder charge might be reduced to manslaughter if the defendant was not capable of premeditation. A few states now permit a guilty but mentally ill plea, which results in the same sentence as if found guilty but supposedly promotes more treatment while incarcerated. While youth waived to adult criminal court can potentially make use of their state's insanity defense, only a minority of states allow the use of an insanity defense in juvenile court.

Sentencing Evaluations

In juvenile court, if the court has already obtained a preadjudicatory evaluation covering the youth's developmental status, treatment needs, and amenability to rehabilitation, that report will often be used in

sentencing. Courts or attorneys may utilize similar reports in the sentencing phase if a prior evaluation has not been done or if a supplemental evaluation is deemed useful.

For youth tried as adults, forensic evaluations are increasingly utilized in sentencing decisions. For serious crimes, a series of U.S. Supreme Court cases have changed the landscape with regard to the sentencing of adolescents. In 2005, in *Roper v Simmons,* the Court held that "evolving standards of decency that mark the progress of a maturing society" had changed to the extent that the death penalty for youth under 18 years of age was "cruel and unusual punishment" and thus unconstitutional. The Court cited three factors regarding adolescents that made them less culpable as a class and thus not deserving of death: (1) that adolescents were developmentally immature and thus more impulsive and more prone to respond to peer pressure, (2) that their behavior was often affected by adverse environmental circumstances over which they had no control (such as where they lived and the circumstances of their families), and (3) that their personalities were still in flux and so their actions could not be seen as reflecting enduring character traits. Since *Roper*, there has been a burgeoning of research on the neurologic development of the adolescent brain demonstrating that while those areas of the brain involved in emotion, particularly the limbic system, mature early in adolescence, other areas, especially the prefrontal cortex, that are involved in restraining impulsive behavior and considering consequences, continue to develop into the early 20s. This developmental sequence helps explain why much adolescent antisocial behavior is time limited to adolescence and is used to support the idea that adolescents are both less culpable than adults and are also more likely to be either rehabilitated from or develop out of criminal behavior. Using analyses along these principles, the Supreme Court held that a sentence of life without parole (LWOP) was unconstitutional for all nonhomicide offenders (*Graham v Florida*, 2010), that mandatory LWOP was unconstitutional and could only be imposed for murder following a hearing (*Miller v Alabama*, 2012), that LWOP sentences should be rare and reserved for the most incorrigible offenders (*Montgomery v Louisiana*, 2016), but that an LWOP sentence could be imposed without a judicial finding that an adolescent was incorrigible (*Jones v Mississippi*, 2021). Some states, by either statute or court holdings, have adopted further specific criteria that need to be considered in considering sentencing adolescents to LWOP. Although these court holdings pertain directly to factors to be considered when sentencing adolescents convicted of murder, these factors of reduced culpability of adolescents and the likelihood of their being rehabilitated by their mid-20s have been applied in sentencing hearings of adolescents facing lesser charges and in sentencing hearings of young adults who are slightly older than 18 years of age but who arguably, in many developmental respects, resemble adolescents under age 18, and so provide a useful framework for structuring opinions about mitigating sentencing in a wide variety of adolescent and early adult cases.

Blended Sentences

Some courts, such as New Mexico, have started using criminal sanctions within the juvenile court, and others, such as Michigan, are experimenting with blended sentences by which the youth, on reaching the age of majority, is automatically transferred from a juvenile correctional facility to an adult one. In Minnesota, judges may impose extended juvenile dispositions with stayed criminal sanctions. Courts also use mandatory minimum sentences for certain crimes. A very promising development has been that of youth drug courts for first-time offenders charged with drug-related offenses. Close court supervision is combined with outpatient drug treatment and a team approach, which appears to be reducing recidivism.

Interventions

The last decade has seen many changes in the juvenile justice system. There has been much more attention to the prevalence of mental illness in this population and the implementation of evidence-based treatments for conduct disorders, substance abuse problems, and comorbid psychiatric disorders. A number of professional organizations have been active in developing guidelines for assessment and treatment in juvenile detention facilities. However, many facilities and programs continue to rely on outdated interventions in which juveniles are treated in groups with their deviant peers. Numerous studies attest to the lack of efficacy of many programs for this population, and research has documented the negative effect that delinquent youth have on one another. Innovative community-based treatment

programs, such as intensive probation, are proving effective in helping youth on probation cut down on reoffending. Another effective approach is multisystemic therapy, which was designed to target and influence the known correlates of antisocial behavior in youth. This may occur with youth living either at home or in foster placement. It uses intensive outpatient services that focus on problems within the child and their family and environment and promotes prosocial behavior. It is a cost-effective treatment that provides an alternative to out-of-home placement and has been shown to be effective with delinquents. Collaborative problem solving is another intervention that is being used effectively in many juvenile facilities. Therapeutic foster care also has been shown to cut down on recidivism in some studies. A number of school-based programs now have good evidence of efficacy in reducing violence. In addition, diversion programs and juvenile mental health and drug courts are showing promise in keeping youth out of correctional facilities.

TELEHEALTH FORENSIC EVALUATIONS

Prior to the onset of the COVID-19 pandemic in 2020, telehealth forensic evaluations of juveniles were fairly rare, although utilizing telehealth for providing treatment to juveniles in juvenile correctional settings located in rural areas where there were few local child and adolescent psychiatrists was not uncommon. Following the onset of the COVID-19 pandemic, much outpatient treatment of children and adolescents moved to virtual platforms, many courts moved to virtual hearings, and many correctional institutions restricted the entry of nonemployees, so telehealth interactions became much more common. Clinicians and courts became familiar and more accepting of telehealth operations, and since many schools moved to online schooling, virtual interactions became more familiar to youth as well. As a result, telehealth forensic evaluations of youth became more common, despite very limited data regarding their comparability with in-person evaluations.

Telehealth evaluations often raise privacy issues that differ from in-person evaluations. If the youth is in an institution, the institution may require a monitor to be in the room with the youth, in part out of a concern that the equipment is utilized properly, which may limit what the juvenile evaluee is willing to discuss. If the youth is at home, there is potentially a concern that an adult may be in the room, out of sight of the camera, and affect the child's responses in ways unknown by the evaluator, either by coaching or simply out of a need to please the adult.

Video techniques generally do not markedly affect interviewing an adolescent who is cooperative and does not have privacy concerns, although it is more difficult to clearly observe nonverbal reactions. Evaluations of prepubertal youth, which, if conducted in person, would include the clinician using toys or drawings with the child, require alternative approaches, the effects of which need to be considered in assessing the reliability of the interview. Formal psychological tests may also require in-person interactions, although several studies of remote administration of particular measures that involve reading questions to adults have shown similar results to in-person administration. Telehealth forensic evaluations are an evolving area of practice but are being increasingly accepted by evaluators, attorneys, and courts.

FUTURE DIRECTIONS

This is an exciting time to be working in the field of child and adolescent forensic psychiatry because expanding research allows for opinions that are based on research data in addition to specialized knowledge of child and adolescent development, which will aid the courts in their deliberations. This subspecialty is gaining recognition and a body of literature along with clinical guidelines. Child and adolescent psychiatrists also have an important role in conducting research in the areas of prevention, intervention, and understanding the effect of trauma on the developing brain.

The juvenile justice system is in need of further reform. Many programs are inordinately expensive, and their efficacy has not been documented. In fact, in some programs, interventions have led to more reoffending or violent behavior. In many jurisdictions, juvenile offenders receive poor legal representation due to excessively large caseloads assigned to juvenile defenders and inadequate compensation rates. The recognition by the courts of the decreased culpability of adolescents, and the rapidly expanding knowledge of the underlying neurobiology of the developing brain, gives hope that

public policy will continue to move in the direction of taking account of developmental information in rehabilitating adolescent offenders. Standards for determining child custody also need to be reviewed in light of changing family structures and the vagueness of “the best interest of the child” standard. Finally, it is hoped that forensic psychiatry fellowships will offer more flexible and diverse programs for those trainees wanting to specialize in child and adolescent forensic psychiatry.

ACKNOWLEDGMENT

The authors would like to acknowledge Dr. Schetky for her contribution to previous versions of this chapter.

54.7 Ethical Issues in Child and Adolescent Psychiatry

ADRIAN N. SONDHEIMER, M.D., AND TAKAHIRO SODA, M.D., PH.D.

Ongoing scientific developments and discoveries continue to advance and enhance the practice of medicine in areas relevant to the care of children and adolescents. The medical profession is no stranger to such continued accrual of new knowledge and to the potential benefits and risks associated with these advances, especially those that, at times, suggest quantum leaps ahead. As the entire globe currently confronts the COVID-19 pandemic, the development and distribution of countering vaccines are starkly illustrative of both possible outcomes. In past centuries the pace of change in the "knowledge base" was slower, but societies have always needed medical practitioners, designated "healers," whose responsibility it was to diagnoses ailments, provide treatments, care for the sick, give advice to the afflicted and their families, and develop new understandings of maladies. Since time immemorial, society's healers have encountered and considered conflicting theoretical stances, goals, and approaches. Steady advances in knowledge in the pursuit of providing optimal care have continuously led to comparisons of consequent risks versus benefits, and practitioners often had to confront the reality that proposed new solutions to problems can induce harmful effects.

These age-old conflicts among and between competing views and goals in the pursuit of "doing good" are ethical ones, and physicians—today's "healers"— exemplify their professional roles when giving these conflicts their due consideration. Situations in which such conflicts, or ethical dilemmas, arise include the degree to which physicians impose their wills on a patient when the patient's wishes oppose the physician's; the potential for physicians' personal aggrandizement or hubris to influence medical decision making; and the recommendation of treatment options that would benefit an individual patient but might conflict with the needs or desires of the family, community, and/or society.

The field of ethics is a discipline that focuses on moral principles or values which guide attitudes and behaviors while examining notions of right and wrong in relation to these human activities. Acting in an ethical and professional manner has been a fundamental tenet of medical practice throughout its history and remains an essential aspect of medical practice. The ethics of medicine has always intended to concern itself with the pursuit of patients' best interests and the societal good while respecting the individual patient's personal rights. Codifications of musings about these considerations serve to advise, admonish, or assist people to behave in desirable ways, and these written compilations reflect the philosophical worldview and religious, spiritual, political, cultural, and economic circumstances of their societies.

CODES OF MEDICAL ETHICS—NATIONAL AND INTERNATIONAL

Medical ethics is the application of the ethical discipline to medicine. The individuals designated to treat the somatic and psychological ills of the community's members—today's physicians—are commonly accorded privileges and respect for their specialized knowledge and abilities. To promote this trust and protect the public, the healers and their communities have produced formalized written codes, or guidelines, governing the behaviors and conduct expected of physicians. These codes of medical ethics focus substantially on the treatment obligations of the healers to the individuals residing within these communities and on behaviors expected of them as professionals.

Several themes and exhortations are commonly found in medical codes of ethics that date back many hundreds of years and emerge in myriad cultures. These include the primacy of respect for human life; physician responsibility for the patient; emphasis on virtue and duties; provision of help; avoidance of harm; equality of care for rich and poor; setting of fees; methods used to establish diagnoses, with the expected employment of clinical observation and reasoning; use of appropriate therapies; confidential nature of the patient–physician communications; prohibition of physician–patient sexual relationships; and provisions for punishment or sanctions in the event of poor technical performance, code violations, or both.

In the United States, the formation of the American Medical Association (AMA) in 1847 was accompanied by the creation of a code of ethics. A society organized in 1844 by 13 medical administrator superintendents of “American Institutions for the Insane” became the foundation for the creation of the American Psychiatric Association (APA) in 1921. In 1973 the APA produced its first code of ethics, which was annotated and revised in subsequent years.

Considerations of children’s needs were largely absent in the formative years of these professional organizations. The dawn of the 20th century saw the beginnings of professional reflections concerning children’s health needs as separate from those of adults. The American Academy of Pediatrics was founded in 1930. In 2007 that body adopted, for the first time, a document focusing on the mission, values, and professionalism distinctive to its practitioners. APA members, independent psychiatrists, pediatricians, psychoanalysts, and other medical practitioners with a primary interest in children’s mental health founded the American Academy of Child (subsequently, and Adolescent) Psychiatry (AAC[A]P) in 1953. The AACAP introduced its first code of ethics in 1980; it was expanded, with accompanying annotations, in 1995, revised in 2007, and substantially rewritten in 2009. In 2014 the code was further revised and enhanced by the inclusion of discussions related to social media, expansion of research matters to include scholarly activities, and a focus on explicit natures of potential boundary crossings. The AACAP code covers ethical issues relevant to clinical, administrative, and scholarly practice in child and adolescent psychiatry. Its narrative is organized around principles and major specified areas of concern inclusive of Developmental Perspective, Promoting the Welfare of Children and Adolescents (Beneficence), Minimizing Harmful Efforts (Nonmaleficence), Assent and Consent (Autonomy), Confidentiality (Autonomy/Fidelity), Third Party Influence (Fidelity), Scholarly and Research Activities, Advocacy and Equity (Justice), Professional Rewards, and Legal Considerations.

This code uniquely introduces a developmental perspective, thus covering an essential aspect of caring for children, adolescents, and their families. It affirms that abiding by these ethical principles is considered an essential aspect of practicing as a competent and capable child and adolescent psychiatrist. Further, continued learning and maintenance of the ability to identify, analyze, and make decisions about ethical dilemmas

is considered a key skill set for all medical students, residents, and physicians. Ethical child and adolescent psychiatrists (CAPs) should possess the knowledge of ethical principles and their use but, even more fundamentally, understand that this knowledge and skill set is an essential aspect of their professional demeanors and should be reflected in their behaviors. The code advises that a key aspect of the ethical practice of CAPs is a developed awareness of one's personal beliefs and the impact of these beliefs on the clinical and professional choices made by the practitioner.

Ethical thought is universalizable, that is, ethical principles and reasoning apply in all situations, nationally and internationally. However, when ethical reasoning is utilized, attention must always be paid to situational context and culture. Thus, while emphases on, for example, competence, honesty, avoidance of exploitation, confidentiality, boundaries, and protection of research participants transcend individual nation-states, their examination, and potential resolutions are partially contingent on geographic location. Many ethical and related codes have been produced by international bodies, including those of the World Medical Association (originated 1949), the World Psychiatric Association (originated 1996), and the United Nations Convention on the Rights of the Child (1989). This last document established the rights of children to survival, development, protection, and participation in society and, by implication, their health care. In 2006, the International Association for Child and Adolescent Psychiatry and Allied Professions (IACAPAP) produced the document Ethics in Child and Adolescent Mental Health, which created principles addressing the rights of children and behavioral guidelines for the professionals who treat them worldwide. More recently, IACAPAP's Declarations of Durban (2014) and Prague (2018) reinforced and elaborated upon these emphases on the rights of children worldwide to mental health and well-being.

However, while children and families in developed countries can struggle to access services, the resources available to developed versus resource-poor countries, as well as the natures of their governance and cultures, serve as the greatest differentiators in mental health approaches to children living in dissimilar locales. In the former, for example, the practitioner might be concerned with the ethics surrounding recommendation of brand versus generic medications in comparison to a practitioner whose pharmacologic armamentarium often is empty.

Similarly, a locale's culture may determine whether a child's protests are welcomed as a sign of developing autonomy versus being viewed as a violation of older adults' decision making for the group, the culturally sanctioned norm. At worst, displaced refugees, homelessness, migration, sex-trafficking, and the production of orphans (secondary to war, capture, and disease) account for huge numbers of children in predominantly resource-poor countries. A paucity of mental health professionals in these locations further ensures that little attention would be paid to children's psychiatric needs. The ethical imperative to improve children's life circumstances and to provide appropriate care, however, remains unaffected by the surround.

MEDICINE AND MENTAL DISTURBANCE

From a historical perspective, within the context of medically influenced writings, mental illness was first formally addressed by the Greek physician Hippocrates and, several centuries later, by Galen in Rome. The ancient Romans dealt with the definition of mental disturbance, the nature of caregivers, guardianship, approaches to care, and legal competence. Thus, Roman society and numerous others that followed, by recommending approaches that they considered to be correct and beneficial medical conduct, were instrumental in contributing to the creation of modern codes of behaviors expected of healers. Focusing on medical illness, deliberately inclusive of those who suffered from mental disturbance, the codes and laws forged by the ancient Romans, reconsidered and expanded in subsequent eras, explicitly addressed ethical conflicts that daily confront medical practitioners, without separating the somatic and psychological spheres.

CHILDREN AND ETHICAL CONSIDERATIONS

When and how did children come into the picture? Some historians have arguably posited that prior to the 17th century, in the western world, children generally were not viewed as developmentally distinct from adults. Pediatrics was first established as a unique specialty in the late 1800s. Over the last several centuries, children and adolescents have been recognized as distinct groups engaged in ongoing growth, as well as knowledge and skill acquisition, in emotional, physical, intellectual,

language, moral, and interpersonal spheres. In the last decades, increasing recognition and support have accrued to the perspective that children have inalienable rights to development and participation in society, as described in the UN Convention on the Rights of the Child. The substages of child and adolescent development imply that children's maturation in developmental spheres correlates with chronologic age and, therefore, that expectations of children's capacities for comprehension, reasoning, and the sound making of decisions will vary with the individual child's degree of attainment. From an ethical perspective, insofar as these capacities remain immature during development, children generally are not granted absolute decision-making rights; rather, these responsibilities remain with their guardians. When the goals of the guardians and their children conflict, however, problems may ensue. Furthermore, children are commonly cared for by individuals or agencies concerned with their welfare, such as schools, individual health practitioners and institutional providers, governmental welfare and protective services, and juvenile justice systems. Information exchange among these parties is necessary for the provision of care, but the transmission of data among them can occur without a child's knowledge, leaving affected children vulnerable to the potential misuse of confidential information. Thus, the factors of continuous developmental maturation, the potential for children–guardian conflicts, and numerous avenues of and needs for information transmission can frequently lead to ethical dilemmas concerning children.

Ethical Dilemmas and Reasoning

Practitioners might recognize the presence of a child-related ethical dilemma when experiencing internal conflict about potential divergent approaches to the provision of clinical care. For example, CAPs consulting to a pediatric clinic, with 15 minutes available to see a 6-year-old distressed patient, must consider whether to spend this limited time with the patient and guardian or with the guardian alone. If psychiatrists choose the latter, they can anticipate obtaining a coherent history without needing to "manage" the individual patient, an approach that could rapidly and succinctly provide the needed medical input. On the other hand, direct observation and interaction with the child might prove crucial to an adequate database. How to provide the best care—an ethical imperative?

Ethically problematic situations like this one are commonly ambiguous—they involve gray areas. In the face of such a conflict, given the

pressure of time and clinical demands, harried clinicians might not register the ethical dilemmas related to the principles of *beneficence* (promotion of well-being) and *nonmaleficence* (avoidance of causing harm). Therefore, it is most advisable for clinicians to resist an immediate response, consider the alternatives, engage in a reasoning process—largely a risk–benefit analysis—and ultimately make their choice based on a resolution that is least damaging and ideally most helpful to the patient.

Ethical Principles and Forensics

Medical ethics is a field of inquiry based on principles that are considered universal, inclusive of the obligations to pursue *beneficence, nonmaleficence, autonomy* (promotion of individual freedom of action and choice), *fidelity* (faithfulness, loyalty, and respect for the rights of others), and *justice* (treatment of individuals with fairness and equality). Parenthetically, within this last category, consideration is also warranted for the concept of *social justice*, that is, the treatment of groups of individuals with fairness and equality. These principles often serve as the foundations for derivations of legal precepts and administrative decisions. For example, the legal concepts of the individual's right to privacy and informed consent for medical procedures largely derive from the principles of autonomy and fidelity. Additional concerns include the possibly conflicting rights of individuals and society, as in the case of proposed quarantine or the mandated use of masks for contagious infectious disease, which pits colliding concepts of individual autonomy against those of communal social justice. The pre-eminent ethical principle of "do no harm" tends to trump others, but even that moral standard can be open to debate when applied to specific situations. Moral dilemmas in medical practice often involve the operation of several ethical principles simultaneously, and the principles may conflict and compete.

The consideration of multiple principles in a reasoning process, however, allows for leeway in decision making. The law, by contrast, although generally based on ethical deliberations, defines acceptable choices and behaviors more narrowly. Not uncommonly, the discussion of ethical considerations segues into an examination of legal ones, conflating the two distinct disciplines. At times, the legal response can be at odds with powerful ethical arguments. For example, in custody disputes that include significantly involved nonbiologically related foster parents, certain jurisdictions adhere to laws that mandate awarding custody to the closest

biologic relative, even to one not involved in the child's current care. Such compulsory rulings might conflict with evidence of the establishment of close and long-standing emotional ties between children and their nonrelative foster parents. Similarly, enforcement of separation of children from parents or handcuffing of nonviolent youngsters for purposes of transport may be lawful but entirely unethical. In such instances, implementation of the law would likely cause harmful, in contrast to beneficial, effects.

Although several distinct ethical concerns may exist simultaneously, over time one approach to the dilemmas usually takes priority as the most beneficial, or least harmful. The child and adolescent psychiatrist clinician, administrator, researcher, or teacher, dealing with a problematic case, must strive to arrive at the least damaging resolution, commonly using a risk–benefit analysis. Awareness of relevant laws is necessary for this reasoning process, but the law is not necessarily the deciding factor.

CHILD-RELATED CONCERNS

Areas of ethical concern common to child and adolescent psychiatry practice include confidentiality, parent–child conflicts in desires and rights, assent to or refusal of treatment or research, physician responsibility for continuation or termination of care, child advocacy and protection, agency, boundaries, and professional responsibilities. Dilemmas arise in many contexts, including inpatient and outpatient facilities, private offices, and institutional settings; in the course of obtaining histories and providing treatments; abuse and neglect; divorce and custody; and forensic settings (e.g., court). Participation in administrative and research/scholarly activities often raises ethical issues. Conflicts arise owing to increased physician awareness of, and sensitivity to, matters of culture, race, religion, and diversity, changes in health care delivery and economics, heightened understandings of the scientific bases underlying disease etiology and expression, the influence of various institutions involved in health care, and the ever-increasing presence of electronic methods of communication and implicit reasoning, used both professionally and socially. Consequently, new dilemmas, or old dilemmas in new garb, confront child and adolescent psychiatrist practitioners, administrators, researchers, and educators on a daily basis.

Multiple Agency

Angela, a pregnant 15-year-old, was informed that her 16-week-old fetus was anencephalic. Obstetrics personnel urged termination of the pregnancy, but Angela refused to abort. One day later, she became acutely suicidal. In the emergency department, a psychiatric evaluation found her imminently dangerous to self. Angela refused to agree to psychiatric hospitalization and an involuntary commitment process was begun. Subsequently, the receiving psychiatric hospital refused to admit Angela without a prior termination of pregnancy. Angela's history indicated that the state child protective services agency, which had functioned as Angela's legal guardian for 5 years, had 1 year earlier removed Angela's then 7-month-old child from her care after a finding of neglect.

CAPs are obliged to recommend and pursue optimal care for their patients. In this case, doing so would require a guarantee of the patient's safety, and, therefore, in Angela's case, hospitalization is indicated. The practitioner, however, must also take into account other interested parties, such as, in this case, obstetric and pediatric personnel who strongly argue for termination of the pregnancy to spare anticipated future suffering of the patient and fetus. Other positions requiring consideration include those of the receiving psychiatric hospital that refuses to admit Angela without prior termination of the pregnancy; Angela's foster parent, who refuses to countenance abortion as an option for a child living in her house; the child protective services agency, Angela's guardian, which refuses to take a decision-making role, arguing that the patient is competent to make decisions; and the patient, who refuses to assent to both psychiatric hospitalization and termination of the pregnancy. While Angela's right to make the decision about her hospitalization varies depending on the state in which she lives, she retains the right to decide about her pregnancy throughout the entire United States. The child and adolescent psychiatrist has the obligation to advocate for Angela in order to ensure that her best interests are protected and she does not experience harm. Thus, working with Angela to better understand her views and helping her to make good decisions while utilizing appropriate strategies to manage her distress, is essential.

CAPs commonly face issues of multiple agencies—the need to be responsive to a case's interested parties, who often are pursuing conflicting agendas. As above, it is fundamental that the child and adolescent psychiatrist protect and advocate for the individual patient. That is, CAPs must act as agents for the minor patient while not permitting themselves to be swayed by the goals of the other parties, their own personal biases, the sources of income that pay for the physicians' efforts, or their allegiances to fellow professionals. CAPs have the obligation to act as the agents for their minor patients, despite their engagement in the care of these patients by parents or guardians with whom the child and adolescent psychiatrist may spend more time than with the child and who often are paying the physician's fees.

"I want you to treat my daughter. She's been misbehaving at home and at school. This has nothing to do with my recent separation from her mom and the fact that my new girlfriend is living in our home. I'm not going to say another word about this—concentrate your efforts on my daughter"!

"I am the only normal one in my family. You've heard what happens at home—my parents are crazy. Who behaves like this? I'll tell you, people who have problems. They should be in treatment, not me."

Who is the patient? When dealing with children and adolescents, it is often useful to use a family systems perspective that focuses on the dynamics between and among the various parties in the nuclear household. This stance can be viewed as a beneficial approach for all the involved parties because it permits CAPs to function as agents for both the family as a unit and its individual members. When the guardians refuse such an approach, however, practitioners face at least two ethical dilemmas. CAPs need to provide optimal care to the child while not alienating the parents and must avoid inappropriately labeling the child with psychopathology when the primary disturbance may reside with the parents. Such an approach requires clinical dexterity and due regard for the autonomy of all the interested parties while maintaining as primary the needs of the child.

EFFECTS OF CULTURE AND RELIGION

As the intermingling of differing, multiple cultures continues to be the ever-growing norm in the United States, CAPs are frequently called on to deal with conflicting notions of expectable behaviors and deviations from them.

"I brought my 13-year-old daughter to the emergency department because she's hitting me. She's sinful, and she's crazy. We've always gone to church together, 5 days a week, and now she refuses to go. She has to go because otherwise, the Devil will take hold of her, as He did to me in my teens when I had her. Her hitting me, her mother, is just the beginning of His hold on her, and through her, the Devil will infect my younger children."

"I don't know why my parents are bothering you with this. They want me to be more observant of our rituals, participate more in our culture, and continue with my education. Both of my parents didn't finish high school and most people my age back home are working at a job. I'm trying to do what they want, but now I found a job and they have no reason to be mad that I'm quitting school."

Varied culturally and religiously defined misbehaviors are found within an array of ethnicities and denominations. CAPs must rely on the profession's scientific knowledge base to evaluate case data in order to arrive at psychiatric diagnoses rather than using the belief systems and mores preferred by a culture or religion. However, CAPs should also be aware of, acknowledge, and have respect for the importance of cultural and religious perspectives to patients and their families. Treatment plans and dispositions should be approached in a similar manner, using resources peculiar to the particular belief system to the extent possible, without jeopardizing the care of the child. In addition, CAPs should note that separation-individuation phenomena manifest and provoke consternation in many, perhaps all, cultures. In the interest of providing good care, CAPs are ethically bound to pay attention to both culture-specific and developmentally normative behaviors. Not infrequently, education concerning normal child and adolescent development, conveyed in a caring manner, is much appreciated by the parent living in an otherwise self-contained culture.

Countertransference

The five abovementioned vignettes likely engendered, in the evaluating and treating psychiatrists, affective responses toward the protagonists. *Countertransference*, the term colloquially used to describe these phenomena, is closely related to CAPs' affective responses to the raised issues. What are the psychiatrists' attitudes toward abortion, teenagers who engage in sexual activity and become parents, parents reluctant to acknowledge the effect of their behaviors on their children, assaultive youths, individuals for whom religious and cultural beliefs and mores are paramount, and youngsters striving for autonomy? It is important for CAPs to engage in self-inquiry and determine the bases for their

countertransferential responses to these factors so as to ensure that these phenomena do not negatively affect optimal care for the children (and adults) under their care. Overidentification by CAPs with the child or adult is dangerous, as are rescue fantasies that focus on children who seem to live with little in the way of adequate adult protection, advocates, or both. CAPs in earlier stages of their training may tend to ally themselves with their patients, whereas older ones, many of whom have become or are parents, may tend to express greater empathy with the guardians. Ultimately, CAPs must focus on the needs of the child and avoid choices that are more reflective of the individual psychiatrist's intrapsychic dynamics.

PROVISION OF CARE

From a clinical perspective, ethical considerations should begin with the first patient contact and extend past the final meetings.

Assent and Consent

"Hello, doctor. I would like to make an appointment for my 9-year-old boy who probably has ADHD (attention-deficit/hyperactivity disorder), and I know he has lots of behavior problems. By the way, I'm not telling him that we're coming to see the doctor. He gets so upset, and I figured you could explain it better once we get there."

Questions that should follow immediately on such a seemingly innocent and sensible inquiry about an appointment ought to address whether the involved child agrees to a medical procedure (i.e., the psychiatric evaluation and interview). Will the child assent to this procedure, is he averse to it, and/or is he being coerced by the parent to attend? To what extent should children's objections to the initiation of an evaluation, or to treatment that might be recommended at its conclusion, be respected—that is, to what extent is children's *autonomy* considered? Have the children been reasonably well apprised by the guardians of the reasons for the proposed evaluation, and, if not, by the practitioners in the course of this first meeting—in other words, has the assent been informed?

Insofar as children ordinarily are legally considered minors until the age of 18 years, children are generally unable to give legal *consent* to proposed medical procedures, but they may *assent* to them. It is the children's guardians who provide consent. Further complications can arise when disagreements exist between a children's legal guardians regarding

proposed care, as may occur in the context of divorced parents. Often one of the parties is legally designated the guardian ordinarily responsible for obtaining medical care for their children. In any case, in emergencies, the urgent need for the provision of care becomes the physician's paramount consideration, irrespective of parental guardianship. In situations short of emergencies, however, lack of consent or opposition by one of the guardians raises ethical and legal dilemmas. The parental disagreement might be exacerbated by psychiatrists' actions favoring the stance of one of the parents, which could negatively affect or harm the child by aggravating the parental conflict.

Standing in contrast, psychiatrists must also consider the children's rights to an evaluation and their need for care.

> "I'm pregnant, my parents don't know, I'm not sure who the father is, and I'm not sure what to do about it. I'm 15 years old, I can think for myself and make my own decisions, I have the money to pay your fee, and I want to discuss this with you without my parents knowing about it."
>
> "I don't see why you want to talk to my parents. Yes, I live with them, but they really don't know anything about me, and I'll be leaving soon when I graduate from high school."

These adolescents are not simply assenting to treatment but are requesting care from psychiatrists. A 15-year-old pregnant girl, in some states' jurisdictions, is automatically considered an adult or "emancipated minor" by dint of her pregnant state, whereas in others, she remains legally a minor. "Mature" or "emancipated" minors can legally access care for themselves. Ordinarily, however, care only can be provided, except in emergency situations, with the consent of an adult. At what age does the adolescent develop the cognitive and emotional maturity to be able to give consent? Is that decision based on chronologic age (e.g., attainment of age 18 years), or is it situation or case-dependent? Given that adolescence is a stage of rapid physical and cognitive maturation and change, this fluidity in growth renders ethical questions regarding autonomous decision making more complex and less certain than when dealing with similar issues in younger children. As adolescents advance toward cognitive maturity, respect for their desires and opinions should progressively be factored into professional decisions in the interest of respecting the youths' entitlement to *autonomy*.

Confidentiality

It is the physician's responsibility to protect, and not convey to others, information about a patient unless the patient has given permission for this transmission. The patient has a right to expect adherence by the physician to this obligation, which serves as a basis for a trusting physician–patient relationship. The principle of confidentiality is often subject to limitations in working with children in that guardians, patients, and agencies want and require information about child patients, and children often are unable to comprehend the risks and benefits involved in the waiver of their rights to confidentiality. In addition, electronic medical records (EMR) and other electronic methods of communication can mean that, without adequate built-in safeguards, multiple individuals and institutions may potentially access confidential patient information.

"It's simple, doc. You've known my kid for a while. She's seriously disabled, she's 10 years old, and we need the state benefits to which she's entitled. Just fill out this 10-page form—it asks for all kinds of information about her—nooooo problem"!

"Doc, can you give me a copy of her chart? The school needs the records to start their evaluation process, and it'll be faster if I just deliver them the information."

A signed release from guardians permitting the transmission of information about children might satisfy legal concerns, but ethical issues remain that warrant exploration. To what extent do children's disabilities affect their capacity to provide assent? Would state/school involvement foster a child's development or hinder it? Is all, some, or none of the requested information pertinent to the child's condition? Is the information requested legally protected, or might it be accessible or transmitted to parties in the future without the patient's or guardian's knowledge? Psychiatrists must evaluate these issues by simultaneously playing the role of child advocates and attempting to protect children from current and possible future misuse of the information that other practitioners or agencies might subsequently provide. Such questions should be addressed with both guardians and, to the extent possible, patients, because families need to be aware of the ways in which information supplied to third parties might subsequently be used. They also should be educated about the potential risks of information disclosure when various forms of electronic communication, such as e-mail, social media, and cell phone texting, are employed.

"About those messages I've sent you about my daughter. You know, asking whether she talks to you and tells you the truth or she lies? Please don't tell her about them or about any of the info I've given you about her."

Adolescent patient to psychiatrist:

"I don't really talk on the phone. Can you text me? I'll definitely get any messages then. And that way, I can let you know what's happening; it would be great to talk between sessions."

Commonly, parents or guardians are eager to know details concerning information the child and adolescent psychiatrist has obtained in the course of treatment of their minor. The use of a family therapy approach at the onset of treatment, with an explicit message emphasizing the goal of judicious exchanges of information while simultaneously acknowledging privacy needs and rights, can circumvent many confidentiality concerns. Informing family members at that time that information requested or supplied outside of treatment sessions would likely be shared with all obviates otherwise sequestered communications. As well, it is warranted to notify all participants at the outset that potentially self-harmful or externally directed aggressive ideations and acts do not fall under the confidentiality obligation. In forensic contexts, minors and their guardians need to be informed from the outset of the lack of confidentiality concerning personal information (i.e., that the information included in forensic reports will be made available to all interested parties and may become part of the public record). Ultimately, practitioners should always exercise tact and restraint in the provision of information to all concerned parties, all the more so when transmitted information is likely to be reviewed by nonmental health professionals.

Separately, the advent of commonly used digital media and electronic communications, while positively facilitating information exchange of all kinds, does not in any way eliminate the need for alertness to the existence of ethical considerations and legal concerns in these spheres. The considerations that govern face-to-face care apply equally to electronic communications with patients and their families, despite their apparent ease of use. Thus, potentials for boundary violations, confidentiality and privacy transgressions, negligence, and defamatory messages are abundant but sometimes not obvious. Further, the seductive simplicity of seeking and finding information about patients and their families, easily obtainable via the Internet, could result in ethical violations when performed without the patients' and families' knowledge and, similarly, if not necessary for patient care. All of these concerns and behaviors involve potential violations of patients' rights to expect respect by physicians for their *autonomy* and avoidance of breaches of *fidelity*.

Fidelity and Mutual Trust

Fidelity, *honesty*, and *integrity* are three cardinal qualities expected of physicians that contribute to the measure of a physician's professionalism. Patients are entitled to expect physicians to deal with them openly, stay with them and not abandon them through the course of their illnesses or disturbances, and make attention to their needs primary before the physician might focus on possible self-interests. These expectations, however, may come under pressure when a physician feels threatened or hemmed in.

"You've seen my 16-year-old son for a month. He's angry and unhappy, fighting with me and failing school. I think he's using drugs. I want you to tell his pediatrician to order a tox[icology] screen and have it performed without his knowledge when he sees the doctor next week. My son would refuse if asked directly. If it turns out negative, he won't know I suspected him of drug use; if positive, I'll keep the results to myself and decide later what I want to do about it."

The patient's guardian requests of the psychiatrist to deal with the patient in a nonstraightforward manner to obtain important information. This request is ethically problematic because the creation of mutual trust between physician and patient is a fundamental tenet for the establishment of a sound treatment relationship. A physician–patient relationship in which neither side could expect honest exchange would be doomed from the outset, even if the knowledge sought in a clandestine manner were significant. The means to ends should be discussed in a candid exchange, even if some of the desired ends are, in the short run, thus rendered more difficult to achieve. Short of emergencies, there is no place for a paternalistic approach that would justify withholding vital information from a patient. It is crucial to the establishment and maintenance of successful therapeutic relationships that all family members understand this principle.

CAPs and others involved in the care of children are periodically faced with behaviors that adults experience as repugnant, threatening, or both.

An inpatient pediatric attending addresses the consulting child and adolescent psychiatrist:

"The nursing staff on my unit have been telling my patient, a 15-year-old boy with hepatic failure, that they wish he would die. He developed severe hepatitis as a child and became a "darling" of the unit during his stays there while receiving and then rejecting two liver transplants. He is back here now being evaluated for a third transplant, but 2

weeks ago, he was charged with sexual abuse of a child, and the staff has completely turned on him."

CAPs tend to have considerably more experience with victims of abuse than with (alleged) perpetrators. Physicians' efforts, therefore, are mostly devoted to the repair of those individuals who have experienced an emotional injury. Children who are accused of doing (or who do) bad things, however, also require care. Nondiscrimination is a fundamental ethical imperative. The provision of the physicians' care is dependent on a patient's needs and not on the whims, preferences, or biases of the practitioners. Thus, it is incumbent on CAPs to act as advocates for the abusing, malfeasant, and nasty child as much as for the victim deserving of sympathy. In other words, despite possibly harboring negative feelings toward patients, physicians must maintain *fidelity* to them and continue loyally to provide disagreeable children with professional service.

Despite such exhortations, situations arise in which CAPs' negative feelings toward children may interfere with the provision of good care, in particular when CAPs feel threatened by the children.

A 15-year-old male teenager in a detention facility, adjudicated for murder, calmly says to the examining child and adolescent psychiatrist:

"I know where you live. I don't like you. You stay in my face, and I'll kill you. That's not a threat—that's a promise."

Psychiatrists, like all human beings, are entitled to self-preservation and considerations of self-interest. To the extent possible, CAPs should avoid allowing these concerns to jeopardize the health of their patients. Termination of care may be appropriate in the event child, and adolescent psychiatrists believe themselves to be in danger, but only if provisions are made beforehand for care to be provided by other practitioners.

Boundaries

Physician behavior toward patients should always be initiated and maintained with the patient's best interests in mind. Medicine's professional ethos emphasizes strict physician adherence to the value of integrity. In the context of the physician–patient relationship, the concept of boundaries refers to limits within the relationship that ought not to be breached. Maintenance of such boundaries helps preserve the integrity of the relationship. Although some physician behaviors clearly violate the physician–patient boundary and are impermissible (e.g., sexual relations

between physician and patient; physician use of confidential patient-derived information for the physician's gain), other behaviors reside in gray areas. Physicians who divulge personal information to patients, or overlook timely payment for services from patients reporting financial difficulties, may be engaging in good, compassionate practice or enticing and exploitative behaviors that service the physicians' needs, or both.

"I saw you eating dinner at a good restaurant a few weeks ago, so I figured you liked it. You've helped our family so much that I wanted to say thank you with a gift card to that place. Don't worry; it isn't a big deal."

"Can you come to my graduation? I couldn't have made it without you."

"Can you lend me a couple of dollars? I'm really hungry and don't have enough money for the potato chips."

"This case is a great example of the subject I'll be presenting, but I need to send in my talk tomorrow. There's not enough time to find the patient and ask her permission to use her information. I'll change the details a bit, so no one will figure out who she is."

Working with children and adolescents can lend itself to the potential for boundary infringements. CAPs who passively enjoy the spectacle of a child's oppositional or adolescent's seductive behaviors and therefore neglect to set appropriate and timely limits, agree to treat children despite current socialization with the family, accept significant presents, prolong children's care owing to an attraction to a parent, or discuss with colleagues or write for publication about a patient for the purpose of self-aggrandizement are, in all these instances, potentially infringing on or violating patient–physician boundaries.

Patients justifiably expect not to be exploited by their physicians and to feel secure in the treatment setting. Despite best intentions to engage in self-monitoring, physicians' positive countertransferences toward patients could result in behaviors that end in a special or favored status for particular patients. In those instances, it is highly recommended that physicians recognize when they indulge in these behaviors and their potential for leading toward more frank violations. Rapid consultation with respected colleagues is the preferred antidote to strengthen and secure physicians' self-control and provide patients with sound and unimpaired care.

CURRENT AND FUTURE ISSUES

Although the ethical principles of beneficence, nonmaleficence, autonomy, fidelity, and justice remain immutable, their consideration must be applied

to constantly changing contexts that include advances in scientific knowledge, innovations in means and modalities of communication, changes in financial structures, shifts in societal priorities, newly created treatment approaches, and novel research foci with patients. It is fascinating to note how rapidly the foci of CAP investigation and discussion change. Thus, in the past decade, prominent areas of concentration have included, among others, treatments of psychiatric prodromes; health insurance and the funding of psychiatric healthcare; the significant influence of the pharmacologic industry; and the potential for improper neuroenhancement. While their visibility and attendant concerns continue, newer issues are achieving ever-greater prominence. For example, racial and economic disparities, equity, and diversity; impacts of social media; alternative sexual lifestyles; and medical marijuana prescription/legalization have come to the fore, while the application of advances in psychiatric genetic knowledge and, separately, emerging technologies and artificial intelligence, are in the process of significantly transforming aspects of CAP practice. Thus, change is a constant, as it presents novel challenges. These challenges, in turn, call for the application of unchanging ethical analysis to the freshly minted ethical dilemmas they pose.

The following subsections focus on 12 relevant areas.

Information Technologies and Data Science

Substantial advances in electronic data collection, storage, retrieval, communication, and reporting have revolutionized medical work. These technologic advances raise novel ethical dilemmas for child and adolescent psychiatry practice. The EMR increases the possibility of the transmission of confidential information concerning minors, without a guardian's consent, over the time period that the information is electronically stored, that is, theoretically forever. The child, owing to age, lacks control over personal information transmission. That same individual later becomes an adult. At that time, potential employers', health insurers', and public agencies' electronically facilitated access to the past information, despite possible legal protections, could negatively affect the former child, owing both to the stigma that might continue to attach to mental disturbance and the effect of pre-existent illness on employer hiring practices and employee acquisition of health benefits. Will the adult have control over personal health data entered into information banks

when that individual was a minor? Who owns this information, who is empowered to make these decisions, and what standards are to be used?

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 was established to create transaction standards and privacy rules overseeing the electronic submission of personal medical information. Although the Act, which became effective in 2003, provided federally mandated privacy protections for this information, loopholes exist, not to mention illegal cybersecurity breaches. In the interest of advocacy for patients, it has become the CAP's professional responsibility to alert children's guardians, as well as the adolescent who may have arrived at a cognitive maturity enabling comprehension of the implications of these privacy concerns.

Simultaneously, electronic systems are increasingly used to provide treatment, as in telemedicine, and many websites complement traditional therapies. In-place security protections of these systems vary. Thus, patients' medical information could be accessed by strangers. As well, individuals are often naïve to the potentially negative implications of entering or posting information on social media, email, and texts, and to an even more recent development, that of allowing access to information by third-party computer or phone applications. Children and adolescents, in particular, due to their developmental immaturity, often lack the capacity to truly understand the immediate and long-term implications of sharing personal data via these mechanisms. Use of these systems by adult professionals equally creates potentially significant complications for the providers as private citizens as well as in their roles as health care personnel. The challenges of keeping patient information secure and maintaining therapeutic relationship boundaries while simultaneously providing effective interventions may frequently be complicated. CAPs must carefully configure their professional and, separately, personal social media accounts to ensure that patients are not "friended" or are not acknowledged as patients, as inadvertent disclosures could easily lead, in varieties of ways, to HIPAA violations. Thus, these digital communication methods can be effective and useful, professionally and personally, but their use requires great caution, vigilance, and self-monitoring.

Combined datasets derived from myriad information sources previously deemed irrelevant, too hard to integrate, or too unreliable, are now used to make associations with numerous psychiatric conditions, which in turn enhance the possibilities for risk prediction. These combined sources

include prior medical and pharmaceutical records, neuroimaging data, and genomic information. The datasets are used for primary prevention and continuity of care, secondary prevention for patients with current and ongoing psychiatric diagnoses, and tertiary prevention via highlighting individuals at high risk for expressions of severe disturbance, particularly suicide. The electronic health record system is no longer a passive network waiting for stored data to be used following patient consent. Rather, it has become a dynamic tool that readily alerts physicians to elements of prior medical histories that patients may not currently disclose, and it shapes physician practice by alerting to needs for diagnostic workups or follow-up care, and, in some cases, it initiates “hard stops” on physician entry of further data into the record until required actions of benefit to the patient are performed.

A child presents to a CAP’s office after a referral from a local school. The school principal describes him as “fidgety” and “never listening to his teachers.” The mother notes that “he is always running around, can’t sit still at home, and unless his favorite TV show is on, he never pays attention.” Earlier in the week, he took a book away from a classmate. He recalls that he “just wanted to look at it.” The CAP considers prescribing stimulant medication after diagnosing the boy with ADHD. However, when typing the information into the EMR, a popup appears, preventing further data entry until the CAP gives evidence of diagnostically considering the presence of oppositional defiant and conduct disorders.

These EHR-based technologies are intended to improve patient care by, for example, alerting physicians to order lab tests that could otherwise be overlooked, such as lipid panels when neuroleptic medications are prescribed. However, they can also be programmed to recommend less universally accepted directions, such as requiring EKGs in advance of stimulant prescriptions or considerations of unlikely diagnoses. The “hard stop” can prove problematic because it negatively impacts physician autonomy–a possible contribution to the phenomenon of physician “burnout.” Relatedly, suspicions have been raised that such required orders might be inserted to optimize reimbursement of hospitals or physicians rather than instituted in the best interests of the patient.

Advances in artificial information (AI) technologies have led to the development of machine learning-based prediction tools. They purportedly aid in the identification of individuals at increased risk of suicide, which would likely influence subsequent physician behavior. Similarly, physicians, fed AI-based alerts, are likely to incorporate these decision support tools into their practices, often by intervening sooner and more aggressively in the management of a patient under observation, or treatment, for psychosis. The nature of prior data input presents ethical obstacles to AI's proper use. Thus, for example, data distorted by systemic racist perceptions regarding the indications for and incidence of such diagnoses as ADHD and conduct disorders in children, and the lack of transparency regarding the sources of the data input, present caveats to wholehearted acceptance of the algorithmic outcomes and/or the degrees the professional's behaviors might be influenced by electronic direction. Thus, datasets inputted with good intentions, that is, to increase surveillance of individuals at risk for psychiatric disorders, simultaneously infringe on patient autonomy and rights to privacy. In addition, the flag, or alert, AI may place on a patient may bias future clinical diagnoses. Unfortunately, few clinicians are likely to possess knowledge of possible inadequacies in data input. Instead, they likely would pay close heed to AI's indications and recommendations, akin to conforming to a supervisor's suggestions during training. Therefore, CAPs should be given instruction on the production methods of AI data and its potential limitations, both ethical and informational.

The following is an anticipated likely scenario akin to current analogous presentations: A recently developed application, marketed to parents, advertises its ability to derive "a likeliness to commit suicide score." It advises installation of the app on their child's cellphone. By monitoring the child's activity, in combination with information obtained from the youth's medical records, the app would alert the parents when it anticipates "the child might harm themselves within 2 months."

If an algorithm predicts a child to have a substantial risk for suicide within the near-term future, should that individual be brought to a CAP for an evaluation? Might legislation implement and demand such a procedure? Might the psychiatrist's decisions be impacted by knowledge of the algorithm's recommendation? Might the CAP endorse hospitalization despite its inherent limitations on patient autonomy? Who would the psychiatrist trust-the algorithm or his/her personal judgment?

Considerations of potential legal liability arise in the event of CAP disagreement with an electronically derived conclusion or recommendation. AI is the future, and it is here, presenting novel ethical challenges to child and adolescent practitioners.

Genomics; Prodromal Treatments Revisited

More than 20 years ago, the Human Genome Project successfully decoded the DNA sequence of a human individual's 23 paired cellular chromosomes. Since then, numerous discoveries have occurred regarding the role genetics plays in human disorders. These findings have been paralleled by a significant decrease in the time and costs necessary to investigate an individual's DNA. Whereas decoding the first genome required 13 years of work and over 1 billion dollars, an entire human genome can now be sequenced for 1,000 dollars in a single day. For less than $100, single-nucleotide-polymorphism (SNP)-based microarrays can detect various structural abnormalities, including copy number variants (CNVs), and also be used to assess common variations associated with numerous human disorders, with the results analyzed and returned to clinicians, or directly to consumers, in a matter of days. Such DNA-based tests investigating specific genetic disorders have profound implications for illness prognostication, treatment, and counseling, as well as their ontology. This especially holds true with regard to psychiatric disorders, as many of their genetic architectures demonstrate substantial overlap and rare structural variants appear to play significant roles in the manifestation of multiple neuropsychiatric conditions. Current Diagnostic and Statistical Manual (DSM) and International Classification of Diseases (ICD) diagnoses primarily rely on gross observational criteria, not on etiology. Genetic- or biology-based recategorization would likely considerably alter a portion of the current diagnostic categories and boundaries.

As well, studies are revealing differences in treatment responses when patient groupings are based on genetic findings, for example, treatment resistance in schizophrenia with duplications of 15q11.2-q13.1, in contrast to DSM-5-TR-based diagnoses. Recent cross-DSM-disorder genomic analyses have found significant overlaps in genetic risks for DSM-distinct disorders (e.g., schizophrenia and bipolar disorder; obsessive-compulsive disorder [OCD] and tic disorders).

The recommendations by such professional organizations as the AACAP, American Association of Pediatrics (AAP), and American Society

for Human Genetics (ASHG) for routine genetic evaluations of patients with suspected autism spectrum (ASD) and intellectual deficiency disorders (IDD) is a recent consequence. Similarly, numerous studies have examined pharmacogenetic assessments to prognosticate optimal pharmacologic treatment of children. For example, FDA labels now recommend dose adjustments for individuals with specific pharmacogenetic propensities that include cytochrome p450 (CYP) and human leukocyte antigen (HLA) polymorphisms. However, the medical field has yet to achieve consensus on the utility of these tests; some professional organizations currently recommend their limited use (e.g., International Society for Psychiatric Genetics; Clinical Pharmacogenetic Implementation Consortium), while others oppose them (e.g., AACAP).

Given these conflicting stances, CAPs are struggling with the integration of genetic information into clinical practice. They must ensure that patients receive appropriate genetic testing when warranted and recommended (*beneficence*), provide counseling for or against testing when immediate benefits do not exist, and interpret tests that they may neither have ordered nor would have recommended prior to their deployment by others (e.g., pharmacogenetic analyses, polygenic risk scores).

From another perspective, these genetic discoveries are again raising possibilities of providing preventive treatments as beneficial interventions. Thus, preventive treatments based on genetic findings might be applied with currently available psychotropic medications or with yet-to-be-developed gene therapies. Informed *assent* and *consent,* and the weighing of the numerous risks versus benefits of these postulated interventions, would need to be mandated as ethical requirements.

Studies in recent decades premised that the appearance of specific behavioral signs and symptoms in childhood or adolescence, coupled with a positive family history of severe disorders, might be pathognomonic or prodromal for the later development of full-blown psychiatric disorders such as schizophrenia. Such theoretical prodromic features were not posited as definitively predictive; they did postulate possible vulnerabilities. Further, these studies addressed whether treatment, with neuroleptic medications or with enhanced psychosocial interventions, might lead to changes in outcomes, such as the prevented development of psychiatric disorders and/or disease progression.

Aside from the complicated matters of informed consent and assent, dilemmas also included the accuracy of disease identification and the huge intrinsic difficulties in monitoring outcomes. It became very clear that it is nigh to impossible to determine whether preventive pharmacologic and/or psychosocial treatment could forestall the later expression of an illness if that disorder was not destined to be expressed to begin with. These concerns, coupled with worries about the potential for unnecessary and harmful medication effects, resulted in the discontinuation of these programs at the experimenting institutions.

Currently, preimplantation genetic testing is available for neuropsychiatric disorders such as Fragile X, Huntington, and Alzheimer disorders; prenatal genetic screening can detect rare chromosomal abnormalities with large effects on brain function, predicting increased risk for ASD/IDD and schizophrenia; and direct to consumer testing is available for genetic variants associated with such neurodegenerative disorders as Alzheimer and Parkinson disorders as well as polygenic risk scores for schizophrenia. Related studies suggest that eliminating embryos with high-risk scores for schizophrenia would lower the prevalence of the disorder to 20% of its current levels.

Clearly, advances in molecular genetics have enabled researchers to risk-stratify individual youths based on polygenic risk scores, narrowing the number of individuals that might undergo future preventive treatments. However, genetic and epigenetic interventions specifically designed to target large-effect genetic variations are ethically challenged due to their rarity, thus making experimental validation difficult. As well, possible indications for early intervention, perhaps in utero or even preimplantation, are not currently countenanced as, to date, no timepoints have been established at which treatments could be delivered to achieve avoidance of the disorders, while in utero treatments give rise to concerns about potentials for damage to both embryo and mother.

All of these developments, and their associated caveats, again raise the specter of possible renewed interest in preventive treatments. Of inherent and great importance, they raise huge ethical concerns surrounding impacts on reproductive freedom (*autonomy*), financial costs to and considerations by society (*justice*), and potential harms to the developing fetus and child (*nonmaleficence*). Clearly, CAPs must be alert to the latent issues raised by enormous leaps in medical knowledge and their potential

applications while working in tandem with medical geneticists and counselors.

A related but separate ethical concern involves CAPs' medical record notes regarding patients' genetic information, which requires strong adherence to safeguarding data (*confidentiality).* Breaches could lead to patient stigmatization and employer or hiring agency discrimination. Similarly, though legal guards exist against genetics-based discrimination for health insurance in the United States, those protections do not hold for life insurance coverage. CAPs also must be cognizant of broad societal discrimination against "atypical" individuals as well as parents of children with genetic syndromes.

Conflict, Violence, and Advocacy—Individual, Group, National, and International

As a country, the United States engages in behaviors that cry out for responses in opposition from CAPs, such as the recent separation of children from their migrant parents at its Southwestern border. Throughout the globe, both at intranation and nation-state levels, the world is chronically beset by adult-conducted conflict, often violent. Consequently, children and adolescents suffer. They are captured, kidnapped, abused, separated from their parents, and witnesses to the killings of family members and others. Subsequently, they become homeless, refugees, migrants, and vulnerable to exploitation. These circumstances persist despite United Nations commission declarations, nobly protecting children's rights, supported by most of its members. As well, in relatively more settled countries, children are often witnesses and subject to domestic abuse.

CAPs are ethically bound to act as advocates for traumatized children. Clearly, the professional, in the one-to-one encounter, is expected to evaluate, make recommendations, and provide treatments that might help alleviate or mitigate the child's trauma. In the face of negative injunctions affecting large groups of children, be they legislative or administrative, CAPs, individually and as professional groups, should feel encouraged to make their voices heard in opposition while simultaneously recommending more useful approaches. Likewise, in the realms of intranation or state-endorsed violence, CAPs can be knowledgeable about and endorse interventions that attempt to mitigate the after-effects on children and, on rare occasions, by choice, participate in that work.

Children lack the autonomy and power that cognitive maturity, access to employment, and voting rights provide. In the United States, their guardians, insurers, or both, inadvertently or deliberately, may make decisions that are not in the children's best interests. Therefore, proper treatment and placement venues, possible needs for evaluation and treatment, the foci and choices of treatments and the need for their continuation, the value of extended physician–patient relationships, and recommendations for adjunctive investigations and care are all matters that may require advocacy by the child and adolescent psychiatrist for a child.

A 10-year-old boy with a history of assaultive behaviors was brought to a hospital emergency department after having attempted to stab a peer with a knife 1 hour before. The patient was still agitated, expressing rage at this peer, and possessed negligible insight and responsibility for his behavior. Nevertheless, the boy's father insisted on the discharge of the patient to his supervision in order that they keep their long-established plans to fly the following day to a distant city. Independent of the family plan, the patient did not want to be hospitalized. The father assured the evaluating child and adolescent psychiatrist that he would immediately obtain psychiatric care for his son in the new location. The patient's insurer expressed ambivalence about hospitalization, especially after learning of the father's wishes, but reluctantly agreed to cover the costs in the event the child and adolescent psychiatrist chose this course of care.

The vignette's guardian's concerns are legitimate, and his intentions may be well-meaning. The insurer's concerns are legitimate as well, although considerably influenced by financial considerations. Owing to safety considerations, however, the child and adolescent psychiatrist must opt for psychiatric hospitalization of the child. The practitioner is obligated to advocate for the child's immediate well-being, even in the face of opposition from the guardian, child, and insurer. *Advocacy* for the individual child implies choosing the least damaging or most beneficial course for the child in dealings with parents, guardians, agencies, insurers, and the patients themselves. Individuals, agencies, or insurers may attempt to dissuade CAPs from their chosen course because the

interests of the payment providers may conflict with the immediate needs of the child. As the child's potential advocates of last resort, however, CAPs should provide the interested parties with the reasons underlying their positions as well as maintain the medically indicated stance, despite possible resistance or antagonism.

Race, Ethnicity, Socioeconomic Status

Dr. Smith, one of three CAPs in the city, is the only CAP that accepts public insurance. He enters a clinic's waiting room and calls for Robert, referred by his school, for an evaluation following "aggressive behaviors" directed toward a peer. Immediately following the call, Robert's parents approach the clinic receptionist and loudly request a different doctor, "one who knows what it's like to be of our race."

The recognition of posited systemic bias, inequities in mental health systems, and both explicit and implicit bias held by children, adolescents, and their parents, as well as practicing CAPs, requires consideration and address. Studies indicate that mortalities related to specific medical conditions decrease when racial minorities are treated by physicians of the same race. Studies suggest that adult psychotherapy patients may prefer and have a better impression of race-matched therapists; nothing is known about race-matching in child and adolescent psychiatry. What are the clinician's obligations in the event of such requests? Is the patient's or family's autonomy to be respected? Does the answer change if the requesting child or family is Caucasian rather than a child or family of color, or vice versa? If, upon investigation, the request for a race-matched provider arose due to traumatic experiences a child or family experienced at the hands of a perpetrator of the psychiatrist's race, might this fact indicate a different response to avoid the imposition of harm than a request arising from perceptions of provider inferiority due to the latter's ethnicity, race or religious affiliation? At a minimum, the underlying motivations behind such requests deserve address.

Significant disparities exist in the diagnostic rates of childhood-onset neuropsychiatric disorders; one explanation hints at the posited presence of systemic bias. For example, a child has an increased likelihood of being diagnosed with IDD and ADHD, relative to Caucasian children, when that youngster belongs to a specified minority. Conversely, the rates of diagnosed ASD are significantly higher in Caucasians compared to those of minority populations. The concentration of CAPs and other ASD

treatment providers in affluent, primarily Caucasian neighborhoods may be factors contributing to these findings.

Unjustifiable uses of violence in the name of authority against Black men and women, the recent and current bans and barriers on entry into the United States from countries whose citizens are predominantly Muslim and/or black- or brown-skinned, and inaccurate attribution of coronavirus disease 2019 (COVID-19) spread to Asian peoples leading to physical assaults on them, all highlight the significant impacts race, ethnicity, identity, and religious affiliation have on the probability that children and adolescents within these and other minorities experience related trauma, directly or indirectly. The ethical principle of beneficence, directed toward helping the individual child, adolescent, adult, or family, might sometimes be placed in opposition to those of justice and equity, as, for example, in the race-blind distribution of resources held up as society's goals and ideals. Yet the emphasis on the latter can involve a denial of the importance to kinship groups of their intermingled traumatic history, skin color, cultural norms, and religious beliefs. Ultimately, the possible presence of implicit or unconscious bias on a professional indicates the benefit to be derived from acknowledging its influence, if any, in order to counteract its effect, thus avoiding causation of harm and leading to helpful decision choices for the individual and family. As well, when CAPs become aware of such biases operating within larger groups in the professionals' spheres of influence, they are urged to identify them and advocate in those settings for the best interests of affected children and youth.

The COVID-19 pandemic has exacerbated and brought to light systemic inequalities and their effects on children and adolescents. In the United States, roughly one-third of the labor force was deemed "essential." Despite restrictions on travel and stay-at-home orders, the vast majority of these workers, other than those laid off, continued to work. Doing so contributed to disproportionate rates of infection, morbidity, and mortality secondary to COVID-19 infection in African- and Latin-American populations. The impact of the death or severe illness of a parent, or of similarly significant support, on the children in these households is obvious. In addition, African and Latin Americans are disproportionately employed in low-wage occupations and are less likely to possess health insurance, which translates into further financial burdens on these already poorer communities and families. With regard to

gender, women have been more likely to lose or quit employment than men, as they have been disproportionately tasked with assuming supervision of their children in response to closed schools and home-bound learning. In addition, the COVID pandemic's heavy toll on the service and hospitality sector, in which women are overrepresented, has further negatively impacted children. The lack of infrastructure development in locales populated predominantly by communities of color, as well as those of rural communities, highlighted by the lack of stable high-speed internet availability, leads to difficulties in remote learning as well as access to telehealth. These disproportionate impacts on educational quality and mental health access, affecting children both directly and indirectly, are equity issues about which CAPs should have awareness as they interfere with the provision of beneficial care and can serve as spurs for involvement in advocacy efforts by professionals.

Telepsychiatry

Telepsychiatry was originally conceived in the 1960s. Recently, however, its use has become much more widespread with the increased availability of videoconferencing technology. Increased access to high-speed internet, ownership of personal computers and cell phones with video capabilities, and software meeting the technical demands for patient confidentiality have all contributed to the rapid spread of telepsychiatry for both patients and mental health practitioners.

Telepsychiatry's use skyrocketed, consequent to the recent advent of the coronavirus 2019 disease pandemic, as many ambulatory clinics and doctor's offices closed to mitigate the risks of viral transmission. Numerous practices successfully adapted by surmounting previous barriers which included clinicians' lack of familiarity with the modality, required regulation-compliant electronic health records, and videoconferencing platforms. Systemic barriers were suspended or removed, such as prior exclusion from health insurance coverage for telepsychiatric services. However, problems remain. Telepsychiatric care remains unavailable for those individuals without stable high-speed internet or telephone access. Privacy can be difficult to obtain for individuals living in communal or family settings. Language barriers are compounded as many telepsychiatric systems lack abilities to provide needed support for non-English speaking individuals.

Ultimately, telepsychiatry presents a challenge to traditional psychiatric practice, which has embraced the face-to-face interpersonal encounter as near-sacred. Digital views and exchanges are several steps removed from that experience. Can the differences between the two approaches be adequately and accurately measured, and by what criteria? Would case outcomes differ or be the same? Or are the differences measurably ineffable?

Is care provided via telepsychiatry equal to that provided in person? A few short-term studies performed on adults have indicated that psychopharmacology appointments conducted virtually can achieve outcomes similar to those provided in-person. Studies with children treated for ADHD indicate that direct management and indirect collaborative care models, in which primary care physicians receive consultation from CAPs via telehealth, can achieve outcomes comparable to those achieved in-person. A couple of psychotherapeutic treatments provided digitally, specifically, CBT and ABA, result in target symptom, mood, and satisfaction scale outcomes equivalent to those produced during in-person encounters. These approaches utilize manualized forms of therapy or rely heavily on work performed by patients and caregivers without CAP presence; the CAP-delivered portions are strictly psychoeducational. Psychotherapeutic modalities conducted virtually, such as play, psychodynamically based, and interpersonal treatments, may be less efficacious than ones conducted in person. These have yet to undergo substantive telehealth delivery model research trials in the child-age population. Allied therapies, such as physical and occupational, have demonstrated limits on efficacies when performed remotely. The provision of telepsychiatric care is certainly better than none, but promoting convenience and decreased costs as justifiable reasons for offering possibly less efficacious treatments raises significant ethical concerns. Many aspects of care cannot be provided virtually, or are more difficult to perform, such as monitoring of laboratory values, vital signs, and physical examinations. Increased collaboration among CAPs, primary care practitioners, traveling nurses, pharmacies, and laboratories may help overcome some deficits. However, that degree of optimal and timely collaboration can be difficult to arrange.

Anecdotally, the lack of direct mutual interpersonal contact among children and adolescents due to school closings and education at home in response to the COVID pandemic has led to a great deal of distress

among thusly affected youths. Is this phenomenon measurable by significant outcome parameters or simply to be viewed as a necessary response to the times? Similarly, do telepsychiatry and its digital distancing herald the future dominant form of care provision, or will there be a reversion to in-person face-to-face encounters? Which approach is most beneficent and least harmful, and how are these comparisons to be measured? In the meantime, while the questions are asked and studies performed, CAPs must provide good care to the best of their abilities without compromising its quality.

Social Media

A technologic communication and media revolution has taken place worldwide. With the establishment of digital means of transmission via ether and cloud, 67% of the world's citizens currently access mobile phones, 59% the Internet, and 50% social media, enabling them to receive news and instantly exchange information with each other. While censorship of these communications is exercised to different extents in varied locales, in the "free world," almost none exists. In the United States, 75% of children and adolescents have unfettered access to one or more communication media such as Facebook, Instagram, and Twitter (platforms that may last into the indefinite future or evanesce), and the nature and substance of their communications are limited only by the youths' degree of exercised self-restraint. As adolescence (and beyond) as a developmental stage is underscored by the ever-increasing importance of the peer group, decreased enforcement of parental controls, and, not uncommonly, beginnings of interpersonal romantic relationships, adolescents constantly employ social media to these ends. As is true of all maturational developments, some expressions are valuable and constructive, while others are not. The potential risks are considerable. Behaviors such as texting, canceling, ghosting, cyberbullying, hate-messaging, and the encouragement of self-destructive behaviors occur in youngsters with steady frequency, leading to despairing responses by recipients and, at times, precipitating embarrassment or worse in the perpetrators. CAPs need to be aware of these potential pitfalls and harms associated with social media use by their often naïve young patients and have a moral responsibility to alert them to their proper and less risk-laden uses.

On the other hand, the emergence of these platforms as a primary means of social discourse has positively enabled their use as media messengers for alerting others to the experience of personal distress. Mental health clinicians may become involved in the management of clinical crises following the appearance of alarming posts made by a child or adolescent. Numerous social media platforms have programmed monitoring capabilities that can alert local crisis intervention, law enforcement, or emergency medical services personnel to the postings and location of individuals whose pronouncements indicate they may be at risk of harming themselves or others.

Marijuana

During the past decade, the use of marijuana (cannabis), a mind-altering substance, has undergone public rehabilitation. Thus, three of the world's countries have legalized its recreational use, many more have decriminalized its possession, and the majority of Westernized countries generally overlook citizen possession of small amounts. Twenty-one of the United States have legalized its recreational use and possession, and in many remaining states, the trend seems to move in that direction. Simultaneously, state government-approved medical research in the United States examining the potential use of cannabinoids for treatment purposes proceeds apace. Preliminary findings suggest the potential for beneficial use of cannabinoids as antinauseants (e.g., during chemotherapy) and as treatments for chronic pain, neuropathies, pediatric epilepsy, obstructive sleep apnea, and dystonias. Other studies have focused on the possible utility of cannabinoids in the treatment of psychiatric disorders, including schizophrenia, social anxiety, and opioid use.

In the United States, decriminalization and the possible legalization of marijuana applies to adults. However, substances that become legally available to older individuals commonly trickle down to adolescents. Statistics indicate that 13% of adolescents used marijuana in 2018 and 33% of youths aged 18 to 25 years did likewise. For comparison purposes, 36% of youngsters aged 18 to 20 used alcohol, also a mind-altering substance that is legally off-limits to this and younger age groups.

While the occasional use of marijuana usually proves harmless, 6% of adolescents use the substance daily, leaving them habitually mind-altered or "stoned." Such heavy use is associated with chronically diminished or

poor academic functioning, slowed cognitions, driving while intoxicated, possibly altered brain structures, potentially exacerbated anxiety and/or depressive disorders, and postulated vulnerability to the precipitation of psychosis. Perhaps most alarming is the association between chronic marijuana use in adolescents that results in 17% of those individuals developing a substance use disorder as adults.

While decriminalization may be indicated for a relatively milder mind-altering substance used on occasion by most, so is vigilance against its misuse. CAPs will commonly encounter teens who occasionally use marijuana and alcohol. It is important for the CAPs to monitor the nature and degree of use carefully in order that therapeutic management and interventions prove beneficial, neither punitive nor permissive. The CAP remains ethically required to resort to an evidence base to support intervention choices rather than personal bias.

Sexual Orientation and Gender Identity

Two significant sexual revolutions took place during the last half-century. The early 1960s witnessed the development of the birth control pill and, subsequently, other pregnancy-prevention devices, leading to a considerable increase in premarital sexual activity, including among adolescents. The very late 1960s and years following saw the beginnings of the era of “coming out,” that is, the public emergence of alternative sexual lifestyles beginning with homosexual self-expression by both genders, resulting in the orientation’s decriminalization, and subsequently involving self-proclaimed identifications as bisexual, transgender, and queer (LGBTQ). Organized psychiatry, reflecting changing societal mores and scientific research indicating the absence of intrinsic psychopathology, moved from its position of classifying homosexuality as a disorder to removing it from the DSM in 1973. The recent decades have witnessed continued vociferous demands of equal rights for, and nondiscrimination against, LGBTQ populations, ultimately resulting in the legitimization of same-sex adoptive parents and foster parenting as well as aspirants successfully attaining political office.

Development of sexual orientation and formation of gender identity solidify during childhood and adolescence, and the public expression of alternative orientations and identities in the adult world has led to adolescent, and sometimes earlier, self-declarations of alternative sexual and gender self-perceptions. Parents of LGBTQ children may respond to

their offspring's declarations in a variety of ways, ranging from antagonistic and belittling to supportive and championing of their children's rights. As is true of all notable social change, significant backlash often occurs. The increased visibility and numbers of self-identifying young LGBTQ individuals fueled the development of "conversion therapies," arising prominently in conservative religious communities and countries designed to promote these individuals' adoptions of heterosexual orientations and lifestyles. Organized psychiatry has since documented negative and potentially dangerous outcomes of these therapies, labeling their use as unethical in 1998. CAPs treating LGBTQ youths are obligated to provide them with the care that supports the children's mental well-being (*beneficence*), does not cause harm (*nonmaleficence*), and respects the individual's right to self-assertion (*autonomy*). Simultaneously, while acting as the child's advocate, the professional should pay heed to adult caretakers who respond with distress to their child's inclinations by supportively aiding the parents' adjustment to the pertinent realities. At the same time, the CAP should never adopt a stance that might damage the child's comfortable and self-accepting expression of alternative sexual orientation or gender identity.

Pharmaceutical Industry

For years concerns have been voiced about the complicated relationships between medicine and the pharmaceutical industry. Pressure has been brought to make public traditionally private information detailing the financial relationships between individual physicians and pharmaceutical companies. Drug companies are now required to make all data derived from their studies publicly available, including negative results. Data has been collected on the number of children and adolescents prescribed multiple psychotropic medications, often with unclear indications. Medical schools imposed restrictions on interactions and exchanges between industry representatives and physician trainees and practitioners. Professional organizations instituted more stringent policies governing their dealings with the pharmaceutical industry. These actions represent continuing angst concerning the ethical dimensions of industry–physician and industry–psychiatrist relationships, in turn stimulating ongoing advocacy for transparency in their partnerships.

The industry, “Pharma,” produces the medications prescribed by physicians. It also funds the bulk of child and adolescent psychiatrist research, directly and indirectly, funds the work of academic researchers, and underwrites and provides financial support for professional journals, conferences, and lectures. The industry engages in these practices, in largest part, because the component companies are for-profit concerns, beholden to their shareholders, and their primary goal is to maximize the purchase of their products. The results of Pharma’s largesse to child and adolescent psychiatrist professionals can and does result in increased discovery and dissemination of new knowledge, expanded evidence-based understandings, and improved patient care. However, given the industry’s desire to subtly as well as overtly influence practice, practitioners need to remain intelligent consumers of the professional literature in order to judge the limitations of research results and their interpretations.

CAPs might unwittingly be induced to prescribe more expensive, in contrast to less expensive, medications or brands in contrast to equally effective generic drugs, thus unnecessarily increasing costs for their patient’s families. The influence of Pharma on clinical practice can lead to an increased emphasis on drug studies in professional journals, at the possible expense of studies devoted to nonpharmacologic components of the child and adolescent psychiatrist’s treatment arsenal. These possibilities, coupled with the current healthcare indemnification environment, could lead to excessive child and adolescent psychiatrist dependence on drug prescription and, on occasion, its excessive use. In addition, the expansion of criteria to include youngsters in diagnostic categories from which they were formerly essentially excluded, as in the case of bipolar disorder, or the creation of new categories, for example, disruptive mood dysregulation disorder, might be perceived by some observers as a consequence of the influence of Pharma as easily as it would be viewed by others as real and considerable psychiatric advances.

Thus, the relationships between Pharma and the profession of child and adolescent psychiatry, as well as with its individual practitioners, raise potential conflicts of interest. Can these conflicts be managed, or should they be eliminated, by sundering all but indirect contacts and contributions between the industry and the profession? The ethical dilemmas are many and profound, and the choices made by individual practitioners and

professional organizations will significantly affect future patient care, research funding, basic scientific knowledge, and professional education.

Funding and Provision of Patient Care

In the United States, healthcare costs have risen steadily for decades for individuals, employers, and the government. At the same time, many have voiced concerns about the quality of provided care. Various administrative interventions have been implemented in an attempt to improve care as well as to contain costs. The Affordable Care Act, enacted in 2010, aimed to improve access to affordable health insurance for more Americans, enhance the quality of health care, regulate the health insurance industry, and decrease health care spending. Recently the Act survived several years of political attacks. Currently, it appears likely to significantly expand its number of covered individuals and families. In addition, the Act's creation and expansion unintentionally highlighted the shortage of CAPs and other mental health providers in most areas of the country. An earlier reform enacted during the 1980s colloquially termed managed care, had a notable effect on child and adolescent psychiatry practice. Its primary goal was cost containment, which often complicated and compromised the delivery of effective psychiatric care for children and adolescents. Managed care's innovations included gatekeeper requirements, prior approval for treatment–even in emergencies, and limitations on treatment length and access to providers. Its legacy continues to limit care options, both for practitioners and families. Then and now, many of the institutions providing insurance payments for mental health care are for-profit companies with obligations to their shareholders, raising possible conflicts of interest that negatively affect their customers' and patients' health.

Sixteen-year-old Julie was psychiatrically hospitalized for expressing suicidal thoughts after having been physically assaulted by her father. Julie's parents had divorced 5 years previously, and Julie since lived with each parent at different times. Six months before the hospitalization Julie became pregnant, was "kicked out" of her mother's home, and obtained an abortion while living with her father. The recent assault was the father's response to Julie's demand to spend time "chilling" with her drug-dealing boyfriend. During the admission Julie exhibited symptoms of a major depressive disorder, although her suicidal ideations had diminished in frequency and intensity. The hospital utilization review informed the attending child and adolescent psychiatrist that the patient's insurance coverage provided a maximum 5-day stay and demanded that the patient be discharged on the 5th day. The parents stipulated "impossible" expectations of Julie in the event that she might come to live with them; Julie demanded both discharge from the hospital and the right to live with her boyfriend; and a state child protective services investigation found no need for its further involvement in the case.

One of the raisons d'être of the current versions of managed care is the pursuit of the ethical principle of *distributive justice*. In the case of health care provision, that translates into the funding of basic care for the largest number of people by controlling costs expended on the care of individual patients. Furthermore, the fact that many private health insurance companies are for-profit concerns is an obvious additional consideration when examining the motivations contributing to financially related administrative stances and decisions. Nevertheless, the child and adolescent psychiatrist, despite awareness of these "macro" concerns, continues to be bound by the professional obligation to provide beneficial care for each individual patient, independent of funding. Although, in the previous case, Julie's hospitalization coverage is about to expire (in theory, so that there will be coverage available for other individuals in need), Julie continues to require care—for her depression, protection, and sustenance. The attending child and adolescent psychiatrist remains ethically and legally responsible for attempting to make the best or least damaging decisions regarding Julie's needs for care in the immediate future. If the child and adolescent psychiatrist deemed that further hospital

stay was indicated, it would be incumbent on the child and adolescent psychiatrist to request additional funding from the insurance company, appeal the company's refusal of funding in writing, or arrange for hospitalization elsewhere. If comfortable with the discharge option but not with the current dispositional choices, the child and adolescent psychiatrist would be obligated to pursue the state child protective services agency to re-examine the case, given that it is this agency's responsibility to provide alternative placement possibilities. Although funding mechanisms may change, the child and adolescent psychiatrist's ethical constraint to provide beneficial care is immutable.

Dr. Green, a child and adolescent psychiatrist, had been providing a combined treatment approach of psychotropic medication and psychotherapy to Ben, an 11-year-old boy who had developed post-traumatic stress disorder (PTSD) 6 months earlier after exposure to a stressful event. Ben's mother informed Dr. Green that her health insurance benefits, obtained via her employment, had changed. The new insurer limited coverage for CAPs to brief medication checks, and benefit payments for psychotherapy were available exclusively for nonmedical mental health personnel. Dr. Green believed that the psychotherapists recommended by the insurer had inadequate training to handle Ben's case.

While frustrating and time consuming, CAPs have an obligation to advocate with insurance companies in their attempts to obtain what they consider optimal care for their patients. Pediatricians share similar concerns about their psychiatrically affected patients. In response, two recent developments have emerged. Some pediatric practices have embedded mental health practitioners, including CAPs, in their practices. A second approach, often state government-sponsored, involves CAP electronic supervision of pediatricians who themselves directly supply mental health care. It is notable that in some parts of the United States, most commonly in large, urban areas, some CAPs have managed the dilemmas and conflicts arising from dealings with insurance companies by choosing not to participate with them and, instead, engaging in fee-for-service practices. While this approach does allow these psychiatrists to provide treatments as they deem appropriate, it raises major ethical

issues related to access to care and clear considerations of social injustices. *Split treatment*, defined as the child and adolescent psychiatrist providing psychiatric evaluations and medication management while nonmedical mental health practitioners provide verbal therapies, has become the norm in numerous healthcare settings. It is unclear if cost savings for families and companies result; it should allow for greater CAP availability to a larger number of patients. However, as a consequence, many psychiatrists have far less knowledge of their patients than do their peers who provide combined treatments, while they yet retain an ethical responsibility for their patients' optimal care. In addition, these CAPs often have little contact with the nonmedical mental health practitioner providing verbal treatment. Reduced knowledge of patients and self- and externally-induced pressures to treat more patients in less time raise the possibilities of poorer attention to patients' needs despite the ethical constraints to provide beneficial care, not do harm, and make the patient's interests the primary concern.

Administration

CAPs serve as administrators in a variety of institutional settings and wear multiple hats. Common to child and adolescent psychiatrist administrators are responsibilities for the provision of clinical mental health services to child and adolescent populations, responses to ever-increasing budgetary pressures, and, in that context, maintenance of staff morale and cohesion. Common administrative maneuvers during times of budgetary constraints include attempts at financial savings via personnel layoffs and cutbacks, reduction of services to patients and their families, and shifting of clinical priorities and foci. For example, the child and adolescent psychiatrist administrator may consider whether funds formerly intended for adolescent inpatient care should be shifted to child day-hospital services or vice versa; whether a child outpatient clinic should be maintained or scuttled if expenses exceed income; and whether a child and adolescent psychiatry employee should be assigned an increase in caseload without a corresponding increase in salary or time availability. These considerations, maneuvers, and decisions cause distress to the administrators, patients, and professional staff.

The child and adolescent psychiatrist administrator is constrained by the ethical injunctions to not do harm and to maintain fidelity to patients. Fiscal realities also necessitate considerations of *distributive justice*,

translated into the attempt to provide reasonable care to the greatest number. Considerations of these fiscal concerns can come at the expense of patients currently receiving treatment. The administrator must seek to ensure that care remains available to them—if necessary, via referral.

Administrators are also responsible for the behaviors of those who report to them.

Mrs. Smith complained to the child and adolescent psychiatrist director of a mental health clinic: “My 8-year-old has a diagnosis of oppositional defiant disorder and, with him present, Dr. Jones accused me at length of being the cause of his troubles. Since then, my son doesn’t listen to anything that I tell him to do. You better get rid of that Dr. Jones.”

The mental health administrator has the reasonable expectation that child and adolescent psychiatry personnel will perform competently and professionally, which includes according to patients and their guardians appropriate respect. Administrators must also investigate patients’ complaints. When allegations have foundation, the administrator must determine whether a professional’s misbehavior or poorly chosen words reflect a momentary aberration or are one in a series of inappropriate actions. Psychiatric work with children and adolescents has the potential for stimulating poorly restrained countertransferential responses that arise primarily from a professional’s unresolved conflicts, possibly stemming from the physician’s childhood, in contrast to behaviors reflecting an objective response to the clinical presentation. It is the child and adolescent psychiatrist administrator’s responsibility to ensure appropriate professional behavior among the caregivers under their supervision. The administrator must also distinguish between a single untoward incident that may be responsive to personal counseling in contrast to the consistent expression of ingrained unprofessional behaviors that would require a significantly stronger response. In both situations, the administrator must endeavor to ensure, as much as possible, that the behaviors do not recur and that professionalism is maintained.

Research, Neuroethics, and Psychopharmacology

Arguably, the major recent advances in child and adolescent psychiatrist knowledge and treatment have resulted from quantum leaps in knowledge of neural function, particularly at the brain receptor and molecular levels.

This knowledge has correlated with an expansion in the knowledge base of neuropsychopharmacology.

As is true of all treatment techniques, the decision of whether to intervene pharmacologically requires a risk–benefit analysis. The potential dangers of acute or chronic side effects must be weighed against the long-term effects of unhindered chronic psychopathology. Knowledge concerning the short- and long-term effects of psychotropic medications on possibly vulnerable developing brains remains a concern. Although some negative effects have correlated with medication treatments (e.g., aspirin with Reye syndrome and central nervous system stimulants with possible growth retardation), studies have not, by and large, followed psychotropic-taking children into adulthood. Many psychiatric disorders first manifesting in childhood or adolescence (e.g., autism spectrum, bipolar, Tourette's, and OCD) are likely to remain manifest as chronic conditions in the ensuing decades, and the long-term effects of the prescribed psychotropic medications are uncertain.

Psychotropic medications commonly have been prescribed by physicians for "off-label" use. For example, many medications prescribed by CAPs for child psychiatric disorders (e.g., schizophrenia, bipolar disorder) only recently received limited FDA approval and thus became legitimized as "on-label." Thus, some medications that target severe behaviorally and cognitively disruptive childhood disorders, which include antipsychotic, mood-stabilizing, antidepressant, and cardiovascular agents, might not have FDA approval for their prescription to children. In addition, prescriptions of these medications for newly defined psychiatric conditions, such as disruptive mood dysregulation disorder, have as yet to obtain FDA approval for this purpose, and their use in these circumstances would again be termed "off-label." Although considered clinical judgment can result in the conclusion that these medications, in fact, might be indicated and beneficial, a rigorous evidence base for that opinion could remain weak or nonexistent. Because many childhood behavioral disorders contain elements of various disease entities without fully satisfying established diagnostic criteria, pharmacologic management is often attempted based on coupling the overt behaviors with hints or suggestions of other signs or symptoms. Also, practitioners attempt to treat with medications because adequate and appropriate psychotherapeutic and environmental interventions often are not accessible, available, or sufficient. These diagnostic uncertainties and

absences of full ranges of care, coupled with inadequate evidence bases, always pose ethical conflicts between the desire to provide good care, for example, by using what are thought to be indicated psychopharmacologic agents—and the possible iatrogenic precipitation of harm.

The lack of knowledge concerning long-term outcomes indicates the continued need for research to expand the child psychiatric scientific database. Political jockeying persists around a mandate to study the effects in children of medications prescribed to adults. While such a directive was originally imposed, that is, the “Pediatric Rule,” it was, in turn, struck down by court order; the pharmaceutical industry has since been encouraged to expand drug trials to include children via the use of incentives. In any event, until an increase occurs in the number of drug trials focusing on children and their longer-term outcomes, prescribing new medications to youngsters without advanced knowledge of potential ill effects could put them at risk. Thus, informed consent is crucial in these circumstances. A description of the treatment protocol, risks and benefits that might accrue consequent to the provision or withholding of the treatment, and avoidance of coercion with respect to patient participation, should be expected by the prospective participants in what are essentially experiments whose predictable outcome is indeterminate. Although consent to a child’s participation in a research protocol must come from fully informed guardians, the child should be advised of all the pertinent factors to the extent of their capacity to understand and noncoerced assent obtained for participation to occur.

The phenomenal increases in knowledge of molecular biology have widened the spectra of innovative drug treatments, not only for diseases of the brain but also for enhancement of what until now has been considered cognitive or affective functioning, or both, within that broad range called “normal.” Stimulant medications, for example, are known to be effective in increasing attention and concentration not only for children diagnosed with ADHD but also in normal populations. Might drugs be used in the future to enhance the sociability of the nondisabled shy younger child or, conversely, reduce the boisterousness of the mildly annoying exuberant child? One needs only to look at controversies regarding steroid augmentation of athletic performance, or neuroenhancers intended to forestall or slow cognitive declines, to comprehend that similar improvement or magnification of unimpaired

brain function abilities lie around the corner. These and related concerns are subject to frequent musings by neuroethicists.

The number of psychotropic medications prescribed for children, inside and external to the United States, has seen a significant increase over the last few decades. Potential explanations include gains in professional knowledge, studies indicating medication efficacy, more medication choices among chemical classes of psychotropic medications, access to medical and psychiatric care by larger numbers of children, large sums devoted to advertising of pharmaceuticals targeting physicians, and child and adolescent psychiatrist professional education that emphasizes "biologic" interventions at the expense of time devoted to the verbal therapies. More recently, publicly aired concerns about this general increase, highlighting polypharmacy in the child and adolescent public sector, and concerns about purported relationships between the administration of selective serotonin reuptake inhibitors (SSRIs) to depressed youngsters and subsequently increased suicidality, all occurring in the context of a pharmaceutical industry having significant interests in the marketing of its products, resulted in some curtailing of medication prescription by CAPs. Of note, it appears that the above-cited drop in SSRI prescriptions was followed by a significantly measurable increase in suicidal behaviors in the target population. That example serves as a fine illustration of the ethical dilemmas CAPs face as they weigh the risks and benefits of therapeutic choices, grapple with an enlarging psychotropic armamentarium, consider ever-broadening clinical presentations for which medication interventions are suggested, and experience increasing economic pressures and inducements to write prescriptions. In the end, it is incumbent on CAPs to weigh evidence objectively, distance themselves from personal considerations and biases, and make choices that foster the best interests of the child.

TEACHING ETHICS AND REPORTING VIOLATIONS

The American Council of Graduate Medical Education mandates the teaching of ethics in child and adolescent psychiatry training programs in order for future CAPs to be aware of the potential emergence of ethical conflicts during their careers. Topics deserving didactic exposure during training commonly include matters generic to all physicians, such as confidentiality, boundaries, professional responsibilities, and relationships

with healthcare providers, companies, and industries, as well as topics focused more specifically on child and adolescent psychiatry practice. The latter include the topics of child advocacy and protection, informed consent and assent, refusal of treatment, child-guardian conflicting rights, agency, compensation sources, autonomy and paternalism, and research-related risks and benefits. In addition, attention should be paid to pitfalls surrounding communications via digital transmissions and practitioners' ethical responsibility to be aware of federal, state, and local laws governing medical and child and adolescent psychiatry practice. Clearly, ethical concerns regarding children arise from the youngsters' needs for adult protection and nurturance, given their physical and cognitive immaturity. Related training in and knowledge of psychodynamics, the origins of motivations, intrafamilial relationships, and systems theory would augment, and can easily be incorporated into, the child and adolescent psychiatrist trainee's ethics education. Further, child and adolescent psychiatrist trainees should be exposed to the contents of the AACAP *Code of Ethics.* The document, using a principled framework, addresses the needs and rights of children and their guardians, as well as the child and adolescent psychiatrist's responsibilities to both. On occasion, trainees and/or experienced practitioners may experience uncertainty regarding an ethical dilemma concerning a child, and referral to the *Code* may help guide the response.

The AACAP Ethics Committee also serves as a potential resource for advice concerning ethical dilemmas. Inquiries to the committee receive suggestions for approaches to resolution after member deliberations. When faced with an ethical dilemma, the potential value derived from consultation with colleagues, and from the committee in particular, cannot be overstressed. In recent years, inquiries presented to the AACAP ethics committee have included concerns about administrative orders to withhold information from families; "double booking" of patient appointments; provision of simultaneous care to multiple family members; transitional age youth access to firearms; inadequate research supervision; noninclusive and/or biased custodial evaluations; the use of agencies and credit bureaus to collect fees; potential breaches of patient confidentiality; poor or potentially harmful patient care; organizationally blocked access to professional consultation coupled with inadequate supervision; video monitoring on child and adolescent psychiatrist inpatient units; disclosure of case details in, and obtaining patient consents for, publications;

abandonment of children by professionals in the context of threatening parents; potential supply of sexual paraphernalia to patients; practice of child psychiatry without formal training; the impacts of television and other media on children; requests of families for funding of research; treatment by a child and adolescent psychiatrist parent of that psychiatrist's child; reporting alleged abuse/neglect to state child protection agencies; and potential adoption of former patients. In addition, the AACAP Ethics Committee has developed a range of educational materials, disseminated in various fora and maintained on the AACAP ethics website, related to child and adolescent psychiatric practice. To those ends, in the recent past, the committee focused on ethical concerns arising from the impacts of systemic racism, immigration bans, family separation, and the COVID pandemic, highlighting the latter's influence on the development and evolution of telepsychiatric practice. Finally, it remains of note that, in 2010, the AACAP implemented a mandate that continues to require of all members the acquisition of biannual ethics education in order to maintain their status in the organization.

Periodically, fulfilling a different function, on rare occasions, the committee receives complaints concerning practitioners alleged to have engaged in unethical practices in matters concerning children and adolescents. When further investigation is indicated, complainants are referred to appropriate organizations and agencies, such as the APA and AMA district branches and state medical licensing boards. Investigations by these entities could result in "no findings" or recommendations for sanctions, which may include reprimand, suspension, or loss of licensure. Abrogation of licensure by a state medical licensing board, consequent to findings of an ethics violation, automatically results in loss of membership in the AACAP, the guild representing the profession's ethos.

The roles of healers in society have a long history, and communities' designated medical personnel have always been faced with ethical dilemmas. With continued growth in relevant scientific knowledge and related technologic achievements, the dilemmas have grown more complex and complicated. The basic understandings, however, remain the same and undiluted, that is, the challenge of doing good and not engaging in harmful behaviors, equally for all patients. CAPs have the additional burden of caring for the immature youngster, as well as maintaining good relations with their guardians and caretakers. Whether the child and adolescent psychiatrist is wrestling with age-old conflicts surrounding

privacy and confidentiality or dealing with novel developments in genetics and transmission technologies, ethical responsibilities represent a never-ending challenge for all practitioners and for the subspecialty as a profession. In the face of unceasing change, therefore, the teaching of ethics, discussions of current dilemmas, revisions of ethical codes, and monitoring of practitioners and practices are a must for the maintenance of the profession's integrity.

54.8 School Consultation and Collaborating With the Educational System

Sheryl Kataoka, M.D., M.S.H.S., Ilaina Blum, M.A., M.F.T., Edward Castelo, M.D., and Roya Ijadi-Maghsoodi, M.D., M.S.H.P.M.

No setting other than a child's home can influence child development more than schools. In addition to the academic curriculum taught throughout a child's education, schools can be instrumental in teaching students social–emotional learning (SEL) skills such as communicating with peers and adults, problem solving, and recognizing and regulating emotions, as stated clearly by Taylor et al. Wang et al. reported that the environment or climate of a school also plays an important role in shaping students' ability to develop cognitively, psychologically, socially, and behaviorally. Thus, whether a psychiatrist is providing treatment for a youth or consulting with a school or district, having knowledge about the school system and how to coordinate with a patient's educational setting can be essential to supporting students' mental health and well-being.

EDUCATIONAL OUTCOMES AND MENTAL HEALTH

Educational outcomes, such as achievement, school attendance, discipline, and high school (HS) graduation, are associated with youth mental health and well-being, as reported by Henry et al. One indicator of negative school performance is chronic school absenteeism, defined as missing at least 10% of school days per year, whether excused or unexcused absences. Students may frequently be absent from school for several reasons, including having a chronic illness, involvement in the juvenile justice system, housing instability, feeling unsafe at school due to harassment or bullying, teen pregnancy, or not finding value in attending school. Risk factors for chronic school absenteeism include children who have experienced maltreatment or other types of trauma, who have a higher number of adverse childhood experiences (ACEs), and who have a

disability or special health care need. Allison et al. found that chronic school absenteeism can influence functioning into adulthood, affecting employment, use of public assistance, and justice involvement. For example, Porche and colleagues found that childhood trauma, mediated by psychiatric disorders, was related to school dropout. Others have also found relationships between school attendance and psychiatric problems such as attention deficit hyperactivity disorder (ADHD), anxiety and depressive disorders, and developmental disabilities. Thus, psychiatric treatment can impact both the mental health of youth and their school performance, with early intervention having the potential to prevent a negative developmental trajectory.

Overview

In this section, we first provide a broad description of the school system with which psychiatrists may interface when working with children. We will present the historical context and relevant policies that have shaped the U.S. educational system, racial and ethnic disparities that exist in schools, common types of schools and the roles of school personnel, and the range of resources, support, and programming that can be found on campuses.

Next, we discuss possible roles a psychiatrist may have with schools, including (1) collaborating with schools to support the treatment plan of their patients, (2) practicing at a school-based health center (SBHC) or through telepsychiatry as part of a school mental health team, (3) consulting to a classroom, school, or district to provide system level supports and mental health education to staff and parents, and (4) consulting to the education system in a time of crisis.

SCHOOL SYSTEMS

Common Terms Used in the Educational System

When discussing educational supports, specifically special education services and programming, psychiatrists should be aware of the “language” of schools. Below is a list of commonly used terms, although differences exist by region (see Table 54.8–1). Refer to the local school district or state’s Department of Education for specific information.

Special Education, according to the Individuals with Disabilities Education Act (IDEA), has six foundational principles: (1) free and appropriate public education (FAPE), (2) appropriate evaluation, (3) Individualized Education Program (IEP), (4) least restrictive environment (LRE), (5) parent and student participation in decision making, and (6) procedural safeguards to ensure that the rights of children with disabilities and their parents are protected and that they have access to the information needed to effectively participate in the process as described by Zirkel (2015).

Table 54.8–1.
Common Education Terms

Common Education Terms	Description
LEA: Local Educational Agency	Public authority tasked with administrative control of schools in a region (i.e., county education office, district)
General/Regular Education	Education for typically developing children based on annually reviewed state standards
Special Education	Specially designed instruction under IDEA to meet needs of child with a disability; can include gifted instruction
IDEA: The Individuals with Disabilities Education Act	Federal law: free appropriate public education for children with disabilities, for special education and related services
FAPE: Free and Appropriate Public Education	In IDEA and Section 504, describes education that's at no cost to parents, meets state standards, and meets student's needs
LRE: Least Restrictive Environment	In IDEA, appropriate educational environment, meets special educational needs, and maximizes being with nondisabled peers
IEP: Individualized Education Program	Written statement for each student with a disability that describes how disability affects education, goals, progress, and services
Accommodations	Changes in how student learns material or demonstrates mastery. Does NOT change what is taught or tested
Modifications	Changes to content and performance requirements. DOES include changes to what is taught or tested

Table 54.8–2.
Examples of Key U.S. Federal Laws Involving the Educational System, by Year

Year	Policy/Legislation	Significance
1965	ESEA: Elementary and Secondary Education Act	Part of President Johnson's "War on Poverty." For equal educational opportunity for all students (i.e., those living in poverty, learning English, disabled). Provided grants to low-income districts, funds for special education centers, scholarships for low-income college students, grants to LEAs to improve the quality of primary/secondary education
1973	Section 504, Rehabilitation Act	Protects the rights of individuals with disabilities, including in public schools (enforced by the Office of Civil Rights) and entitles children with disabilities to a "free and appropriate education."
1974	FERPA: Family Educational Rights and Privacy Act	A federal law that protects the privacy of student education records applies to all schools receiving federal funds. Gives parents certain rights to child's education records until child is age 18 (then right goes to child). *See the section on HIPAA vs. FERPA later in this section.*
1975, 2004	IDEA: Individuals with Disabilities Education Act (Formerly Education for All Handicapped Children Act)	Mandates free and appropriate public education to eligible children with disabilities in the United States, by providing them with special education and related services in the least restrictive environment.
1987	McKinney-Vento Homeless Assistance	In addition to other programs, this act includes the Education for

	Act	Homeless Children and Youth Program
2001	NCLB: No Child Left Behind Act	Contained standards-based education reforms, established high standards and measurable goals to improve outcomes of students defined by states; federal funding was dependent on states implementing assessments.
2015	ESSA: Every Student Succeeds Act	Reauthorization of the ESEA, replacing NCLB. Retained annual standardized testing requirements but allows LEAs to apply for subgrants for local accountability plans. Includes the reauthorization of the McKinney–Vento Homeless Assistance Act, which requires schools to identify students experiencing homelessness and collaborate with other service providers and emphasizes school stability.

Educational History and Policies Influencing Mental Health in Schools

As Flaherty and Osher (2003) described, mental health clinicians have collaborated with school personnel for over 100 years. From the inception of school mental health during the Progressive Era, beginning in the 1890s, schools started expanding to include more students and introducing services such as “mental hygiene” in response to academic and behavioral challenges in the educational setting. Since the latter half of the 20th century, U.S. schools have been shaped by the Civil Rights era and federal legislation that initiated a focus on addressing equity in education for those students with disabilities and those living in underresourced neighborhoods. Table 54.8–2 highlights some of the key federal education laws that have and continue to shape practice.

Disparities in the Educational System

Despite federal legislation that has called for equity in public education for over 50 years, there remain significant racial and ethnic disparities for multiple educational outcomes, affecting children across their lifespan as reported by Carter et al. (2017). For example, according to the U.S. Department of Education, Black preschool (PS) children experience disproportionate PS suspensions at rates over 2.5 times that of their enrolled population in the United States, with similar out-of-school discipline rates continuing into their elementary and secondary education. Native American youth are suspended at four times their enrolled population during K-12 schooling and expelled from school at six times their population. Native American and Black youth are also disproportionately referred to and arrested by law enforcement for school-related offenses at least twice the rates of their enrolled populations. In 2019, the U.S. Commission on Civil Rights reviewed racial and ethnic disproportionality of school discipline for students with disabilities. The report concluded that despite disproportionate discipline for students of color, these students did not commit more disciplinable offenses than their White peers, although received harsher and longer punishments than did White students. They summarized research showing that out-of-school discipline is associated with poor classroom engagement, greater school dropout, and juvenile justice involvement. The Commission recommended that federal nondiscrimination laws needed to be enforced, and schools should be provided resources and training for alternatives to out-of-school discipline. Psychiatrists can play an important role in supporting schools in these efforts, including consulting to educational systems on implementing trauma-informed practices, and on improving school climate, including student support, engagement, and school connectedness, as reported by Ijadi-Maghsoodi et al. (2017) and Kataoka et al. (2018).

Common Educational Settings

Psychiatrists may find that their youth patients attend a wide array of educational settings, each with varying resources and regulations (Table 54.8–3). The strengths and limitations of a school setting also need to be considered, in light of the strengths and needs of each individual child. The following is a description of some of the more common types of educational settings. For more information, see the Institute of Education Sciences Fast Facts (2021).

Table 54.8–3.
Educational Environment for All Students With Disabilities Under IDEA, 6–21 Years Old, 2018

Educational Environment	Proportion of Students With Disabilities
Regular school, with <40% time in general education	13.1%
Regular school, with 40–79% time in general education	18.0%
Regular school, with >79% time in general education	64%
Separate school for students with disabilities	2.7%
Separate residential facility	0.2%
Parentally placed regular private school	1.4%
Homebound/hospital placement	0.4%
Correctional facility	0.2%

Data from U.S. Department of Education. Digest of education statistics. https://nces.ed.gov/fastfacts/display.asp?id=59

Early Education Settings. High-quality early care and education centers (i.e., PSs) that serve children from birth to pre-kindergarten can play an important role in social–emotional and behavioral development as well as readiness for academic learning. One well-studied program for young children, the HighScope Perry Preschool Project, found that attending this PS resulted in greater positive long-term outcomes than for similar peers that did not attend this PS, such as fewer teen pregnancies and greater HS graduation, home ownership, and higher earning jobs. Head Start and Early Head Start are federal efforts to provide enrichment from birth to 5 years old for low-income families, which has also been found to have positive long-term outcomes for children. However, PSs have not been universally available to all children nor of universally high quality. The Institute of Medicine and National Research Council's report, Transforming the Workforce for Children Birth Through Age 8: A Unifying Foundation (2015), outlines the system changes needed to ensure high-quality PS settings, such as core competencies in practices that support

the growth and development of young children and engage diverse families.

Public Schools. All students in the United States have access to free education from kindergarten through 12th grade and are required to participate in education as defined by state laws (by attending a public, private, or some homeschooling programs). Public schools are funded primarily by state and local governments, with the remaining funding from the federal government. Public schools must comply with state and federal regulations including IDEA and the Every Student Succeeds Act (ESSA) (see earlier Policy section for details). In 2016, 90.5% of U.S. students attended a public school, with 4.6% of all students attending a public charter school.

Charter Schools. Charter schools were first established in 1992 in Minnesota, as an alternative to public schools. A charter school is a public school that operates under a legislative contract, or *charter*, with an authorizer or sponsor. Sponsors can include state education agencies, special boards, or even school districts. Charter schools are given autonomy and flexibility in curriculum, structure of the school day or year, and budget management but must meet the accountability standards outlined in the school's charter. If a charter school is not meeting these standards, the sponsor can revoke the charter. These schools are free and open to the public and if seats are not available, admission is by lottery.

Private Schools. The majority of students who attend private school, attend a religious (most frequently Catholic) school. In 2016, of all students in the United States, 7.6% attended a religious private school and 1.9% attended a nonsectarian private school. The Department of Education does not have jurisdiction over private elementary and secondary schools that are parentally placed (as opposed to publicly placed nonpublic schools, described below). Unless a private school receives federal aid, the federal government does not have control over such things as the school's curriculum or personnel and does not accredit these schools. See additional information in the later section entitled, *Private Schools and Special Education.*

Publicly Placed Students in Nonpublic Schools. Students with a disability may be placed in a private school—at no cost to their parent or guardian—to receive the special education and related services that they require in order to access their education, under IDEA. Students in these schools have an IEP that determines that the nonpublic school setting is the LRE for them to access the curriculum.

Homeschooling. According to the National Center for Education Statistics, homeschool students are students who receive their instruction at home instead of at a private or public school (excludes those enrolled in public or private schools for at least 25 hours per week or schooled at home due to a temporary illness). Regulation of home schools is state dependent as there is no federal law that governs or mentions homeschooling.

Alternative Programs/Schools. There is a subset of students in public, general education schools who might be considered “at risk” due to having a higher probability of failing academically or dropping out of school. Often, these students face life circumstances, inequities, and structural risk factors, that can compromise their ability to successfully complete school, such as homelessness, teenage pregnancy, domestic violence, transiency, incarceration, or serious health issues. For students with these challenges, who do not qualify for special education services, yet struggle to remain in their general education program and who want to stay in school and earn a diploma, public schools may offer alternative programs or schools. According to the National Center for Educational Statistics, placement in alternative schools and programs is usually based on recommendations from school personnel or administrators or requested by the parent or student.

Most alternative programs or schools are part of the public HS (though in some areas it extends to middle school [MS] as well). Alternative programs can include a separate classroom or school within a general education campus or an alternative school on a separate campus. Some alternative programs are specially designed for teenage mothers. These alternative programs vary widely by state and Local Educational Agency (LEA) according to Addis et al.

Roles of School Personnel

When psychiatrists work with child and adolescent patients, it is often indicated and beneficial to communicate with school personnel and become familiar with the culture of the school and community. This can help maximize understanding of the student's experience and inform the treatment plan. Below is a brief description of various school personnel who might be involved in a student's school programming:

Teachers are the primary school staff who typically are the most involved with students. According to the U.S. Department of Education in 2017, elementary school (ES) teachers have approximately 23 students for 6 hours each day; MS and HS teachers may have approximately 20 to 25 (or more) students per class, often teach four or more classes per day, and usually teach specific subjects.

Aides or paraprofessionals ("paras") often are assigned to work with a specific student and work under the classroom teacher. Aides can be in a general education or special education class and may accompany the student to activities outside of the classroom (e.g., lunch, recess).

Special education teachers are credentialed to provide alternative instruction to smaller groups of students with learning disabilities, emotional disorders, autism, speech/language deficits, developmental delays, and/or other handicapping conditions that are interfering with learning. For students to receive instruction from special education teachers, they must have an IEP.

Resource Specialist Program (RSP) teachers mostly work with students who have mild or moderate disabilities in either a push-in (i.e., in the general education class) or pull-out (i.e., in a separate, nongeneral education class, such as a resource room) approach. Some resource teachers administer the achievement testing for the IEP assessments.

School mental health counselors are often the primary mental health support within a school. They often provide short-term therapy and crisis support to students on campus. Students do not necessarily need an IEP to meet with a school mental health counselor.

School academic/guidance counselors often primarily assist students in academic or vocational planning and class selection. They may intervene with issues that arise at school but do not typically provide specialized or mental health interventions.

School psychologists conduct educational assessments and help construct IEPs. They may also provide individual and group therapy to students who qualify for counseling services through an IEP, and they

often work with several schools in the district, so may not be assigned to one school full time.

School adjustment counselors and/or social workers have been added to the school staff in many locations, with their primary role being to provide psychosocial interventions to students and sometimes their families. Students do not necessarily need an IEP to meet with a school adjustment counselor or school social worker.

School nurses and nurse practitioners address acute health care needs of students, provide health education, and administer medications to students. School nurses usually travel between several schools and may be involved with storing medications taken during the school day.

Occupational therapists (OTs) work with students individually or in small groups to address challenges or deficits in areas such as fine and large motor skills (including writing and using tools) as well as sensory integration and/or sensitivities. They may be involved with developing alternative strategies in the classroom and/or individualized interventions. The OT usually is involved with a student as part of a recommended IEP service.

Speech–language therapists/pathologists (SLP) meet with students who qualify for such services through an IEP and have speech (e.g., articulation), language, and/or communication and social skills difficulties. They meet individually and/or in small groups.

School resource officers (SROs) are employed by the local police department, sheriff's agency, or school system and work closely with school administrators for the purpose of creating a safer environment. The responsibilities of SROs are similar to other police officers (i.e., have the ability to make arrests, respond to calls for service, and document incidents).

School administrators (i.e., principals, vice principals) coordinate between and within the school and the community by managing all services (teaching, discipline, custodial) within their school building and reporting to the *superintendent.*

Superintendents guide educational activities among all the schools within a school district and report to an elected school board in public schools, or an appointed board in private, parochial, or charter schools.

SCHOOL RESOURCES AND PROGRAMMING

In addition to becoming familiar with the types of personnel in a school system, a psychiatrist should also understand the range of resources and programming that may be available at a school. Schools are an ideal setting to disseminate effective health promotion and prevention interventions, provide early detection of mental health conditions, and link students and families to needed services. One overall framework for considering the integration of all supports on a campus is the multitiered systems of support (MTSS), which describes supports generally available to all students on a school campus. Two specialized programs for eligible students include a 504 Plan and an IEP.

If there is suspicion, concern, or evidence that a student is struggling in school, there are various avenues that can be taken to provide supports for that student.

1. A student can receive *tiered interventions* within the general education school program.
2. A student can formally receive accommodations/modifications/supports through a *504 Plan* within the general school program.
3. A student can be assessed by the public school to determine if the student qualifies for special education services through an *IEP.*

Multitiered Systems of Support

Response to Intervention (RTI) is an MTSS used by teachers and other school staff as a set of steps to help a child improve in an area of need by providing targeted educational supports within the general education setting according to Stoiber and Gettinger (2016). Interventions in a multitiered system gradually increase in intensity from Tier 1 to Tier 3 (though some schools include additional tiers), and a student may receive tiered interventions in one, two, or all three tiers until their academic or behavioral needs are met, or until the student needs an IEP evaluation. Progress is tracked within each tier and if the student does not improve within one tier, they will move to the next tier. As the student exhibits sufficient progress, the student may move back to a previous tier. Maintaining the student in the general education setting, while providing the requisite supports, is often a central goal of the tiered approach. This tiered approach, as detailed by Stephan (2015), applies to the whole child,

in supporting instruction as well as the social, emotional, and behavioral development of the student (Fig. 54.8–1).

Tier 1 is usually a whole-class approach, typically applied to over 80% of the school population. From an instructional perspective, a classroom teacher may use a research-based curriculum. Similarly, from a social–emotional perspective, students may receive health promotion and universal prevention programming in the classroom as part of Tier 1 supports, such as SEL, which teaches students how to manage emotions and develop supportive relationships.

Tier 2 usually involves more focused instruction of a specific skill, utilizes a different instructional method and at a higher frequency than that provided in Tier 1, and is often provided in smaller group settings than in Tier 1, which allows for relatively more attention and guidance. Approximately 15% of general education students access Tier 2 supports, which can include selective prevention interventions in group modalities.

For Tier 3 services, students may receive highly individualized instruction or may work in very small groups multiple times per week. The student will continue to spend most of the day in a general education classroom. Poor progress following an adequate trial of Tier 3 intervention may result in consideration of an evaluation for special education services through an IEP. Approximately 5% of students will receive Tier 3 services. For social–emotional needs, this could be individual or family therapy.

Psychiatrists can help schools identify and implement appropriate programs depending on the needs and resources of the school system. Several repositories of evidence-based and promising practices have been developed to assist practitioners and agencies (including school districts and schools) select scientifically supported interventions based on designated criteria (e.g., age, setting, and target outcome). See Table 54.8–4 for evidence-based social, emotional, and behavioral interventions by tier of support and presented by PS, ES, MS, and HS.

FIGURE 54.8–1. Tiered systems of instructional and social, emotional, and behavioral supports.

Table 54.8–4. Examples of School Social, Emotional, and Behavioral Interventions by Tier of Support

Tier	Target Population	Grade	Intervention	Description	Outcomes
1	Universal, Underresourced Communities	PS	ParentCorps[b]	Parent and teacher training to create a safe and nurturing environment and improve teacher–parent communication, SEL in the classroom	Improves academics, behaviors
1	Universal	PS, ES	Incredible Years Training for Teachers[a]	Teacher training for positive classroom management	Decreases conduct problems, improves emotion regulation, social skills, and school readiness
1	Universal	ES	Good Behavior Game[a]	Classroom behavior management approach that encourages prosocial behavior through games	Decreases aggressive behavior, substance use, suicide
1	Universal, SEL	ES	Promoting Alternative Thinking Strategies (PATHS)[b]	Teach self-control, feelings and relationships, and social problem solving	Decreases aggression, disruptive behaviors, delinquency
1	Bullying Prevention	ES	Steps to Respect[a]	Staff training to increase awareness and responsiveness and classroom SEL for bullying	Decreased bullying and bystander behaviors, improved climate
1	SEL, School-Wide Climate Change	ES, MS	Positive Action[b]	Brief classroom lessons from K–8th grade to teach emotions, behaviors, and positive actions	Lower absenteeism, suspensions, grade retention, substance use, violence
1	Substance Use and Violence Prevention	MS	Life Skills Training[b]	Classroom intervention that teaches self-management, social skills, problem solving, drug resistance	Decreased drug use, violence, delinquency, and risky behaviors
1	Dating Violence Prevention	MS, HS	Safe Dates[a]	10-session dating violence prevention program for MS and HS students	Reduces dating violence, improves communication skills
1–2	Substance Use Prevention	ES, MS	Strengthening Families 10–14[a]	Seven sessions to increase family protective factors and resilience	Decreases substance use, antisocial and aggressive behavior
2	Aggression	ES, MS	Coping Power[a]	5th–6th grade students receive anger management and social problem solving, and parents learn parenting skills and family communication (16 months)	Improves academic performance and prosocial behaviors, and decreases substance use and conduct problems
2–3	Traumatic Stress	ES, MS	Cognitive Behavioral Intervention for Trauma in Schools[a]	CBT-based group intervention for youth exposed to trauma/violence, with optional parent and teacher sessions	Decreases PTSD and depressive symptoms
3	Depression	MS, HS	Interpersonal Psychotherapy Adolescent Skills Training[a]	Short-term intervention focusing on the developmental and interpersonal needs of adolescents and building communication and social problem-solving skills	Improves depression and improves well-being

[a]Promising Programs (https://www.blueprintsprograms.org).
[b]Blueprints Model Programs.
CBT, cognitive behavioral therapy; ES, elementary school; HS, high school; MS, middle school; PS, preschool; PTSD, post-traumatic stress disorder; SEL, social–emotional learning.

504 Plan

If a student needs more formalized supports within the general education setting than can be provided within the tiered model but is not yet considered for special education services as part of an IEP, the school may develop a 504 Plan. This can follow a trial of tiered support or be developed and implemented on its own without a student being tried in any other support systems. A 504 Plan refers to section 504 of The Rehabilitation Act of 1973 that addresses protections for students with disabilities.

Section 504 states: “No otherwise qualified individual with a disability in the United States… shall, solely by reason of her or his disability, be excluded from the participation in, be denied the benefits of, or be

subjected to discrimination under any program or activity receiving Federal financial assistance….”

A 504 Plan formalizes specific supports, accommodations, and/or modifications that the school will implement for a student based on the student’s identified “impairment.”

Students qualify for a 504 Plan if:

- They have a physical or mental impairment.
- The impairment substantially limits at least one major life activity.

Physical or mental impairment: Some examples of physical or mental impairments are physical disabilities, health conditions, mental health disorders, and learning disabilities. Depending on the severity and duration of the limitation, *short-term impairments* (such as a leg fracture) and episodic impairments such as asthma may qualify a student for 504 accommodations.

Examples of major life activities: Some examples of limits in major life activities that would be included in a 504 Plan qualification include deficits in one or more of the following: caring for oneself, communicating, eating, learning, reading, seeing, sleeping, speaking, or walking.

504 Plans identify adjustments (i.e., supports, accommodations, or even modifications) that a student with an impairment needs in order to sustain participation in and access to the general education classroom. A 504 Plan formally delineates ways the school will help the student access the curriculum and benefit from instruction. Because the supports, adjustments, accommodations, and/or modifications developed and written in a 504 Plan are usually intended to be implemented within the general education setting, general education teachers are typically the primary, or sole, school staff responsible to implement or monitor the accommodations or supports documented within a 504 Plan.

Craig is an 8-year old boy in second grade. He had been asked to leave several private preschools due to significant motor activity and marked irritability, such as becoming upset with teachers and peers over trivial things. After entering kindergarten at a public school, parents continued to get complaints from teachers about Craig's difficulties with inattention, sitting still, tracking oral instructions, and initiating work. His irritability with peers also persisted. Therefore, his kindergarten and first-grade teachers discussed his need for a possible diagnostic assessment. A child psychiatrist evaluated Craig and diagnosed him with ADHD, combined type.

At the end of first grade, the school held a 504 Plan meeting to discuss *accommodations*. Given a "disabling condition" of ADHD, the school determined he met criteria for a 504 Plan and recommended accommodations including preferential seating, frequent checks for understanding, movement breaks, concise and neutral redirection (i.e., nonverbal redirection, such as tapping on his desk), and developing a recess plan (i.e., generating a list of activities with teachers and peers he would try to play with; clarifying when to go to the yard teacher).

There are unlimited types of supports that can be included in a 504 Plan. *Accommodations* are changes in how a student might learn material or be required to demonstrate skill mastery (i.e., be tested), but what is being measured is not changed. Accommodations do not change what is being taught and/or what the student is being tested on. Students receiving accommodations are typically subject to the same grading scale as students who are not receiving accommodations as reported by Harrison et al. (2013).

Modifications are changes made to the content and performance requirements for a student, usually based on or in response to an identified area of deficit, weakness, or disability. This can include a change in what is being assessed, assigned, or taught as compared to the general education curriculum. A distinguishing factor between accommodations and modifications is that modifications refer to the process of altering what a student learns or receives on a test (e.g., a sixth-grade student who might need fourth-grade–level spelling words) whereas accommodations refer to supports that help a student access the general education curriculum (e.g., a sixth-grade student who is not

required to write spelling sentences for all 20 weekly spelling words). Modifications are more intensive changes to the difficulty level and/or the quantity of material to be learned. Modifications are usually required for students whose impairments necessitate more intense adjustments. 504 Plans can be revised as indicated and should be updated as a student progresses from one grade level to the next and especially at major grade/school changes (i.e., elementary to MS; MS to HS). See Table 54.8–5 for examples of specific types of accommodations and modifications.

504 Plans and Postsecondary Programming. Unlike services provided through an IEP, which discontinue once a student formally exits HS (i.e., via graduation, taking and passing the GED or HS proficiency examination) or reaches 22 years old, *accommodations provided as part of a 504 Plan can be carried on past HS.* Students entering post-HS educational programs (e.g., colleges and universities) can continue to receive 504 Plan support since most such educational programs receive federal funding. Public and private postsecondary institutions are required to provide accommodations to students with disabilities under either the Americans with Disabilities Act (ADA) Title II or Section 504. According to the U.S. Department of Education Office of Civil Rights (OCR),

> OCR enforces Section 504 in programs and activities that receive Federal financial assistance from [the Department of Education] ED. Recipients of this Federal financial assistance include public school districts, institutions of higher education, and other state and local education agencies. The regulations implementing Section 504 in the context of educational institutions appear at 34 C.F.R. Part 104.

Students who received 504 Plan supports in HS may continue to need such supports when they transition to college or university and are encouraged to contact the center for students with disabilities at their postsecondary school to explore these options and arrange for the necessary supports. Psychiatrists working with students in post-HS educational programs should be aware that their patients may be eligible for continued 504 plan supports.

Table 54.8–5.
Accommodations and Modifications

Categories	Application
Accommodations	
Presentation	▶ Allow students to audiotape lessons. ▶ Allow student to use alternatives to test books (including audio records). ▶ Reduce amount of work per page. ▶ Enlarge print size. ▶ Provide adjusted paper for writing and math (e.g., wide-lined notebook paper; enlarged graph paper). ▶ Use multimodal communication especially for instructions (e.g., pairing auditory and visual information). ▶ Read all instructions aloud to student. ▶ Frequent checks for understanding.
Response	▶ Allow alternative response form (i.e., orally vs. in writing). ▶ Only call on student when student raises their hand. ▶ Eliminate participation grade/use alternative means for grading participation. ▶ Use of a scribe for written responses. ▶ Extended time allowances for responses. ▶ Opportunities to complete work or take tests in a separate location. ▶ Allow student to use a dictionary and/or grade spelling separately. ▶ Do not downgrade for handwriting. ▶ Allowances to use a calculator and/or printed math facts sheet (e.g., multiplication table).
Timing/Scheduling	▶ Extended time allowances for in-class work, homework, projects, and/or tests. ▶ Opportunities to take breaks, including movement breaks. ▶ Extended time allowances during passing periods.

	▶ Allowances to take tests over multiple days/periods.
Setting	▶ Allowances to take tests in a separate location (i.e., quieter setting). ▶ Preferential seating to maximize learning (e.g., closest to the source of instruction; at back of room to allow for movement). ▶ Being provided with special lighting or acoustics. ▶ Nonpunitive use of sensory tools (e.g., chair band, seat cushion, foot rest).
Modifications	
Assignment	▶ Spelling tests using alternative words to be tested on. ▶ Reduce assignments in amount or modify content significantly. ▶ Provide alternative material or assessments that differ from standard grade-level type or amount.
Curriculum	▶ Teach adjusted content and use material that differs from standard level. ▶ Adjust grading requirements and standards as expected of same-grade peers. ▶ Provide alternative projects with adjusted grade-level materials.

Individualized Education Plan

If a student needs more specialized services and programming than what can be provided via a 504 Plan, then a student may be involved in the IEP process (see Table 54.8–6 for comparisons between 504 Plans and IEPs). The IEP process can begin following either of the two “lower-level” supports mentioned above (i.e., MTSS/RTI or 504 Plan supports) or the IEP process can be initiated without the student having received tiered or 504 supports.

The IEP refers to the individualized program that is developed only after a student has been approved to be assessed, has completed the IEP assessment, has been determined to meet eligibility for receipt of special

education services under the designated eligibility categories by the IEP team, and the IEP team has agreed upon the recommended goals, services, and programming. In these regards, the IEP itself is the "end product" that is the result of a specific, standardized, and structured process.

Table 54.8–6.
Comparison Between 504 Plans and IEPs

Description	504 Plan	IEP
Who qualifies?	1. Has a physical or mental impairment 2. Impairment limits at least one major life activity	1. Meets eligibility criteria for at least one of the Special Education categories 2. Exhibits difficulties that have existed over an extended period of time and, to a marked degree, adversely affect a student's educational functioning
Who typically implements services?	General education staff	Specialized staff (e.g., special education teacher, school psychologist, speech therapist, etc.)
Does school receive funding to implement recommended changes?	No funding	Federal/state/local funding for services
Are protections available postsecondary school?	Yes	No

An important aspect of the IEP process is the *timeline*. Although federal law states that assessments must be conducted within 60 days of receipt of parental/guardian consent for the evaluation (i.e., signed assessment plan form), *the exact timelines can vary from state to state*. See Figure 54.8–2 for the steps involved in the IEP process.

IEP Assessments. A psychiatrist should be aware of the types of tools and information included as part of the IEP assessment: review of records, administration of any indicated testing based on the suspected area(s) of disability, observations of the student, and/or consulting with outside providers, such as the psychiatrist. Most initial IEP assessments include formal, standardized tests, especially when the suspected area of disability relates to a student's academic achievement, speech and/or language functioning, processing, and/or social, emotional, and behavioral functioning. Each school and/or district may administer and use different tests, rating scales, or assessment tools. Table 54.8–7 describes some examples of the categories and types of assessments commonly used, though not the only tests used, for IEP assessments.

General Components of an IEP Meeting. At an initial (or triennial) IEP meeting, two main areas are covered: (1) review of current assessments to discuss "present levels of performance (PLOP)" and (2) determination of eligibility.

IEP Meetings Requirements:

1. Must be held annually, at minimum, to collect data, update goals, and make any changes.
2. Can be reconvened at any time in response to parent request or team agreement.
3. Must be convened when there is a request for a change in services/supports (either an increase, decrease, or discontinuation of services).
4. Must be convened if a student with an IEP is being considered for disciplinary action (i.e., “manifestation determination hearing”).
5. Must be convened when a student transfers to a new school/school district in order to accurately document the change in location and provide any appropriate updates based on the services and programming at the new school.

FIGURE 54.8–2. Steps in the initial IEP process.

If the student is found to meet eligibility criteria, the IEP team meeting will then develop recommendations for the special education programs and services that the student needs; this is known as the team's offer of Free and Appropriate Public Education (FAPE). The IEP team can determine (1) goals and objectives based on individual needs; (2) recommended services and programming and/or placement based on the goals; and (3) accommodations, modifications, and/or supports based on the recommended placement. The IEP team will also decide on the percentage of time that the student is to receive instruction within and outside of the general education setting.

Table 54.8–7.
Examples of Commonly Used Assessment Tools by Category

Category	Instrument
Intellectual or Cognitive Tests	
Cognitive Tests for Children <6 years old	
	Bayley Scales of Infant and Toddler Development-Third Edition (Bayley-III)
	Wechsler Preschool and Primary Scale of Intelligence-Fourth Edition (WPPSI-IV)
Cognitive Tests for Children >5 years old	
	Wechsler Intelligence Scale for Children-Fifth Edition (WISC-V) (6–16 years old)
	Wechsler Adult Intelligence Scale-Fourth Edition (WAIS-IV)
	Stanford-Binet Intelligence Scale-Fourth Edition
	Woodcock-Johnson IV Test of Cognitive Abilities
	Differential Ability Scales-II (DAS-II)
Educational Achievement Tests	
General Achievement Tests	
	Wide Range Achievement Test-5th Edition (WRAT-5)
	Woodcock-Johnson Test of Achievement-Fourth Edition (W-JIV)
	Wechsler Individual Achievement Test-Third Edition (WIAT-III)
	Kaufman Test of Educational Achievement-Third Edition (KTEA-III)
Tests of Specific Areas of Achievement	
	Gray Oral Reading Test-Fifth Edition (GORT-5)
	Test of Written Language 4 (TOWL 4)
	Woodcock Reading Mastery Tests-Revised-Normative Update (WRMT-R/NU)
	Dynamic Indicators of Basic Early Literacy Skills (DIBELS)
	KeyMath 3 Diagnostic Assessment

Speech and Language Tests

Comprehensive Speech/Language Tests

- Clinical Evaluation of Language Fundamentals-Fifth Edition (CELF-5)
- Peabody Picture Vocabulary Test-Revised (PPVT-3)
- Expressive One-Word Picture Vocabulary Test (EOWPVT)
- Goldman-Fristoe Test of Articulation
- Test of Language Competence (TLC)
- Test of Problem Solving (TOPS)
- Test of Language Development (TOLD-3)

Auditory Processing Screening Assessments

- Test of Auditory Processing (TAPS) (often given by psychologists)
- SCAN-3:A Tests of Auditory Processing Disorders in Adolescents and Adults

Processing Tests

- Beery–Buktenica Developmental Test of Visual-Motor Integration (VMI) (includes VMI, Visual Perceptual, and Motor Coordination subtests)
- Bender Visual Motor Gestalt Test
- Test of Visual Perceptual Skills (nonmotor)-Third Edition (TVPS-3)

Adaptive Functioning

- Vineland Adaptive Behavior Scales (VBAS)

Social/Emotional Measures/Rating Scales

- Behavior Assessment System for Children (BASC-2)
- Child Behavior Checklist (CBCL)
- Children’s Depression Inventory (CDI)
- Beck Depression Inventory (BDI)
- Screen for Child Anxiety Related Disorders (SCARED)

UCLA PTSD Reaction Index for DSM-5

Behavior Rating Scales

Conners' Rating Scales

Behavior Rating Inventory of Executive Function (BRIEF)

If the student is found to *not meet eligibility criteria* for any of the special education categories, then the IEP team may discuss alternative options (i.e., tiered interventions; development of a 504 Plan). If a parent disagrees with the IEP team's recommendations, then the parent can discuss that during the meeting. If a resolution cannot be achieved at the meeting, then the parent can take steps to pursue other options (e.g., mediation, complaint, due process hearing).

Parents and guardians are considered to be key members of the IEP team. At or prior to the IEP meeting and in writing, the school is required to inform parents and guardians of their rights under IDEA and state law. One key right is the right to active participation in the IEP meeting and process. Other key rights of parents and guardians include, but are not limited to, the following (categorized as procedural safeguards):

Table 54.8–8.
IEP Eligibility Categories

Eligible Category	Description	Examples of Disorders/Conditions
Specific Learning Disability (SLD)	Disorder in one or more of the basic psychological processes involved in understanding or in using language (ability to listen, think, speak, read, write, spell, or do mathematical calculations)	▶ Dyslexia ▶ Dyscalculia ▶ Dysgraphia ▶ Brain injury ▶ Developmental aphasia ▶ Perceptual disabilities
Emotional Disturbance (ED)/Emotional Disability (ED)	One or more of the following characteristics over a long period of time and to a marked degree that adversely affects one's educational performance: A. An inability to learn that cannot be explained by intellectual, sensory, or health factors. B. An inability to build or maintain satisfactory interpersonal relationships with peers and teachers. C. Inappropriate types of behavior or feelings under	▶ Affective/mood disorders ▶ Anxiety disorders ▶ Psychotic disorders ▶ Certain impulse control disorders (including trichotillomania)

	normal circumstances. D. A general pervasive mood of unhappiness or depression. E. A tendency to develop physical symptoms or fears associated with personal or school problems.	
Other Health Impairment (OHI)	Having limited strength, vitality, or alertness, including a heightened alertness to environmental stimuli	▶ Attention deficit hyperactivity disorder ▶ Tourette syndrome ▶ Asthma ▶ Diabetes ▶ Epilepsy ▶ Sickle cell anemia
Autism (AUT)	Exhibits diagnostic impairments consistent with the diagnosis of AUT. Educational performance affected by engagement in repetitive activities and stereotyped movements, resistance to environmental change or change in daily routines, and unusual responses to sensory experiences.	▶ Autism spectrum disorder
Speech/Language	Meets one or more of	▶ Apraxia of speech

Impairment (SLI)	the following criteria: A. Articulation disorder. B. Abnormal voice C. Fluency disorders D. Language disorder	▶ Dysarthria ▶ Aphasia ▶ Stuttering ▶ Phonologic disorder ▶ Muteness ▶ Selective mutism
Intellectual Disability (ID)	Subaverage general intellectual functioning, existing concurrently with deficits in adaptive behavior and manifested during the developmental period	Mild, IQ = 50–70 Moderate, IQ = 35–49 Severe, IQ = 20–34 Profound, IQ < 20
Multiple Disabilities	Combination of disorders causing severe educational needs that they cannot be accommodated in special education programs solely for one of the impairments	Combination of conditions
Deaf–Blindness	Requires severe communication and other developmental and educational needs	
Deafness/Hard of Hearing (DHH)	Severe impairment in processing linguistic information through hearing	
Hearing Impairment	Impairment in hearing (permanent or fluctuating) adversely affects educational	

	performance, but that is not included under the definition of deafness	
Orthopedic Impairment (OI)	Severe OIs that include impairments caused by a congenital anomaly and impairments from other causes	▶ Cerebral palsy ▶ Amputations ▶ Fractures
Traumatic Brain Injury (TBI)	An acquired injury to the brain resulting in total or partial functional disability or psychosocial impairment, or both	
Visual Impairment (VI)	Impairment in vision that, even with correction, adversely affects a child's educational performance	▶ Partial sight ▶ Blindness

1. Giving informed written consent for their child to be evaluated and to seek an independent evaluation if they feel compelled to do so.
2. Access to their child's educational records.
3. Dispute resolution through steps that can include state complaint, mediation, a resolution session, and/or a due process hearing.
4. Explanation of these rights in writing, and in their native language when possible.

Eligibility categories. There are usually 13 special education eligibility categories, with some districts using slightly different terms or titles, but in general, the categories are listed in Table 54.8–8 below. Siperstein et al. (2011) reported that students who qualify for emotional disturbance (ED) represent one of the main categories of youth with psychiatric illnesses, a

group who has been shown to struggle academically over time, despite receiving services.

Key Parts of an IEP. Although all districts are legally required to include certain sections in their IEPs, all districts have their own IEP format. Therefore, IEPs from different school districts vary in how they are organized. Below is a list of some of the key sections found in most, if not all, IEPs and those that may be useful for psychiatrists to review.

1. *Identifying information.* This can include school of attendance, school of residence (if different), pertinent dates such as the date of the current IEP, date of initial entry into special education, and date(s) of subsequent annual meetings and estimated assessments (i.e., triennial assessment).
2. *PLOP.* A description of the student's current level of functioning and/or test results is included.
3. *Goals*. A list of goals with (a) target areas to be addressed by special education services, based on eligibility and identified areas of need, and (b) the person responsible for addressing the intervention (e.g., special or general education teacher, specialist, counselor).
4. *Eligibility/disability category*. Some districts will indicate a "P" for a primary handicapping condition and "S" for a secondary handicapping condition. Some districts only allow one eligibility. See Table 54.8–8 for eligibility categories.
5. *Recommended services* typically include *instructional settings* such as general education classroom, RSP, Special Day Class (SDC), Specially Designed Instruction (SDI), Specialized Academic Instruction (SAI); "push in" (inclusive education with a specialist that assists the student in a general education setting) and "pull out" (student pulled out of the general education class to receive specialized services). The *location of services* can also vary (on a general education campus or specialized campus such as a nonpublic school).
6. *Additional services and related services* include speech and language therapy, occupational therapy, adaptive physical education, assistive technology, and transportation. *Behavioral Intervention Services* can begin with a functional behavioral assessment (FBA) to develop a positive behavioral intervention plan (strategies and supports to address the target behavior). Also potentially included is *Extended*

School Year (ESY) Services, specialized instruction or related services during extended breaks (such as during summer breaks).

7. *Percentage of time* is also recorded, which designates the percent of time within and outside the general education setting. School districts are required to provide a FAPE within the LRE. Therefore, the IEP team may initially recommend what appears to be a "minimal" amount or lower level of intensity of services before trying more intensive services. However, there is no mandate that an IEP team must start with a lower level of services before considering or offering more intensive services.
8. *Other sections***.** Statewide assessments includes a description of any adjustments to statewide testing that the student may receive.

Craig is now a 9-year-old and in third grade. He has continued to struggle in school despite his 504 Plan accommodations he had in second grade. Last year, he continued to be in and out of his seat, knocking items off his desk, and disrupting the whole class, especially when he would talk out of turn. He continues to have challenges with following instructions, and at home, he struggles with sitting down and completing his homework, even with fewer items per page. As a result, he lags behind in reading and writing, but he is doing better at recess with a set of his own preselected activities and awareness to speak to a yard teacher when upset.

Given his continued disruptions in class and parental concerns regarding his academic achievement, his parents submit a letter to his principal, requesting a formal assessment for an IEP. The IEP team met following the school's assessment and determined that he meets a primary eligibility of other health impairment (OHI) due to his ADHD and secondary eligibility of specific learning disability (SLD) in reading. The IEP team recommended he receive SAI as a pullout in a special education class for 300 minutes per week, adjustments to reading materials across subjects (such as allowances for math word problems to be read to him), and continuing those accommodations listed in his 504 Plan (which were incorporated into his IEP).

Private Schools and "Special Education"

Some parents choose to enroll their child in a private school, called a Parentally Placed Private (PPP) school enrollment. Private schools are not required to provide “FAPE,” special education services, or an IEP. However, no school can discriminate against a child with a disability for reasons related to that disability. As such, all schools are responsible to provide supports to ensure that a child with a disability can have equal access to educational opportunities at their campus (e.g., providing ramps for students in wheelchairs). In addition, if they choose, some private schools may develop and work with the LEA to develop a plan for specialized services within the private school. This is known as an Instructional Services Plan or an Individual Services Plan (ISP), which tends to be less comprehensive than an IEP. For example, private schools often agree to give accommodations (e.g., extra time on tests, preferential seating). If a student who is attending a PPP school qualifies for special education services through the IEP process, the services offered are very likely to be offered only at the local public school.

ROLE OF PSYCHIATRISTS IN SCHOOLS

Having a thorough understanding of the school system, the personnel, and resources potentially available to students is an important first step for psychiatrists working with schools. This next section will describe several ways that psychiatrists can apply this knowledge in working with the school system. A *psychiatrist in practice* may play a collaborative role, working with the school as part of a patient’s treatment plan, such as coordinating medication treatment with a school nurse, supporting a teacher with specific behavioral strategies, or as an advocate in supporting a student in accessing needed special education services. *A school psychiatrist* may be an employee of the educational system or of an outside organization such as a community agency or university, who evaluates and treats students referred by the school system such as through a SBHC. A *school consultation* model involves a psychiatrist who serves as a consultant to a classroom, school, or district, and who may provide staff- and administrator-level recommendations for system improvement. Finally, a psychiatrist may be called upon to assist a school during a time of crisis, such as during a disaster or sudden death.

The Role of a Psychiatrist in Coordinating Care With Schools

One important role that a psychiatrist may play with a school system is in collaboration as part of patient care. For example, a student's outpatient psychiatrist may work directly with school staff (following parent or guardian consent) to discuss the impact of their diagnosis on daily functioning including school functioning, help establish and clarify expectations based on a student's PLOP, obtain information from the school to inform treatment plans, and promote effective communication among parent/guardians, school staff, and the clinician.

When working with schools, it is important to understand that schools follow a federal law that regulates how data can be disclosed, the Family Educational Rights and Privacy Act of 1974, (FERPA). Limits of confidentiality must be considered within both the health care system (the Health Insurance Portability and Accountability Act [HIPAA]) and educational system (FERPA). See Table 54.8–9 for comparison between HIPAA and FERPA. After obtaining consent and discussing confidentiality parameters, information such as patient diagnoses, assessment results, pertinent information from clinical interventions, and how medications may impact student school functioning can be shared between school personnel and clinicians.

Psychiatrists may communicate with the school to set up school observations to aid in clinical data collection for their client's treatment plan or provide documentation to the school delineating patient diagnoses. Bidirectional communication is crucial in ensuring positive outcomes for students. Identifying the key school personnel who can support a student in the school setting can be a vital part of the collaborative process and treatment plan. The following is a list of important considerations for the psychiatrist when collaborating with school staff:

- When possible and indicated, convey your understanding that the school personnel are the "experts" in that setting.
- Direct communication (i.e., over the phone, virtual or in-person visit, email) is often an ideal way to maximize exchange of specific ideas and information.
- Be aware that teachers may likely have notable time limitations to meet during the school day, so be gracious and aware of this time limitation.
- Note that sometimes the teachers have already had difficult interactions with the student and/or parent. Thus, be mindful of

entering into potentially tense dynamics or conflicts.

- Ideally, one goal from this communication is to *join* with the teacher (two professionals working collaboratively) and to *clarify* (i.e., get specific information about how the student is doing, what challenges the teacher sees as primary difficulties, what the teacher perceives are contributing to that challenge).
- Ask specific yet *open-ended* questions as much as possible (minimize general yes/no or good/bad questions). Examples of key questions to consider:
  - How is the student doing with independent work?
  - What are the student's social interactions like?
  - How often does the student ask for help?
  - How does the student respond to redirection?
  - How does the student do during less structured times?
  - What has been tried that has helped? (and, if so, how long has it helped?)
  - What has been tried that has not helped?
  - How does the student do with homework, classwork, and tests?
  - Does the student need the information to be repeated?
  - Does the student seem to have difficulty adequately explaining their answers?
  - Does the student seem to give up and say things like, "It doesn't matter"?
  - Are there any stressors (including peer relationships, family, housing, food insecurity, racial stress, immigration, economic, trauma, or loss) you are aware of that may be impacting the student?
  - What are the student's relationships or connections like with staff at the school?
- As informed, psychologically minded, and experienced school personnel might be, they are not medical professionals. A psychiatrist needs to describe *how the patient fits a specific diagnosis* rather than solely stating the diagnosis, and abbreviations should be avoided in verbal and written communication.

Table 54.8–9.
Descriptions of HIPPA and FERPA

	HIPPA	FERPA
Law	Health Insurance Portability and Accountability Act of 1996	Family Educational Rights and Privacy Act of 1974
Source of the Law	U.S. Department of Health and Human Services	U.S. Department of Education
Federal or State Law	Federal	Federal
What Entities Does It Cover	Businesses that focus on health care information (health care providers, health plans, and health care data clearinghouses)	Schools and postsecondary institutions (public and private schools)
What Information Does It Cover	Personally identifiable information about a patient stored by an organization (except that stored by a school)	All information in a student's records (student's grades, academic report cards, transcripts, class schedules, disciplinary records, personal and contact information, family information, and medical care given to a student at school).
Who Does It Cover	All patients of an organization.	Covers both current and previous students of the school.
What it Requires	Requires that covered entities apply appropriate administrative,	Schools give legal guardians control over a student's information until the

	technical, and physical safeguards to protect the privacy of individually identifiable health information (protected health information or PHI), in any form. The only individuals with access should be the patient, those providing care, and people the patient allows to access their PHI, such as family members.	student is 18 years old or starts their postsecondary education. These rights transfer to the student when the student reaches the age of 18 or attends a school beyond the high school level.

Communicating Through a School Letter. A psychiatrist may need to write a letter to their patient's school to best transmit critical psychiatric information, especially to convey recommendations for the school setting. Such letters can also ensure that pertinent data needed to substantiate a recommendation for special education services are provided, without unnecessarily compromising patient or family privacy by overincluding information not immediately relevant to schools. Directives from a nonschool professional for inclusion of a student based on a particular special education category or placement in a specific school may not be seen favorably by school personnel; thus, it is more effective to describe how a child's behavior is consistent with specific special education eligibility criteria and how the student's functional school needs are consistent with the types of services and/or programming required and recommended. In addition, the letter should highlight any prior history of difficulties in school and prior school interventions, including if the patient has received formal special education services through an IEP, supports under a 504 Plan, and/or informal interventions within a general education program. The letter should summarize any history of suspected or identified learning issues, any interventions provided within the school or at home, effect of interventions, and attendance problems. A letter that

documents the student's level of physical activity and any medical conditions is helpful, as this information is required for the IEP. Provide specific information regarding the patient's RTIs, specifying any current problems or stressors, especially those that may affect the patient's functioning at school. Provide specific examples.

When describing the clinical diagnoses and medications, avoid using abbreviations. It may be helpful to acknowledge previous diagnoses which have been given and to explain the rationale for the current diagnoses, as previous IEPs may include information that is inconsistent with the current clinical assessment. Also indicate if mediation will need to be administered at school or not. Finally, for treatment and educational recommendations, specify recommendations for patient's further or continued psychiatric treatment. A description of the patient's behaviors as consistent with special education eligibility criteria (see Eligibility Categories for specific descriptors) can be helpful. Try to describe the child's current or predicted school functioning in ways that school professionals can recognize (1) whether the child can function all or most of the time in a general education classroom with support throughout the week; (2) whether the child will require intensive specialized instruction and teacher supervision throughout most of the day; or (3) whether it appears that the child will require sustained special instruction and therapeutic support both in the classroom and through the entire school day in a setting where trained personnel are available to deal with crises.

Direct Service Models

Direct service models can involve a psychiatrist providing clinical care for students in the school system or in partnership between community organizations and schools to support an array of mental health services in the school or linked to a community agency. SBHCs and comprehensive school mental health systems (CSMHSs) are two models that reflect such models of direct service, providing mental health care to students via a collaboration with community providers. Utilizing telemental health is another avenue by which psychiatric consultation services can be delivered in school settings.

Many schools have mental health supports less comprehensive than in SBHCs or CSMHPs yet provide important components of student mental health. Examples include early identification screening programs, web-based mental health resources, and on-site or video consultations with

off-site mental health clinicians. The model adopted by a school often depends on resources, state law, and student and school needs and priorities.

School-Based Health Centers. SBHCs can improve health equity, often serving underresourced communities to improve access to primary care, mental health, dental care, and other services, with the ultimate goal of supporting health, wellness, and learning. Often located on or near a school campus, the SBHCs help students and families address access to care barriers such as transportation, cost, and parent time off from work. As of 2016 to 2017, the School-Based Health Alliance reported that there were 2,584 SBHCS in the United States, a number that has doubled over the past two decades, according to Love et al. SBHCs integrate into schools, building an interdisciplinary team of providers who deliver prevention and integrated care that effectively meets the complex medical, behavioral, and social health needs of children and adolescents. SBHCs are found across elementary, middle, and HS settings. Research shows that SBHCs significantly improve children and adolescents' access to and utilization of medical, mental health, and substance use services, particularly among underresourced populations.

Comprehensive School Mental Health Programs. CSMHPs provide a full array of tiered services, including universal mental health promotion activities, selective prevention, and indicated early intervention services such as clinical assessment and treatment. CSMHPs rely on collaborative partnerships between school systems and community programs so that school-employed mental health professionals are meaningfully supported by community mental health programs. Increasingly, community mental health staff partner with school-employed mental health staff and educators to provide this more comprehensive integrated model. From a national sample of 1,064 school districts, around 50% reported contractual/formal agreements with community-based agencies to augment service provision. Community mental health program partners may include community mental health centers, hospitals, and universities. The shared goals of these partnerships emphasize improving student behavior, addressing barriers to learning, increasing access to mental health care, and improving student attendance and academic achievement as reported by Hoover et al. (2021).

Telemental Health in Schools. Telemental health for children and adolescents is widely accepted as an effective delivery model of mental health services in a variety of settings, including schools. Improving technology and increased exposure to telehealth allows students, teachers, and administrators greater access to psychiatric consultation. Medication management, evaluation for support services, assistance with diagnostic clarification, and integrative collaboration with school staff can all be completed by utilizing remote services. Several school telemental health programs demonstrated increased efficiency, greater capacity for volume, and increased access to care for children in underserved urban and rural community settings. Several issues to consider include privacy, access to appropriate technology, and the ability to engage students and families. Preliminary studies by Mayworm et al. show the promise of telemental health as a psychiatric consultation delivery model.

School Consultation

One role that a psychiatrist can have with schools is as a school consultant, in response to an identified need or question from the school system (i.e., initiated from a teacher, principal, district leader, etc.). Although the psychiatrist brings a valuable wealth of expertise about mental health, child development, and the interface of the social determinants of health, the consultant should address the school question with an approach of mutual "joining" with the system and school community.

Bostic and Bagnell describe a School Consultation Framework with five components to consider when serving as a consultant in the school:

1. *Who is the consultee, and what are the limits of confidentiality?*
   The consultant must establish procedures to clarify who is appropriate to contact or to evaluate. The consultant may be asked by the school administrator to observe a classroom and consult to staff about questions on how best to work with particular students. When the consultant is asked to meet directly with a student, *the consultant must obtain parental permission before interviewing any student.* Clarifying confidentiality parameters should occur with staff, students, and parents. This includes delineating how and where information is shared (i.e., if clinical information is written and placed in student or personnel records).

2. *What is the consultation question, and what are the expectations of the consultee?*
   Consultants help others define problems and furnish solutions. Though a consultant may ask for specific interventions for a student, the consultee may actually expect or wish a consultant to speak with administrators or recommend removing the student from the consultee's classroom. Consultants should focus on the objective of the question to clarify both the consultee's explicit request and implicit desires. Defining the consultation questions and expectations in collaboration with the consultee is crucial for the success of the consultation, so both agree on the problem and realistic goals for any intervention.
3. *How is the larger system experiencing this problem?*
   A problem will affect school staff members and administrators differently, and each individual may have different expectations for the consultation. The consultant should identify the key stakeholders in a consultation question and answer, including who requested the consultant, who knows about the consultation, who consented to it, and who will be informed about the consultant's findings. Clearly communicating and defining the goals and expectations of the various individuals and entities may increase buy-in of the proposed solution.
4. *What legal or ethical factors should be considered?*
   A variety of legal and ethical factors may impact the identified consultation and question and proposed solutions. Specific laws governing the education system may yield unique opportunities for students, but families and schools may not consider their applicability in a particular case. If the consultation question involves a specific student, especially if a direct interview or evaluation will be completed by a psychiatrist, written consent signed by a parent or guardian is generally required outlining permission for the release of medical information to the school. Parents may decline the psychiatric consultation offered by the school or deny consent for a psychiatrist to consult with school staff about their child. Structural racism, fears about immigration status, concerns about child protective services involvement, and stigma about receiving psychiatric services are all potential barriers to parents obtaining psychiatric treatment. Exploring and understanding parental concerns and fears, stigma, and expectations; providing psychoeducation; and discussing confidentiality limits may promote acceptance of the consultation. However, if parents decline direct contact between a consultant and

their child, a consultant may still address teacher questions without seeing the child. Parents cannot prevent a clinician from observing a student and consulting directly with school staff.

In cases of suspected abuse, the consultant may help guide or assist staff in expressing concerns to an appropriate agency. In acutely dangerous situations such as those in which suicide or homicide arise, the consultant may aid the consultee in facilitating emergent treatment or warning those at risk of being harmed. With any proposed intervention, legal and ethical ramifications must be considered. To increase the likelihood of progress in a difficult situation, consultants should promote clear and collaborative efforts of the student, family, and school.

5. *How does the consultant understand this problem from a biopsychosocial perspective?*

   Using the biopsychosocial model to conceptualize a consultation question can help to expand potential solutions in the school setting. For example, when asked to evaluate a student's "problem behaviors," a psychiatrist needs to consider the biologic and psychological risk and protective factors, ACEs, the family and community's culture and beliefs, peers and school environment and other social stressors, and social and structural determinants of health. Thinking about these various influences may provide a variety of targets for intervening in a particular problem, including at the classroom and teacher level, with the family, in addition to intervening with the student. Given racial and ethnic disparities in the education system, as discussed earlier, the consultant's biopsychosocial perspective is essential.

Consulting to Schools in a Time of Crisis

Whether responding after a student's sudden death by suicide, preventing violence on campus, or supporting a school during a broader community crisis such as the COVID-19 pandemic or the wildfires in the western states, a psychiatrist's consultation can be valuable in supporting the school community before, during, and after recovery from a crisis. Crises involving a school can occur unexpectedly and suddenly, disrupt the entire school community, and interfere with learning. For over 40 years, crisis teams at the regional and school level have disseminated preparedness and crisis management strategies. Funding from the U.S. Department of Education through such mechanisms as Project SERVE (School

Emergency Response to Violence) and Readiness and Emergency Management for K-12 Schools (REMS) grants have supported schools and districts in response to school crises. As mentioned earlier, schoolwide prevention efforts, such as violence prevention programs and early referrals to needed mental health services through schools, can help mitigate the effects of school crises (see Table 54.8–4 for examples of evidence-based school prevention programs). Vona and colleagues described a multitiered system of a support framework for crisis intervention, with strategies before, during, and after a crisis involving a school.

Responding After a Death by Suicide. Given that death by suicide is a major cause of death for young people, schools can play a critical role in disseminating universal suicide prevention strategies. One example of an effective intervention is the Signs of Suicide (SOS) program, which teaches students about the warning SOS risk and how to seek assistance from trained school staff. Promising results of the SOS program indicate improvement in students' attitudes about intervening with peers and themselves when suicidal intent is present and a decreased likelihood of attempting suicide for those receiving the intervention.

Although rare, one of the most devastating incidents a school community can experience is the death by suicide of a student or staff person. In preparation, schools can develop preplanned, postvention procedures that would be implemented following a death by suicide. The main purpose of postvention is to disseminate resources for those emotionally impacted, identify those who may need more intensive services, provide coping strategies, and facilitate a return to the routine of school. Prevention is particularly geared toward those who may be at risk for suicide themselves and in preventing a contagion effect.

Responding to a Threat of Violence. Although mass school shootings such as those at Sandy Hook Elementary School or at Stoneman Douglas High School are rare events, psychiatrists may be called upon to conduct a threat assessment of the potential "risk" that a student may act violently toward others. Weisbrot outlines several key points to understand regarding threat assessment, such as (1) there are often warning signs and others who were made aware of plans of violence, (2) "pushing out" students through out-of-school discipline may not eliminate the threat to a school and can lead to disengagement of a student who may be in need

of supports, and (3) social media posts and writings that threaten harm and violence need to be taken seriously and assessed.

One threat assessment protocol for schools, the Virginia Student Threat Assessment Guidelines (VSTAG), has been found to decrease rates of peer aggression, improve school climate, and decrease out-of-school suspensions detailed by Cornell et al. The VSTAG is a structured assessment technique that rates 19 risk factors for violence as low, medium, or high. When evaluating schools implementing threat assessment techniques, Cornell found that students at “high” risk by formal threat assessment were 12.5 times more likely to attempt violence than those categorized as not at high risk. Males, those in upper ES, those receiving special education services, and disproportionately Black students were more likely to be *referred* for a threat assessment. However, when the structured threat assessment was used, the authors report that no racial or ethnic disparities in out-of-school suspensions nor in determinations of threats deemed “serious” were found, thus demonstrating racial bias in referral. Threats that were more likely to be rated as serious included those involving battery, threats to kill, those involving weapons, and those targeting school administrators.

Responding to Disasters and Other Community-Wide Trauma. One final example of a key consulting role that psychiatrists can have with schools is in supporting efforts by a school or district during and following a natural or man-made disaster or a major catastrophic public health situation such as the COVID-19 pandemic. Community-wide traumatic events such as these can impact the education, health, and well-being of students but often challenge the school staff and administrators in similar ways. In particular, these types of events can reverberate across multiple social determinants of health, exacerbate existing inequities, and disproportionately affect underresourced communities of color. Ijadi-Maghsoodi and colleagues described a unique public–public partnership between a public university and a large, urban county system that had begun creating a countywide infrastructure for web-based trauma and resilience-informed resources prior to the pandemic. This partnership, including psychiatrists and other mental health professionals, collaborated with systems of care such as local school communities in response to the impact of the pandemic, including creating online training for teachers and other school personnel addressing teacher well-being, supporting

students with anxiety, psychological first aid for teachers, and the effects of racism in schools (see learn.wellbeing4la.org/ website for details).

In summary, there are many ways that psychiatrists can interface with schools, reinforcing the educational mission of schools and supporting the development of the whole child, starting with health promotion and prevention. Table 54.8–10 includes a list of website resources that may be useful for psychiatrists as they provide school consultation, school mental health services, and coordinating care with schools for their patients.

54.9 Prevention of Psychiatric Disorders in Children and Adolescents

William R. Beardslee, M.D.

Over the last few decades, there has been a significant expansion of empirical research supporting the efficacy and effectiveness of programs to prevent the onset of mental health and behavioral problems in children and youth. The Institute of Medicine issued reports in 1994 and 2009 on the prevention of mental health disorders, including one specifically on the prevention of mental, emotional, and behavioral disorders in young people. The latter chronicled an expanding body of efficacy and effectiveness trials of preventive interventions, highlighting a deeper understanding of risk and protective factors for mental illness, as well as advances in neuroscientific understanding that underpins preventive intervention.

Since then, a number of relevant new reports from the National Academy of Sciences have been released. For example, the NAS published 2016 a report on parenting and young children ages 0 to 8, which describes programs for families with children in a developmental period that is crucial for lifelong prevention, and the NAS also released a 2019 report on addressing child poverty, which is an essential risk factor to address in the prevention of childhood mental disorders. Most notably, the NAS published in 2019, "Fostering Healthy Mental, Emotional, and Behavioral Development in Children and Youth: A National Agenda," which emphasizes not only the continued strong research supporting preventive interventions since the 2009 prevention report was released but also the importance of widely disseminating and implementing prevention programs so many more children, youth, and families may benefit. The strong empirical support for preventive interventions, as detailed in the Institute of Medicine (IOM) and National Academies of Science (NAS) reports, suggests that it is now time to implement evidence-based programs to decrease the incidence of behavioral, emotional, and mental disorders in children and youth. Practical strategies for correcting problematic developmental trajectories have been identified, and the salient characteristics of target populations have been defined. Rigorous preventive interventions have been implemented across diverse populations and have been shown to be effective. Finally, informative longitudinal studies have followed children into adulthood and demonstrated differential outcomes and the important influences of risk and protective factors at multiple levels.

There are other reasons why the implementation of preventive interventions ought to be pursued with urgency. Prevention Science, at its core, identifies risk factors for the development of future pathology and seeks to reroute that trajectory by increasing protective factors, including adaptive coping skills. Risk factors for child and youth mental health disorders can occur on many levels, ranging from the highly individual, such as genetic predisposition or cognitive style, to broad social and environmental contexts, such as living in a community without adequate access to resources. Some of the most salient risk factors for childhood mental illness, including lack of social connections, having a parent with active mental health challenges, living in poverty, and exposure to chronic stress, are exacerbated by the global COVID-19 pandemic, which at the time of writing, is still devastating most countries around the world. The psychological fallout of this era-defining public health crisis has yet to be seen but is anticipated to be great. Programs to prevent mental health disorders in youth are more important than ever.

Coinciding with the COVID-19 pandemic in the United States was the murder of a Black man, George Floyd, whose highly publicized death was the catalyst for widespread acknowledgment of the problem of racial injustice in this country. Racial inequality is notably intertwined with poor health outcomes, as has been apparent in the way communities of color have been disproportionately affected by COVID-19. Racial disparities and other forms of inequality are important risk factors for mental health disorders and must be addressed to prevent mental health disorders in children and youth.

The study of the prevention of psychiatric disorders offers an unusual opportunity to study mechanisms by which disorder is either expressed or prevented and, as such, is an important part of overall research on development. Preventive intervention research also highlights the influence of broader forces on children's development, such as neighborhood characteristics, inequality, and lack of access to resources.

There has been some reluctance by psychiatrists and other mental health professionals to engage in advocacy for and practice of preventive interventions. This is perhaps because prevention requires a major paradigm shift away from a traditional concentration on diagnosis and treatment of those who are seriously ill and what can be done for the child or adolescent immediately. Prevention asks a different question: what does the child, the family, and even the broader community, need 1, 3, or 5 years down the line in order to ensure the best possible trajectories of healthy development? Although some psychiatrists have been reluctant to embrace developments in preventive intervention, psychiatrists and other mental health professionals are in key positions to identify those children who are at the highest risk for the development of psychiatric disorders and institute appropriate interventions. It is important that the same quality of treatment and prevention services be available to all children and families. This requires being able to implement and disseminate evidence-based prevention and treatment interventions widely.

In addition, as the field of prevention has increased in its understanding of the role of genomic variations in the onset of illness and of the biologic, as well as the psychosocial, context of risk and protective factors for illness, preventive interventions are increasingly conceptualized as including both biologic and environmental components. The full integration of genomics in mental health preventive interventions has been slow because many of the investigators and clinicians who have been involved with the interdisciplinary development of preventive interventions are not familiar with molecular genetics.

In fact, focusing on prevention requires mental health professionals to recognize that mental health and physical health are inseparable and, hence, preventive interventions in one realm often exert a positive effect on another. Successful preventive interventions are inherently interdisciplinary, drawing on findings and insights from psychology, sociology, medicine, adult and child psychiatry, social work, developmental neuroscience, and genetics. Mental, emotional, and behavioral disorders are developmental. That is, they have their onsets at different points across the lifespan, requiring a series of interventions that can be positioned at different points across the lifespan.

The development of a new domain of science can be facilitated by the introduction of new knowledge from related fields that require a major reassessment of previous beliefs. This reassessment can subsequently lead to an integration of these new insights into the traditional core knowledge base of the science.

Every medical specialty is being challenged to consider how genomic variations influence the onset of illnesses as well as the selection of treatments that can be tailored to be maximally effective for each patient. This new orientation provides an opportunity to begin to practice "individualized, personalized medicine." This approach to diagnostic evaluation focuses on biologic vulnerabilities that can be identified in each individual patient. Consequently, preventive interventions, in the same way as therapeutic interventions, will increasingly be conceptualized to include both biologic and environmental components. Consideration of molecular genetics is essential in this regard.

This chapter focuses on preventive interventions for children, youth, and families. The current understanding of prevention research is guided by several key principles. First, it is essential to anchor medical practice in the recognition that access to care, including prevention, is a basic human right and a basic civil right. There is increasing recognition that the practice of medicine involves moral principles, including addressing inequities and disparities. Second, because improving the health of a population is an essential goal, preventive interventions must be delivered widely to all who would benefit. Third, health disparities remain a growing and profound problem, and preventive interventions can help address such disparities. Fourth, awareness of cultural and linguistic competence and the need for cultural humility must guide the adaptation and delivery of preventive interventions. Finally, given the relative maturity of prevention science and emphasis on implementation in recent authoritative national reports, a focus on prevention is timely and necessary.

DEFINITIONS

In an attempt to clarify the research evidence and advance the science of prevention, the 1994 IOM Committee on the Prevention of Mental Disorders recommended the adoption of an alternative definitional taxonomy for mental health interventions: prevention, treatment, and maintenance. The use of the term “preventive intervention” in this classification system was restricted to interventions provided prior to a patient receiving a psychiatric diagnosis. The term “treatment” was reserved for interventions targeted at patients with a diagnosis. The term “maintenance” referred to the care provided to patients with chronic illnesses who had not had remission as a consequence of their primary treatment.

The IOM Committee recommended that preventive interventions, which were previously referred to as primary prevention, be subdivided into three categories based on their targeted population. These categories are universal, selective, and indicated preventive interventions, as described below.

Universal preventive interventions are targeted to the general public or all of a subset thereof (for example, all 6-year-olds in Massachusetts). By definition, universal interventions are provided to individuals who have all levels of risk, including no risk factors at all. A common example of a universal preventive intervention is the fluoridation of a water supply to improve the dental health of a community. Selective preventive interventions are targeted to individuals whose risk of developing mental disorders has been demonstrated to be increased. These identified risk factors may be associated with an imminent onset or with risk at a later point in development. Biologic markers that indicate a predisposition for a mental disorder but are detected in individuals that are free of symptoms represent an example of medical criteria that can be used to initiate a selective preventive intervention. Indicated preventive interventions are targeted to high-risk individuals identified as having detectable signs or symptoms associated with the ultimate development of a mental disorder. Symptoms or signals, which are early warning signs of the future development of a psychiatric illness, may arise years before a patient develops a sufficient number of symptoms to meet the full diagnostic criteria that are required to establish the occurrence of the psychiatric disorder. Indicated preventive interventions can be initiated early in the natural course of a mental disorder when the first signs and symptoms appear.

Sufficient evidence has accumulated to include mental health promotion as a fourth major category of preventive intervention (see Fig. 54.9–1). Mental health promotion aims to enhance an individual’s ability to achieve age-appropriate developmental tasks or developmental competence and to have a positive sense of mastery and well-being, as well as to strengthen an individual’s ability to cope with adversity.

The term risk factor is used in both prevention and treatment, but the implications of risk for these two concepts are different. In prevention, a risk factor must predate the onset of the illness and can be the characteristic that is used to identify a target population. The reduction of risk factors that are both causal and malleable is a goal of preventive interventions. Once the diagnosis of an illness has been made, risk factors that are subsequently identified may be used to guide treatment decisions and provide insight into prognosis. One well-studied example of a risk factor is parental mental illness. Another is undergoing severe loss, such as the death of a family member.

FIGURE 54.9–1. The mental health intervention spectrum for mental disorders. (Reprinted from Mrazek PJ, Haggerty RJ. *Reducing Risks for Mental Disorders: Frontiers for Preventive Intervention Research*. National Academy Press; 1994.)

Protective factors decrease the risk of the onset of mental illness. An individual with one or more protective factors is at a lower risk for the development of a specific psychiatric illness than an individual without the protective factor. Most protective factors are nonspecific and have been perceived to be universally beneficial. Common examples of protective factors include a supportive family environment, adequate family financial resources, and access to high-quality education.

Increasingly, research has highlighted the ways in which biologic and environmental risk and protective factors interact. The study of epigenetics has emphasized the important ways in which environmental influences can profoundly affect gene expression across generations. Exploration of gene–environment correlations and gene–environment interactions offers important ways to study mechanisms.

EXAMPLES OF RESEARCH ON THE PREVENTION OF MENTAL HEALTH PROBLEMS IN YOUTH

Figure 54.9–2 presents a schematic representation of the different interventions that are likely to be effective across the span of childhood. Early in life, interventions for high-risk families (e.g., home visitation, center-based care) have been shown to be valuable. As children enter school, both academic enrichment activities and social skills training are valuable, as are various kinds of parent training. As youngsters enter adolescence, there is evidence that some programs can cut the incidence of major depression, and others can substantially reduce substance abuse.

Across the bottom of the diagram, three types of factors that occur across the span of childhood and adolescence are emphasized: the importance of addressing families in adversity; the importance of interventions that strengthen the fabric of schools and communities; and policy interventions such as those that provide ready access to preventive and treatment services, and that support families. A central theme in the 2009 IOM report is that preventive interventions can reduce or minimize toxic biologic and psychological processes, richly reinforce self-regulatory prosocial behavior, teach prosocial skills and values, and foster acceptance. What follows is a discussion of a selection of preventive interventions that are particularly relevant to psychiatric practice and which illustrate general points about prevention approaches. Rather than trying to comprehensively review all prevention approaches, the focus is on preventive interventions that are particularly relevant to psychiatric practice and that illustrate more general points about prevention approaches. First is a review of community-level interventions for child maltreatment prevention, from which useful lessons about community-level risk factors and prevention can be drawn. Next, this chapter reviews interventions for families that have experienced specific types of adversity. This is followed by a discussion of interventions to prevent externalizing behaviors, depression, psychosis, and substance abuse.

COMMUNITY-LEVEL PREVENTIVE INTERVENTIONS FOR CHILD MALTREATMENT

Maltreatment of children is a significant public health issue and a potent risk factor for later psychiatric illness, including post-traumatic stress disorder, substance misuse, depression, and suicide attempts. Factors associated with child maltreatment can be conceptualized at the individual, family, and community levels. Due to structural inequality in American society, some family-level risk factors, including the experience of food insecurity, unemployment, and poverty, are apparent at the community level, as well. Communities with high levels of unemployment and high rates of poverty are associated with higher rates of child maltreatment, and collective efficacy and social network size in these communities are associated with lower rates of child maltreatment. Reducing inequality and increasing support within a community are, therefore, ideal targets to prevent child maltreatment at the community level. Addressing these risk factors may have additional benefits in reducing mental health problems in children, as poverty, child maltreatment, and other related manifestations of disadvantage are significantly linked to child mental health. Efforts to improve poverty, food insecurity, and unemployment are particularly important in the wake of the COVID-19 pandemic, which has exacerbated existing problems in these areas and weakened protective factors, such as social cohesion and social network ties within a community.

FIGURE 54.9–2. Interventions and their targeted developmental stages.

An example of a community-wide prevention program is the Strong Communities for Children initiative. This program utilized outreach workers to mobilize volunteers and community organizations to form their own local action plan to “keep kids safe” and used resources acquired through the outreach campaign to help build social support networks for parents and provide direct assistance to in-need families. This program was successful in both high- and low-resource communities, with increased social support, collective efficacy, parental efficacy, and child safety at home, and decreased parental stress and child maltreatment, compared to communities that did not implement the Strong Communities program. This program is notable for changing social norms, a formidable feat, and for creating lasting positive change with a small starting budget and a team of a few paid workers. A replication study in Israel is currently underway.

Preventive Interventions Targeting Family Adversity

Examples of effective parenting programs in risk situations are the effective programs designed and implemented by Wolchik, Sandler, and colleagues at the University of Arizona. These programs are the New Beginnings Program (NBP) for families facing divorce and the Family Bereavement Program (FBP) for families facing bereavement.

The NBP is a group-delivered program designed to improve parenting quality and decrease child exposure to parental conflict, two factors associated with child outcomes after divorce. The program has been studied in two efficacy and one effectiveness trial (the former of which tested the program in a research setting, and the latter of which tested the program while implemented in real community contexts).

In the efficacy trials, the program was first found to be associated with improved parenting and reduced child mental health problems post-test, compared to a waitlist condition. The second efficacy trial used a randomized, controlled clinical trial design to compare the NBP parenting sessions alone, the parenting sessions with an additional child-delivered coping program, and a literature control group that provided mothers with books about child adjustment to divorce. The researchers found no significant differences between the mother-only and mother-and-child interventions, but both conditions of the NBP were associated with significant gains in parenting and reductions in child externalizing problems post-test. The results of 6- and 15-year follow-up studies revealed that the young adults who received either version of the NBP intervention were less likely to have mental health problems, substance use issues, high-risk sexual behavior, or involvement in the criminal justice system and were more likely to experience improvements in self-esteem and grade point average. The NBP was then tested in a randomized effectiveness trial, where the program was implemented through family courts in four countries. Strengthened parenting and reduced child mental health problems were associated with the NBP compared to the active control post-test and after 10 months. Non-Hispanic White families experienced benefits with the program, but this was not true, on average, for Hispanic families, emphasizing a need for culturally appropriate adaptation.

For families struggling with the loss of a parent, Sandler and colleagues developed the FBP. With a similar structure to the NBP, FBP provides caregivers and children with 12 group sessions, four of which include shared activities for both the caregiver and the child or adolescent. The control group received three books discussing child, adolescent, and adult grief over the course of 3 months. A 6-year follow-up indicated that effective parenting, operationally defined as caregiver warmth, acceptance, and consistent discipline, had increased in families receiving the FBP.

The results of the NBP and FBP programs demonstrate that relatively brief interventions have the potential for long-term sustained effects in families that have experienced a major stressor, such as divorce or the death of a parent. More generally, interventions that are highly specific and increase the capacity of parents to parent effectively have a strong knowledge base.

Preventions Targeting Youth Externalizing Behaviors

Webster-Stratton originally developed a treatment intervention for young children with conduct disorder and their families. This intervention, The Incredible Years Parenting Series, includes therapist-led group discussion that emphasizes parent training. Parents view standardized videotapes that present parents and their children engaging in both desirable and problematic interactions. Findings indicate that this program improved parent and child interactions and significantly reduced the children's conduct problems and increased cooperation, compared to a control group. This treatment was later modified to become an indicated preventive intervention for children with early symptoms of conduct disorder but who did not meet diagnostic criteria. More recently, this intervention was modified further to allow it to be used as a selective intervention for children enrolled in Head Start programs who were all considered to be at high risk but were not symptomatic at the time of the intervention. Teachers in the active intervention group used more positive classroom management techniques, and their students had fewer conduct problems and more emotion regulation than control students. Since then, this program has been widely disseminated.

Poduska, Kellam, and colleagues document the long-term effects of a universal classroom-based intervention with children during their first- and second-grade years. Their intervention, the Good Behavior Game (GBG), is directed at improving the classroom management skills of teachers, socializing children to become better students, and reducing aggressive and disruptive behavior. A randomized, controlled trial was carried out in 40 first-grade classrooms in 18 elementary schools in Baltimore, Maryland. Significant positive results were found, although these outcomes varied by gender, baseline level of risk, and cohort. Generally, the children with the highest level of risk from the fall of the

first grade through the seventh grade benefited more than other children who were assessed to be at lower risk. The most aggressive boys in first grade who received the GBG were the children who demonstrated the greatest reduction in aggressive behavior over the course of first through seventh grades. These boys were less likely to develop antisocial personality disorder as an adult and had a 50% reduction in lifetime illicit drug use. These results highlight the benefit of early behavioral interventions.

Preventive Interventions Targeting Depressive Disorders

Quite fruitful work has been done in the area of the prevention of depression. There are both specific risk factors for depression, such as having a parent with depression, a depressogenic cognitive style, or a prior depressive episode, and nonspecific risk factors, such as poverty, exposure to violence, and social isolation. Research suggests that children who have either specific or nonspecific risk factors are at increased risk for the disorder and that interventions targeting these risk factors may prevent the onset of depressive symptoms and disorders. Recent meta-analyses support the value of preventive intervention approaches targeting depression and their efficacy in preventing episodes of major depression in both adults and youth.

An example of a strong depression prevention program is the Coping with Depression Course (CWD), developed by Lewinsohn in the mid-1970s. After finding much success in the reduction of depressive symptoms in adults who received this prevention and treatment course, Clarke and colleagues adapted the CWD for use with an indicated sample of adolescents and demonstrated the prevention of unipolar depressive disorder. Later, Clarke and colleagues used the CWD course with adolescents with subsyndromal depressive symptoms and parents experiencing depression. Only 9.3% of these adolescents went on to develop a major depressive disorder, compared to 28% of adolescents who were at similar risk but did not receive preventive intervention. Garber and colleagues undertook a four-site replication of this study, again using adolescents at double risk because their parents had experienced major depression and they themselves either had prior depression and/or symptoms of depression. This study demonstrated a strong and sustained effect of the prevention program. At a 33-month follow-up, adolescents in the group cognitive-behavioral prevention program had significantly fewer onsets of depressive episodes compared to those in the comparison group; however, for adolescents whose parents were currently depressed at the time of enrollment, the average rate of onset did not differ statistically between the intervention and nonintervention groups. Brent and colleagues found at a 6-year follow-up, adjusting for current parental depression at enrollment, adolescents in the cognitive behavioral prevention program still had a lower incidence of depression. The effect of the program was strongest against a new onset of depression in the first nine months after enrollment in the program, but gains were maintained through several years of follow-up.

A second example of a preventive intervention targeting youth depression was developed by Compas and colleagues, who explored preventive interventions for children with depressed parents using a family group cognitive-behavioral (FGCB) strategy. Children between the ages of 9 and 15 who had a parent with a history of major depressive disorder participated, along with their parents, in either the 12-session FGCB intervention or received three sets of written materials about depression in the mail every 8 weeks. Eighteen and 24-month follow-ups demonstrated that the FGCB preventive intervention significantly reduced the onset of the children's depressive episodes for up to 2 years after the intervention ended compared to the control group. Additionally, this preventive intervention reduced the children's internalizing and externalizing symptoms. Compas and colleagues found a mediating role of parental behavior, specifically parental guilt induction. Similar to Sandler and colleagues' FBP, it was found that a reduction in negative parental behaviors improved family functioning; One year after the end of the intervention, reductions in parental guilt induction were associated with significantly lower internalizing symptoms and lower levels of negative cognitive style in the youth participating in the FGCB program.

An illustration of a preventive intervention that reduces the risk associated with depression in parents is the Preventive Intervention Project, which targets relatively healthy children aged between 8 and 15 years who have a biologic parent with a clinical mood disorder. Two manual-based programs were tested. The first intervention consisted of a two-session group lecture format for the depressed parents;

the second intervention used a clinician-facilitated format consisting of 6 to 11 sessions, including separate meetings with parents and children, as well as a family meeting. In both formats, psychoeducational information about mood disorders was provided, and parents were helped to better support the initiatives of their children. In the clinician-facilitated format, efforts were made to link information about mood disorders to the depressive illness experiences of the parents in the intervention. At the 4.5-year follow-up, parents who received either the lecture format or the clinician-facilitated intervention reported improvements in their behaviors and attitudes regarding their children, and the internalizing symptom scores of the children who had received either of the interventions improved when they were assessed at follow-up. Moreover, there was a significant relationship between the number of positive changes that the parents reported in their behaviors and attitudes regarding their children and the improved understanding of the course and treatment of mood disorders that was achieved by their children. This family-based approach is particularly applicable to implementation in a clinical setting, which could be accomplished by adding a relatively small number of additional sessions to the standard treatment of those adult patients with mood disorders who have children in the therapeutic range. Beardslee's family-based depression prevention approach has been adapted successfully for use in different ethnic and cultural groups, both in the United States and around the world.

Another area with very promising prevention strategies is that of intervention for mothers with young children. One example of this class of intervention, Silverstein and colleagues used a problem-solving educational intervention with mothers in Head Start with depressive symptomatology. In a randomized clinical trial, mothers with lower-level baseline depressive symptoms who received the educational program had fewer depressive symptom elevations than mothers with lower-level baseline depressive symptoms who did not receive the program. No effect was found, however, for mothers whose level of depressive symptoms was higher at baseline.

Prevention of Early-Onset Psychosis

Several investigators have focused on children and youth at high risk for the development of schizophrenia and the prodromal symptoms of psychosis. The goal of much of this work has been to identify risk factors or biologic markers that could inform studies designed to prevent the onset of an initial episode of psychosis or to optimally treat a patient at the very earliest point in the initial onset of the illness. Although these intervention strategies all have been multidimensional, one critical aspect of these interventions is the prudent use of antipsychotic medications. For example, McGorry and colleagues gave young first-episode psychosis patients a low dose of risperidone therapy to treat their early symptoms; results revealed that risperidone was very effective in reducing psychotic symptoms and improved the individual's quality of life, treatment experience, and adherence.

In the United States, with efforts to reduce the duration of untreated psychosis (DUP) between early symptoms to engagement in treatment, Srihari, McGlashan, and colleagues have developed the Specialized Treatment Early in Psychosis: Early Detection (STEP-ED) program, an adaptation of McGlashan and Johannessen's Early Treatment and Intervention in Psychosis (TIPS) study. The TIPS Early Detection in Psychosis Study, conducted in Norway and Denmark, provided the general public, schools, and Early Detection teams with information about prodromal, first-episode schizophrenia symptoms. This program shortened the DUP by an average of 1.5 years. The STEP-ED researchers have been conducting a trial of the TIPS-adapted model in the United States since 2014 and hope to improve presentation, engagement, and early outcomes through the reduction of DUP. Another way to prevent the onset of psychosis, other than reducing the DUP, is to detect symptoms early and intervene to prevent psychosis. McFarlane and colleagues created and implemented the Family-aided Assertive Community Treatment (FACT) program and conducted a 2-year follow-up study. Adolescents were assigned to one of three groups, clinically low-risk (CLR), clinically high-risk (CHR), or very early first-episode psychosis (EFEP), based on their score on the Positive Symptom Scale of the Prodromal Symptom Scale. Individuals designated to the CHR and EFEP groups received FACT, which incorporates a variety of interventions, including psychoeducational multifamily group (PMFG) therapy, elements of assertive community treatment, supported education and employment, and psychotropic medication. Those in the CLR group received community care, which consisted of monthly monitoring

through phone assessments. Results demonstrated that 2 years after treatment, FACT was effective in reducing symptoms, whether positive, negative, disorganized, or general symptoms. Participants in the FACT condition, who were at risk or experiencing very early psychosis, also had improved Global Assessment of Functioning scores, work and school participation, and global outcomes. The findings suggest that preventive interventions can be effective in preventing the onset or progression of psychosis and that family interventions are extremely important in the treatment and prevention of psychotic symptoms. Given consistent evidence that demonstrates that subsequent episodes of psychosis are associated with a less optimistic prognosis and probable neurodegenerative cerebral changes, the development of preventive interventions for schizophrenia and bipolar disorder is a high public health priority. The identification of children who are at risk as a result of carrying susceptibility genes for these disorders is a research strategy that has not yet been systematically implemented.

Prevention of Substance Abuse Disorders

Many researchers have developed preventive intervention programs for substance abuse in children and in adolescents. Botvin and Eng developed a universal prevention program, life skills training (LST), which has been shown to be quite successful in reducing substance abuse in middle and high school students. During 30 lessons over the course of 3 years, students participating in LST were taught skills, information, and attitudes to resist temptations to use substances in adolescence. In dozens of efficacy trials, LST has reduced cigarette smoking, alcohol consumption, methamphetamine usage, and marijuana use by as much as 80% compared to control groups. Similar results have been found with minority group students. Some LST trials have discovered that elementary school programs have positive long-term effects. The LST intervention's effects have been maintained up to 12 years after the completion of the program. A booster program designed for LST has demonstrated maintenance of and even bolstered the original intervention's effects.

Likewise, Kumpfer and colleagues developed the Strengthening Families Program: for parents of youth 10 to 14 (SFP). This 14-week, family-focused substance abuse prevention program has demonstrated significantly greater reduction rates of substance use in high school students compared to school-based alcohol prevention programs. SFP also has generated many significant positive effects on family functioning and parent-child relationships. SFP has been successfully adapted for many cultural groups, such as Hispanic, African American, Native American, and Asian Pacific Islander families, and has been widely adopted internationally.

Now that children and adolescents have greater access to mobile devices and computers, Internet-based prevention programs have become increasingly popular. In a meta-analysis by Champion and colleagues, seven school-based substance abuse prevention programs delivered through either the Internet or CD-ROMs, including Consider This, ASPIRE, CLIMATE, Head On, and several other programs, were assessed for their effectiveness in preventing alcohol, tobacco, and cannabis use in adolescents. Five of the seven programs were found to reduce drug and alcohol consumption in the follow-ups, which were completed between 6 and 34 months after the cessation of the program. Although the reviewers discuss how the effect sizes were modest, the reduction of substance use after the implementation of Internet and computer prevention programs provides evidence for how these new methods for disseminating interventions have the potential to be very effective and can be used by individuals in a variety of urban and rural settings.

ISSUES IN THE PREVENTION OF MENTAL ILLNESS

Barriers to Providing Clinical Preventive Interventions

Despite the very strong scientific evidence about the benefits of preventive interventions, there are relatively few psychiatrists who are involved in the administration of evidence-based preventive interventions. There appear to be three major barriers to the adoption of these interventions. First, there is no clinical infrastructure for delivering preventive and early intervention services. The provision of services to large numbers of children requires the coordination of multiple agencies, disciplines, and service delivery systems. Without a well-developed and accessible clinical infrastructure, most families are unable to receive preventive services even where treatment services exist. A second barrier to the

provision of early clinical intervention is that there are insufficient resources to pay for these services. The lack of reimbursement through either public payment plans such as Medicaid or by private insurers prevents most psychiatrists and other mental health clinicians from providing preventive services. A third barrier to initiating early interventions is the absence of an academic curriculum designed to train general and child psychiatrists in the assessment of children who demonstrate very early symptoms of psychiatric disorders. Information and training in available evidence-based, early-intervention, manual-based protocols are not routinely provided to psychiatry residents.

There is a significant and growing public health awareness of the disparity between the recognition of the need for both prevention and early intervention services and the absence of a plan for developing an efficient and effective systematic delivery of such services. An immediate goal should be the development of new clinical initiatives that would begin to provide appropriate services to the highest-risk populations.

Economic Issues

Ideally, psychiatric administrators should take responsibility for the management and funding of preventive interventions. However, to achieve this goal, new mechanisms to reimburse the provision of preventive services within the mental health field must be created. One issue will be a revision of diagnostic and billing codes to define specific evidence-based prevention services and to ensure payment for the delivery of these services. The standard medical reference for procedures that will be paid for by insurance companies is the Current Procedural Terminology (CPT) codes of the American Medical Association. CPT codes have been designed to define virtually all clinical procedures that have been accepted as legitimate services. Unfortunately, payment for many of the current CPT codes that could be used to support services designed to prevent psychiatric illness has not been classified as traditional psychiatric interventions that are covered by medical insurance. Furthermore, even if insurance policies were to change and begin to make payments for preventive interventions that were authorized, many of the available CPT codes that are related to prevention-related services have been assigned very low relative value units (RVUs). When a CPT code is given a low RVU assignment, payment for the service will be quite low. Although a common compendium of CPT codes is established for all medical subspecialties, virtually no mental health specialists are able to use available codes for risk reduction and anticipatory guidance because of the difficulties that exist in receiving adequate payment. This needs to change, and appropriate provision for payment needs to be made.

Another administrative problem is that payment for psychiatric services has traditionally required that a psychiatric diagnosis be identified for the patient prior to the clinician receiving payment. By definition, children who are receiving preventive services do not have a psychiatric diagnosis that would be included in the 10th or 11th revision of the International Statistical Classification of Diseases and Related Health Problems (ICD-10 or ICD-11) at the time of the provision of a preventive intervention. Instead, these children may have problems that could be classified using a “V code.” Unfortunately, many insurance companies make the argument that the services provided to deal with problems that are categorized using V codes are not medically necessary. Therefore, these services are not eligible for medical insurance, and these payers deny payment to any psychiatric patients that have not been assigned a traditional Axis I diagnosis. Newer payment approaches that emphasize payment for covered lives offer considerable promise for funding prevention.

Training Issues

The next generation of psychiatric clinicians must be better trained in the science of the prevention of mental disorders. Much needs to be done to achieve this goal. For evidence-based prevention programs to be implemented on a national scale, it is absolutely necessary that clinicians be appropriately trained to provide these specified interventions. Supervised training experiences to provide trainees with appropriate skills will have to be incorporated into the traditional residency curriculum as one of the “core competencies” that must be developed during residency training. The ability to identify children at risk and deliver evidence-based preventive interventions must become an academic expectation of training. However, for this goal to be achieved, the importance of preventive interventions will need to become more explicitly stated in the residency training requirements that are available to provide

guidance to the design of clinical training programs. Ultimately, board certification and recertification must require the demonstration of clinically relevant applications of preventive interventions as part of the core knowledge base that is examined.

Research Issues

Continuing a strong research program in prevention is essential. As noted, it provides one of the best ways of understanding the mechanisms by which either disorder is expressed, or the balance of risk and protective factors is altered, and disorders are prevented. Research investigators should be encouraged to assess multiple risk factors and multiple outcomes crossing the domains of mental health, substance abuse, physical health, and learning disorders. Priority should be given to sequential preventive interventions that can strategically target high-risk children prenatally, in infancy, in early childhood, in elementary school, during the teenage years, and finally, in young adulthood. In addition, research efforts must consider and track high-risk youth and the different interventions they need at different stages (e.g., high-quality child care, daycare, and early education followed by access to high-quality schools). Finally, preventive intervention studies must aim to assess the mechanisms by which such interventions work. Greater attention to genetics, epigenetics, and gene–environment interactions is warranted as this work goes forward.

The following case example illustrates how newer pharmacogenomic approaches offer great promise. George was 16 years old when he started experiencing depressive symptoms after his girlfriend decided to end their relationship. George had a family history of bipolar disorder, and by using pharmacogenomic testing, a clinician familiar with preventive approaches to mental illness was able to treat him safely.

When George presented to the clinician, he reported sleeping for more than 10 hours a night, rarely leaving his home, and having little interaction with his friends. His maternal uncle had struggled with bipolar disorder for many years. Although his parents had no history of mania or hypomania, both his mother and his father had been successfully treated with selective serotonin reuptake inhibitors for episodes of major depressive disorder.

A series of eight outpatient cognitive-behavior therapy sessions targeting his depressive symptoms proved to be minimally effective. Subsequently, George was placed on a dose of 20 mg of fluoxetine per day while being followed closely for the possible emergence of suicidal ideation. Within 2 weeks, he reported that he needed to sleep for only 1 or 2 hours each night and was experiencing marked surges of energy.

His psychiatrist became concerned that George was becoming hypomanic and was at risk of developing bipolar disorder. Prior to selecting another medication to manage these new symptoms, he ordered pharmacogenomic testing of a panel of genes with the goal of minimizing additional adverse reactions. George was determined to have a normal genotype of his cytochrome P450 2C19 gene, indicating that he could effectively metabolize 2C19 substrate medications. However, his cytochrome P450 2D6 and 2C9 genotypes documented that he was a poor metabolizer of both 2D6 and 2C9 substrate medications. In addition, his serotonin transporter genotype was associated with an increased risk for the onset of depression, and his GRIK3 genotype indicated that he was at an increased risk for the development of bipolar disorder.

George was started on a low dose of lithium, and the fluoxetine that he had been receiving was discontinued. After 2 months of outpatient treatment on lithium, he complained of having less energy and had become very discouraged about his ability to complete his planned applications to attend college. Given the results of his pharmacogenomic genotype testing, he was placed on a dose of 10 mg of escitalopram per day in addition to the lithium. After 4 weeks, he reported feeling much better and had not experienced a recurrence of hypomanic symptoms. He was subsequently able to complete his college applications without further difficulty.

George was maintained on lithium and escitalopram throughout his first year at college. During the summer before the beginning of his second year away at school, both medications were discontinued, and he remained euthymic.

Although fluoxetine is an effective and economical treatment for major depressive disorder in adolescents, fluoxetine is primarily a 2D6 substrate medication. Of note, the cytochrome P450 2C9 enzyme plays a secondary role in the metabolism of fluoxetine. Patients with both of these pathways compromised are at very high risk of developing side effects while taking standard doses of fluoxetine.

The clinical observation that manic activation may occur in depressed adolescents when treated with selective serotonin reuptake inhibitors has been frequently reported. However, clinicians have concluded that the benefits of treating many depressed adolescent patients with antidepressant medications have outweighed the risks of activating bipolar symptoms in the relatively few adolescent patients who develop manic symptoms when treated with these medications. Fortunately, it is now possible to identify genetic risk factors for activation and offer alternative medications. Managing the treatment of depression in a manner that minimizes activation can be conceptualized as an example of an indicated preventive intervention designed to prevent the onset of a first full episode of bipolar disorder. More generally, this case illustrates a way of thinking that is likely to be more useful in both treatment and prevention going forward.

LOOKING FORWARD TO THE FUTURE

There is a debate in the prevention field regarding the cost–benefit ratio for universal interventions. Some universal prevention studies have been shown to provide the most benefits to children who are at the highest risk. In contrast, many children who are at minimal risk do not benefit at all. This pattern of response supports the view that early screening and interventions targeted to help populations with specific high risks, including early prodromal symptoms, could be considered for some disorders. Integrating the new, rapidly evolving personalized medicine approaches will become increasingly important in the future, as well as understanding how to effectively disseminate widely those prevention approaches that are strongly supported empirically.

As there are potent nonspecific risk factors for multiple disorders (risk factors including poverty and exposure to violence), more attention also needs to be devoted to addressing these public health drivers. The IOM recognized this in emphasizing the role of poverty, stating in their 2009 report they were "persuaded that the future mental health of the nation depends crucially on how, collectively, the costly legacy of poverty is dealt with."

It is now possible to implement evidence-based selective and indicated preventive interventions to minimize risk factors associated with the onset of mental disorders. Broader implementation of these interventions for children and adolescents at risk for depression, conduct disorder, and psychosis will require continued political commitment. Given the anticipated psychological aftermath of the COVID-19 pandemic and the growing awareness of the terrible inequities in our society, the importance of implementing preventive interventions is greater than ever.

ACKNOWLEDGMENTS

This chapter is dedicated to the extraordinary work and life of Dr. David Mrazek, who passed on May 6, 2013, and his collaborator and wife, Dr. Patricia Mrazek. They were coauthors with me on earlier editions of this chapter. Ms. Anne Diehl, MPH, a freelance researcher, contributed a great deal to this chapter by reviewing the literature, discussing key issues, and assisting with the editing and submission process.

54.10 Child Mental Health Services Research

Bonnie T. Zima, M.D., M.P.H., and Regina Bussing, M.D., M.S.H.S.

Child mental health services research integrates advances in child psychiatric care and research methods to examine unmet needs for mental health services, service use across care sectors, and quality of care along the care continuum (e.g., prevention, early detection, assessment, treatment, follow-up). To meet this challenge, health services research uses a compendium of quantitative and qualitative research methodologies that bring together expertise from multiple medical specialties and disciplines (i.e., social sciences, biostatistics, economics, health policy, computer science), community partners, and consumers. For child mental health services research, the breadth of expertise also includes the perspectives of primary caregivers, teachers, social workers, pediatric primary care providers, probation officers, and child advocates.

Child mental health services research addresses a wide variety of questions to generate the evidence needed to improve care in real-world treatment settings. Early stages of child mental health services research typically describe access to care and its predictors, the extent of unmet need for child mental health services, and the prevalence of broad indicators of quality of care (e.g., continuity of care, filled medication prescriptions). Findings at this stage are typically a wake-up call alerting others of the potential magnitude of a problem in child mental health care, such as prescription rates of atypical antipsychotic medication among very young children. Some studies may also explore how mutable factors at several levels (i.e., system, community, family, child) independently predict who receives care

while adjusting for the clinical need to identify target areas for reducing disparities in access to or quality of care. Examples of questions driving such research are: Among children with a psychiatric disorder and impairment, who is more likely to access care? What are the potential mechanisms underlying disparities in child mental health care?

In addition, child mental health services research focuses on the delivery of care. In real-world treatment settings, implementation of an evidence-based practice (i.e., uptake, engagement, continuity, sustainability) likely varies, and predictors of implementation stages can identify barriers and facilitators for more large-scale use. An example research question is, how should evidence-based practices be modified for use in community-based settings to improve their effectiveness? Following decades of research on integrated care models, mostly for adult depression, there also continues to be a need for research to guide how to integrate, deliver, and sustain the provision of mental health care in pediatric primary care. With advances in technology-enabled care (e.g., telehealth, app-supported evidence-based therapies, feedback from real-time sensor data, clinical decision support tools), research is needed to adapt these advances to improve access to child mental health care, quality of care, and equity.

With the rise in the number of quality measures, child mental health services research also examines the gap between recommended and usual care and their predictors to identify disparities in care. Improving the quality of child mental health care is of public health significance because child psychiatric disorders are prevalent, disabling, and costly. The use of established efficacious treatments in community settings is typically low, and the underuse of recommended care may negatively impact a child's developmental trajectory. Examples of questions common to quality of care research are: What proportion of children receive care that would pass a national quality measure? What organizational, provider, family, or child characteristics are predictive of acceptable care? Is adherence to national quality measures for child mental health care associated with improved outcomes? And if so, for whom and at what cost? To date, the majority of research examining adherence to quality measures is based on administrative data, such as claims or hospital discharge at the individual level or aggregate data at the health plan level, which have their limitations.

Nevertheless, significant progress in data coordination of electronic health record (EHR) data across large healthcare systems using common data elements has been made, providing new opportunities to leverage very large datasets to address questions relevant to child mental health services research. The rapidly evolving field of data science, defined by the National Institute of Health as "the interdisciplinary field of inquiry in which quantitative and analytical approaches, processes and systems are developed and used to extract knowledge and insights from increasingly large and/or complex sets of data," provides the methods to integrate EHR-derived data with other relevant data sources, addressing biologic and lifestyle domains. The contents of EHRs may include structured data like vital signs, medication timing and dosing, procedures, and diagnoses, which is compatible with computing algorithms. EHRs also contain unstructured text and images that will require new analytical tools like natural language processing tools to become analyzable. Other data science sources are biologic, such a genomic, proteomic, or metabolomic data, and lifestyle data, such as can be derived from mobile devices and self-tracking tools. Although challenges to coordinate EHR data across different healthcare systems are prominent, advances in data science will fundamentally contribute to the next generation of mental health services research.

In addition to the enriched scope and methods afforded by expanding EHR and data science, child mental health services research also intersects with the rapidly maturing field of implementation science. Implementation science has been defined as the scientific study of methods to promote the systematic uptake of research findings and other evidence-based practices into routine practices, to improve the quality and effectiveness of health services. The emphasis is placed on fitting mental health interventions in the real-world service systems and examines variables at various levels, including patients (e.g., depression remission rates), providers (rates and quality of evidence-based depression treatment), organizations (e.g., collaborative care designs, EPIC workflows supporting evidence-based treatment protocols), and policy (e.g., mental health insurance coverage policies). And finally, the disparate general and mental health outcomes associated with the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and the COVID-19 pandemic have highlighted the urgency of advancing disparities research from documenting disparities and their predictors to the development of population-

level interventions that can be rapidly implemented in real-world treatment settings. Child mental health services researchers will be called upon to continue the core tradition of integrating expertise from these specialties and disciplines with input from community partners, families, and youth to provide the scientific undergirding to improve access to equitable, high-quality child and adolescent mental health care.

As an introduction to child mental health services research, this section briefly describes the historical context that shaped the field, including landmark national reports, the establishment of key professional organizations, research studies, and health policies. Access to care is described as a separate component of quality, following Avedis Donabedian's conceptualization of quality, which argues that accessibility is a separate yet influential component of quality. This is followed by an overview of a well-established model of quality of care with examples of quality of care research and national quality measures, an introduction to a three-tiered conceptual model to organize advances in measurement-based care (MBC), and areas for future research. To supplement, the reader is encouraged to read cross-referenced sections and chapters to stimulate further inquiry about the prevalence of child psychiatric disorders, healthcare disparities, dissemination, and implementation science, MBC, and technologic advances in mental healthcare delivery, health information, and computational methods.

HISTORICAL CONTEXT

Table 54.10–1 summarizes the historical context of child mental health services research by landmark events and their significance. The first half of the twentieth century was characterized by increasing federal initiatives that raised public awareness of the need to improve the quality of life for children, such as a child's right to preventive health care, safe working conditions, and a free public education, particularly for those identified as seriously emotionally disturbed or handicapped. After the midcentury mark, child psychiatry was identified as a relatively new medical subspecialty, with its first national professional organization established in 1953 and board certification in 1959. During the next three decades, landmark epidemiologic studies provided some of the first prevalence estimates of child mental health problems in community-based populations and their correlates. These studies were significant because the findings raised awareness of the substantial proportion of children who met criteria for a psychiatric disorder and the need to improve early detection and access to child mental health services.

During the 1980s, the pediatric community identified psychosocial conditions, such as poverty, family dysfunction, and child exposure to traumatic events, as part of the new morbidity of child health that included learning and behavioral disorders. The conceptualization of child health was further broadened in the following decade to include attention deficit/hyperactivity disorder (ADHD) within the definition of chronic conditions among children with special healthcare needs. Within this same time period, a philosophy for a system of care for children was operationalized. The two core values were that care should be child-centered and community-based. These values were later echoed a decade later in the guiding principles underlying the pediatric medical home. Remarkably, these principles share similar dimensions of "quality" as identified in the "articles of faith" underlying good medical care by R. I. Lee and L. W. Jones more than 50 years earlier. Nevertheless, sustained articulation of these values and principles is important because it provides a relatively consistent framework from which programs serving children with mental health problems can plan and implement new models of care for children with mental health problems. Table 54.10–2 summarizes the guiding principles of these two conceptual models.

During the 1990s, federal initiatives increasingly focused on improving child mental health care and promoting basic science, clinical, and health services research for childhood psychiatric disorders. In preparation for a national epidemiologic study to estimate the prevalence of childhood mental disorders and service use, the Methods for the Epidemiology of Child and Adolescent Mental Disorders (MECA) Study was conducted. The MECA Study was a multisite, community-based study that further refined standardized assessment methods of psychiatric diagnosis, impairment, mental health service use, and risk factors and also provided prevalence estimates of childhood psychiatric disorders and mental health service use in four diverse geographic areas.

In response to increasing adaptation of system of care principles to the delivery of community-based services for children and their families, a large-scale effectiveness study was conducted, namely, the Fort Bragg Demonstration Project. Provision of a continuum of care was found to provide more services and be more costly but did not produce better clinical outcomes. These thought-provoking findings encouraged the field to conceptually expand outcomes for children beyond clinical status (e.g., to system-, community-, family-, and parent-level outcomes) and to integrate the influence of varying service use (e.g., intensity, persistence, type) in the determination of effectiveness.

Table 54.10–1.
Historical Context for Child Mental Health Services Research: Landmark Events and their Significance

	Event(s)	Significance
1909	White House Conference on Dependent Children	Raised public awareness of poor living conditions and high cost of homes for emotionally disturbed children. National recommendations for improved child programs stimulated the development of child welfare and foster care system.
1912	Federal Children's Bureau created	Establishment of the oldest federal agency for children. Located in the U.S. Department of Health and Human Services' Administration for Children and Families, the agency is responsible for assisting states in the delivery of child welfare services; providing grants to states, Native American tribes, and communities to operate a range of child welfare services (e.g., child protective services, family preservation and support, foster care, adoption, and independent living); and making major investments in staff training, technology, and innovative programs for children.
1919	The Child Welfare League of America chartered	Establishment of the oldest and largest national nonprofit organization dedicated to developing and promoting policies and programs to protect U.S. children and strengthen U.S. families.
1920	The Dawson Report published in England	Considered to be one of the founding documents in the history of epidemiology by introducing the concept of primary care. Lord Dawson believed health care in a given district should be based on "primary health centers," which he termed "institutions equipped for services of curative and preventive medicine to be conducted by the general practitioners of that district." Difficult cases requiring special treatment would be referred to "secondary health centers." In addition, "secondary services" would be equipped for the care of infectious diseases and chronic ailments such as epilepsy or mental illness. "Teaching hospitals," with medical schools, would treat the most difficult illnesses and provide physician training.
1922	Pediatric Section of AMA approves the Sheppard–Towner Act while the AMA House of Delegates condemns it.	The Sheppard–Towner Act supported federal funding to states for health services for mothers and children. The AMA opposed it, calling it "an imported socialist scheme." Following this disagreement, AMA leadership promptly ruled that no section could independently adopt a resolution. This ruling was described as, "sterilizing the Pediatric Section [that] made the American Academy of Pediatrics inevitable".
1930	White House Conference on Child Health and Protection	Children's Charter was established, outlining a set of 19 principles in the areas of education, child

		labor, vocational training, recreation, family welfare, health, growth and development, disabled children, and related areas, including the Bill of Rights for the Handicapped Child.
1930	American Academy of Pediatrics established	On June 23–24, 1930, at Detroit's Harper Hospital, 35 pediatricians drew up the constitution and by-laws for AAP. The purposes of the AAP were: 1. To create reciprocal and friendly relations with all professional and lay organizations that are interested in the health and protection of children. 2. To foster and encourage pediatric investigation, both clinically and in the laboratory, by individuals and groups.
1933	Roger I. Lee, Lewis Webster Jones, and Barbara Jones, *The Fundamentals of Good Medical Care*, a publication of the Committee on the Costs of Medical Care	Defined quality of care as follows: "Good medical care is the kind of medicine practiced and taught by the recognized leaders of the medical profession at a given time or period of social, cultural, and professional development in a community or population group."Identified eight articles of faith underlining the concept of good care: 1. Good medical care is limited to the practice of rational medicine based on the medical sciences. 2. Good medical care emphasizes prevention. 3. Good medical care requires intelligent cooperation between the lay public and the practitioners of scientific medicine. 4. Good medical care treats the individual as a whole. 5. Good medical care maintains a close and continuing personal relationship between physician and patient. 6. Good medical care is coordinated with social welfare work. 7. Good medical care coordinates all types of medical services. 8. Good medical care implies the application of all the necessary services of modern scientific medicine to the needs of all the people.
1935	L. Kanner, *Child Psychiatry*	First English-language textbook on child psychiatry.
1938	Fair Labor Standards Act signed into law by President Franklin Delano Roosevelt	Prohibited interstate shipment of goods made in firms that employ children younger than age 16 years or children younger than age 18 years in hazardous occupations.
1946	National Mental Health Act	Authorized the Surgeon General to improve the mental health of U.S. citizens through research into the causes, diagnosis, and treatment of psychiatric disorders.
1949	National Institute of Mental Health (NIMH) is established	One of 27 institutes and centers that make up the National Institutes of Health. It is the largest

		research organization dedicated to mental health in the world.
1950	Mid-Century Conference on Children and Youth held	Prepared the Pledge to Children, which summarizes commitments by adults to children to promote education, strengthen family life, safeguard civil equality, improve workplace conditions, enhance democratic citizenship and institutions, and advocate for the development of the child's individual talents and potential.
1953	American Academy of Child and Adolescent Psychiatry established	The leading national professional medical association, currently composed of more than 6,500 child and adolescent psychiatrists and other interested physicians dedicated to treating and improving the quality of life for children, adolescents, and families affected by these disorders.
1955	Mental Health Study Act	Authorized NIMH to study and make recommendations on mental health and mental illness in the United States. The act also authorized the creation of the Joint Commission on Mental Illness and Health.
1958	Community-based epidemiologic survey of mental health problems among those living in a northeastern U.S. community	First wide-scale epidemiologic study of problem behaviors among a U.S. community-based sample. Using systematic assessment methods for problem behaviors, investigators identified high rates of fear and worries among children aged 6–12 years in a general population sample, suggesting that symptoms are in part developmental. Established the feasibility of child self-report of emotional and behavioral symptoms. Used multiple-informant data and reported discrepancies in mother and child reports for some symptoms.
1959	Board certification in child and adolescent psychiatry offered for the first time by the American Board of Psychiatry and Neurology	National application of standards for clinical knowledge and skills in child and adolescent psychiatry.
1961	Kerr White and colleagues, "The Ecology of Medical Care," published in *New England Journal of Medicine*	Seminal article that promoted the development of health services research. The authors "observed that traditional indexes of public health—including mortality and morbidity—do not adequately describe the actions of individual patients and doctors." They argued that doctors should combine research of pathologic processes with exploration of the use of medical care resources, their relative availability in different contexts, and the patient's decision-making processes. In their view, "the patient may be a more relevant primary unit of

		observation than the disease, the visit, or the admission." Findings from this study examining the relationship between U.S. and U.K. populations and the experience of illness and different levels of medical treatment suggested that health care delivery and the training of physicians did not bear any logical relationship to the actual experience of illness in a given population. These data suggested that greater attention should be devoted to primary, continuing medical care as opposed to episodes of hospitalization or consultation of specialists. Furthermore, medical education and research should take greater account of the environment of health care and consider more systematically how health care resources should be deployed.
1964–1975	Isle of Wight studies	Extensive longitudinal cohort study over 5 years of intellectual and educational retardation, psychiatric disorder, and physical handicap of the entire population (estimated *N* = 3,500) of children aged 9–11 years. Screening for neuroepileptic disorders among entire population of 5- to 15-year-olds. Survey of 10-year-old children to directly compare to children of the same age range living in an inner borough of London. Additional studies examining the mental health profile of young children aged 5–7 years. Research methods included: 1. Multiple-informant data (child, parent, teacher, school records, psychiatric records, and pediatric records). 2. Two-stage screening strategy. 3. Comprehensive battery of assessments. 4. Identification of psychiatric diagnoses using social impairment as a criterion for severity and symptom pattern as a criterion of type. 5. Longitudinal design to study the age of onset, identification of risk factors, and description of course of illness over time. 6. Causal hypotheses of risk factors (e.g., organic brain dysfunction, family discord, reading difficulties). 7. Standardized neurodevelopmental assessments used to relate neurologic findings to psychiatric disorders. 8. Examination of differences in participants and nonparticipants.
1966	Avedis Donabedian, "Evaluating the Quality of Medical Care," published in *Milbank Memorial Quarterly*	Proposed conceptual model for the evaluation of quality of care that remains widely used in health services research.

		Identified three main domains for examining quality: (1) structure, (2) process (technical, interpersonal), and (3) outcomes.
1969	Joint Commission on Mental Health for Children	Raised public awareness of high unmet need for child mental health services and overuse of mental health care delivered in restrictive treatment settings. Recommended establishment of a child advocacy system to coordinate federal, state, and local actions, development of community services focused on prevention and remediation, and delivery of child services in settings resembling normal living conditions. Identified need for research examining the effectiveness of child mental health services.
1974	Large epidemiologic study of 2,034 youth ages 6–18 years in New York	Included a sample of 1,000 youth in the welfare sector and 1,034 randomly selected youth. Prevalence estimates of psychiatric disorders were higher among children in the welfare sector than in the general population (21.0% vs. 17.5%). Documented high unmet need for services, such that <50% of children with serious impairment were referred for care.
1975	Education for All Handicapped Children Act passed (Public Law 94–142)	Federal law whose purpose is to ensure that all children with disabilities have access to a free appropriate public education that emphasizes special education and related services designed to meet their unique needs; to ensure that the rights of children with disabilities and their parents or guardians are protected; to assist states and localities to provide for the education of all children with disabilities; and to assess and ensure the effectiveness of efforts to educate children with disabilities.
1977	President's Commission on Mental Illness and Health	Identified need for studies of the incidence and prevalence of mental disorders in the United States. Recommended an increase in the provision of child mental health services and the capacity to provide a continuum of care to children.
1979	NIMH contracts to develop standardized assessment methods of children and adolescents in general population samples	Stimulated a wave of epidemiologic studies examining the reliability and validity of checklists, rating scales, and diagnostic interviews in geographically diverse populations in the 1980s to 1990s. Promoted the development of assessment tools for use in community-based populations, such as the Child Behavior Checklist, Clinical Global Assessment Scale, Child and Adolescent Psychiatric Assessment, Diagnostic Interview for

		Children, and Diagnostic Interview Schedule for Children.
1980	NIMH Epidemiologic Catchment Area Study	First large-scale, multisite epidemiologic study of psychiatric disorders among 20,291 adults in U.S. households and institutions. Stimulated further development of the Diagnostic Interview Schedule and provided prevalence estimates of treated and untreated psychiatric disorders in the community.
1981	Select Panel for the Promotion of Child Health	Acknowledges significant improvement in services to children with disabilities (including serious emotional disturbances) but identifies wide variation in the availability of child-related services. Developed national recommendations to improve the delivery of services to children, including greater access to care, expansion of services to include prevention and early detection and treatment of developmental problems, improved quality of care in residential treatment settings, enhanced community support for child programs, and greater involvement of families in the delivery of mental health services.
1982	Children's Defense Fund report, *Unclaimed Children*	Raised public awareness of high unmet need for child mental health services in the United States. Identified children with severe emotional and behavioral problems as "unclaimed" by the public agencies responsible for serving them.
1984	Child and Adolescent Service System Program (CASSP) established	NIMH-funded program to support states in the development of interagency efforts to improve the system of care for children with mental health problems. Provided technical assistance to community-based programs in the adaptation of systems-of-care values and principles to the delivery of services in children with severe emotional and behavioral problems.
1986	Beth A. Stroul and Robert M. Friedman, *A System of Care for Severely Emotionally Disturbed Children and Youth*	Pivotal document from the CASSP Technical Assistance Center, Georgetown University Child Development Center, in Washington, D.C., that articulated the core values and guiding principles for the system-of-care philosophy for children.
1989	Agency for Health Care Policy and Research established (later renamed Agency for Healthcare Research and Quality)	The health services research arm of the U.S. Department of Health and Human Services (HHS). Supports research in the following areas: 1. Quality improvement and patient safety 2. Outcomes and effectiveness of care 3. Clinical practice and technology assessment 4. Health care organization and delivery systems 5. Primary care

		6. Health care costs and sources of payment
1989	System of Care for Severely Emotionally Disturbed Children and Youth	Introduced a philosophy underlying a system of care for children with severe emotional and behavioral problems. Identified core values for system of care for children: Care should be child centered and community based. Outlined 10 guiding principles for system of care.
1989–1995	Fort Bragg Demonstration Project	Large-scale effectiveness study of providing a continuum of services to children and their families with four components: A longitudinal cohort study comparing outcomes and costs of providing a model continuum of care vs. traditional mental health services. Provision of a continuum of care was related to the following: 1. Improved access to care. 2. Higher adolescent and parent satisfaction with services. 3. Greater costs. 4. Reduced rates of hospitalization or residential treatment. Continuum of care did *not* produce better clinical outcomes than traditional mental health services.
1989	Institute of Medicine report on Research on Children and Adolescents with Mental, Behavioral, and Developmental Disorders	Comprehensive review by national experts of the dimensions, causes, determinants, and interventions for childhood psychiatric disorders, as well as child mental health research infrastructure. Raised public awareness of an estimated 12% of U.S. children having a diagnosable mental illness, advances in the assessment and treatment of childhood disorders, promising research directions, and resource needs for research.
1989	Agency for Health Care Policy and Research created.	Supported by the Omnibus Budget Reconciliation Act of 1989. Mission included “to support research designed to improve the quality, safety, efficiency, and effectiveness of health care for all Americans.” Activities included large multidisciplinary, multi-institutional projects that focused on patient results in certain medical conditions, development of practice guidelines, and participating in the development of a health care reform plan.
1990	National Plan for Research on Child and Adolescent Mental Disorders	Comprehensive 5-year plan of how NIMH intended to stimulate new basic and clinical research, promote research training, and provide leadership and coordination to stimulate advocacy and research dissemination in child mental health.

1990	The 1990s declared by the U.S. Congress the “Decade of the Brain”	Provided national public endorsement for federal, state, and community initiatives to support a wide range of mental health research, as well as initiatives to improve the quality of care for the mentally ill.
1990	The National Committee for Quality Assurance is created.	A large, nonprofit organization dedicated to improving health care quality through measurement, transparency, and accountability. Products include the Healthcare Effectiveness Data and Information Set (HEDIS), a set of quality measures used to report on quality of care at the health plan level.
1991–1996	Methods for the Epidemiology of Child and Adolescent Mental Disorders (MECA) Study	Pilot studies followed by multisite study of 1,285 child–caregiver pairs in four geographic areas using household interviews. Stimulated the development of standardized assessment methods of psychiatric diagnosis, impairment, mental health service use, risk factors, and administrative infrastructure for large-scale epidemiologic study. Produced prevalence estimates of psychiatric disorders with and without impairment criteria and mental health service use.
1992	Passage of the Comprehensive Community Mental Health Services Program for Children and Adolescents with Severe Emotional Disturbances	Authorized federal funding of more than $100 million/year for implementation of systems of care in 38 different communities. Supported the development of community-based continuum-of-care programs for children, including assessment, case management, outpatient treatment, day treatment, in-home services, respite care, therapeutic foster care, and group homes for children with severe emotional disturbances.
1992	American Academy of Pediatrics, Ad Hoc Task Force on Definition of the Medical Home	The guiding principles for the medical care of infants, children, and adolescents should be accessible, continuous, comprehensive, family-centered, coordinated, and compassionate. Comprehensive care encompasses the following services: 1. Provision of preventive care. 2. Ambulatory and inpatient care for acute illness 24 hours a day, 7 days a week. 3. Provision of care over an extended period of time to enhance continuity. 4. Identification of the need for subspecialty consultation and referral and knowing from whom and where these can be obtained. 5. Interaction with school and community agencies to be certain that special health needs of the individual child are addressed. 6. Maintenance of a central record and data base containing all pertinent medical information

		about hospitalizations. This record should be accessible, but confidentiality must be assured.
1997–1999	Development of practice parameters by the American Academy of Child and Adolescent Psychiatry	Twenty practice parameters were developed for the assessment and treatment of specific psychiatric disorders, as well as child mental health problems (e.g., suicide, sexual abuse).
1998	National Institutes of Health Consensus Development Conference on Diagnosis and Treatment of Attention Deficit Hyperactivity Disorder	Review the scientific evidence, open public discussion, and closed-panel deliberations by a 13-member multidisciplinary national expert panel. Findings from this conference support the following: 1. The validity of the diagnosis of attention-deficit/hyperactivity disorder (ADHD). 2. The substantial effect of ADHD on children, their families, and society. 3. Effectiveness of psychosocial and medication treatments. 4. Need for additional research on the long-term effects of stimulant medication treatment. 5. Need to improve early detection, access to care, and quality of evaluation and treatment. 6. Need for further basic science and clinical and intervention research.
1999	White House Conference on Mental Health	First major public introduction to mental illness in the United States and scientific advances in the assessment and treatment of psychiatric disorders. Called for a national antistigma campaign for persons with mental illness.
1999	Surgeon General's Call to Action to Prevent Suicide	Developed a national plan to increase awareness and prevent suicide in the United States.
1999	Surgeon General's Report on Mental Health	First Surgeon General's report dedicated to mental health and mental illness. Communicated three main messages: (1) Mental health is fundamental to health; (2) mental disorders are real health conditions; and (3) the efficacy of mental health treatments is well documented, and a range of treatments exists for most mental disorders. Included a chapter on children and mental health.
1999	Multimodal Treatment Study of Children with ADHD (MTA study)	First large-scale, multisite, randomized clinical trial of treatment of a childhood mental disorder. Compared the effectiveness of intensive behavioral treatment, tightly managed medication treatment, combined behavioral and medication treatment, and standard community care for ADHD. A randomly selected sample of 579 children ages 7.0–9.9 years recruited from six university-based clinic referral sources. No oversampling to include sufficient number of girls or children from minority race/ethnicity backgrounds to test treatment differences.

		The following results were found when using core ADHD symptom reduction as the outcome: 1. Medication management was superior to behavioral treatment and routine community care. 2. Combined treatment did not yield significantly more benefit than medication management alone.
1999	The Agency for Health Care Policy and Research is renamed the Agency for Healthcare Research and Quality	The agency was reauthorized under the Healthcare Research and Quality Act of 1999. Its mission is to produce evidence to make health care safer, higher quality, more accessible, equitable, and affordable. Development of practice guidelines was removed from the new mission, and it was made explicit that the agency is not a regulatory body.
1999	National Quality Forum created.	This nonprofit, membership-based organization was created in response to recommendations from the President's Advisory Commission on Consumer Protection and Quality in the Health Care Industry. The main activities are: (1) convene working groups to foster quality improvement in both public- and private-sectors; (2) endorses consensus standards for performance measurement; (3) ensure that consistent, high-quality performance information is publicly available; and (4) seek real-time feedback to ensure measures are meaningful and accurate.
2000	White House Meeting on Child Mental Health	Major public meeting specifically addressing the need to improve the diagnosis and treatment of children with emotional and behavioral disorders.
2000	U.S. Surgeon General's Conference on Children's Mental Health, Developing a National Action Agenda	Developed recommendations for a National Action Agenda on Children's Mental Health based on feedback from a broad cross-section of more than 300 child mental health stakeholders
2000	National Institute of Mental Health and the Food and Drug Administration (FDA) Workshop on Psychopharmacology for Young Children, Clinical Needs and Research Opportunities	A nationally sponsored meeting of researchers, practitioners, ethicists, industry staff, and family and patient representatives, whose mission was to examine the current state of knowledge regarding psychopharmacology for young children and discuss a variety of topics relevant to research in this age group, including safety, efficacy, investigational methods, and ethical aspects. The meeting was in response to the increasing use of psychotropic medication among preschool-age children, for which the efficacy and safety of psychotropic medication have not been systematically evaluated. Recommendations included additional research in developmental psychopathology to clarify

		diagnosis and provide sensitive and specific methods for clinical trials.
2000	National Research Council and Institute of Medicine, *From Neurons to Neighborhoods: The Science of Early Childhood Development*	A 17-member committee of national experts convened to update scientific knowledge about the nature of early child development; disentangle knowledge from erroneous popular beliefs; and discuss the implications of this knowledge base for early childhood policy, practice, professional development, and research. With 11 national recommendations, this monograph advocated for improving the national capacity to meet the high unmet need for mental health services among preschool children and conducting research examining the effectiveness of early intervention programs for children.
2000	Clinical practice guidelines for ADHD developed by the American Academy of Pediatrics	National recommendations for the evaluation and diagnosis of ADHD, as well as treatment of the school-age child with ADHD in the primary care sector.
2000	Agency for Health Care Policy and Research evidence report, *Treatment of Attention-Deficit/Hyperactivity Disorder*	As part of the Evidence-Based Practice Program, a multidisciplinary research team conducted a systematic review of the scientific evidence for the treatment of ADHD to develop a base from which clinical guidelines, performance measures, and other quality improvement tools could be developed.
2000–2002	Development of quality indicators for childhood psychiatric disorders by the American Psychiatric Association Task Force on Quality Indicators for Children	Conceptualized the quality of care for children in five main domains: Prevention, access, quality/process/appropriateness, satisfaction/perceptions of care, and outcomes/effectiveness. Developed multiple recommendations for quality care and corresponding sample indicators.
2001	Surgeon General's Conference on Children's Mental Health, *A National Action Agenda*	Made the following recommendations: 1. Promote public awareness of children's mental health issues and reduce the stigma associated with mental illness. 2. Continue to develop, disseminate, and implement scientifically proven prevention and treatment services in the field of children's mental health. 3. Improve the assessment and recognition of mental health needs in children. 4. Eliminate racial/ethnic and socioeconomic disparities in access to mental health care services. 5. Improve the infrastructure for children's mental health services, including support for scientifically proven interventions across professions.

		6. Increase access to and coordination of quality mental health care services. 7. Train front-line providers to recognize and manage mental health issues and educate mental health care providers about scientifically proven prevention and treatment services. 8. Monitor the access to and coordination of quality mental health care services.
2001	National Advisory Mental Health Council's Workgroup on Child and Adolescent Mental Health Intervention Development and Deployment, *Blueprint for Change: Research on Child and Adolescent Mental Health*	A 21-member work group of national experts reviewed major research findings on child and adolescent psychiatric disorders over the prior decade and identified three major research priority areas: 1. Basic science and the development of new interventions. 2. Intervention development, moving from efficacy to effectiveness. 3. Intervention deployment, moving from effectiveness to dissemination.
2001	Institute of Medicine's Committee on Quality of Health Care in America, *Crossing the Quality Chasm*	Proposed six aims for improving the quality of care for the twenty-first century: Health care should be the following: 1. Safe: Avoiding injuries to patients from the care that is intended to help them. 2. Effective: Providing services based on scientific knowledge to all who could benefit and refraining from providing service to those not likely to benefit (avoiding underuse and overuse, respectively). 3. Patient-centered: Providing care that is respectful of and responsive to individual patient preferences, needs, and values and ensuring that patient values guide all clinical decisions. 4. Timely: Reducing waits and sometimes harmful delays for both those who receive and those who give care. 5. Efficient: Avoiding waste, including waste of equipment, supplies, ideas, and energy. 6. Equitable: Providing care that does not vary in quality because of personal characteristics such as gender, ethnicity, geographic location, and socioeconomic status.
2002	President's New Freedom Commission on Mental Health	National commission, whose mission was to conduct a comprehensive study of the U.S. mental health service delivery system, including both the private and public sector providers, and advise the president on methods of improving the system. The main goals were the following: 1. Review the current quality and effectiveness of public and private providers and federal, state,

		and local government involvement in the delivery of services to individuals with serious mental illnesses and children with serious emotional disturbances and identify unmet needs and barriers to services. 2. Identify innovative mental health treatments, services, and technologies that are demonstratively effective and can be widely replicated in different settings. 3. Formulate policy options that could be implemented by public and private providers and federal, state, and local governments to integrate the use of effective treatments and services, improve coordination among service providers, and improve community integration for adults with serious mental illnesses and children with serious emotional disturbances.
2002	Agency for Healthcare Research and Quality, *Systems to Rate the Strength of Scientific Evidence*	Identified 19 generic systems that fully address key quality domains for a particular type of study and 7 systems that address all three quality domains grading the strength of a body of evidence. These systems may be useful to the development of clinical practice guidelines or other health-related policy advice.
2002	International Consensus Statement on ADHD	A consensus statement developed by a consortium of international scientists that supports the validity of ADHD and its adverse effect on the lives of children and their families using scientific evidence. The statement was developed as a reference to the status of the scientific findings about ADHD to dispel periodic public perception that ADHD is not a real medical condition.
2003	President's New Freedom Commission on Mental Health: Transforming Mental Health Care in America	Recommendations for Transformed Mental Health System: 1. Americans understand that mental health is essential to overall health. 2. Mental health care is consumer and family driven. 3. Disparities in mental health services are eliminated. 4. Early mental health screening, assessment, and referral to services are common practices. 5. Excellent mental health care is delivered, and research is accelerated. 6. Technology is used to access mental health care and information.
2004	U.S. Food and Drug Administration (FDA) black box warning on pediatric antidepressants	The FDA directed manufacturers of all antidepressant medication to add a boxed warning that reported (1) antidepressants increase the risk of suicidal thinking and behavior in children and adolescents with major depression and other psychiatric disorders, (2)

		anyone considering the use of an antidepressant in a child or adolescent for any clinical use must balance the risk of increased suicidality with the clinical need, (3) patients who are started on therapy should be observed closely for clinical worsening, suicidality, or unusual changes in behavior, and (4) disclose whether the particular drug is approved for a pediatric indication(s) and, if so, which one(s).
2005	Caring for California Initiative	First statewide study of the quality of care for children with ADHD, major depression, and conduct disorder in publicly funded outpatient specialty mental health programs.
2006	Institute of Medicine's (IOM) Committee on Quality of Health Care in America, *Improving the Quality of Health Care for Mental and Substance Use Conditions*	Recommended that the prior IOM health care system redesign strategy was applicable to mental and substance use health care but required some adaptation to address greater obstacles to patient-centered care, a weaker quality measurement and improvement infrastructure, more separated care-delivery arrangements, less use of information technology, a more educationally diverse workforce with a greater use of solo practice, and a differently structured marketplace.
2006	National Advisory Mental Health Council's Workgroup on Services and Clinical Epidemiology Research, *The Road Ahead: Research Partnerships to Transform Services*	Six issues driving recommendations shaping the future research agenda to transform mental health services are (1) partnerships in research, (2) quality of care, (3) fairness, (4) recovery, (5) communication, and (6) ongoing evaluation.
2007	Treatment for Adolescents with Depression Study (TADS) 36-week outcomes	Among 327 patients from 13 academic and community sites randomized to combination therapy, fluoxetine therapy, and cognitive behavior, combined treatment appears to be superior to monotherapy using symptom reduction and overall clinical improvement rating as outcomes.
2007	National Stigma Study-Children	First large-scale, nationally representative survey of public knowledge, attitudes, and beliefs on children's mental health reported substantial rates of stigma (35–57%) and negative perceptions of medication treatment (52–85%).
2008	Mental Health Parity and Addiction Equity Act	A federal law that generally prevents group health plans and health insurance issuers that provide mental health or substance use disorder benefits from imposing less favorable benefit limitations on those benefits than on medical/surgical benefits.
2009	The Children's Health Insurance Program Reauthorization Act	Mandated the identification, refinement, and development of child health care measures for voluntary use in Medicaid and Children's Health

		Insurance Programs. Called for submission of initial core set of 24 quality measures to Department of Health and Human Services by 2010. Funded the 5-year Pediatric Quality Measures Program. Required annual review of the national Core Set starting in 2013.
2010	Patient Protection and Affordable Care Act	Landmark legislation for health care reform. Mandated development of a National Quality Strategy and earmarked support for the Patient-Centered Outcomes Research Institute.
2018	Bipartisan Budget Act	Extended 4-year funding to the Children's Health Insurance Program. Requires all states to report adherence to quality measures in the national Child Core Set starting in 2024.
2019	Wit v. United Behavioral Health	A federal court in Northern California found that one of the largest managed behavioral health care companies rejected the insurance claims of tens of thousands of people seeking mental health and substance use disorder treatment based on defective medical review criteria. This case found evidence of a separate and unequal system of medical care review that is inconsistent with the treatment of physical health conditions, such as cancer or heart disease.
2020	The Coronavirus Aid, Relief, and Economic Security (CARES) Act	A $2 trillion stimulus package which includes $425 million of appropriations to the Substance Abuse and Mental Health Services Administration to respond to the pandemic, $250 million going to new funding for Certified Community Behavioral Health Clinic Expansion grants, $100 million for emergency response activities, and $50 million for suicide prevention.

Scientific advances in the assessment and treatment of ADHD also laid the foundation for conducting the first large-scale, randomized clinical trial of two treatment modalities. The Multimodal Treatment Study of Children with ADHD, or MTA study, examined the effectiveness of highly standardized psychosocial, medication, and combined treatment protocols for ADHD. Based on the use of reduction of ADHD symptoms as the main outcome at 14 months, medication management was found to be superior to intensive psychosocial treatment and usual community care, and combined psychosocial treatment was found to be of no significantly greater benefit than medication management alone. Findings from the MTA study, however, should not be interpreted as conclusive that psychosocial interventions are inferior to medication treatment. Instead, alternative analyses from this rich data set have illuminated key methodologic issues, such as the selection of outcome measures, the use of composite versus individual outcomes as indicators of effectiveness, and the effect of moderators (e.g., sociodemographic factors, clinical severity, parental education, and income) and mediators (e.g., treatment adherence) in the assessment of an intervention's effectiveness. Nevertheless, treatment effects were found not to be sustained. At 36 months, the treatment groups did not significantly differ on any outcome measure. In addition, based on saliva assays for methylphenidate as an objective indicator of medication adherence, only 53.5% of children were consistently adherent to stimulant medication treatment during the initial 14-month treatment period. Further, the findings are not generalizable to community-based populations.

In the early twenty-first century, a report from the Institute of Medicine's (IOM) Committee on Quality of Health Care in America raised national awareness that the "American health care delivery system was in need of fundamental change." The wide difference between the care that should be received and the care that was actually being received was described as the quality chasm. A follow-up report found that the IOM's recommendations to transform the health care system were generally applicable to mental and substance use disorders but also identified distinctive characteristics of health care for mental and substance use conditions. Harold Pincus and colleagues noted that "the [Committee's] fundamental conclusion [is] that coordination and collaboration with the rest of medicine are essential (and vice versa), but it is also critical to ensure access to the depth and expertise provided by psychiatrist and other mental health and substance use specialists."

Table 54.10–2.
Core Values of Children's System of Care and Pediatric Medical Home

Children's System of Care	Pediatric Medical Home
Mental Health Care	Medical Care
Access to a comprehensive array of services	Accessible
Smooth transitions to the adult service system	Continuous
Early identification and intervention	Comprehensive
Full participation of families and surrogate families	Family-centered
Integrated and coordinated care across child-serving agencies Inclusion of case management	Coordinated
Individualized services Least restrictive, most normative environment Protection of child rights and effective advocacy efforts Equitable and culturally sensitive service delivery	Compassionate

Within this same time period, national professional organizations developed practice parameters and treatment guidelines that enabled child mental health services researchers to develop quality indicators based on evidence of effectiveness and clinical consensus. Using documented adherence to quality indicators in the medical record to estimate quality of care, from 1998 to 1999, the Caring for California Initiative (CCI) was the first statewide quality-of-care study for children with common psychiatric disorders in publicly funded outpatient mental health programs. The CCI found that on average less than one-half (48.5%) of medical records passed all eligibility quality domains at the probable acceptable care level, a rate similar to general health care among U.S. adult and child populations. Medication safety monitoring was particularly weak, such that roughly one-fourth (28.5%) of the records of children receiving psychotropic medication treatment had documented monitoring of at least one clinically indicated vital sign or laboratory study. National concerns regarding the safety of psychotropic medication were also raised during this time period. In 2004, the U.S. Food and Drug Administration (FDA) issued a black box warning on all antidepressant medication to alert health care providers of an increased risk of suicidality in children and adolescents. Further, high national rates of stigma related to medication treatment raised awareness of the need for further examination of the mechanisms underlying engagement, uptake, and adherence to recommended care for children with psychiatric disorders and their families.

Although improving the quality of child mental health care has been a long-standing national priority, two federal health policies in the early 21st century legislatively mandated the development and use of quality measures for child health and mental health. In 2009, the Children's Health Insurance Program Reauthorization Act (CHIPRA) was signed. This law mandated the identification, refinement, and development of child health care measures for voluntary use in Medicaid and the Children's Health Insurance Program (CHIP). It called for submission of initial core set of 24 quality measures to the Department of Health and Human Services by 2010, with annual updates starting in 2013. This

legislation also funded a 4-year Pediatric Quality Measures Program (2010–2014). Within this program, seven centers of excellence were funded to develop new measures and refine existing ones for "potential core enhancements" as well as ten demonstration programs to develop, test and evaluate, and/or report on adherence to quality measures.

During the following year, the landmark Patient Protection and Affordable Care Act was signed in 2010. Within this complex legislation, the development of the National Quality Strategy was mandated. This strategy to transform health care had three aims: (1) better care; (2) healthy people and healthy communities; and (3) affordable care. The six priority areas were safety, person or family engaged as partners in care, effective communication, and coordination of care, effective prevention and treatment, work with communities to promote wide use of best practices, and make quality of care affordable. In 2022, the National Quality Strategy was substantially revised to prioritize a person-centric approach from birth to end of life as individuals journey across the continuum of care. This legislation also funded the Patient-Centered Outcomes Research Institute (PCORI) to support research that informs better choices among alternative treatment strategies, supports a patient-centered orientation, and directs attention to individual and system differences that may influence strategies and outcomes. As stipulated by the 2018 Bipartisan Budget Act, which included a 4-year funding extension to CHIP, state reporting of quality measures from the Child Core Set will be mandatory starting in 2024. In response, criteria for addition and removal of core set measures have been revised to require a large proportion of states have the capacity to report adherence rates on a national quality measure.

ACCESS TO CARE

Significant gaps continue to exist between clinical needs and mental health service use for children with psychiatric disorders in the community. A number of conceptual models were developed to explain differential access to care. Of note, these models attempted to identify factors that can be changed through quality improvement interventions (referred to as *mutable factors*) to improve the likelihood of contact with services among children meriting assessment and treatment. A brief review of historically relevant access models is provided, because their frameworks continue to inform current quality improvement efforts.

Conceptual Models of Access to Care

Donabedian's early model of the medical care process acknowledges the complex interactions between patient and provider behaviors, as well as the influence of contextual factors, such as the characteristics of the settings (e.g., formal and informal treatment settings and social, economic, and cultural factors) that take place in the process of seeking and receiving care. From the patient's perspective, service use and, ultimately, health outcomes are initiated by the recognition of need. This step is followed by the decision to look for care and the processes of seeking care, assuming the sick role, and maintaining and terminating care. On seeking care, provider behaviors also become influential and include diagnosis, therapeutic decision making, and potential collaboration with other providers during these processes.

Subsequent conceptual models further specify factors that are influential to the access to care. Ronald Andersen's Behavioral Model of Health Services Use, for example, proposes that predisposing (e.g., sociodemographic factors such as gender), enabling (e.g., availability of insurance or treatment resources), and need (e.g., illness severity) factors form the basis of the decision-making process. Alternatively, the Health Belief Model suggests that individual psychological attributes, such as attitudes, beliefs, and perceived benefits of treatment, represent the major determinants of seeking care. Other models of access, such as Bernice Pescosolido's Family Network-Based Model of Access to Child Mental Health Services, emphasize the role of social networks in this decision-making process.

Overall, help-seeking pathway models propose a series of links between the initial recognition of a mental health problem and the eventual use of mental health services, framing these steps within the context of an "illness career" and network experiences thought to influence career progression as well as adherence to professional treatment suggestions. Few studies, however, have implemented study designs complex enough to analyze network influences, temporal sequencing, and combined

multisector care patterns for youth. Studies addressing access to care have been most commonly based on the Andersen model, using cross-sectional designs to identify relevant predictors.

Stigma as Barrier to Access

The 1999 Surgeon General's Report on Mental Health had the foresight to identify stigma as a significant barrier to access and continuity of mental health care. Youth with mental disorders face significant stigma in various forms, including public (expressed as prejudice and discrimination), courtesy (stigma suffered by family members or associates of individuals with mental disorders), and self-stigma (stigmatized individual's acceptance of negative views by others). Successful recovery from mental illness requires awareness of stigma and its potential adverse consequences and effective means to combat it.

To examine factors that shape prejudice and discrimination toward children with mental disorders, the National Stigma Study-Children (NSS-C) used vignettes depicting several stigmatizing scenarios, including ADHD, depression, asthma, or "normal troubles." Results indicate that scenarios of ADHD and depression and those depicting adolescents elicited the highest rejection responses. Respondents who thought a child suffered from a mental illness rather than from asthma or "normal" troubles indicated that they would seek social distance from the affected child, apparently resulting from perceptions that a child with mental illness is dangerous. In a comparison of child and adult depression vignettes, more respondents evaluated childhood depression as serious (83%) than adult depression (51%) and endorsed treatment of all types, including coerced care, for children with depression.

However, high stigma surrounding childhood disorders poses unique access barriers for youth and their families and merits further study to identify ways to combat these harmful perceptions. The NSS-C data were collected as part of the General Social Survey in 2002, and despite this historical limitation, still represent relevant generalizable insight on stigma perceptions relevant to youth. There has been some increased willingness to disclose mental health problems to friends and family in recent years, and public media disclosures by celebrities of their mental health struggles, yet, there is little indication that overall stigma perceptions surrounding mental disorders have lessened, considering that public perceptions studied across 22 years changed toward increasing perceptions of potential dangerousness and more support for coercive treatments. Earlier general societal antistigma programs relied on three pillars: protest, education, and contact. Subsequent formal evaluation of these traditional programs challenged the effectiveness of the hypothesized change agents and newer antistigma interventions consider new paradigms, including inclusion of patients, family, and friends in intervention development. For example, a recently developed college program seeks to create/influence new generations of medical, social, and political leaders during their formative years of college, by fostering safe and stigma-free zones on campus. The program uses a toolbox approach developed in partnership with multiple stakeholders, including the students, based on intervention principles such as outreaching early, an "by students for students" approach, and using "bait and flip" efforts to attract campus-wide engagement. Early results show encouraging reductions in stigmatizing behaviors and prejudice, as well as improved campus mental health culture perceptions using this intervention approach.

QUALITY OF CARE

The Institute of Medicine defined quality as "The degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge." The overarching goal is to improve the alignment between clinical needs, delivery of recommended care, and health policies to sustain quality care. In lay terms, the goal is to deliver the right care, at the right time, at the right place, every time. This simple but powerful statement should also include "and for everyone," to underscore the imperative to reduce disparities in child mental health care that may be confounded by structural racism and social determinants of health.

Models of Quality of Care

Components of quality of care are often conceptualized as structure, process, and outcomes, following Donabedian's model of quality of care. Structural factors include system and clinic organizational

factors, as well as provider, child, and family characteristics. Examples are health plan benefit structure, care sector, clinic volume, provider caseload, provider training and discipline, and parent education, as well as child insurance coverage, clinical profile, and sociodemographic characteristics. Processes of care are dichotomized into technical and interpersonal aspects of care. A common technical care process is medication treatment, which may, for example, be assessed using quality indicators or criteria pertaining to medication evaluation, use, and monitoring. For children, variables within the domain of interpersonal style may include the assessment of aspects of parent-provider communication and shared decision making. For example, how well a child and/or parent believes their concerns are listened to or how much involvement the primary caregiver had in the decision process of making the diagnosis, developing a treatment plan, and participating in the care of their child over time. Outcomes may also include child-, parent-, family-, community-, and system-level characteristics. Outcomes for children, parents, and families include symptom reduction, improved functioning, child and parent satisfaction, reduced parent strain, and improved family cohesion. Examples of community- and system-level outcomes are improved school attendance and reduced costs, respectively.

Building on the Donabedian quality of care framework, McGlynn and colleagues proposed a more transactional approach to examining quality of care for mental health. The ordering of the components of quality of care is reversed, such that outcomes influence both care processes and structural factors and processes of care directly affect change in structural characteristics. They also suggested that in examining quality of care for mental health problems, an analytical strategy be used that "simultaneously examines the outcomes, the processes associated with producing those outcomes, and the structural context in which the process was delivered."

However, with either of these conceptual models, interpretation of data examining the relationship between care processes and clinical outcomes should be done carefully. A study sample may underrepresent children from race or ethnic minority backgrounds, reducing statistical power to examine disparities. A child's clinical severity may drive more intensive service use (e.g., repeat emergency department visits) while a child's psychosocial complexity (e.g., poverty, parental unemployment) may hinder access or continuity of outpatient care. Missing data is also a common problem. In the community, clinic follow-up is often poor. If the data source only includes children who remain in care and have a standardized measure of a clinical outcome over time (e.g., EHR), it is difficult to determine if a child who drops out of care no longer clinically needs care or not.

Quality of Care for Child Mental Health

Psychotropic Medication Prescription Trends. Research examining national trends in psychotropic medication use, based on secondary databases (i.e., pharmacy claims), and how rates vary by sociodemographic and clinical characteristics provides important monitoring of potential overuse of psychotropic medication among children. Among commercially insured young children (2 to 7 years) from 2007 to 2017, annual antipsychotic use was 0.27% in 2007, peaked at 0.29% in 2009, and statistically significantly declined to 0.17% by 2017. Antipsychotic use was higher in boys than in girls, and the most common diagnoses were pervasive developmental disorder, conduct or disruptive behavior disorder, and ADHD. Although use of antipsychotic medication declined from 2009 to 2017, a majority of use remained off-label and for conditions lacking effectiveness and safety data. In addition, metabolic monitoring is important for children taking antipsychotic medication, given the risk for increased body mass index, impaired glucose metabolism, and hyperlipidemia. Among children enrolled in Medicaid in two states, 61% of children saw more than one provider type and children seeing primary care and specialty mental health provider with prescribing privileges were significantly more likely to receive metabolic monitoring compared to children seen only by a primary care provider. Together, these findings support the need for improved medication safety monitoring and quality improvement interventions, such as shared care arrangements, for children receiving antipsychotic medication treatment.

Gaps between Recommended and Usual Care. Findings from studies examining care processes for child psychiatric disorders suggest that gaps exist between recommended and usual care. Medical record data from a statewide sample of children receiving care for common psychiatric disorders in

publicly funded outpatient mental health programs documented that adherence to quality of care indicators for clinical assessment was high (78% to 95%) but adherence to quality indicators related to service linkage, parental involvement, use of evidence-based psychosocial treatment, and patient protection were moderate to poor (8.0% to 74.1%). Medication safety monitoring was particularly weak, such that roughly one-fourth (28.5%) of the records of children receiving psychotropic medication treatment documented the monitoring of at least one clinically indicated vital sign or laboratory study. Using child-level data from multiple data sources, quality of care for ADHD in primary care and specialty mental health clinics in a large managed care Medicaid program was examined using a longitudinal cohort study design. Continuity of care was poor, and in primary care children received on average only one to two follow-up visits a year. In the specialty mental health clinics, less than one-third of children received any stimulant medication, and in both sectors, stimulant medication refill prescription persistence was poor (31% to 49%). With few exceptions, ADHD diagnosis, impairment, academic achievement, parent distress, parent-reported treatment satisfaction, perceived benefit, and improved family functioning did not differ between children who remained in care and those that received no care.

Table 54.10–3.
National Child Behavioral Health Quality Measures in 2021 Child Core Set

NQF #	Steward	Measure Description	Data Source(s)
0108	NCQA	Follow-up care for children (6–12 years) prescribed ADHD medication Percentage of children newly prescribed ADHD medication who had at least three follow-up care visits within a 10-month period, one of which was within 30 days of when the first ADHD medication was dispensed. Two rates are reported Initiation phase: Percentage of children ages 6 to 12 as of the index prescription start date (IPSD) with an ambulatory prescription dispensed for ADHD medication, who had one follow-up visit with practitioner with prescribing authority during the 30-day initiation phase Continuation and maintenance (C&M) phase: Percentage of children ages 6 to 12 as of the IPSD with an ambulatory prescription dispensed for ADHD medication who remained on the medication for at least 210 days and who, in addition to the visit in the initiation phase, had at least two follow-up visits with a practitioner within 270 days (9 months) after the initiation phase ended	Administrative EHR
0576	NCQA	Follow-up after hospitalization for mental illness Percentage of discharges for children ages 6 to 17 who were hospitalized for treatment of selected mental illness or intentional self-harm diagnoses and who had a follow-up visit with a mental health practitioner. Two rates are reported: Percentage of discharges for which the child received follow-up within 30 days after discharge Percentage of discharges for which the child received follow-up within 7 days after discharge	Administrative
2801	NCQA	Use of first-line psychosocial care for children and adolescents on antipsychotics Percentage of children and adolescents ages 1 to 17 who had a new prescription for an antipsychotic medication and had documentation of	Administrative

		psychosocial care as first-line treatment	
n/a	NCQA	Use of multiple concurrent antipsychotics in children and adolescents	Administrative
		Percentage of children and adolescents ages 1 to 17 who were treated with antipsychotic medications and who were on two or more concurrent antipsychotic medications for at least 90 consecutive days during the measurement year	

NQF, National Quality Forum; NCQA, National Committee on Quality Assurance; ADHD, Attention Deficit/Hyperactivity Disorder; EHR, electronic health record; n/a, not applicable.

National Quality Measures. In response to national recommendations to improve the quality of mental health care, there has been a proliferation of quality measures, predominantly focused on adults. Nevertheless, the 2021 Child Core Set of quality measures for beneficiaries in Medicaid and CHIP, includes four measures related to child mental health. The measures monitor follow-up care for children prescribed ADHD medication, timeliness of follow-up outpatient care(at 7 and 30 days) after hospitalization for a mental illness, metabolic monitoring for children receiving antipsychotic medication, and use of first-line psychosocial care for children on antipsychotic medication. The operational definitions for the measures are summarized in Table 54.10–3. Across measures, clinical validity is scarce, state Medicaid agency adherence rates vary widely, and some states have challenges accessing or linking the data required to publicly report measure adherence rates. Starting in 2024, Medicaid and CHIP agencies will be required to report on all Child Core Set measures and the behavioral health measures in the Adult Core Set, stimulating greater urgency to address limitations in existing data sources and methods.

Future research is needed to examine whether adherence to national child mental health quality measures is associated with clinical outcomes that are meaningful, which likely vary by stakeholder perspective (e.g., satisfaction, guideline-concordant care, cost, value). When examining quality of care, it is imperative to examine variation in quality by sociodemographic and clinical characteristics to identify disparities as well as to explore target mechanisms driving inequities. However to advance this line of research, greater public investment is needed in data infrastructure, such as improved data coordination across large electronic health care record data bases using common data elements, better clinician decision support tools, and greater integration of standardized clinical outcome measures using patient portals to reduce selection bias toward having outcome data from only patients who remain in care.

Measurement-based Care. MBC is conceptualized as a driver for quality improvement. However, given the breadth of MBC types, it is useful to conceptualize these by categorizing them by population levels which are individual (Tier 1), clinical aggregate (Tier 2), and national levels (Tier 3). At the individual level (Tier 1), the main purpose of MBC is to inform clinical decision-making. MBC is conceptualized as routinely collecting patient-reported outcome measures, such as standardized symptom rating scales. The target mechanisms for change include improving early detection of treatment resistance and facilitating patient–provider communication. During psychotherapy, routine outcome monitoring may be especially effective to identify patients who are not clinically improving and improve fit between evidence-based therapies to clinical needs.

At the clinical aggregate level (Tier 2), the main purpose of MBC is to monitor performance. The proposed mechanism of change is that feedback on variation in clinical outcomes by provider, clinic, hospital, or agency will identify target areas for quality improvement and guide resource allocation decisions. Tier 2 is conceptualized as the clinical aggregate level to encompass common methodologic challenges in program evaluation at the patient, provider, clinician, clinic, hospital, or agency (county or

State) levels. Within this continuum, priority is placed on methods that measure provider adherence to recommended care processes and clinical outcomes.

At the national level (Tier 3), the main purpose of MBC is to monitor change in adherence rates to national quality measures. For example, adherence to quality measures in the Child Core Set is used to assess the quality of care provided by states to Medicaid and CHIP beneficiaries. State agency reporting on a standardized set of measures is envisioned to facilitate tracking performance over time. The proposed mechanism of change is public reporting on quality measure adherence rates will drive quality improvement by identifying target areas that state Medicaid agencies can be held accountable to address. Incremental increases in measure adherence rates over time are interpreted as improvement in quality of care.

AREAS FOR FUTURE RESEARCH

Despite substantial progress, there remain far more questions to be addressed which require development of innovative study methods and improved data infrastructure. Although there has been rapid expansion of telehealth and technology-supported treatments, more rigorous, large-scale research is needed to examine the impact of these technologic advances on the delivery of care, quality of care, and disparities in care. Access to the internet, for example, is not equitable and there are concerns that the digital divide may exacerbate disparities in care, especially among our most vulnerable children. In addition, the centralization of EHR data within care networks using common data models provides an exciting opportunity to leverage these databases to examine child mental health care quality and health disparities. This line of research will likely also identify limitations to stimulate further refinement of data coordination methods and predictive analytics for use in child mental health services research. With these advances, lessons learned from landmark events described in the historical context of this field should be heeded and the shared values of quality care should remain critical underpinnings for future research.

54.11 Impact of Terrorism and School Shootings on Children

Nayla M. Khoury, M.D., M.P.H., and Wanda P. Fremont, M.D.

Over the last few decades, terrorist attacks, threats, and their aftermath have been increasingly frequent in countries throughout the world. The effects of terrorist activities have a significant clinical impact on children and their families. Additionally, school shootings, a specific form of domestic terrorism, have been increasing in recent years. A growing amount of research documents the effects of these exposures, especially data that helps to differentiate reactions to terror from those associated with other types of violence. In addition, the indirect effects of terrorism, including exposure to media and television coverage of violent images, have been noted to be of increasing concern. To develop a proactive and strategic response to these reactions, clinicians, educators, and policymakers must understand the psychological effects of terrorism, including school shootings. Many of the effects of terrorism-induced trauma on children are similar to the effects of other human-caused and natural disasters. Therefore it is essential for the clinician to have an understanding of children's reactions to trauma. The important contributing influences on children's reactions to trauma include risk and protective factors, developmental factors, neurobiologic consequences, and family and community strengths and vulnerabilities. Recently, with the increase in terrorist bombings and access to media coverage worldwide, more studies have examined the unique effects of terrorism-induced trauma on children. This research covers a range of violent acts that are classified as terrorism. These include isolated events in countries not at war (the Oklahoma City bombing and September 11 terrorist attacks) and repeated terrorist attacks in areas of political conflict (terrorist activities in Northern Ireland, state terrorism in Guatemala, the Scud missile attacks during the Persian Gulf War, and bombings and kidnappings in Israel). Earlier studies completed in the 1970s and 1980s were primarily descriptive and anecdotal in nature. More recent studies have been more rigorous and focus on protective and risk factors that affect children's reactions, as well as systems of care that support children in the aftermath of these events. They include longitudinal studies that assess the long-term consequences of terrorist activities and

school shootings. Diagnostic implications, clinical interventions, and treatment strategies have developed as a result of the increasing knowledge obtained about the effect of terrorism on children.

DEFINITION OF TERRORISM

The U.S. Defense Department defines terrorism as “the calculated use of violence or threat of violence to inculcate fear: Intended to coerce or to intimidate governments and societies in the pursuit of goals that are generally political, religious, or ideological.” The goal of terrorism is not only to cause visible disaster but also to inflict psychological fear and intimidation at any time—during periods of peace or conflict. Unlike family or community violence or the trauma resulting from war, terrorist activities are not confined to a specific geographical area or time. Terrorist events occur suddenly without any forewarning and frequently result in severe trauma. The threat persists indefinitely. New terrorist threats and actions may exacerbate underlying anxieties. Terrorism capitalizes on media coverage. Powerful visual images create strong emotional responses, including fear, panic, despair, and rage, even in individuals who live far from the traumatic events. The events are given well-recognizable labels (e.g., “the blood bus,” “the explosive refrigerator in Israel,” “the Chowchilla bus kidnappings,” “the Scud missile attacks,” “the 9/11 terrorist attacks”).

Mass school shooting incidents are another form of domestic terrorism that occurs worldwide and elicits similar media coverage and strong emotional responses. From the 1999 Columbine High School massacre to the 2018 Parkland high school shooting, these events cause panic and public outcry for increased preventive efforts and legislative reform. Although these types of events occur more in the United States than in any other country, they can happen anywhere. Examples include the 2007 attack in Finland at Jokela Secondary School and the 2008 attack at Seinajoki University of Applied Sciences in Kauhajoki.

Mass school shootings have led to increasing youth homicide rates over the past two decades. The Centers for Disease Control reports that between 1994 and 2016, multiple victim school–associated youth homicide incident rates increased and involved a disproportionate number of youth homicide victims. An overwhelming majority of the associated mortality is due to firearm-related injuries.

While the definition of mass shootings varies depending on the number of injuries/fatalities (typically three to four fatal or nonfatal injuries), they are differentiated from violence related to gangs, family members, or interpersonal violence and are more unpredictable and seemingly random. Similar to other forms of terrorism, they involve unrelated persons in a public space occupied by multiple unrelated persons. Less common than community violence or single-victim incident violence, they have far-reaching consequences for victims, families, and communities.

CHILDHOOD REACTIONS TO TERRORISM-INDUCED TRAUMA

Although many of the reactions of children to terrorism-induced trauma are similar to children’s reactions to other forms of human-caused violence and natural disasters, terrorism-induced trauma results in unique stressors and reactions in children. The clinician must have a good understanding of the variables that affect children’s responses to trauma and the variety of responses that children manifest. It is, therefore, important to review the literature on childhood reactions to trauma and their clinical manifestations. Children vary in their reactions to traumatic events. Many demonstrate resilience and will be unaffected by these events in the long term. Some suffer from anxiety and bad memories that dissipate with time and emotional support. Other children may be more severely traumatized and experience long-term problems that significantly interfere with their functioning. The reader is encouraged to refer to the section in this text on posttraumatic stress disorder (PTSD) in children and adolescents.

Several factors contribute to a child’s differential response to trauma. These include the child’s age and level of psychological maturity, the severity and level of exposure to trauma, the duration of exposure to violence, predisposing risk factors, protective factors and resiliency, the influence of parents’ responses to disaster, family protective factors, the degree of social and community support (including educational, political, and religious influences), and the extent and context of displacement and relocation.

Predisposing risk factors include previous traumatic exposures. Research has shown that other types of trauma, including childhood maltreatment and community violence exposure, influence outcomes. Childhood adversities, including maltreatment and community violence, are known to increase vulnerability to subsequent victimization and psychiatric disorders, including PTSD. While issues of interpersonal and community violence are beyond the scope of this chapter, there are overlaps in documented potential mental health outcomes.

Trauma-related symptoms are documented as potential outcomes for youth regardless of the type of trauma. Children's emotional reactions may develop immediately after the trauma or may occur later. *Acute stress disorder* (ASD) is the most common psychiatric disorder following a traumatic event. *PTSD* is a reaction that may occur after a period of at least 1 month following the event. Children or adolescents suffering from ASD or PTSD may re-experience the trauma by having nightmares or recurring flashbacks of the trauma. They may become fearful, distractible, anxious, or depressed. Their play and study may be affected in addition to their pattern of sleep. In young children, repetitive play may occur in which themes or aspects of the trauma are expressed. Their dreams may be frightening but without any recognizable content. Trauma-specific re-enactment may occur. Adolescents and children may feel numb and withdraw from the external world or avoid situations that arouse recollection of the trauma. Symptoms of increased arousal may occur that include hypervigilance, sleep difficulties, irritability, difficulty concentrating, and outbursts of anger.

In addition to ASD and PTSD, children may develop comorbid disorders, including anxiety disorders (e.g., generalized anxiety disorder, social phobia, specific phobias, panic disorder, agoraphobia, obsessive-compulsive disorder), depression, and substance abuse-related disorders. Children may present with partial or variable symptoms of these disorders.

Children who are indirectly exposed to a traumatic event may also manifest symptoms of anxiety, including trauma-specific fear, fear of being alone, the habit of clinging to others, and event-specific fears.

Children's responses to terrorism-induced trauma include many of the symptoms and reactions to nonterrorist traumatic events. However, terrorism-induced trauma results in unique stressors and reactions in children. Terrorism, by its nature, is likely to cause psychological stress. Because terrorists can strike at any time and at any location, the threat of terrorism is omnipresent and enduring. Mass school shootings can cast doubt on the safety of a school for children and their families. The unpredictable, indefinite threat of terrorist events, the profound effect on adults and communities, and the effect of extensive terrorist-related media coverage exacerbate underlying anxieties and contribute to a continuous state of stress and anxiety. The resulting anticipatory fear and anxiety may be severe.

Other types of violence, such as childhood maltreatment and community and neighborhood violence, are associated with externalizing symptoms in some studies. This has not been found in most studies on youth following terrorism trauma. Instead, mental health outcomes for youth exposed to terrorism or mass school shootings includes increased risk for trauma-related symptoms, anxiety, depression, and functional impairment.

RISK AND PROTECTIVE FACTORS FOR CHILDREN EXPOSED TO TERRORISM

Several risk and protective factors influence children's reactions to terrorist events. These include factors relating to the history of the terrorist event and individual, family, and community strengths and vulnerabilities.

History of the Terrorist Event

The level of exposure to terrorist actions, either directly or indirectly, affects a child's response. The degree of exposure to terrorist actions is related to the prevalence of PTSD. The more severe the traumatic event, the greater the risk of the child developing posttraumatic symptoms. Children who experience loss directly are more symptomatic. Suffering physical injury or witnessing the death or physical injury of others is associated with higher rates of PTSD and comorbid depression and anxiety. The degree of personal loss (i.e., the relationship of the child to the victim) is also correlated with the

severity of PTSD symptoms. Knowing an injured or deceased person increases the risk of symptom development. Children who lose a parent manifest the highest rates of PTSD. In addition to the level of trauma, the duration of exposure predicts the risk for the development of psychiatric problems in children.

Individual Factors

Individual factors and vulnerabilities that affect a child's differential response to terrorist events are related to developmental factors. These include a child's age and level of psychological maturity. Additional individual factors influencing responses include neurobiologic responses, predisposing risk factors, protective factors, and effects of resiliency.

Childhood Development Influences on Terrorism Reactions. How children understand and conceptualize traumatic events resulting from terrorist activities is greatly influenced by their developmental level with respect to cognition, emotional, and social factors.

PRESCHOOL-AGE CHILDREN. Preschool-age children between the ages of 3 and 5 years express their concerns for safety in terms of separation from parents and other primary caregivers. At this age, they are not able to cognitively understand the finality of death and do not fully understand the actual events that are occurring. Preschoolers rely on cues about danger from caretakers. They are more comforted than older children by reassuring and supportive parental behaviors. They may manifest their anxiety by having difficulties in separating from their parents. Regressive behaviors, including thumb sucking, enuresis, and fear of the dark, are not uncommon in young children. In addition, children aged 5 years and younger may manifest symptoms of fear, anxiety, sleep problems, and aggressive behaviors.

LATENCY-AGE CHILDREN. Latency-aged children, 6 to 11 years, are prone to derive a sense of safety from clear-cut rules. At younger ages, they have difficulty abstracting and thus tend to polarize complex situations into "right" and "wrong" or "good" and "bad." As they mature, they develop an increasing sense of empathy and altruism. Children in this age group recognize the finality of death and are capable of fearing for others. Latency-age children are extremely influenced by indirect effects of violence and trauma. Their reactions to terrorist events may include depression, PTSD, and anxiety. Symptoms of anxiety include irrational fears, sleep problems, nightmares, somatic complaints (headaches, stomachaches), irritability, angry outbursts, and school avoidance. Signs of depression may include sadness, withdrawal, feelings of hopelessness, and problems with attention. These problems may result in academic difficulties.

ADOLESCENTS. Adolescents aged 12 to 18 years are likely to be vulnerable to idealistic notions and an unrealistic sense of immunity to harm and omnipotence. This may influence their judgment regarding the degree of danger in their environment. When exposed to an extreme act of violence, such as a terrorist attack, young adolescents may feel overly responsible for protecting their parents from danger. Adolescent responses to terrorist events are more similar to adult responses. They may exhibit symptoms of acute or PTSD, including intrusive thoughts, hypervigilance, and emotional numbing. Additional symptoms may include nightmares, sleep disturbances, avoidance, and withdrawal. They are at increased risk of developing depression, substance abuse problems, and peer problems. Shame, humiliation, self-blame, and guilt may result from a sense of powerlessness.

Neurobiologic Consequences of Trauma in Children. Research on chronic stress, such as child abuse and neglect, and acute stress, such as disaster, war, or medical trauma, supports the hypothesis that trauma produces long-lasting effects on brain functioning. The human brain undergoes significant development during childhood and adolescence. Trauma may have a particularly devastating effect on the developing brain and may cause permanent changes in neurotransmitter systems that are stimulated by stress. Early childhood exposure to traumatic events influences the neurobiologic response to stress in the developing brain in such a way that it predisposes affected individuals to mood and anxiety disorders later in life. An important mediator of the stress response is corticotropin-releasing factor (CRF). Stress causes the hypersecretion of CRF. CFR is a key mediator of the stress response.

Dysregulation of the CRF system in the pituitary gland and brain causes an exaggerated glucocorticoid response. This response contributes to the symptomatology of traumatic syndromes, such as an increased startle response and symptoms of anxiety and mood disorders. Excessive stress hormones also affect myelination and synaptogenesis in the developing brain. This is associated with structural alterations in the corpus callosum, hippocampus, amygdala, ventromedial prefrontal cortex, and cortex. Elevated glucocorticoids have also been shown to affect the immune system causing altered glucocorticoid sensitivity in target immune cells, shifts in immune cell distribution, elevated proinflammatory cytokines, and a decrease in regulatory T cells. These changes result in impaired immunity and inflammation responses. Trauma has been associated with epigenetic changes through alternations in methylation resulting in changes in gene expression. Gene variation is also thought to contribute to the biology of differential risk for developing PTSD. The level of genetic influence on the variability of PTSD risk in the population has been shown to be 5% to 20%, with some variability for sex. New research is emerging on the biology of human resilience, including biologic and genetic protective factors that buffer the adverse neurobiologic responses to stress. In addition, emerging research suggests psychosocial factors such as positive relationships can provide a healthy buffer in the face of childhood adversity. More research is needed to understand whether the neurobiologic changes are reversible or permanent. An understanding of the neurobiologic consequences of trauma is important to determine treatment.

Predisposing Risk Factors. All children who are exposed to traumatic events experience a threatened sense of safety and potential for personal danger. However, children with predisposing risk factors are at greater risk of developing symptoms of anxiety and depression. Risk factors include exposure to past traumatic events during childhood, childhood anxiety, childhood conduct problems and antisocial behaviors, learning disabilities, and a history of psychiatric disorders. Gender also plays a role, with female gender being associated with increased risk for poor mental health outcomes following a traumatic event in the community and in certain forms of terrorism such as school shootings. Certain communities, including under-represented minorities, are more vulnerable to the effects of trauma, given high rates of childhood adversities and historical and ongoing structural violence. Children who have survived the death of a parent or another significant person are more vulnerable to the effects of trauma. In addition, each child reacts differently, depending on temperament and sensitivity and whether they tend to internalize or externalize experiences and emotions.

Protective Factors and Resilience. Many children who are exposed to trauma do not develop pervasive chronic posttraumatic symptoms. Factors associated with resilience among children after exposure to traumatic events are related to both psychological, biologic, and community support characteristics. Resilience is related to the variability in psychological interpretation of physiologic arousal and relies on the presence of consistent caregivers. Initial biologic responses to a fearful event include an increase in cortisol level in the brain and an increase in heart rate. Recovery from a traumatic event includes the ability to respond to the event in a supportive environment without extreme avoidance and in the absence of persistent physiologic arousal. The development of a perpetual state of fear, with both emotional reaction and abnormal physiologic response, leads to posttraumatic symptoms. Factors related to resilience include a child's characteristics and resources (persistence, motivation, adaptability, optimism, willingness to approach novel events, self-esteem, intelligence, social skills), developmental stage, family characteristics (support, open communication, consistency), and community support. Understanding risk and protective factors that contribute to a child's response to trauma is important to develop strategic interventions. Early intervention facilitates the process of recovery in vulnerable individuals.

Family Factors and Vulnerabilities

Children's response to trauma and their ability to cope with these disasters are strongly influenced by their parent's response to the violent events. There is a positive correlation between children's and parents' symptomatology. Parental involvement in mediating stress reactions in children exposed to terrorist attacks is a protective factor and helps to reduce a child's vulnerability to the trauma. Parents who underestimate their children's reactions may unintentionally hinder their children's process of

mastering the trauma. Terrorist incidents affect adults profoundly. Therefore parents, adult caretakers, and teachers may not be able to provide the support and reassurance needed to help avoid potential long-term emotional harm to their children. Increased levels of distress and less adequate coping skills have been noted in children whose parents responded to traumatic events with negative emotions. Positive coping responses in children are associated with parents who responded with positive emotional reactions. Family factors that have been shown to increase resiliency and buffer stress responses in children include a stable, secure emotional relationship with at least one parent, a parental model of constructive coping mechanisms, and physical proximity of children to parents.

Community Factors

Children's responses to terrorism are significantly influenced by community members' responses. While community violence can be an important childhood adversity that increases vulnerability for youth, community support and relationships within the community can be critical protective factors. Strong social support and positive community influences increase resilience. Community educational, political, and religious support fosters moral development in children. The presence of a caring adult who is able to provide emotional support, encourage self-esteem, and promote competence has a moderating influence on acute and long-term mental health outcomes. Community value systems, beliefs, and ideology contribute to resiliency by giving meaning to dangerous events, allowing children to identify with cultural values, and enabling children and adults to function under extreme conditions.

CHILDREN'S RESPONSES TO MEDIA EXPOSURE TO TERRORIST EVENTS AND SCHOOL SHOOTINGS

Media coverage of terrorist activities has a significant effect on children's emotional responses. The media plays an important role in providing information to the public, especially during times of disaster. The images portrayed are powerful and intensely emotional. They are frequently repeated over and over again. Terrorist organizations depend on the media dissemination of their activities to increase responses of fear, thus creating an environment of persistent threat. Similarly, school shooters often rely on and seek the attention of media. Similar to suicides, media contagion effect has been well documented in the aftermath of a mass school shooting. Studies have shown that one-third or more children watch the news. Extensive research has examined the influence of violence and aggression on children and their families. Recently, with the increase in terrorism and access to media throughout the world, more studies have examined the effects of children's reactions to media coverage of terrorism. The results research, covering a range of violent acts, has shown that remote exposure, such as viewing terrorism on television, has a significant clinical effect on children's responses.

Because media exposure is so extensive and the effect on children's reactions is significant, it is important to provide a summary of relevant factors pertaining to children's exposure, interpretation, and constructive and destructive effects of television and the media.

Several studies have examined the extent of children's exposure to the media, which has dramatically increased over the last decades. On average, children ages 8 to 12 in the United States spend 4 to 6 hours a day watching or using screens, and teenagers are reported to spend up to 9 hours per day. With the rise of social media and personal electronic devices among youth, it is now possible to get access to news including terrorist events and school shootings nearly 24 hours per day. News coverage in these mediums may be more stimulating, distressing, and unfiltered.

Childhood Developmental Influences on Media Responses

Children's understanding and interpretation of television and the media are related to their cognitive and psychological developmental levels. Children are less able than adults to regulate their emotions after watching traumatizing images.

Preschool-Age Children. Preschool-age children are most affected by visual images and emotional sounds. They are more upset by images of dead bodies or bloodied survivors and crying victims or witnesses than falling buildings or announcer commentaries. They are not able to understand the extent

of the tragedy. Preschoolers cannot distinguish between live pictures and replays. If events are shown over and over again, they believe that the catastrophe is repeatedly occurring in real life. They are likely to believe that the terrorism is happening at the same time they are watching the coverage, and they believe that it is occurring in close proximity to their home.

Latency-Age Children. Latency-age children (ages 6 to 11 years) have a better understanding of the event but will interpret it concretely. They have difficulty understanding the effect of the terrorist threats and adult responses to these threats. They are more sensitive to injured children or those whose parents were killed. School-age children are more likely to focus on their safety and their family's safety.

Adolescents. Adolescents are more capable of abstraction than younger children. They are equally affected by visual images; however, they are also concerned about the effect of threats on the future and community responses. They are able to understand more complex philosophical and existential issues such as social justice, politics, and theology. Their personal struggles with identity, meaning, and place in society may be compromised seriously or distorted by the perception of the world and its human interactions as dangerous, untrustworthy, and immoral. This worldview may have a negative effect on their sense of the future.

Although there has been extensive research about children's exposure to the entertainment media, there is far less scientific research about children's exposure to the news, especially exposure to terrorist media coverage. Media coverage of terrorist events has both positive and negative consequences.

Constructive Effects

Several constructive effects of the media have been emphasized. The media plays a vital role in disseminating information quickly to local, national, and international regions. Media coverage facilitates family and community cohesion. It facilitates the dissemination of educational information, and it can serve as a vehicle for discussion in older children and adolescents. The media, the Internet, and the telephone may serve as an extensive support system. Television stations are able to broadcast advice on how to help children to cope with stress and anxiety related to disastrous events. Data obtained after the September 11, 2001, attacks noted that sustained advertising through multiple media outlets was effective in informing individuals about counseling resources and encouraging them to seek mental health services.

Destructive Effects

The increased incidence of negative effects and stress-related symptoms in children exposed to media coverage of terrorist events has been examined recently in studies of the aftermath of the *Challenger* disaster, the Oklahoma City bombing, the Scud missile attacks and the Gulf War, the World Trade Center attacks, and the conflicts between Palestinians and Israelis. Repeated media exposure is especially detrimental for young children because of their cognitive immaturity. The effect of repeated coverage may promote the trauma and increase the intensity and duration of the effects. The media may have a negative effect on parents and caregivers, which directly affects the coping abilities of their children. More research is needed to measure the effects of media coverage of terrorist events and to determine whether they have detrimental or positive effects on mental health outcomes.

LITERATURE REVIEW OF TERRORIST EVENTS

Early research on the effects of terrorism indicated that children exposed to violence are greatly affected by the experience. These studies examined children's responses to terrorist activities in Northern Ireland, state terrorism in Guatemala, and terrorist attacks in Israel. Children manifested many psychological symptoms, including anxiety, depression, anger, feelings of hopelessness with regard to the future, difficulties with trust, anticipatory fears, and an altered sense of security. More recent studies have used statistically valid structured assessments to document children's reactions and symptoms. Research has been conducted in the aftermath of the 1993 World Trade Center bombing, the 1995

bombing in Oklahoma City, the 1991 Gulf War and its effects on Palestinian and Kuwaiti children, Scud missile attacks, and terrorist activities in Israel in the last two decades, the 1998 American Embassy bombing in Kenya, and the September 11, 2001, terrorist attacks. These studies emphasized the importance of a thorough assessment of children's responses and the influence of the media on children's reactions to a terrorist event. The rates of PTSD in children exposed to terrorist activities range from 28% to 50%. Other psychiatric problems have been identified, including anxiety, separation problems, depression, mood changes, sleep difficulties, regressive symptoms, and behavioral problems.

The importance of the influence of risk and protective factors on responses to terrorism has been identified. Research has increasingly focused on factors (personal, family, and community) that contribute to the persistence of psychological problems and factors that foster resilience. The results of these studies have contributed to the design of prevention and intervention strategies to help children and their families to cope and recover from the effects of terrorist attacks.

The 1991 Persian Gulf War and Scud Missile Attacks

Repeated terrorist attacks, including the Iraqi Scud missile attacks and terrorist activities on civilian sites in Israel, occurred during the war in the Persian Gulf in 1991. Further data measuring children's affective reactions and coping skills to terrorist events were gathered during studies conducted by several researchers during and after the attacks. The results of the research supported earlier data that correlated the degree of exposure to trauma to the prevalence of PTSD. Children who directly experienced loss due to terrorist attacks were more likely to develop symptoms of PTSD. The degree of personal loss was also correlated with the number of trauma symptoms. Knowing an injured or deceased person increases the risk of symptom development. The studies in Israel also focused on risk and protective factors and the long-term consequences of terrorist activities. Several studies addressed the importance of parental involvement in mediating stress reactions in children. Earlier research identifying the protective effects of family relationships was conducted on Cambodian adolescent refugees who survived 4 years under the Pol Pot regime from 1976 to 1979, during which 1 to 2 million people were exterminated. Adolescents who were able to re-establish contact with a family member had fewer psychiatric symptoms than adolescents who lived alone or in a foster home. The natural families were successful in maintaining traditional child-rearing practices. Clear adult–child boundaries and high expectations for conformity and responsibility were found in these families. Naomi Bat-Zion and Rachel Levy-Shiff noted that parents' responses were a central mediating factor for Israeli children's reactions to Scud missile attacks. Negative emotional expressions by parents were associated with increased levels of distress in children, whereas positive emotional manifestations were associated with increased coping efforts.

Laor and colleagues studied the long-term consequences on Israeli children of the Scud missile attacks. Children of mothers with poor psychological functioning showed more stress symptomatology in families who were displaced. The association between children's and mother's symptoms was stronger among younger children (ages 3 to 4 years). Unhealthy family interactions—either disengaged or enmeshed styles—exacerbated children's stress. These children manifested more symptoms, and their capacity to recover from the trauma was jeopardized. Conversely, children with adequate family cohesion manifested less stress in reaction to trauma and were better able to recover from the initial effect of the trauma.

Correlation between media exposure to terrorist activities and posttraumatic stress symptoms was verified in several studies. The effect of the media on children living in a war zone was also studied in Palestinian and Kuwaiti children during the Gulf War. Palestinian children who were exposed to traumatic events indirectly by the media had a higher incidence of anticipatory anxiety and cognitive expressions of distress than children who were exposed directly, who in turn manifested more symptoms of PTSD.

1993 World Trade Center Bombing

The first major terrorist attack in the United States occurred on February 26, 1993, when international terrorists bombed the World Trade Center in New York City. Six people were killed, and thousands of persons were trapped inside the building. One study compared the reactions of children who were

present in the building at the time of the explosion to a community sample of children who were indirectly exposed (children whose exposure was limited to interpersonal relationships with persons directly affected and media coverage of the event). Children who were directly exposed to the attack were more symptomatic. Children in the comparison group had mild symptoms, which did not interfere significantly with their functioning. A marked discrepancy was noted between the parents' report of PTSD symptoms and fear in their children and the children's direct report of their fears. In a follow-up study 9 months later, parents of both groups noted a decrease in PTSD symptoms and fear in their children. However, the children did not report any significant decrease. The results of this study emphasize the importance of evaluating children directly in addition to evaluating their parents.

1995 Oklahoma City Bombing

On April 19, 1995, the Alfred P. Murrah Federal Building, a U.S. government office complex in downtown Oklahoma City, Oklahoma, was bombed. Until the September 11, 2001, attacks, it was the deadliest act of terrorism on U.S. soil. A total of 168 people were killed, including 19 children, and more than 800 people were injured. Until then, few studies had examined children's reactions to terrorist events. Several studies were conducted in the aftermath of the attack, most notably those of Betty Pfefferbaum and colleagues. The significance of the effect of media exposure on terrorist attacks was identified in these studies. In one study, preschool-age children who attended day care in a facility near the Federal Building were examined. Although many of these children had minor injuries, none of them died or experienced serious injuries. Parents tended to underestimate symptoms in their children. All children met the exposure criterion for PTSD, although none of their parents reported diagnostic criteria for the disorder. Staff reports of children indicated that they met the exposure and re-experiencing criteria (posttraumatic play, discussion with peers). Only three children met the criteria based on parent report. The importance of direct observation of young children after exposure to trauma is essential for an accurate assessment of their reactions. The results of these studies also supported the literature documenting developmental differences in responses to trauma. Children were more likely to exhibit regressive behaviors and functional problems than the numbing and hyperarousal criteria. None of the preschool children reported symptoms of avoidance, restricted range of affect, or sense of foreshortened future that are typical of older children and adolescents.

Research on the Oklahoma City bombing also addressed the effects of media exposure to terrorist events and indirect exposure on children's responses. Lenore Terr and colleagues first studied these effects of distant trauma after the Space Shuttle *Challenger* explosion in 1986. She examined the responses of children who had watched the explosion on television rather than directly witnessed the disaster. Terr and her colleagues defined distant trauma as "the reaction (memory, thinking, symptoms) to a disastrous event, observed at the time of the event, but from a remote, and safe distance." Children's responses included symptom patterns similar to PTSD. Children's reactions to distant trauma also included trauma-specific fear, fear of being alone, and clinging behaviors. Children who lived on the East Coast were more symptomatic than children who lived on the West Coast. East Coast children had a significant increase in dreaming, drawing, and behavioral enactment, trauma-specific fears (e.g., death and dying, explosions, fires, airplanes), and clinging behaviors. Children throughout the United States had diminished expectations of the future. Latency-age children were more affected than adolescents. Most symptoms diminished within 1 year; however, for children with partial PTSD, symptoms (i.e., posttraumatic play for young children and hopeless attitudes about the future for adolescents) often persisted. Terr and colleagues defined a spectrum of trauma-related conditions that resulted from remote exposure to violence, including viewing media coverage of disaster events. Because one of the goals of terrorists is to inflict fear in the broader community, it is important to examine the effects of less direct and distant forms of exposure.

Pfefferbaum and colleagues assessed more than 3,000 middle and high school students 7 weeks after the Oklahoma City bombing. Most of the children heard or felt the blast, more than 40% knew someone who was killed or injured, and approximately two-thirds reported extensive television viewing of the bombing. Seven weeks after the event, one-third of the children reported continuing worry about themselves or their families. Female gender, acute reactions of fear and arousal, interpersonal exposure, and bomb-related television viewing were associated with an increase in posttraumatic stress

symptomatology. Children who experienced personal losses were at greater risk of watching significantly more terrorist-related television coverage than were children without direct losses. This further exacerbated the traumatic experience. Children who witnessed the bombings on television reported trauma-related stress for more than 2 years. In addition to broadcast media, print media (i.e., newspaper and magazine) exposure was also examined. Print media exposure correlated more strongly with enduring posttraumatic stress than exposure to broadcast media. Most of the children reported mild posttraumatic stress reactions and minimal effect on functioning. The clinical significance of the results is unclear, and further research is needed to determine whether they are at risk for future stress reactions.

1998 American Embassy Bombing in Nairobi, Kenya

More than 200 individuals were killed and thousands were injured on August 8, 1998, when a terrorist bomb destroyed the American Embassy in Nairobi, Kenya. Pfefferbaum and colleagues extended their studies of children who were indirectly exposed to terrorism, exploring issues that were not examined in the Oklahoma City studies, including exposure to other traumatic events. More than 500 indirectly exposed children in a convenience sample of Nairobi schoolchildren were assessed 8 to 14 months after the embassy bombing. Most of the children in the study lived in a community in which trauma was common and had experienced other crimes of violence and the death, illness, or injury of family or friends. Children who were at greater risk of developing symptoms of posttraumatic stress to the bombing incident had experienced a higher number of previous traumatic events, more severe posttraumatic stress reactions to past events, and stronger acute reactions. Little or no impairment of children's functioning was noted. Similar to the Oklahoma City school samples, the children in this study experienced little direct exposure to the terrorist actions, and posttraumatic stress reactions and impaired functioning were relatively low. Future studies are needed to explore the significance of risk and protective factors, as well as a more comprehensive set of outcomes, including long-term longitudinal data.

September 11, 2001, Attacks

The deadliest terrorist events were the attacks on September 11, 2001. There were 2,973 fatalities, not including the 19 highjackers—246 on the four airplanes, 2,602 in New York City at the World Trade Center, and 125 at the Pentagon. These events significantly affected U.S. and world history, governmental policies, and the lives of individuals in the United States and other countries. Indeed, "pre-9/11" and "post-9/11" have become commonly used terms worldwide. The terrorist attacks and their aftermath, including repeated media coverage of the events, have had a powerful effect on children and their families.

July 22, 2011, Utøya Youth Camp Attack

On July 22, 2011, a lone man disguised as a police officer opened gunfire, killing 69 people at a summer camp for adolescents on the Utøya islet in Norway and shooting and injuring 66 other youth. The Utøya mass shooting is the most severe terrorist attack during peacetime in Norwegian history.

Multiple studies were conducted with the adolescent survivors and demonstrated functional impairment one year following the attack and risk for medical sequelae up to two years later. In a study by Stene, Schultz, and Dyb, 1 year following the attack, 61% of survivors had impaired academic performance and 29% impaired school well-being, both of which were associated with symptoms of posttraumatic stress, anxiety, depression, and somatic symptoms. Stensland and colleagues conducted a case-control study to examine whether exposure to terrorism increased the risk of migraines. They found increased risk for both migraine and tension-type headache. A variety of sleep disturbances were found in 2-year follow-up in a study done by Gronli and colleagues of 42 survivors when compared with matched controls; these disturbances were more prevalent in a subgroup of survivors with psychiatric disorders. Strom and colleagues demonstrated that school performance was also affected 1 year later but noted that grades improved in the last year of high school, indicating possible recovery with improved school absenteeism. They note that these students reported high satisfaction with school

support and conclude that these results suggest the importance of providing in-school support for trauma-exposed students and helping them remain in school.

April 2013 Boston Marathon Bombings

On April 15, 2013, two pressure cooker bombs exploded during the Boston Marathon killing three people and injuring an estimated 264 others. A manhunt for the suspects followed. The subsequent investigation determined that the bombings were an act of terrorism.

Comer and colleagues studied the psychological impact of exposure to this event on children. He examined the rates of PTSD in children who witnessed the event and the impact of media exposure. Children who witnessed the bombings were six-times more likely to develop symptoms of PTSD. Two to six months after the attacks surveys from parents, living within 25 miles of the bombing and manhunt, showed that 11% of the parents identified PTSD symptoms in their children. This rate is similar to what was found among 9/11 New York City children 6 months after the attacks. Watching the manhunt on television was even more strongly associated with problems such as conduct issues or anxiety than exposure to the bombings themselves. Most children watched 1.5 hours of coverage on the day of the bombings, with 20% watching greater than 3 hours. About one-third of parents surveyed tried to restrict children's access to the media. Recognizing the potential psychological impact of media exposure on children, researchers advised that, "if there is a child who shouldn't watch an R-rated movie they should not be watching news with the same amount of violence and aggressive behavior."

School Shootings

The occurrence of school shootings has increased significantly during the past two decades. However, there have been few studies regarding the psychological effects on students who witnessed the shootings. Of those studies that were conducted, numerous challenges, including methodologic and design issues, attrition, under-represented minority youth, and variation in definitions and measures, contributed to difficulties in interpreting data and making conclusions. Research examining youth responses to school shootings was done in the aftermath of shootings at Jokela, Finland (2007), Virginia Tech (2007), Kauhajoki, Finland (2008), Northern Illinois University (2008), Seattle Pacific University (2014), Thurston High School, Springfield, Oregon, 1998.

A review of this research indicates that most young people demonstrated no long-term dysfunction. A minority of youth experienced severe and chronic symptoms. Clinically significant reactions were determined by proximity to the trauma, peritraumatic dissociation, posttraumatic emotional regulation difficulties, social support, and coping styles. Short-term responses included acute stress responses and emotional distress. Longer-term responses included PTSD, anger, and social withdrawal.

Risk factors for developing significant symptoms included proximity to trauma, history of previous trauma, female gender, fewer psychosocial resources, and media exposure to the event. Protective factors included social support seeking, resilience, gratitude, flexible coping styles, and secure attachment styles.

Children's Reactions. Research on children's reactions to these attacks corroborates the results of previous research studies. The degree of exposure, proximity to the disaster area, association with parental reactions, the experience of distant trauma (including media coverage), and history of pre-existing trauma were associated with increased stress symptoms. Children's reactions included symptoms of posttraumatic stress, depression, panic attacks, anxiety, separation anxiety, and agoraphobia. The largest study of children's responses was commissioned by the New York City Board of Education and was supported by the U.S. Department of Education through Project SERV (School Emergency Response to Violence). The study, conducted in collaboration with the New York City Department of Health and Mental Hygiene, surveyed 8,266 randomly selected children in grades four to twelve in the New York City metropolitan area 6 months after the September 11 attacks. Christine Hoven and colleagues surveyed children who attended schools in different areas of proximity to Ground Zero. Those children closest to the World Trade Center were most likely to have seen or heard the planes hitting the towers, seen the flames, been exposed to the dust and smoke, and struggled with fleeing to safety. Children farther away from the towers were more indirectly exposed to the attacks, including

interpersonal exposure through direct victimization of a family member or friend or through extensive media exposure.

Seventy percent of all children had either direct or indirect exposure. The incidence of PTSD in this group increased from 2% to 10.5% following September 11. Children who lived outside of New York City showed an equal prevalence of symptoms of PTSD and other psychiatric problems (depression, panic attacks, anxiety, conduct problems) as children living within the city. The diagnosis of separation anxiety doubled, and that of agoraphobia tripled. Children who were exposed to trauma before the attacks were more likely to experience PTSD and psychiatric problems. More than one-half of the total sample of children who exhibited symptoms of PTSD had experienced previous traumatic events. This high frequency of previous trauma exposure emphasizes the need to address and identify prior trauma experiences when conducting needs assessments and intervention strategies following a terrorist event. Hoven and colleagues noted that although some of the children in the sample did not meet the criteria for a DSM psychiatric disorder, they still suffered from disorder functional impairment in the aftermath of the terrorist events, which they suggest was mediated by grief/bereavement reactions. They emphasized the importance of identifying and providing specialized treatment for grief reactions in traumatically bereaved youth.

Parental stress reactions were also noted to have a significant effect on children's responses. The results of several studies noted a correlation between parents' responses and the frequency and severity of posttraumatic stress symptoms in children. Gerry Fairbrother and colleagues assessed predictors of posttraumatic stress reactions in children using a parent report administered by a New York City telephone survey. Parents reported that almost 20% of their children experienced severe or very severe posttraumatic stress reaction, and approximately two-thirds of children had moderate posttraumatic symptoms. Parental reactions were associated with the severity of posttraumatic reactions in children. Mark Schuster and colleagues surveyed 560 adults throughout the United States 3 to 5 days after September 11 using random-digit dialing. Parents with substantial stress reactions were more likely to report that their children had symptoms. Thirty-five percent of adults surveyed reported that their children had one or more stress symptoms. Forty-seven percent of adults noted that their children were worried about their own safety or that of a loved one. This data continue to support the importance of evaluating parents' reactions to a disaster when assessing children's response and needs for treatment.

Further studies after the September 11 attacks assessed children's psychological and behavioral responses by surveying their parents, either by telephone or Web-based interviews and assessments. William Schlenger and colleagues assessed psychological responses 1 to 2 months after the September 11 attacks using a Web-based epidemiologic survey based on the Posttraumatic Stress Disorder Checklist and the Brief Symptom Inventory. Adult reports indicated that children who were distressed by the events manifested symptoms of sleep disturbances, irritability, and fear of separating from their parents. Another study examined behavioral problems in New York City children by comparing three cross-sectional telephone surveys of adults. Two surveys were conducted after the September 11 attacks. The first survey was conducted 4 and 5 months and the second between 6 and 9 months after the attacks. The results of these surveys were compared to a representative survey conducted before September 11. The results of the study indicated that behavioral problems decreased in the first few months after the attacks but then returned to the predisaster levels after 6 to 9 months. These results support findings in an earlier study of children's behaviors before and after Hurricane Andrew.

Children's Reactions to Media Coverage. The effect of extensive terrorist-related media coverage on children's stress reactions was noted in several different studies after the September 11 attacks. Media coverage was extensive, and repeated coverage of the graphic images of planes striking the World Trade Center caused considerable concern about the added emotional effects of viewing the traumatic events. Results of a national study conducted a few days after September 11 concluded that children age 5 to 19 years watched 3 hours of television news on the day of the attacks. Only 8% of children did not watch any coverage of the event. Parents who reported that their children were upset restricted their children's television viewing. In children whose viewing of television was not restricted, the number of hours of television viewing correlated with the number of stress symptoms. A study commissioned by the New York City Board of Education 6 months after the attacks noted that 62% of children spent much of their time and 33% of children spent some of their time learning about attacks on

television. Approximately 75% of children increased the amount of time they spent reading newspapers and magazines, and more than 30% obtained information from the Internet. A total of 10.5% (75,000) of students manifested symptoms of PTSD 6 months after September 11, including children who were not affected directly by the event. Among these children, the prevalence of stress was higher among children who spent more time watching television coverage of the events than children who spent less time. The author noted, however, that these results did not determine a direct causality between television viewing and PTSD rates. Exposure to the images on television may have exacerbated children's stress responses; however, anxious children may have been more likely to seek information from the media than nondistressed children.

The effects of television viewing of the September 11 attacks also were examined in adults. Specific disaster-related television images were associated with PTSD and depression among persons who were exposed directly to the disaster. The number of hours of television coverage viewed and an index of the content of that coverage was associated with PTSD symptoms.

Studies in several other geographical areas in the United States support the effects of media exposure. The indirect exposure of September 11 via television, the Internet, and printed media was examined in a study of elementary schoolchildren in the southeastern United States by Saylor and colleagues. PTSD symptoms were reported in children who saw reports on the Internet (versus television and printed material), saw images of death or injury, or feared that a loved one might have died in the attacks. There was no measurable benefit to seeing "positive" or "heroic" images. Older children and boys were noted to have greater media exposure and more trauma-specific PTSD symptoms.

The correlation between television viewing of the September 11 attacks and an increased sense of insecurity and stress symptoms was also demonstrated in a study of elementary school-age children in Washington, D.C. A few studies examined reactions of children who lived on the West Coast. One month after the attacks on the World Trade Center, adolescents in California experienced heightened perceptions of vulnerability to death, which extended beyond the terrorist attacks and generalized to unrelated risks. After exposure to terrorist attacks, even from across the country, adolescents internalized a perception of the world as more risky and dangerous. Children in an ongoing longitudinal study who were assessed after the 9/11 attacks demonstrated posttraumatic stress symptoms and fears at levels comparable to children who directly experienced disasters.

Following mass school shootings, similar findings have been documented in a recent review that suggests media exposure may increase risk of psychiatric disturbance and that vulnerable youth may seek more media exposure in a reciprocal fashion.

Counseling Interventions. Few studies examined the frequency of counseling interventions following the September 11 terrorist attacks. In a telephone survey 1 to 2 months after the September 11 attacks, more than 100 parents were asked to describe the experiences and reactions of their children, most of whom were in school or day care at the time of the disaster. More than 20% of the parents studied reported that they received counseling. Parental posttraumatic stress, male gender, and having more than one sibling living in the household were factors that were correlated with receiving counseling. Two additional phone surveys of 423 and 112 parents, respectively, reported that 10% and 22% of symptomatic children received mental health services. These services were more likely to have been accessed by children whose parents reported having current symptoms of PTSD. Gerry Fairbrother noted that only 27% of children who had been identified in his first study to have severe or very severe stress reactions received any mental health treatment 4 to 5 months after the September 11 terrorist attacks.

In another survey, military health system beneficiaries in the Washington, D.C., area after the September 11 attack on the Pentagon were studied using the Electronic Surveillance System of the Early Notification of Community-Based Epidemics (ESSENCE) database. The number of visits to behavioral health clinics for anxiety disorders and acute stress reactions in children increased after the attack.

Much literature on mass school shootings has focused on a number of primary preventive efforts; some include gun reform laws, school safety initiatives, and increased mental health access for all youth through increased integrated services, such as mental health in school-based or primary care settings.

Primary prevention efforts post-trauma also target identifying youth in need of selective or more indicated services. Secondary or selective prevention efforts include supporting wellness, coping, and resilience, normalizing reactions, and target exposed youth who may be at increased risk. School-based interventions are useful for primary and secondary efforts, given their central role in the lives of most youth, and as such can increase ease and access to treatment. Other community sites such as religious institutions, after-school and youth programs, and even shelters and refugee camps have been effectively used for delivering interventions. Tertiary prevention or indicated services are reserved for those with persistent clinical symptoms and functional impairment in the aftermath of a terrorist attack or mass shooting and involve more specialized mental health services.

Project Liberty. In the aftermath of the September 11 attacks, the largest federal health program in U.S. history, Project Liberty, was created to provide mental health services to approximately 1.5 million people. It was funded through grants totaling $155 million from the Federal Emergency Management Agency (FEMA). The New York State Office of Mental Health (NYSOMH) administered and designed the program and collaborated with almost 200 local agencies to provide service delivery to New York City and 10 surrounding New York counties. The overall goal of Project Liberty was to provide free and anonymous community-based disaster services to help individuals to recover from the psychological distress that they experienced as a result of the attacks. Services provided included disaster-related outreach, individual and group counseling, psychoeducation, and referral services for both adults and children. The services were developed based on the assumption that although most persons' distress reactions were disturbing to them, they constituted normal reactions to a traumatic event. Most services were planned to be of short duration, with the expectation that reactions would dissipate over a short period of time. Interventions helped people to identify their trauma responses and understand them as normal reactions to a traumatic event and to reconnect people with their pre-existing social supports. Populations identified to need the greatest support included victims' families, survivors and their families, displaced individuals, emergency and recovery workers, children, older adults, persons with limited financial and social support resources, certain cultural and ethnic groups, and persons with a history of psychiatric problems. Project Liberty provided face-to-face counseling and educational and outreach services to an estimated 1.2 million individuals in the New York City metropolitan area between the time services began a few weeks after September 11 through December 31, 2003, when services were terminated. An important component of Project Liberty was to provide assurance/quality improvement activities to assess the quality of the delivery and effect of services. Data on demographic variables, symptom clusters, variables predictive of further need versus recovery, and long-term outcomes were gathered. In addition, data were collected to monitor how well the services provided adhere to the treatment manual and guidelines.

As part of the quality assurance program, counselors completed encounter logs that included checklists for reactions to the September 11 attacks. These results were used to help guide program planning and responses to service recipients. Nancy Covell and colleagues collected data on service utilization and reaction patterns among children who received Project Liberty counseling services. Nine percent of Project Liberty community-based service recipients who received counseling between September 2001 and December 2003 were children. Census data for the 15 boroughs and counties serviced by the project indicated that children constituted 25% of the population. During a later phase of the project, funded by Project Liberty and organized through the New York City Department of Education, an additional 36,337 children received counseling services between January 2003 and December 2004. With these additional services, approximately 20% of Project Liberty's total services for individual (including family) counseling were provided to children. The most commonly reported reactions for children's responses paralleled responses recorded for adults. Reactions included sadness, fear, anxiety, concentration difficulties, anger, irritability, intrusive thoughts and images, and difficulty sleeping. Children's responses differed according to their age. Elementary-school–age children were more likely to display signs of withdrawal and isolation, anxiety, and difficulties with concentration and memory. Older children (ages 12 to 17 years) were more likely to exhibit symptoms similar to adults, including avoidance and "numbing" reactions, in addition to substance abuse.

CLINICAL INTERVENTIONS AND TREATMENT

The effectiveness and comparative advantages of specific treatment modalities and interventions for children exposed to terrorism have not been extensively studied. Only recently have researchers developed rigorously designed studies to examine the effectiveness of treatments in children exposed to nonterrorism-induced trauma (e.g., sexual abuse, single-incident traumas, natural disasters, community violence, and war-induced trauma). The results of this research are promising and have significant implications for intervention strategies and treatment of children exposed to terrorism. These include community, school-based, individual, and family interventions and treatments. Essential components used in all treatment approaches include addressing protective and risk factors. Emphasis is placed on providing assistance to parents and caregivers and including them in treatment. Psychoeducation, cognitive restructuring, exposure, and coping skills management are frequently used treatment strategies. Guidelines and suggestions specifically related to media coverage of terrorist events are also crucial interventions to prevent the exacerbation of terrorist-induced trauma. Resources for information on commonly used assessment tools following a terrorist attack are provided in Table 54.11–1. Resources for information on children and terrorism are provided in Table 54.11–2. Guidelines for parents, health care providers, and educators are listed in Table 54.11–3, and guidelines related to media coverage are outlined in Table 54.11–4.

Community-Based Interventions

Based on their research into the effects of the 1995 Oklahoma City bombings, Robin Gurwitch and colleagues identified essential responses to community-wide acts of terrorism that included early community-based intervention; clinical needs assessment to identify children at risk; multimodal, trauma-loss–focused treatment programs; and program evaluation of treatment efficacy. Early community-based interventions focus on safety and protection. Restoration of rest and sleep, emotional support by parents and caregivers in the community, and stress-related symptom reduction are emphasized. Community-wide screening is critical to identifying children at risk. Screening may take place in schools, primary care settings, or neighborhood centers. Although there is no consensus on the most effective method of assessment, numerous structured interviews and self-reports are available. Screening identifies children at risk and children in need of acute, trauma-related services. An essential component of the screening process is distinguishing normal, developmentally appropriate reactions to trauma from abnormal reactions. Screening information may be used to develop specialized treatment programs based on the unique needs of the child, family, or community. Screening results also serve to provide pretreatment data for evaluating outcome studies of treatment effectiveness. Triage and referral, based on knowledge of psychopathology and risk factors, are essential components of the intervention. Active involvement of parents, caregivers, health care providers, educators, and community leaders is emphasized.

Strengths and Difficulties Questionnaire (SDQ)

From Pfefferbaum B, North CS. Child Disaster Mental Health Services: a review of the systems of care, assessment approaches, and evidence base for intervention. *Curr Psychiatry Rep* 2016;18:5. doi: 10.1007/s11920-015-0647-0.

Community and school interventions, family therapy, adult therapy, and group therapy have been used to treat traumatized children and families, help them with coping skills, and address issues related to trauma and loss, but no systematized studies have shown their effectiveness. Psychoeducational group meetings (i.e., parents or community meetings) reduce symptoms of individual, family, and community fear and arousal levels.

Community resilience has emerged as a way to conceptualize how communities can adapt and thrive post-trauma. One approach to assessing a community's needs and relative strengths include the Communities Advancing Resilience Toolkit (CART), which was developed by the Terrorism and Disaster Center (TDC), in Missouri and at the University of Oklahoma Health Sciences Center (OUHSC) in Oklahoma. Theory-based and evidence-informed, the toolkit consists of instruments for collection and assessment to support intervention implementation. The CART Assessment Survey is one such instrument and can be used to obtain baseline information about a community, identify strengths and challenges, and examine change over time after a disaster or intervention. This toolkit is noted to be multilayered and may be effective even in low-resource settings such as refugee camps.

School-Based Interventions

School-based interventions to treat PTSD symptoms have received empirical support in the literature. Annette La Greca and colleagues developed a school-based intervention manual to help children cope after Hurricane Andrew. Their manual has been distributed to schools internationally and has been used in other disasters, including the Oklahoma City bombing. Robin Gurwitch and Anne Messenbaugh expanded the work of La Greca and colleagues after Hurricane Andrew and the work of Storm and colleagues after the Australian bushfires. They developed a manualized treatment program for use following traumatic community events, including acts of terrorism. The program, Healing After Trauma Skills (HATS), emphasizes the active involvement of parents and caregivers and includes educational materials on basic safety skills and psychological stress responses. It uses treatment exercises to

address symptoms and behavioral difficulties associated with trauma and loss. Similar manuals and materials have been developed in the aftermath of the September 11 terrorist attacks. Among the materials that have been widely distributed internationally are *Helping America Cope: A Guide to Help Parents and Children Cope with the September 11th Terrorist Attacks* by La Greca and colleagues and the American Red Cross publication *Facing Fear: Helping Young People Deal with Terrorism and Tragic Events*. The preliminary results of the interventions and manuals developed to aid children after terrorist attacks are promising. However, outcome data have not been examined, and further research is needed to evaluate their effectiveness.

Increasing attention has been paid to social-emotional competence as a focus of primary prevention efforts and the basis for multiple studied interventions that schools can offer at-risk youth, given its role as a protective factor against mental health outcomes for youth exposed to trauma. Most studies of SEC programs include nonreplicated pilot studies with mixed but promising results.

Selective interventions have more evidence. A recent review by Yohannan and Carlson found school-based CBT and ERASE-Stress interventions feasible and with high rates of fidelity and noted that school-based CBT had high rates of acceptability. Enhancing Resiliency Amongst Students Experiencing Stress program uses a combination of CBT, bioenergetic exercises, meditation, art therapy, and narrative therapy and has been studied in a variety of settings post disasters, war, and terror-related traumatic events.

Cognitive Behavioral Intervention for Trauma in schools (CBITS) was designed and studied by Jaycox and colleagues to be delivered in inner-school settings by school staff in order to facilitate access and ease of treatment; it has been used as a selective intervention for at-risk youth and has been studied

with youth from diverse backgrounds. CBITS is a 10-week small group treatment program with one to three individual sessions dedicated to creating a trauma narrative. The key elements of CBITS include core CBT techniques: psychoeducation regarding the effects of trauma, relaxation, cognitive restructuring, graduated in vivo exposure, and social problem-solving. Not specifically designed for post-terrorism trauma, CBITS has been effectively culturally adapted in various communities, such as with Latino and Asian immigrants, African Americans in low SES settings, and American Indian youth.

Individual and Family Interventions

Children and families who manifest significant psychiatric impairment and dysfunction need more intensive health treatment. A variety of treatment modalities have been utilized and studied in traumatized children. Cognitive-based techniques, including trauma-focused CBT, have been the most rigorously studied treatment for traumatized youth in general, although other treatment modalities have an evidence base, such as eye movement desensitization and reprocessing, prolonged exposure, and narrative exposure. Most reviews comparing interventions do not find a difference between active groups, although there remains little evidence for debriefing as an early intervention.

Regardless of technique, interventions should be developmentally appropriate, promote safety and social support, build resilience, and include the family when appropriate, particularly given the association between parents' reactions and the severity of the child's posttraumatic symptoms. Families have a role to play in boosting resilience and are included in most evidence-based trauma treatment for youth. Therapeutic modalities are frontline with medications utilized only as adjunctive or for comorbid disorders.

Most interventions for youth within three months of a traumatizing event come from studies of war-affected youth or following a natural disaster rather than a terrorist or school shooting incident. One exception is a study of hypnosis-assisted therapy conducted by Lesmana and colleagues on children exposed to a terrorist bomb attack in Bali in 2002. This study built upon hypnosis as a technique utilized for trauma treatment in various settings and added a spiritual component for cultural relevance. PTSD symptoms were significantly decreased in 77% of the group compared with 24% of the control group.

Table 54.11–3.
Guidelines for Parents, Health Care Providers, and Educators: Terrorism and Trauma

Helping children and adolescents overcome psychological problems in the aftermath of terrorist events is an important challenge for families and communities. Proactive and preventative methods to help children to cope with loss and anxiety may help to facilitate positive posttraumatic adjustment and allow for healthier outcomes in children's growth and development. Several important general guidelines and suggestions are recommended for parents, health care providers, and educators to help children in the aftermath of terrorist attacks.

Adults should focus on positive ways of understanding and coping with their responses to terrorist events. Since September 11, 2001, many resources have been made available to help parents to cope with the terrorism-related fears and anxieties. The National Mental Health Association, Centers for Disease Control and Prevention, and American Academy of Child and Adolescent Psychiatry are among some of the agencies that have published extensive information.

Any parent who is overwhelmed by the effects of the disaster should seek help from primary care providers, educators, mental health agencies, and clergy. If parents are not able to manage their responses to the trauma, they will not be effective in reassuring their children and helping them to discuss their concerns.

Children cannot be sheltered entirely from knowing about or reacting to the disturbing event. Their fears of not knowing or understanding what has happened may be more disturbing than the truth. It is therefore important for parents to present information to children according to their developmental level. Children should be encouraged to express their concerns, and their feelings should be validated. Listening is more important than talking. All questions should be treated with respect and not ignored or dismissed. Responses should be made with calm reassurance and empathy. If a child's question causes anxiety or discomfort, the adult should not remain silent, because the child might interpret the silence as a sign of danger. It is permissible to tell the child that the question cannot be answered immediately but will be responded to after the adult has had time to think about it.

Younger children may act out their feelings rather than verbalize them. When possible, children should be encouraged to express their feelings in words. Answers to their questions should be honest and brief. More information than is requested should not be provided.

Older children may be hesitant to talk about their feelings. Discussing terrorist activities with them, without overwhelming them, and encouraging questions or correcting misperceptions are helpful.

Some children's and adolescents' responses may be confusing. Their defenses may be covering up their fears and anxieties. For example, they may make comments such as "We should not be upset, nothing has happened to us." Just as adults should be aware of their own defenses and coping styles, they should be sensitive to children's defenses and ways of coping.

If a child chooses not to talk about the events, the decision should be respected. Children may not be ready to share their experiences immediately; they may wait several days or weeks. Adults should make sure that children know that they are available to listen and discuss their feelings whenever the children need them.

Adults need to reassure children that they are safe and will be protected. Maintaining familiar routines helps children to know what to expect and is comforting to them. Reassuring children that they are loved and that they will be cared for will give them a sense of security. However, they should not be offered false assurance. Children should be taught to manage their fears and anger constructively by showing them how to handle their emotions in healthy ways. They can be made to feel more in control by allowing them to make decisions (meals, what to wear, what movie to see, etc.)

Children may be encouraged to draw pictures or write about their feelings. An important way for children to work through their worries is play. At times, it may be helpful for an adult to redirect the play into caring or helpful themes (such as pretending to make meals for emergency helpers or building hospitals). Focus and attention should be given to those who are helping in the community and nation at that time. Children may feel empowered by participating in events to help those who have suffered. Offering children opportunities to channel their feelings into positive actions allows for healthier outcomes.

Children should be given a reasonable sense of hope for the future. An example may be giving children historical references to how a country overcame previous threats to become a strong nation. Other examples include sharing past problems that children have had with classmates or family members and how they resolved their difficulties, or by giving examples of conflict and resolution within the community.

Children should be educated about racism and stereotyping. They should be told that discrimination and prejudice are unacceptable. Children learn from adults, who must be careful to monitor their own morals and values in front of their children.

Most children will develop healthy coping skills if given the support and reassurance from adults. Some children need more help, especially if they are at greater risk or have experienced the loss of a loved one. Children who may need more intensive help should be referred to a mental health professional. Children's prolonged responses to anxiety and stress may interfere with their ability to function at home, at school, or with peers. The signs of stress may be similar to those seen in adults: Avoidance (refusing to go places that remind them of a traumatic event), emotional numbing (diminished response or lack of feeling), re-experiencing trauma (through nightmares or daytime recollections), and hyperarousal (tendency to be easily startled, sleep disturbances). Children's responses also may differ from those of adults and may include disorganized or agitated behavior rather than fear and helplessness, constant repetitive play of themes of trauma that preoccupy and distract them from their daily activities, and frightening dreams that are not related to terrorist activities. In these cases, children should receive support and help from a mental health professional to prevent these symptoms from continuing to cause problems in the future as children grow.

Trauma-focused cognitive-behavioral therapy (CBT) has been the most rigorously studied treatment for traumatized children in general and has been studied for use in children as young as 3. Randomized, controlled studies have shown the effectiveness of CBT in targeting symptoms of PTSD and anxiety in youth following different types of abuse. Cognitive restructuring (reprocessing the traumatic event and identifying traumatic triggers), relaxation training, anger management skills, and grief management are important methods of treating PTSD after disasters. However, the effectiveness of CBT for treating children exposed to chronic trauma, past history of trauma exposure, and serious family dysfunction has not been studied.

Interventions such as ARC (attachment, regulation, competency) and ICT (integrative treatment of complex trauma) have been developed for individuals with early, developmental, and complex trauma.

Minimal data are available on the effectiveness of pharmacotherapy for treating symptoms of PTSD in children. Although other selective serotonin reuptake inhibitors (SSRIs) have not been approved by the FDA, they have been shown to have therapeutic effects on symptoms of depression in children. Because symptoms of anxiety and depression are common in children following trauma, treatment with SSRIs has been considered a treatment option. However, caution must be used because of concern about the potential increase in suicidal ideation when these medications are used in children. Close monitoring for adverse side effects of suicidal thoughts is necessary when prescribing SSRIs to young patients. Given known hyperarousal symptoms following traumatic events, medications that target this system may be helpful adjuncts. Commonly used medications may include alpha agonists to help down-regulate the hyperarousal system and target anxiety and attention difficulties or to help with sleep difficulties.

Table 54.11–4.
Guidelines Related to Media Coverage

Because the media plays a major role in informing the public about terrorism and may be a causative agent in symptom formation, it is critical for parents and families to have guidance about the use and misuse of media in traumatic times. Several media-related guidelines have been identified to help prevent traumatizing children specifically from media coverage of terrorist events. Parents, educators, health care providers, politicians, and journalists must increase their awareness about the potentially harmful effects of media exposure on children. Parents should closely monitor disaster-related television viewing by children.

Children's exposure should be limited. Adults would also benefit from limiting their own exposure to reduce their stress reactions so that they and their young children are better able to cope. General recommendations on limiting screen time: young children 18 months or younger screen time only for video chatting along with an adult; 18–24 months, watching educational programming with a caregiver; 2–5 years of age, limiting children to one hour per weekday and 3 hours per weekend for noneducational screen time; children ages 6 and older, encouraging healthy habits that limit screens for children. Recommendations for mitigating the negative effects of news coverage include: watching news with child when appropriate, asking child what questions they have, provide reassurance regarding his/her safety in simple words, look for signs that news may have triggered fears or anxieties.

Vulnerable persons who have risk factors, such as young children and parents with previous traumatic experiences, should be especially cautious. The use of media should take into consideration a child's developmental level. Young children should not watch adult-oriented shows. Older elementary school-aged children may tolerate being exposed to news "briefs" in which simple concise statements of the facts are made (e.g., reports that occur on major networks between television shows) but may not be ready to watch news shows that spend 30 minutes with interviews, photos, and more detailed discussion of devastation.

Parents and caregivers are advised to watch the coverage with children when they are permitted to watch television. This supervision provides adults with the opportunity to observe children's signs of distress and be available to answer questions and discuss relevant topics.

School staff also must be aware of the importance of monitoring media exposure and should consider policies related to viewing coverage of traumatic events.

Constructive uses of the media should also be taken into consideration. The media may be helpful for parents by providing them access to valuable information to help them when dealing with children in the aftermath of terrorist attacks. Media reports can be used to help reassure children that many adults are working to maintain a safe and protected environment for them Adults may choose to offer taped news reports or specific types of media discussion that will help a child feel secure in the knowledge that adults are taking charge and responding in ways that are protective. Films about resilience, survival, family and community consolidation, and triumph over adversity may play a constructive role by giving children a reasonable sense of hope for the future. Long after an event, children may watch shows with their parents to help them understand terrorism, for example, "Through a Child's Eyes; September 11, 2001," which is an Emmy Award-winning HBO children's special that deals with young school-age children's responses to the September 11 attacks.

Certain limitations exist when applying trauma-specific interventions to children who have experienced ongoing violence, whether in the form of complex trauma, community violence, or the continual threat of terrorism. Crisis intervention alone does not prevent the long-lasting effects on children exposed to terrorism. Compounded effects of multiple traumas have not been addressed. The unpredictability of terrorist attacks, the indefinite nature of violent threats, the lack of specific geographical boundaries, and the effects of media coverage result in unique stressors and pose specific challenges for the treatment of terrorism-induced trauma in children.

FAMILY TRAUMATIC GRIEF

Ben was a 7-year-old boy whose maternal uncle, a firefighter, died in the September 11, 2001, World Trade Center attacks. His uncle did not return to his company on that day. Ben was first seen in treatment 1 month after September 11. He was at school when the attacks occurred. His father picked him up. After they returned home, Ben, his parents, and his 5-year-old sister watched the news and the repeated images of the falling towers. Ben knew that his uncle was a firefighter, but he did not know whether he had responded to the attacks. Ben's mother was very distraught as she tried desperately to find out what had happened to her brother. Ben's father stayed home from work during the first week after September 11 and assumed most of the household chores and child care, which his mother had been primarily responsible for prior to the attacks. Ben was very worried about his mother. He was aware that the family was concerned about his uncle, and he asked frequent questions about him. His parents had been ambivalent about what to tell their children. Initially, when they did not know for certain whether Ben's uncle had died, they were hesitant to accept the possibility of his death and maintained hope that he was alive. They told their children that they were hopeful that he would be found. Both parents made a conscious effort to make sure that their children were not exposed to television coverage. However, after the children were in bed, they spent several hours watching the news coverage. They talked to their family and friends by phone and tried to protect their children by talking in another room while the children were playing. After Ben's parents were notified of his uncle's death, they struggled with their feelings of shock and grief. They did not tell their children about their uncle's death for several days. By continuing to "not know," Ben's parents may have reacted to their terror and loss by using protective defenses of shock and disbelief. Ben and his sister continued to ask questions: "Was Uncle Gary one of the firefighters who died trying to rescue the people in the tower?" The children's direct questioning challenged the adults' defenses of denial. Ben's mother was irritated by his frequent questions and then felt guilty for being angry with him. Ben, in turn, became upset, whiny, and oppositional. He also became very clingy and insisted on being with his parents, following them to each room of the house. He did not want to go to the bathroom by himself. At night, Ben would join his parents in their bedroom, which was very uncharacteristic of him. Ben's parents eventually told their children that their uncle had died. Ben continued to ask questions about his uncle's death. "How did he die? Did he burn to death?" His mother, in a state of traumatic bereavement, did not know how to answer his questions. Ben's father tried to reassure his son that his uncle was now in heaven.

When school resumed the following week, Ben refused to go. He complained of "belly aches" in the morning. When his parents tried to help him to get ready for school and reassure him, he started crying. He refused to get dressed for school and had temper tantrums. Ben's mother took him to school. He went willingly with her, but when it was time for him to leave her and enter the classroom, he started crying and refused to let go of her. She struggled to see him in so much anguish, and after speaking with the school counselor, she decided to take Ben home for the day. The school counselor noted that several of the children had not yet returned to school. Ben had no prior history of school problems and had always enjoyed attending school.

Ben continued to have difficulties separating from his mother and continued to refuse to go to school. He no longer asked questions about his uncle, and his parents avoided talking about him in front of their children. Ben continued to complain of stomachaches. His parents became increasingly concerned and made an appointment for him to see his pediatrician. They noticed that Ben's physical complaints were more frequent on the days he was expected to go to school, but they wanted to make sure that he did not have an underlying medical problem. Ben's pediatrician completed a full medical workup and did not find any underlying organic problems that could be contributing to his complaints of abdominal pain. She reassured Ben's parents that no further medical tests were needed. She explained to them that she believed Ben's current difficulties were related to the recent trauma that the family had experienced and referred them to a child therapist.

The child therapist met with Ben's family initially. Ben's parents focused on their worries about their son. They felt that his problems were related to the recent traumatic events and the death of his uncle. They acknowledged that they felt overwhelmed and were grieving the loss of their uncle. Ben

said that he was worried about his parents, especially his mother. “She pretends she is OK, but I don’t believe her.” The therapist then met with Ben alone. Ben said he was worried about his mother. He was also afraid that another attack would occur. The therapist commented that this was a scary time, and a lot of children were frightened, sad, and mad. Ben was quiet and did not answer. While they were talking, Ben drew a picture of his uncle’s fire truck. The therapist asked Ben about his uncle. He said that he liked to spend time with his uncle, who had “awesome baseball cards.” Ben and his uncle’s family would get together every Sunday. Ben commented that the Sunday before his uncle died, he went to a friend’s birthday party while his family visited his uncle’s family. He was very sad that his uncle died, but he also felt “bad” that he chose to go to his friend’s party instead of spending time with his uncle. The therapist assured Ben that his uncle knew that Ben loved him. She explained to Ben that he did not cause his uncle’s death. Ben responded, “I know, but I felt like I jinxed him.”

When the therapist met with Ben’s parents alone, she asked them how they were coping. Ben’s mother noted that in addition to mourning the death of her brother, she was also very frightened that another attack would occur. She had frequent nightmares and was afraid to leave the house. She was afraid for her husband’s safety. He worked long hours and commuted to his job in Manhattan by subway. Her main supports were her sister, who lived out of state. She had a few close friends, but their families were also affected by the September 11 attacks, and she did not want to be a burden to them by talking about her fears and loss. Ben’s father was also worried about his wife. He noted that he coped with stress “by being a workaholic.” Both parents continued to watch the television coverage of the events, usually at night after their children had gone to bed. They stated that they tried to avoid talking about the terrorist attacks in front of their children because they “did not want to upset their children further.”

The therapist continued to meet with Ben and his family. Family sessions were held, in addition to individual sessions with Ben and sessions with his parents. Family sessions focused on encouraging the family to communicate more directly with each other and to express their feelings of grief and anxiety. The therapist helped to normalize Ben’s parents’ reactions by explaining to them that their feelings of fear were normal reactions to an extreme situation. She encouraged them to use their supports, including their friends and family. She helped them to develop coping strategies. Ben’s mother had stopped exercising after the attacks, an activity she had previously enjoyed. Ben’s father was able to reduce his work hours and spend more time with his family during the crisis. Both parents were advised to decrease the amount of time they spent watching television. The therapist explained to them how their reactions and defenses affected their children. Ben’s parents were given guidance regarding how to talk to their children. They were encouraged to listen to their children, and they were taught how to understand their children’s feelings and behaviors. In particular, the therapist helped Ben’s parents to understand how his difficulties with separation and school refusal were related to their responses and anxieties, especially his mother’s worries. The therapist helped Ben’s parents to understand his experience and how he was feeling guilty that he may have caused his uncle’s death by not visiting him. The importance of returning to a regular routine and ordinary daily life was emphasized. This included making sure that Ben’s parents were consistent in helping him to attend school every day. To facilitate his return to school, the therapist spoke with his school counselor to collaborate on treatment. It was agreed that Ben’s mother would drop him off at school and the school counselor would meet him at the school door. Ben would meet with the counselor every day during the first week. He would also be allowed to call his mother during the first week. The therapist and school counselor agreed to collaborate and communicate regularly to make appropriate adjustments to the treatment plan as needed. In addition, once Ben returned to school, he would participate in a peer group that the school counselors had developed to help children with similar experiences and losses.

The therapist also met with Ben individually. She helped to reassure him that the adults in his life, including his parents and teacher, would do their best to make sure that he and the other children were safe. Ben’s therapist helped to normalize his feelings, explaining to him that other children also experienced feelings of sadness, anger, fear, and confusion. She facilitated the symbolic expression of his feelings by supporting and joining him in play and in art projects. She listened to him when he expressed his feelings verbally and clarified his feelings by helping him to find words to name his

emotions. She avoided probing questions and followed Ben's lead. Ben's attachment and identification with his uncle were actively facilitated by helping him remember and talk about his uncle.

Lastly, the therapist offered guidance to Ben and his family regarding what symptoms to monitor over time and the recommendation around when to seek more specialized trauma-focused treatment if symptoms persist or become functionally impairing.

FUTURE DIRECTIONS

The continuing frequency of terrorist events around the world and their effect on children and families underscore the urgency for an effective public health approach to providing for the needs of children and their families. Mental health organizations and providers must be educated and prepared to help children in the aftermath of terrorist activities. Similarly, the rise in school mass shootings underscores the need for a stepped-care approach. Terrorism is a community mental health issue because terrorism is a form of psychological warfare whose target is to intimidate and cause fear. Several mental health activists have made recommendations to help communities organize and plan appropriate interventions and treatments. Collaboration among community, educational, and mental health care organizations is essential. In addition, collaborative efforts between mental health organizations nationally and internationally have been initiated and continue to grow and develop. In the United States, the mental health approach to disaster has developed over several decades, primarily based on experiences with natural disasters. Following the 1995 Oklahoma City bombings, many modifications to the federal approach were made, including more effective crisis intervention methods and better triage and referral services, to address the unique effects of violent acts of terrorism. The effect of the events of September 11, 2001, further emphasized the difficulties in identifying the extent of services needed, the scope and depth of personnel and funding necessary to provide services, and the anticipated duration of treatment. The lack of sufficient data and comprehensive information prevented adequate funding by federal mental health agencies to address mental health needs of children and their families. Obtaining money and resources will continue to be a significant challenge. Advocacy for program development and funding to increase community services for children affected by terrorism is needed.

In the general community, trained mental health providers who have experience working with children are needed to identify children at risk and provide community-wide services and more intensive treatment interventions. Standards for mental health providers who work with children and families exposed to terrorist events should be established. Within school settings, there has been increasing effort to train school staff to provide primary prevention efforts of increasing social-emotional health and boosting resiliency. In certain communities, schools have been the focus of selective interventions to identify youth at increased risk following a traumatic event such as a school shooting and in some cases, to provide selected treatment. In all settings where youth reside, more collaboration is needed to establish referral networks to specialized mental health services when needed and to offer a continuum of care to youth in need.

The correlation between media exposure to terrorist events and traumatic stress symptoms in children is well documented. Collaboration between community agencies and the media is necessary. Public policy limiting media coverage is a controversial issue but needs to be addressed.

The research on childhood reactions to terrorism-induced trauma highlights the need for a systematic public health approach that provides community-based interventions, screening of children at risk, triage and referral services, community-based trauma and loss programs, and multimodal outcome studies. During the last decade, policy and procedures for the conduct of organized interdisciplinary research have received more attention. These advances resulted in more cooperation between researchers to address the issue of how ethically to obtain research data during times of crisis. Planning to incorporate research infrastructures into disaster preparedness plans is necessary. Further research on terrorism and its unique effects on children and families should be encouraged. More research on the effects of early interventions and treatment is needed to provide reliable mental health response planning. Further research identifying children who are at risk for developing PTSD and related symptoms will allow for more efficient triage services. Studies on longitudinal effects and the long-term effect on development in

children exposed to terrorist violence will provide information useful for initial and later treatment interventions. More reliable and objective measures are needed to quantify parents' reactions and the effects of social supports. Methods for evaluating a child's intrinsic resiliency will help to differentiate coping models learned from parents. Assessment of the capacity of the public health system to respond to terrorist events will help to determine optimal response recommendations for the future. Efforts should be focused on increasing community services for children affected by terrorism and encouraging further research on terrorism and its unique effects on children and families. Responses from mental health providers and organizations, educators, spiritual leaders, and community organizations will be better able to help children to cope and will minimize long-term psychological problems to enhance healthier outcomes and growth.

54.12 Impact on Parents of Raising a Child with Psychiatric Illness and/or Developmental Disability

Alice R. Mao, M.D., Matthew N. Brams, M.D., Kathryn Forneris, D.O., M.P.H., and Pieter Joost Van Wattum, M.D., M.A.

The birth of a child is generally anticipated with joy and many complex emotions. Parents have conscious and unconscious expectations about the child's looks, temperament, personality, and other characteristics based on past experience. Expectations develop about the child's developmental course and future, including education, career, and generational continuity. Parents also have expectations for themselves in their new roles, which are shaped by past experiences and other important role models. One of the important tasks of parenthood is the adaptation and modification of these fantasies and hopes to match the reality of the actual child and their abilities.

The task of raising a child requires fostering autonomy while providing appropriate limit-setting at each developmental stage. The child has an increasing need for separation and individuation as they move into adolescence and then into adulthood, which must be combined with nurturing parental structure and support. Ultimately, the goal is for the child to become an adult who is able to successfully form relationships, support themself, and take on a socioculturally defined mature family and societal role. Unfortunately, if a child is not developing normally or is suffering from a psychiatric disorder that is affecting multiple domains of functioning, their ability

to achieve these goals is compromised and caregiver burden is increased.

When a child is diagnosed with a psychiatric or developmental disorder, parents typically undergo a complicated adjustment and grieving process. This may include anger or sadness that their child is not developing normally, coping with the narcissistic injury that the “imperfect” child is a negative reflection of their parental competency. In addition, parents may irrationally blame themselves for causing a disorder to manifest in their child. Disorders with heritable causative factors may lead to parental self-blame and/or blame from nonaffected family members. The contrast between the imagined parenting experience of raising a normally developing child and the reality of caring for a child with a psychiatric and/or developmental disorder may lead to intense disappointment and increased caregiver burden.

This section reviews the effect on parents and caregivers of raising a child with serious psychiatric disorders, specifically bipolar disorder (BPD), attention-deficit/hyperactivity disorder (ADHD), schizophrenia, and autism/developmental disorders. Unique stressors faced by parents raising children with these disorders are summarized. Psychological responses to these stressors and research on specific interventions developed to help parents and family members cope effectively are reviewed. Individual psychotherapeutic work with parents of psychiatrically ill children may be enhanced by understanding the life-changing consequences of dealing with a chronic mental illness or developmental disability. Importantly, the parent’s ability to implement complex and multimodal treatment interventions for their child is affected by their responses to their situation. Early intervention for parents after their child receives a psychiatric diagnosis may improve the long-term outcome for the child.

IMPACT ON PARENTS OF RAISING A CHILD WITH AN AUTISM SPECTRUM DISORDER

In the mid-1940s, Leo Kanner and Hans Asperger independently reported on disorders in childhood that were characterized by repetitive or stereotyped behaviors, language abnormalities, and difficulties in social interaction. Initial reports included observations of similarities between parents and their affected children. Asperger suggested possible genetic factors; however, prevailing theories attributed the children's symptoms to their parents' behaviors. Currently, autism spectrum disorders (ASDs) are clearly recognized as biologically based neurodevelopmental disorders.

Unique Stressors

Psychiatrists caring for parents of people with ASDs will be better prepared if they are aware of the multiple issues that affect families. This subsection points out the unique stressors associated with raising a child diagnosed with ASD; highlights issues related to the life cycle of the family; summarizes findings from studies of parents coping with raising a child with ASD; discusses the psychiatric disorders common in these parents, including the "broad autism phenotype" (BAP); and suggests some approaches to therapeutic work with this population.

Parenting a child with special needs, especially when accompanied by an intellectual disability (ID), is stressful. Stressors uniquely impacting the parents of children with ASD include diagnostic uncertainties, the prolonged duration of the diagnostic process, the extreme variability in the child's developmental course, the effect of the child's atypical social communication despite the child's typically normal physical appearance, and the burden of creating and organizing the child's treatment program.

Diagnosis of ASD is often delayed when primary care providers do not screen for or recognize signs of developmental disorders. Referrals to subspecialists may be time-consuming and lack definitive results. Siklos and Kerns reported that parents saw an average of 4.5 professionals and waited almost 3 years to obtain a diagnosis. More than 50% of parents were dissatisfied with the diagnostic process. Geographic variations in the prevalence of ASD,

as well as rates of children receiving school-based special education following diagnosis of ASD, are well documented, suggesting that state policies, community resources, and community-level demographic factors impact the diagnosis and treatment of ASD. In 2005, Mandell and Palmer reported varying prevalence rates of ASD among states based on education-related spending, the number of school-based health centers, and the number of pediatricians in the state. In 2020, Safer-Lichtenstein, Hamilton and McIntyre found that state-level demographic factors, including household income, average adult educational attainment, and political leanings, also impacted the rates of ASD diagnosis and treatment. Obtaining a timely diagnosis and accessing subsequent care are important for parents. Suboptimal disciplining techniques used prior to the ASD diagnosis being made can result in caregiver loss of confidence and self-efficacy.

The spectrum of autism disorders is very broad; therefore, predictions about a specific child's prognosis are imprecise. Irregular patterns of skill development are common. Developing appropriate expectations for a child and predicting future development is challenging for most clinicians because of wide variations in developmental progression.

Of the behaviors associated with the diagnosis of ASD, abnormalities in social communication appear to be a particular source of distress for families. A study performed by Safronoff and Farbotko in 2002 found that autistic children's difficulty with verbal and nonverbal communication results in parents feeling unable to meet their child's wants or needs. The inability to understand her child and their behavior is reported significantly more frequently by mothers of autistic children than control mothers.

Lack of consistent behavior across time, people, and environment is frustrating and confusing for parents. Children with more obvious impairments, such as those affected with Down syndrome, are excused and tolerated by others, but the typically normal physical appearance of a child with autism leads others to expect appropriate behavior. Fear of their child's unpredictable, disruptive, and unusual behavior, as well as others' responses to it, leads parents to avoid

public situations, which in turn leads to restriction of family activities, social isolation, and increased burden in completing everyday household chores, such as grocery shopping.

Typical recommended interventions for children with ASD are obtained from several different systems—public education, ancillary health care therapists, hospital-based, center-based, and community-private practitioners. The family is typically left in charge of coordinating care with a complicated network of professional providers who have differing or conflicting opinions, recommendations, physical locations, and financial/insurance requirements. The lack of curative interventions from traditional care providers, the lack of empirically supported therapies, the nature of ASD symptoms, and the chronicity of these disorders have led to the emergence of unconventional treatments by alternative practitioners with poorly supported claims of cure or rapid improvement, further complicating an already convoluted process of establishing appropriate care for the affected child. Thus, the family is confronted with the challenge of obtaining intensive treatment for their child during a critical time frame with little professional guidance.

Lifespan Issues

Each developmental stage presents the family with unique and specific issues. Early childhood is characterized by the family's realization of an abnormal developmental trajectory, the diagnostic process, and issues of definitive diagnosis. Parental guilt, mourning the loss of raising a normally developing child, the unexpected negative responses of extended family members to the child's unusual behaviors, and the possible additional diagnosis of ID are all issues that color this period. The child's irregular sleep patterns, hyperactive behavior, lack of effective communication, peculiar eating and elimination habits, as well as safety issues, and the lack of ability to obtain appropriate child care, are practical concerns facing most parents. Accepting the diagnosis, finding community services, and planning for the future are tasks for the family. Families report that education about the disorder and information about

resources were the most helpful interventions they received during this period. Other useful resources were learning and behavior assistance, speech therapy, and family support.

With a good school program, middle childhood may be a relatively easier life phase. Behavioral problems often improve; families have adjusted their expectations of the child and have accepted the delays in development, abnormal social interaction and communication. Developing an educational program that includes the necessary special education services, offered in the setting that is most conducive to the child's learning, is the goal of collaboration with the school system. The focus may be on the development of adaptive behaviors in the areas of self-care, domestic chores, and social behaviors. However, parents may grieve anew as they recognize the child's inability to participate in many social activities because of their anxiety, language, or developmental differences. Sibling issues can occur at any time; however, they are common during this time period. The affected child behaves oddly, is not a typical playmate, and requires much of the parents' time and energy. Parents often underestimate siblings' worries and overestimate siblings' abilities to understand the implications of an ASD diagnosis.

By adolescence, almost all families report worries about their child's future. Public education services end, and adult services may be uncertain. Behavioral concerns include aggression, increased sexuality, and an increased sense of independence without the skills necessary for self-management. Higher-functioning children may become aware of their differences from peers. Nonaffected siblings may be leaving home, creating a higher burden of care for parents who have relied on their help. The aging of grandparents may also lead to less support and greater family strain.

The most pressing issues for adulthood are appropriate living arrangements and vocational opportunities. The move toward deinstitutionalization has eliminated the option of residential placement for most families; thus, many adults with autism continue to live with their families. There are limited opportunities for appropriate social experiences and employment. Young adults with comorbid ID may find services through this diagnosis. Individuals

with higher cognitive skills often continue to lack job-related skills and remain un- or underemployed. Seltzer et al. found that 57% of parents aged 50 or older live with their child with a developmental disorder versus 16% of normally developed children. Research performed by Anderson et al. further explored rates at which young adults with ASD, specifically, live with their parents or guardians, noting that individuals with ASD between the ages of 21 and 25 years old were more likely to live with a parent or guardian and for a longer duration than their peers with intellectual disabilities, learning disabilities, or emotional disturbances.

Guardianship and long-term estate planning are worrisome issues for parents. The divorce rate has been found to be higher in parents of autistic children when compared with parents raising normally developed children (25% vs. 13%). Distinct from typically developing children, where the divorce rate is high until approximately age of 8, the likelihood of divorce remains high through early adulthood for parents of children with autistic spectrum disorder. The financial strain for therapeutic interventions cannot be overlooked; In 2014, Buescher, Cidav, Knapp, and Mandell estimated the cost of caring for an individual with ASD across the lifespan at $1.4 million to $2.4 million USD, with costs increasing for individuals diagnosed with concurrent ID.

Psychological Responses to Raising a Child with an ASD

Stress. Many published studies have documented that parent of children with ASD report more stress than parents of children with other developmental disorders or parents of typically developing children. A variety of factors have been found to cause and/or mediate this finding, the most important of which is the gender of the parent. The preponderance of studies examining gender differences in parental response soundly endorse the observation that mothers report significantly more stress than fathers in general and within given family units. Explanations for this finding include those mothers shoulder the greater burden of child care, even if they work outside the home; perceived parenting competence contributes more to

mothers' self-esteem than to that of fathers; and fathers use more effective coping strategies than mothers.

Most studies support a positive correlation between the amount of stress mothers report and the behavioral problems of the child. These behaviors include oppositionality, noncompliance, aggression, irritability, and unpredictability. None of these behaviors are core features of ASD, but they often accompany these disorders. Neither the severity of the ASD per se nor the level of adaptive functioning were found to correlate with reported stress or poor maternal outcome. However, these were not universal findings, as other authors have found that autism severity or the number of services the child received, which was interpreted as a measure of autism severity, did correlate with levels of maternal stress.

Several studies have aimed at understanding factors other than the child's autism that affected the well-being of individual family members. Factors such as the partner's depression and anxiety were positive predictors of stress for both mothers and fathers. Attributes of the affected child were predictors for maternal but not paternal stress. Factors that have been found to decrease parental stress include positive coping styles, belief in the efficacy of treatment, and social support. Parent education and the acquisition of behavioral management skills have also been found to be beneficial. Greater marital quality is predictive of lower levels of stress.

Coping. Coping describes "a process by which an individual responds to threats of stress. Coping strategies are generally divided into two categories; (1) emotion-focused strategies, which aim to reduce or mask feelings of distress, including engaging in denial, hoping for miracles, fantasizing, using food or drugs, distancing, and avoiding; and (2) problem-focused strategies, which aim to solve or change the problem, including confrontive coping, fighting for what is wanted, expressing anger and other feelings, taking chances, and engaging in positive reappraisal. Several studies have examined the consequences of particular coping styles for parents of ASD children. Emotion-focused styles have been found to correlate with

increased depression, isolation, and marital problems. Conversely, problem-focused coping was associated with lower levels of depression. Pottie found that escape, blaming, withdrawal, and helplessness lead to decreased positive mood, whereas problem-focused strategies, including social support, positive reframing, emotional regulation, and compromise coping, resulted in increased positive mood. Moreover, coping style more robustly predicted levels of depression than locus of control and social support, although these factors were also contributory.

Research on coping over time suggests that, in general, young adults are more likely to use problem-focused strategies, while middle-aged adults are more likely to use emotion-focused methods. Gray found evidence for this in his longitudinal study of coping with children with ASD. Religion and faith became much greater in relative importance as a coping strategy; attachment to the child and greater appreciation for their good qualities also emerged as more common strategies. In general, the use of an array of coping strategies is beneficial; however, Gray found that parents used fewer strategies over time. Studies show mixed findings regarding increased effectiveness of coping as parents age. Fitzgerald reported that advanced age of affected ASD children was associated with better maternal mental health, implying adaptation on the part of the mothers. However, Smith and coworkers found high levels of depression in parents of both toddlers and adolescents.

A rare focus on fathers revealed that fathers of children with ASD or Down syndrome reported more use of wish-fulfilling fantasy and information seeking than control fathers. Different styles of paternal coping have been hypothesized as the explanation for decreased levels of stress reported by fathers compared to mothers. Studies show that fathers use avoidance and engagement in outside activities more frequently as coping strategies than mothers.

Tunali and Powers proposed a model of cognitive strategies that would facilitate coping for mothers of children with autism. These strategies included greater emphasis on being a “good mother” rather than on career development; greater frequency of recreation with family members rather than individual recreation; less emphasis

on individual leisure; less emphasis on others' opinions of child-rearing practices; greater emphasis on parenting and partner support than on intimacy and shared leisure in marital relationships; and higher tolerance of ambiguity.

Quality of Life. Several authors have used the conceptual framework of "quality of life" (QOL) to understand the impact of rearing a child with an ASD. The World Health Organization defines QOL as "individuals' perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards, and concerns." QOL is a multidimensional concept that encompasses physical health, mental health, relationships, personal beliefs, and values in relationship to the environment. A significant body of research spanning cultures and countries indicates poorer QOL in parents of children with ASD when compared to parents of typically developing children and parents of children with other disabilities. These differences in QOL could be related to several factors, including stressors related to raising a child with autism, decreased social support for parents of children with ASD, and genetic and environmental factors affecting the parents of children with ASD, themselves, that may impact their perception of QOL.

On the World Health Organization Quality of Life-BREF, parents of children with pervasive development disorder (PDD) were compared to parents of children with mental retardation (MR), cerebral palsy (CP), and typical development. Parents of children with PDD showed a significant impairment in QOL as compared to the other groups, whereas few differences were noted between the MR, CP, and typically developing groups. Within the PDD group, mothers had lower QOL than fathers. These differences were posited to be caused by the stress of raising children with severe developmental disorders, the presence of the BAP in the parents or other family members, and parental psychiatric disorders.

Analysis of data from the 2003 National Survey of Children's Health (NSCH) revealed significantly poorer QOL in families of children with ASD when compared to families of children with ADHD

or typical controls, most notably in the areas of burden of care and isolation. In a population-based study of psychological functioning and coping, mothers of children with ASD rated their overall health as comparable to mothers of nonaffected children, but they reported poorer mental health. In a study of health-related QOL in parents of children with high-functioning autism (HFA) or Asperger syndrome, mothers had lower physical health scores than fathers of affected children and control mothers.

Psychiatric Disorders and the Broad Autism Phenotype

As data were gathered supporting the role of genetics in autism, the idea that the genetic liability for ASD may also be expressed in nonautistic relatives of autistic probands with qualitatively similar but milder behavioral and cognitive features of autism gained momentum. These phenotypic features, including social impairments, communication impairments, and rigidity, constitute the concept of the “broad autism phenotype” (BAP), which is supported by cotwin studies and family studies of siblings and parents. Social difficulties include lack of interest in social interaction and lack of close, confiding relationships. In one study, 37% of parents of children with ASD reported no friendships, compared with only 4% of parents with Down syndrome. Communication problems are pragmatic, referring to deficits in the social aspects of language. Clear-cut obsessional and repetitive behaviors occur infrequently; however, rigidity, characterized by resistance to and difficulty in accepting change, is more common. These differences in language, anxiety, rigidity and communication may cause parents to feel inadequate to help in the behavioral treatment of their children who experience similar impairments.

Bolton reported that the BAP was seen in 20% of siblings of those with autism versus 3% of siblings in the control group. Similarly, Sasson et al. (2013) reported that higher rates of all BAP traits were found in parents of children with ASD, with the prevalence of each trait ranging from 14% to 23% versus 5% to 9% for control parents. Additionally, parents of children with ASD were more likely to present

with multiple traits of BAP when compared to control parents. Ingersoll et al., 2011 found parental BAP was associated with less social support, increased stress and higher rates of depression. Ingrams et al. found that parents expressing BAP used maladaptive coping strategies.

Studies that focused on the stress of raising a child with autism have found increased rates of several psychiatric disorders in parents of affected children, most robustly major depressive disorder (MDD) and social phobia. Piven and Palmer reported MDD in 33% and social phobia in 14.6% of proband parents in comparison to 11.7% and 3.3%, respectively, in Down syndrome parent controls. Smalley and coworkers found a lifetime prevalence of major mood disorders in 40.3% of parents and 32.4% of siblings of children with autism, compared to 19.2% of parents with children with tuberous sclerosis or seizures.

Results of a large meta-analysis performed by Schnabel et al. (2019) found that 31% of parents of children with ASD had depressive disorders, compared to the World Health Organization's estimated 4.4% of the general population throughout the world. Rates of anxiety disorders in parents of children with ASD (33%) were also significantly more common than the estimated global prevalence (3.6%). With regard to MDD, the increased risk does not appear to be due to raising a child with ASD, given that the majority of depressed parents had their first episode prior to the birth of their affected children. Moreover, these psychiatric disorders have not been found to be associated with the presence of BAP. Potential explanatory models for these findings have involved overlap of the risk alleles that are common to both autism and recurrent mood or anxiety disorders or a result of assortative mating of parents with BAP with spouses with major depression or social phobia. Other mood disorders and substance use disorders have also been reported to occur more frequently in parents of children with ASD in comparison to general-population parents or parents of children with other developmental disorders.

Summary

Parenting a child with an ASD is a stressful, lifelong process that significantly affects all individuals involved. Psychiatrists providing care to these parents need to be aware of the nature and magnitude of this undertaking. Parents should be encouraged to become active in their child's therapies, join available support services, and use positive coping strategies. Monitoring for the development of depression and anxiety disorders and conducting an evaluation for the broader autism phenotype are also indicated. Although specific data are not available for ASD, cultural factors color parents' beliefs about their children's mental health conditions and need to be considered by mental health practitioners who treat the parents.

IMPACT ON PARENTS OF RAISING A CHILD WITH BIPOLAR DISORDER

There has been increasing awareness of the tremendous burden that is placed on parents and caregivers who are raising a child with BPD. Past theories have implied that the dysfunctional family system is causing the illness in the child, it is the child's illness that negatively impacts the family instead. There is growing evidence to support interventions for family members and caregivers of patients with BPD because decreasing stress may improve long-term outcomes for both the family and the child.

Unique Stressors

Research has shown that children, adolescents, and adults who have BPD have severe global impairments in multiple areas of functioning. They are at higher risk for academic failure, poor interpersonal relationships, substance abuse, psychosocial and occupational difficulties, legal problems, suicide attempts, and neuropsychological deficits. In many cases, the parents of children with BPD may also be struggling with their own mood disorders. The child's unpredictable course may create additional stressors that exacerbate parental illness, leading to impaired parenting. Emotional dysregulation in parent and child may increase conflict and

compound family stress. Not only is an episode of illness stressful for each of the family members, but the fear of relapse is also present even when the illness is stabilized.

The diagnosis of pediatric-onset BPD is imprecise. However, there is agreement that the presentation of BPD in children and adolescents differs substantially from the presentation in adults. In contrast to the discrete episodes of manic or depressive symptoms observed in adults, children usually exhibit ultradian cycling, irritability, explosive temper outbursts, and decreased frequency of interepisode recovery. Due to the unpredictable nature of the illness presentation, accompanying affective instability, and often violent or aggressive behaviors, the caregiver role can be demanding, distressing, and harmful to health and QOL. Frequently, the diagnosis of BPD is delayed because the child's behavior is initially labeled as oppositional or defiant; therefore, appropriate pharmacotherapy and psychotherapy interventions are also delayed.

Lifespan Issues

As their child begins exhibiting BPD symptoms, parents are generally bewildered by the child's mood swings, disruptive behaviors, and general inability to conform to their peers. Most often, the children appear developmentally normal and have normal intellectual functioning. Therefore, they do not come to the attention of school staff or teachers until they exhibit disruptive behaviors or receive failing grades. Practitioners are usually reluctant to diagnose a child with BPD. These children have been described as "diagnostically homeless." In other words, they often exhibit symptoms that can fit the criteria for multiple other disorders, such as attention-deficit/hyperactivity disorder, mood disorder not otherwise specified, conduct disorder, and intermittent explosive disorder. When the diagnosis of BPD is finally made, parents have described experiencing an array of emotions ranging from relief to depression.

Adolescents with BPD are even more challenging to parents because their desire for autonomy, coupled with impaired judgment, can lead to harmful consequences. Parents of adolescents with BPD

struggle to control their children's promiscuous behavior, dangerous driving habits, substance abuse, and oppositional behaviors. Frequently, the adolescents are not compliant with pharmacotherapy because the medications have side effects such as weight gain or sedation. Some adolescents perceive that the medications alter their personality and make them more socially inhibited. They frequently take little responsibility for the consequences of their actions and tend to perceive their parents as being overly controlling rather than appropriately protective. Parents struggle with guilt, self-blame, and feelings of helplessness because they can no longer physically restrain the adolescents if they choose to leave the home or refuse to take their medications.

Parents of adults with BPD face the greatest obstacles because they have limited legal recourse to protect or help their children if treatment is refused. Because adults have euthymic episodes with longer periods of interepisode recovery, they may cycle into depression or mania without parents being aware of the polarity switch. Consequently, reinitiating treatment may be delayed. During acute episodes, adults with BPD frequently alienate parents, spouses, or other caregivers with their aggressive, abusive, or impulsive behavior. Parents may be overly taxed by the responsibility of emotionally and often financially supporting their adult child.

Caregiver Burden

The effects on caregivers of living with an ill relative have been defined as family burden. The burden of caring for a psychiatrically ill family member has been divided into two categories:

1. *Objective burden* is any disruption to family life that is verifiable and observable. Examples of objective burden include high rates of separation and divorce in marriages with a psychiatrically ill spouse; restricted social and leisure activities, often related to fears of stigma; and financial difficulties.
2. *Subjective burden* involves the personal feelings of carrying such a burden, such as feeling distressed, unhappy, or upset. The types of subjective burden include guilt if the relative feels

responsible for contributing to the illness; rejection toward the patient; anger that the illness has spoiled the relative's life; and grief contrasting the present with memories of the person before the illness. Subjective burden experienced by relatives has been linked to the development of affective symptoms.

Review of Research on Caregiver Burden for Bipolar Disorder. There is limited data on the degree of stress experienced by caregivers of children with pediatric BPD. Some information about the consequences of caring for a family member with BPD can be obtained from studies of caregivers of adult bipolar patients. Factors affecting family burden of adult BPD include prolonged illness and high levels of dysfunction among patients, as well as caregivers' illness beliefs and coping style. Presence of suicidal ideation in BPD patients is also a predictor of their caregivers' worsening health and development of depressive symptoms over time.

The Family Experience Study, a longitudinal study of the primary caregivers for patients with BPD, examined the cost and consequence of caring for a relative or friend with BPD. Primary caregivers were evaluated within 1 month after patients entered the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD), using measures of burden, coping, physical health, mental health, resource utilization, and cost. At study conclusion, more than half of the caregivers experienced moderate or high burden levels, which were related to patient problem behaviors, interference with caregivers' ability to fulfill other role obligations, or disruption of household routine. Compared to less burdened caregivers, caregivers experiencing higher burden levels reported more physical health problems, depressive symptoms, smoking and drinking, health service use, and limited social support. They also reported having to provide more financial support to their bipolar relative. Limited data has also shown a differentiation between burdens experienced by female caregivers and those experienced by male caregivers. While female caregivers suffer more from relationship difficulties with the BPD patients, male caregivers suffer more from limited autonomy in their personal lives and also from

uncertainty regarding the patient's capacity and fluctuating bipolar symptoms.

Most adult patients with BPD spend more time in periods of remission or with subthreshold symptoms than in an acute episode. However, most studies of caregiver stress are completed when patients are acutely ill, which may overestimate stress. In one study, investigators focused on stress in caregivers of euthymic adult bipolar patients aged 18 to 65 during periods of subthreshold symptomatology. Caregivers showed a moderate level of subjective burden on the Social Behavior Assessment Schedule. The variable most highly related to caregiver distress was found to be the patient's behavior (hyperactivity, irritability, sadness, and withdrawal). Parents were most worried about their children's abilities to perform at work, in school, and in social relationships. It is also important to note whether caregivers are more affected by BPD patients' depressive episodes or by their manic episodes. A study on 500 caregivers reported that only BPD patients' depressive episodes, but not their manic episodes, correlate with more subjective and objective caregiver burden.

Subjective and Objective Burden. Factors that increase caregiver's subjective burden are poorer patient social and occupational functioning, a relapse during the previous 2 years, and a history of rapid cycling. Rapid cycling is defined as having four or more episodes of mania or depression per year and is found in a significant fraction of patients with bipolar disorder. It has been associated with greater disability and worse prognosis, as evidenced by higher use of intensive psychiatric interventions.

Risk factors associated with increased objective burden levels include caregiver responsibility for medication administration, violence from the patient, caregiver social isolation, rejection by the patient during periods of illness, and patient irritability leading to more frequent arguments and conflicts. Some studies have suggested that the effect of clinical variables can be mediated by caregiver coping styles and their level of understanding of the patient's illness and symptoms.

Raising a child with BPD can be complicated if the parent is also suffering from a mood disorder. Research has shown that the offspring of parents with BPD have an increased risk for inheriting mood disorders. A meta-analysis of 17 studies of offspring of parents with BPD found that 52% of offspring had challenges with the interpersonal, cognitive, and behavioral manifestations of BPD. Children of bipolar parents also have an elevated risk of major depression, as well as other psychiatric conditions such as generalized anxiety disorder, oppositional defiant disorder (ODD), and obsessive-compulsive disorder. To further complicate matters, parents with BPD are even less capable of coping with the burden of raising a child with BPD.

Interventions

Family interventions for bipolar disorder are generally psychoeducational, with the goals of teaching family members the signs and symptoms of BPD, developing early intervention strategies for new episodes, and providing consistent medication regimens. The psychoeducational approach recognizes that lack of information about the disorder, compounded by uncertainties about the future, can increase caregivers' stress. Thus, in addition to providing information, clinicians help patients and their families emotionally cope with the illness, its prognosis, and expected treatments.

Family-focused therapy (FFT), which is usually provided in combination with pharmacotherapy, involves both BPD patients and their caregivers. Patients and caregivers are jointly trained in psychoeducation, problem-solving skills, and communication enhancement. Eight randomized trials have supported that FFT decreases mood symptoms, promotes faster recovery from mood episodes, and reduces recurrences.

Although there are some randomized, controlled trials that highlight the positive benefit for the patient of family-focused treatment in addition to pharmacotherapy in BPD, few trials using contemporary methodologies have analyzed the specific effects of caregiver-focused interventions. A randomized, control trial

published in 2008 studied the impact that interventions for caregivers had on relapse rates in the euthymic bipolar patients they cared for. Caregivers in the experimental group were provided twelve 90-minute sessions that focused on knowledge of BPD and training in coping skills. The patients did not attend the groups, but were assessed monthly during both the intervention and at the 12-month follow-up. The patients whose caregivers attended the intervention group experienced fewer recurrences than those in the control group. In addition, the intervention had different effects depending on the type of episode analyzed: manic, hypomanic, depressive, or mixed. Significant differences were found in the number of subjects who experienced a hypomanic/manic relapse and the time to such an episode. The differences in depressive and mixed episodes did not reach statistical significance.

Relapse prevention may improve by facilitating early identification of the first signs of an episode, leading to earlier intervention. Additional benefits include dispelling caregivers' misconceptions about the illness and issues such as caregiver criticism or overinvolvement. Some studies have shown that family psychoeducation also develops a mutual understanding with the patient. It also increases positive interactional behaviors and reduces expressed emotion. High expressed emotion with negative affective style and family burden has been related to poor illness outcomes.

A 2002 pilot study of manual-driven, multifamily psychoeducation group (MFPG) treatment for families of children with mood disorders represents a rare study focused on pediatric subjects. It addressed two questions: Do families of children with BPD and families of children with MDD or dysthymic disorder (DD) differ at treatment entry, and do they benefit equally from intervention? Conclusions were that BPD families entered treatment with more-impaired children and more extensive treatment histories than families of children with MDD or DD; however, all families benefited from intervention. A qualitative analysis revealed that families in the study gained emotional support, improved coping skills and decision making as it related to their child's illness, shifted their attitudes with regard to the illness, and experienced improved interaction with their

affected children. Clinical impressions suggested that interventions combining families of children with BPD and depressive spectrum illnesses were clinically feasible and potentially beneficial. The authors suggested that intervention modalities geared toward families of children with BPD may also include families of children with other mood disorders, given that both groups may benefit from these types of interventions.

A 2010 randomized controlled trial studied the effectiveness of Family-Focused Treatment-Health Promoting Intervention (FFT-HPI). FFT-HPI consisted of 12 to 15 cognitive-behavioral sessions that taught the caregiver how to manage the patient's illness, set goals for self-care, and reduce depression, strain, and health risk behaviors while caring for the patient. Compared to the control, a series of educational videotapes, FFT-HPI reduced depressive symptoms and health risk behaviors in the caregiver. When caregivers were better adjusted, patients also displayed fewer depressive symptoms. This finding suggested that caregiver-oriented therapy can improve patient outcomes, even when the patient is not part of the therapy.

Conclusions

Although most treatment research has focused on pharmacotherapy for pediatric BPDs, a growing literature suggests that psychosocial interventions are also important to provide families with an understanding of symptoms, course, and treatment of BPDs. Interventions to teach youth and parents methods for coping with symptoms (e.g., problem-solving, communication, emotion regulation, cognitive-behavioral skills) and prevent relapse have been shown to be helpful to parents. Identifying and addressing stressful aspects of raising an individual with BPD could reduce the emotional burden and potential negative impacts on the caregiver's mental health and QOL.

Gaining support from other parents who are raising children with BPD may reduce guilt, self-blame, and inappropriate feelings of responsibility for their child's condition. Moreover, providing support

for the parents may ultimately improve the child's outcome. With support and education, parents are better able to implement multimodal treatment interventions to improve adaptive and functional outcomes for their child. In cases of multigenerational BPD, treatment of the parent's mood disorder can also have a positive effect on the child's symptoms, which can bolster parental perceptions of self-competence. In conclusion, psychosocial interventions that involve families, psychoeducation, and skill building may offer added benefits to pharmacotherapy interventions.

IMPACT ON PARENTS OF RAISING A CHILD WITH ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

Parenting a child with ADHD has challenges similar to those faced by parents of children with other developmental and/or behavioral disorders. These challenges include increased parental stress, marital discord, and maternal depression. Advocacy issues and long-term care concerns, although present, are generally less urgent. Nonetheless, rearing children with ADHD involves separate and unique aspects of care that are influenced by both child-derived and parent-derived characteristics. Complicating this scenario is the likely interaction among these characteristics.

Effect of Child Characteristics on Parenting Stress

Several authors report increased parenting stress in mothers of children with ADHD. Child characteristics of ADHD that specifically correlate with parental stress are the severity of ADHD symptoms, aggression, oppositional behavior, and, to a lesser degree, the presence or absence of medical illness in the child. This highlights the effect of comorbid and associated symptoms on the level of stress within the family of the ADHD patient.

Unlike most children with more severe disabilities, children with ADHD, especially of a more moderate level of severity, are expected to master the developmental challenges of typical childhood,

adolescence, and adulthood. From kindergarten through middle school, they are expected to relate to their peers, join extracurricular peer group activities, participate in sports, and succeed in mainstream education. In adolescence, they drive cars, date, work, and attend school. They are expected to enter early adulthood with the typical goals of learning a trade, going to college, obtaining employment, and establishing long-term relationships and friendships. However, due to inattention, impulsivity, and/or hyperactivity, ADHD patients do not always meet these goals. Studies show that children with ADHD, especially those with a hyperactive/impulsive component, are at much higher risk for accidental injuries and trauma, emergency room visits, motor vehicle accidents, grade retention, high school dropout, drug use, unplanned pregnancies, and sexually transmitted diseases.

Furthermore, data has also shown that individuals diagnosed with ADHD between 5 and 12 years of age are more likely to engage in criminal activities as young adults compared to non-ADHD individuals. While individuals with the inattentive subtype are more likely to be involved in activities that require planning (e.g., selling drugs and burglary), individuals with impulsive symptoms have a higher rate of crime involvement and are more likely to be arrested and convicted. In addition, more than half of these children were fired from one or more jobs by the age of 21 years. These consequences of ADHD create stress within the family and can lead to a higher incidence of parental divorce or marital discord and child abuse.

Effect of Parent Characteristics on Parenting Stress

Parenting stress is also correlated with specific attributes of the parents who are rearing children with developmental disabilities. For example, in parents raising children with autism, maternal depression and the perception of one's share of the caretaking burden have been linked to increased stress. Similarly, in Anastopoulos' study of mothers of children with ADHD, parenting stress, as measured by the Parenting Stress Index (PSI), correlated

highly with maternal psychopathology (e.g., depression, bipolar disorder) and lack of employment outside of the home. Seipp and coworkers reported that during observed mother–son interactions with boys with ADHD, mothers with greater overt hostility had less positive parenting behavior, which was associated with greater oppositionality in the son. Moreover, mothers with sons with ADHD and comorbid ODD were less responsive to their child's needs and more overreactive than control mothers. This finding may be more directly related to specific maternal or child characteristics or the interplay between the two.

Rearing a child with ADHD is greatly complicated if parents also have ADHD and struggle with similar cognitive and behavioral manifestations. An estimated 40% to 60% of adults with ADHD are rearing an affected child. Because the prevalence of ADHD in adults is estimated at around 4.5%, there are millions of parents with ADHD rearing children with ADHD. This situation creates a multitude of additional management issues, increasing the family's stress level. Parental ADHD, especially if untreated or poorly managed, may contribute to parental neglect, inadequate supervision, inconsistent and inappropriate discipline, and increased parent–child conflict. Therefore, the parent without ADHD may be unfairly burdened with the responsibility of managing the child with ADHD. Furthermore, maternal depression and early maternal negative parenting techniques are predictors of future conduct problems in children with ADHD. Conversely, early positive parenting techniques, including positive feedback, praise, and optimistic affect, are associated with fewer conduct issues.

Mrs. M, a 34-year-old homemaker, had been married for 10 years and had two children. Both her 8-year-old son and her husband were diagnosed with ADHD, although only her son was medicated. Mrs. M's son continued to have significant impulsive aggression directed toward his younger sibling, serious academic struggles, and poor peer relationships secondary to "immature behavior." Her husband had poor job performance, with deficient organizational skills and failure to attend important meetings due to "forgetfulness." He was reluctant to take medications because of concerns about side effects and "drug dependence." Mrs. M's family of high achievers compared her unfavorably to her more accomplished sister and her family. Moreover, her family had a history of depression but worries about the stigma of psychiatric illness preventing her from seeking treatment. She has been stressed because she and her husband have discussed divorce. She had no sources of emotional support and felt overwhelmed.

Clinical Implications

The assessment of ADHD patients who are parents needs to include consideration of the patient's ability to meet the demands of parenthood, especially in the presence of a childhood psychiatric disorder. The consequences of rearing a child with ADHD should not be underestimated, especially given the frequency with which the disorder also affects one of the child's parents. Studies have shown that the degree of parental dysfunction correlates with the development and severity of the child's ADHD-derived disorders, such as conduct disorder and ODD. Furthermore, poor parental skills can also lead to poorer self-control in ADHD children, which is a catalyst for more disruptive behaviors.

IMPACT ON FAMILIES OF RAISING A CHILD DIAGNOSED WITH SCHIZOPHRENIA

The National Institute of Mental Health estimated that in 2002, 1.1% of the population suffered from schizophrenia. The estimated yearly cost of schizophrenia in the United States was 62.7 billion dollars in 2002. Globally, the cost is estimated to be between 1.5% and 3% of national health care budgets. This subsection discusses the burden borne by parents and siblings of a child with schizophrenia. Whereas the other disorders discussed in this section are usually observed earlier in the child's life, schizophrenia typically develops between the mid-teens to early 30s, with rare cases of earlier onset after a significant period during which the child appeared to be on track to become a healthy, independent adult.

Early psychodynamic theories of schizophrenia focused on the role of mothers of patients with schizophrenia. They were often called "schizogonic" or "schizophrenogenic," and their lack of maternal warmth was, without any sound scientific evidence, blamed for their child's development of schizophrenia. Only in the mid-1960s was this concept countered, and since then, schizophrenia research has been approached from a biopsychosocial perspective based on the notion that the expression of the disorder is due to a genetic predisposition combined with exposure to environmental and individual stressors. This puts the role of the parent and family in a different light.

Caregiver Burden

To better assess the issues with which families of schizophrenic patients grapple, Hoenig and Hamilton introduced the concept of "family burden," which was defined earlier in this section. The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study found four factors that caregivers identified as most burdensome in their experience with their ill family member: (1) patient problem behavior, (2) the patient's impairment in activities of daily living, (3) lack of patient helpfulness, and (4) resource demands and disruptions in the caregivers' personal routine. Other factors related to the level of burden were social and professional support, age, and education level. Family members who were able to share

their experience with others and who received financial support experienced a lower level of burden; younger and less-educated caregivers experienced more burden than older and more-educated caregivers.

Parents and siblings of patients with schizophrenia often grieve the loss of the child or sibling they knew before the onset of the illness. They may also experience feelings of embarrassment and stigma related to their family member's illness, which, in turn, may lead to isolation. Aging parents frequently worry about what will happen to their children when they can no longer care for them. In a study of 157 mothers of children with serious mental illness, only 11% reported definite plans for their offspring's future residence; 66% had completed financial plans; and 75% hoped a family member would assume care, but only 25% thought that this would actually occur. Older parents need professional help with planning for the future, in particular estate planning, to enable case management, and ongoing services after the parent's death.

Siblings play a unique role in the life of the patient with schizophrenia and may have specific needs. They have additional levels of burden, such as guilt about being healthy, fear of developing schizophrenia, and fear of passing on "bad genes" to their offspring. Several coping mechanisms have been identified in siblings, including normalization, caregiving, and grief. Smith and coworkers identified several factors that predict whether siblings will be involved in the future care of the ill sibling. Pull factors, which predict involvement, are early experiences in socialization, strong sibling relationships, and personal caregiver gains, such as developing personal strengths while caring for the sibling. Push factors, which predict disengagement, are geographic distance and a belief that the ill sibling has control of their symptoms.

Cultural Aspects of Burden

Across cultures, families of patients with schizophrenia often suffer from the stigma that accompanies the diagnosis of a psychotic disorder. Several studies have indicated that black caregivers, on

average, experience less distress than Hispanic and white caregivers: A seemingly surprising finding in light of the greater likelihood of additional stressful conditions such as prejudice, discrimination, and lower income that African-Americans face. In addition, African-American family members tend to be more involved in caregiving activities, which are also associated with higher levels of distress. Potential protective factors, such as religious involvement and social support, do not appear to differ according to race and ethnicity. Studies indicate that the QOL for caregivers who live with a chronically ill family member is lower than those living alone or with healthy family members, and the financial burden is significant. QOL for siblings is better than for parents and children of schizophrenic patients, but across cultures, women tend to experience more distress than men because they tend to provide more care for ill children or siblings.

Treatment and Family Burden

A multidimensional approach is required to assess and understand the burden experienced by families of schizophrenic patients. The Schizophrenia Patient Outcomes Research Team (PORT) recommended that, in addition to pharmacotherapy, patients with ongoing family contact should be offered family psychosocial intervention lasting at least 9 months, emphasizing education about the illness, family support, crisis intervention, and problem-solving skills training. This may relieve the burden experienced by the family, who in turn is better able to take care of the ill relative. Several support models exist, including single- and multiple-family group models. Although models vary, effective programs share the following characteristics and assumptions:

1. Schizophrenia is an illness.
2. Program leadership is provided by mental health professionals.
3. Participating family members are not seen as patients.
4. Family therapy is not included to avoid the suggestion that the family is to blame for the relative's illness.

5. The focus remains on patient outcome, including prevention of relapse and improvement of functioning and well-being of the patient.

Families participating in such programs can reduce relapse rates by up to 50%, which is comparable to pharmacotherapeutic effect sizes. However, according to PORT, participation in such programs is limited. Although 75% of patients had contact with family members, only 31% of families had received information, advice, or treatment. Barriers to access included patient factors (concerns about family burden and confidentiality), family factors (lack of awareness regarding benefits, time constraints, reluctance to become more involved), and provider factors (staff resources, time and training, reimbursement issues, lack of awareness of benefits). Community-based programs, such as the National Alliance for the Mentally Ill (NAMI), Family-to-Family, and Journey of Hope programs, are run by volunteers from patients' families and focus on family needs, advocacy, and system reform. Participation in these programs leads to improved overall well-being for family members, greater facility in navigating the mental health care system, and increased understanding of schizophrenia. Shorter duration and lower costs may make them more accessible to family members.

Conclusions

Schizophrenia is a chronic illness that often causes an enormous burden for the patient's family. However, during the last decade, research has increasingly shown that support for patients and their families through psychoeducation and support programs can have a significant effect on the perceived burden by both families and the patient. It can lead to improved outcomes for the patient, with fewer episodes of relapse and better QOL, whereas families are more able to understand the diagnosis and its consequences for their child or sibling and to take on the role of caregiver. In addition, these programs reduce the financial burden of schizophrenia on the health care system. However, many factors hamper the implementation of

these programs; it is the role of the treatment provider to offer the best possible and evidence-based care to patients and their families.

SUMMARY

This section has described the consequences of having a psychiatrically ill child on their parents by considering four diverse disorders that usually first appear in childhood or young adulthood. Although not all-inclusive, these disorders were chosen to illustrate themes generally experienced by any family so affected. Common to all of these disorders are the grief and disappointment that parents experience when they realize that their child is not typically developing. Self-blame is frequent, particularly for inheritable disorders. Factors that shape parental response include the age of onset of the disorder, chronicity of the disorder, the extent to which the disorder affects the acquisition of basic developmental milestones and functioning, the presence of aggression, and the stigma associated with the specific disorder. The presence of the disorder or an associated condition in a parent, as well as in the child, greatly affects the outcome for all members of the family. The lack of appropriate services, especially when the youngster reaches adulthood, is a prevalent dilemma for parents. Psychiatric practitioners need to consider the profound effect that raising a child with a serious psychiatric disorder has on a parent who is their patient.

54.13 Pediatric Sleep Disorders

Although precise estimates of the frequency of sleep disorders in children and adolescents are somewhat variable among studies, the understanding of the epidemiology of sleep pathology and its relationship to comorbid psychiatric diagnoses has grown substantially in recent years. Research in cognition and brain development over the last 20 years also has significantly advanced the understanding of the genetic and neurobiologic bases of sleep disorders in children and adolescents. With an increasing understanding of sleep disorders, treatment interventions have also become more refined and useful.

This section reviews the research and clinical methods used to study sleep, new findings on the neurodevelopmental and cognitive effects of sleep loss and fragmentation, and the clinical description and treatment of sleep disorders in children and adolescents and their interface with psychiatric disorders.

SLEEP EVALUATION METHODS

One of the primary tools for studying sleep is *polysomnography* (PSG), which incorporates a variety of measures of physiologic changes experienced during sleep. The American Thoracic Society developed a set of recommendations for the interpretation of pediatric PSG that has become the standard for sleep labs nationally. With the aid of portable technology, PSG is increasingly being performed at home, although the methods and results are not quite as sophisticated as when performed in the lab. While PSG remains the gold standard for sleep studies, other less complicated and less expensive techniques are available for studying a variety of sleep disorders in children and adolescents.

Actigraphy was developed in the early 1970s and has come into increasing use in both research studies and clinical practice. Actigraphy allows for the study of sleep–wake patterns and circadian rhythms via the assessment of body movements. The device is

typically worn on the wrist and can easily be adapted for home use. With the advent of personal fitness trackers, manufacturers have increasingly been designing better algorithms for gathering data on sleep; to date, however, these devices have shown high variability and many inaccuracies.

A number of survey instruments exist for detecting problematic sleep in children and adolescents, including self-report questionnaires (such as the Sleep Disturbance Scale for Children, the Child Sleep Questionnaire, the Child and Family Sleep History Questionnaire, and the Sleep Disorders Inventory for Children), sleep diaries, and parent report forms. Sleep logs or diaries provide information on bedtime, sleep latency, wake time, and the number of nocturnal awakenings, in addition to exercise and the use and timing of caffeine, alcohol, and drug use. Sleep logs are typically completed for a 2-week period by parents and caregivers or adolescents themselves. Although subjective, sleep logs provide a wealth of useful information for treating insomnia and sleep phase disorders and are available readily in many forms on the internet. Finally, the Epworth Sleepiness Scale, commonly used with adults as a subjective measure of the propensity to fall asleep in certain situations and to monitor treatment efforts, has recently been modified for use in children and adolescents.

NEUROCOGNITIVE EFFECTS OF SLEEP DISRUPTION

Most of the research examining neurocognitive sequelae of sleep loss and fragmentation in children has focused on the effects of sleep restriction and sleep-disordered breathing (SDB) on daytime performance in children and adolescents. As little as one night of acute sleep restriction in children can result in significant attention deficit. A study conducted in a sample of 7- and 8-year-old healthy children subjected to 1 hour of sleep restriction for 1 week demonstrated impaired attention and concentration, along with significant reorganization in brain cortical electroencephalographic

(EEG) response as measured by multiarray P300 (cognitive) evoked potentials. By contrast, one additional hour of sleep in children aged 8 to 12 years over 1 week resulted in parent and child reports of improved emotional functioning and objective improvements in memory, attention, and math fluency. Similarly, in children 7 to 11 years old, one additional hour in bed, averaging 27 minutes of additional sleep, demonstrated improvements in teachers' blinded ratings of emotional liability and impulsivity.

Obstructive sleep apnea syndrome (OSAS), which is characterized by sleep fragmentation due to multiple arousals and disruption in ventilation following episodes of complete or partial airway obstruction during sleep, has been studied with respect to its effect on neurocognitive functions in children. Numerous studies report academic deficits and learning problems in children with OSAS that appear to be reversible after treatment of the condition. Hyperactive, inattentive, and disruptive behaviors resembling those found in attention-deficit hyperactivity disorder (ADHD) have been increasingly reported in children with snoring and OSAS. Similar behavioral changes are seen in some children with periodic limb movement disorder (PLMD) and restless legs syndrome (RLS).

In adults, sleep deprivation adversely affects functions mediated by the prefrontal cortex, particularly attention and working memory, upon which most cognition depends. Deduction and critical thinking (logic-based tasks) show little change in accuracy with sleep deprivation but do reflect cognitive slowing. Divergent skills involved in decision making, however, are greatly affected by sleep loss and involve trouble assimilating changing information, updating strategies based upon new information, innovation, risk assessment, and maintaining interest, insight, communication, and memory. Unfortunately, a lack of sleep, in addition to increasing levels of responsibility, lead to somewhat of a perfect storm, contributing to the high-risk behavior so commonly observed among adolescents.

A number of studies have indicated reduced intelligence scores among children with SDB compared to normal controls, including significantly impaired general conceptual ability. Lower academic achievement has also been observed in children with OSAS

compared to children without reported histories of SDB when matched for age, race, gender, socioeconomic status, and school attended.

The increasing reliance upon technology, such as computers and smartphones, represents perhaps the greatest novel threat to our children's sleep. The United Nations currently estimates that more of the world's population has access to a smartphone than a working toilet. New research has found that excessive screen time contributes to childhood obesity and is associated with aggressive thoughts and behavior, cognitive impairment, and delayed literacy. In addition to the physiologic and psychological arousal from screens that contributes to impaired sleep, the bright lights from screens can block the natural evening flow of melatonin, further contributing to insomnia.

SLEEP DISORDERS IN CHILDREN

It is estimated that approximately 25% of children will suffer from a sleep problem at some point during childhood. The types of problems affecting children vary greatly in their frequency and severity, ranging from the more common bedtime resistance and anxiety to the occasional primary sleep disorders, such as narcolepsy and OSAS. Regardless of the primary complaint, parents frequently report sleep difficulties among their children, and these reports are remarkably consistent with most researchers identifying up to 50% of preschool children, roughly 30% of school-aged children, and approximately 40% of adolescents as having sleep difficulties. Among a representative U.S. sample of 13- to 16-year-olds, the 30-day prevalence of insomnia was 9.4%, and the lifetime prevalence was 10.7%; further, 88% of the adolescents with a lifetime history of insomnia reported current sleep difficulties, further indicating the chronic nature of insomnia among youth. Much higher rates of sleep disorders are generally reported among those with neurodevelopmental and psychiatric disorders. Among children with intellectual disability, for example, 30% to 80% have sleep problems, while 50% to 90% of children with autism spectrum disorders (ASDs)

are affected. Despite a high overall prevalence, however, sleep problems are not often discussed during visits with primary care practitioners and are therefore left undiagnosed and untreated.

Classification of Sleep Disorders

The *International Classification of Sleep Disorders*, Third Edition (ICSD-3), and the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), and its text revision (DSM-5-TR) are the primary classification systems for sleep disorders. While the ICSD-3 and the DSM-5-TR cover much of the same ground, the ICSD-3 classification is more comprehensive and precise. The DSM-5-TR specifies 12 main categories of sleep disorders (see Table 54.13–1).

Sleep-Disordered Breathing. The term SDB encapsulates a variety of difficulties, including primary snoring, upper airway resistance syndrome (UARS), and OSAS, and it occurs relatively frequently in otherwise healthy children. Although accurate figures are difficult to obtain, it is generally estimated that 2% to 5% of all children may be affected by OSAS, and 7% to 12% of children may suffer from primary snoring.

Whereas adults with OSAS most often present with *excessive daytime somnolence* (EDS), children rarely exhibit this symptom and instead tend to present with externalizing behaviors, such as hyperactivity, aggression, social withdrawal, and learning difficulties. In one study, fewer than 15% of children with OSAS exhibited EDS at all. Diagnosis of OSAS further requires a consistent clinical history and physical examination. To augment these two diagnostic measures and reveal the extent of the effect on sleep, children should also undergo overnight PSG.

Children with OSAS present with loud snoring, sweating, agitated sleep, and a variety of related sleep problems (e.g., persistent enuresis, night terrors, somnambulism, bruxism, etc.). EDS, somnambulism, bruxism, and anxiety are also frequently noted in adolescents with OSAS. Physical examination often demonstrates

craniofacial abnormalities and adenotonsillar hypertrophy, and PSG indicates frequent apneas/hypopneas and oxygen desaturations. Outcomes of OSAS can include significant health problems, such as failure to thrive, hypertension, pulmonary hypertension with or without cor pulmonale, and mental health problems.

Table 54.13–1.
DSM-5-TR Classification of Sleep Disorders

- Insomnia Disorder
  - Hypersomnolence Disorder
  - Narcolepsy
  - Breathing-Related Sleep Disorders
    - Obstructive Sleep Apnea
    - Central Sleep Apnea
    - Sleep-Related Hypoventilation
  - Circadian Rhythm sleep-Wake Disorders
    - Delayed Sleep Phase Type
    - Advanced Sleep Phase Type
    - Irregular Sleep-Wake Type
    - Non-24-Hour Sleep-Wake Type
    - Shift Work Type
  - Parasomnias
    - Non-Rapid Eye Movement Sleep Arousal Disorder
    - Nightmare Disorder
    - Rapid Eye Movement Sleep Behavior Disorder
    - Restless Legs Syndrome
- Substance/Medication-Induced Sleep Disorder
- Other Specified Insomnia Disorder
- Unspecified Insomnia Disorder
- Other Specified Hypersomnolence Disorder
- Unspecified Hypersomnolence Disorder
- Other Specified Sleep-Wake Disorder
- Unspecified Sleep-Wake Disorder

Data from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022.

The most common treatment for pediatric SDB is adenotonsillectomy, which cures the problem in approximately 85% of affected children. A continuous positive airway pressure (CPAP)

mask is often used for children who fail surgical treatment or for whom surgery is not indicated.

Insomnia. *Pediatric insomnia* has been much less studied and is more poorly understood than adult insomnia. A number of efforts have been made to define pediatric insomnia, estimate its prevalence among different pediatric populations, and develop clinical guidelines for behavioral and pharmacologic treatment.

The prevalence of pediatric insomnia is estimated at about 1% to 6% among general pediatric populations, with a much higher prevalence in children with neurodevelopmental and chronic medical and psychiatric conditions. When bedtime resistance and disruptive nighttime awakenings are included, the prevalence of sleep-disrupted behavior approaches 25% to 50% in preschool-aged children. Psychiatric symptoms have been reported in almost 50% of children with persistent insomnia. It has been proposed that persistent insomnia may also represent an early sign of emotional distress in susceptible children with poorly preserved sleep homeostasis.

The ICSD-3 describes two forms of behavioral insomnia of childhood as unique diagnostic entities to emphasize sleep difficulties that result from inappropriate sleep associations or inadequate parental limit setting. *Limit-setting type* is due to parents having difficulties establishing and enforcing bedtimes, while *sleep-onset association type* is characterized by reliance on maladaptive and inappropriate sleep associations such as rocking, watching television, feeding, and falling asleep in the parents' bed. The child is usually unable to fall asleep in the absence of these conditions at both bedtime and following nocturnal arousals. Behavioral insomnia generally leads to sleep fragmentation and increased nighttime awakenings, insufficient sleep duration, later bedtimes, and daytime sleepiness.

Good sleep hygiene and behavioral interventions, such as extinction or bedtime fading, are the first recommended treatments for pediatric insomnia. Children who do not respond to behavioral interventions may be considered for the pharmacologic management

of their insomnia. There are no U.S. Food and Drug Administration (FDA)-approved medications for the treatment of insomnia in children. Nonetheless, a large study of over 1,000 child and adolescent psychiatrists found that 96% recommended at least one prescription medication, and 88% advised an over-the-counter medication for sleep in a typical month. Despite the lack of FDA approval, however, limited empirical evidence supports the use of melatonin and clonidine for childhood insomnia. Meanwhile, benzodiazepines, guanfacine, pyrimidine derivatives (e.g., zaleplon and zolpidem), sedating antidepressants (e.g., trazodone and mirtazapine), sedating antipsychotics (e.g., quetiapine), and sedating antihistamines (e.g., diphenhydramine, doxylamine, and hydroxyzine) are often employed to improve symptoms of insomnia in children and adolescents but have virtually no solid evidence to support their use.

Coincident with the increasing use of herbal medications and dietary supplements in the United States, a number of studies have been conducted over the last decade that demonstrates that melatonin is an effective, safe, and well-tolerated agent, especially in cases of sleep-initiation insomnia caused by circadian factors. Several placebo-controlled studies of melatonin in normal, healthy children with idiopathic sleep-initiation insomnia have shown that melatonin administered at bedtime reduces sleep-onset latency time and increases total sleep time (TST).

Little information is available on the use of the nonbenzodiazepine hypnotic agents zaleplon and ramelteon, but studies have found both zolpidem and eszopiclone ineffective for ADHD-related insomnia. In addition, hypnogogic hallucinations and paradoxical agitation have been demonstrated when adult doses of these agents have been prescribed to children and adolescents. Clearly, more safety trials and pharmacokinetic studies are needed prior to recommending these drugs for use in pediatric insomnia.

Cognitive behavior therapy for insomnia (CBT-I) is the most effective treatment in adults for decreasing sleep latency and the frequency and duration of nighttime awakenings, improving sleep quality, and increasing TST. CBT-I incorporates a number of

evidence-based psychological and behavioral strategies, including stimulus control (e.g., removing clocks from the bedroom, maintaining a quiet sleep environment, etc.), sleep restriction (e.g., limiting the amount of time in bed until the patient is sleeping 90% of the time they are in bed), arousal reduction (e.g., relaxation techniques such as belly breathing and biofeedback), addressing cognitive distortions associated with insomnia (e.g., catastrophizing such as “if I don’t fall asleep soon, I’ll be a complete wreck tomorrow”), circadian rhythm maintenance (e.g., going to bed and awakening at the same time each day), and sleep education and hygiene. CBT-I is well accepted by patients, and 70% to 80% achieve a therapeutic response, while 40% achieve clinical remission. Numerous randomized studies of adults demonstrate that CBT-I is even more effective for insomnia than sleep medications and that it is equally effective whether delivered one on one, in a group setting, or via the internet.

Although most studies of CBT-I have focused on adults, recent research demonstrates its efficacy among pediatric populations as well. Reductions in sleep latency and wake after sleep onset, along with increased sleep efficiency among both children and adolescents, have been demonstrated to last for at least 6 months posttreatment. In addition, the first randomized controlled trial of CBT-I in adolescents found a medium to large effect size.

While sleep hygiene is typically recommended by practitioners, sleep hygiene alone is not sufficiently effective for the treatment of pediatric sleep difficulties. Discontinuing exposure to blue light via screens for an hour or two before sleep, limiting caffeine, alcohol, and drugs (such as marijuana and nicotine), in addition to creating a comfortable sleep environment with limited light and noise while being judicious about the timing of exercise, are, however, valid sleep hygiene strategies that can augment the utility of CBT-I.

Narcolepsy. Major strides in the understanding of the etiology of narcolepsy have been taken in recent years as remarkable discoveries have identified a new neuropeptide, hypocretin or orexin, which is linked to animal models of narcolepsy. The exact

prevalence of childhood narcolepsy is unknown. The youngest patient on record was diagnosed at age 12 months. In retrospective studies, about one-third of adults with narcolepsy indicate onset prior to 15 years of age and roughly 15% prior to 10 years of age.

Children with narcolepsy are commonly misdiagnosed with other neurologic and/or psychiatric disorders, such as epilepsy, ADHD, mood disorders, and psychotic disorders. Excessive daytime sleepiness is the most common presentation of narcolepsy in school-aged children, although according to some reports, 50% to 70% of childhood narcolepsy patients present with symptoms of cataplexy. Nighttime sleep is frequently disturbed in patients with narcolepsy, and periodic limb movements during sleep are also common. The diagnosis of narcolepsy requires sleep laboratory assessment, including nocturnal PSG and a multiple sleep latency test.

Effective treatment of narcolepsy in children and adolescents demands establishing a regular sleep schedule, providing extensive education on sleep hygiene, and implementing scheduled daytime naps if possible. Excessive daytime sleepiness in children and adolescents with narcolepsy is commonly treated with psychostimulants such as methylphenidate and dextroamphetamine. Modafinil and armodafinil are alertness-promoting medications that can provide long-lasting benefits and have been shown to be effective in pediatric patients with narcolepsy.

Tricyclic antidepressants such as clomipramine, protriptyline, and imipramine have long been known to be effective for symptoms of cataplexy. Serotonin-specific reuptake inhibitors and mixed-action antidepressants have also been prescribed to patients with cataplexy. Sodium oxybate (Xyrem) and calcium, magnesium, potassium, and sodium oxybate in combination (Xywav) have been recently approved by the FDA for pediatric use and are effective for the treatment of excessive daytime sleepiness and cataplexy associated with narcolepsy.

Due to the complexity of narcolepsy symptoms and their effect on child development, a variety of treatment modalities, including individual and family therapy, school advocacy, and academic interventions, should be used to optimize symptom control.

Parasomnias. *Parasomnias* are disruptive physical acts that occur during specific sleep stages or during the transition between sleep stages and include non-REM types (somnambulism and sleep terrors), REM sleep behavior disorder, somniloquy, bruxism, nightmares, and RLS. Although the incidence of general psychopathology in children with non-REM sleep parasomnias is quite low, the overall prevalence of having at least one parasomnia by age 13 years has been reported to be as high as 78%. The events, although rarely requiring clinical intervention, are often very troubling for parents.

Somnambulism, or sleepwalking, is relatively common in childhood, with annual prevalence rates approaching 17%. Although somnambulism rarely results in harm to the subject, it is possible for an episode of somnambulism to become a confusional arousal, in which the likelihood of accidental violence (to oneself or others) is much greater. The prevalence of confusional arousal is less well established, although a 4% incidence was noted in a longitudinal study of 212 children of ages 6 to 16 years selected at random in Stockholm.

Sleep terrors are somewhat less common than somnambulism and are difficult to quantify because of the self-report nature of the data and the fact that parents often confuse them with nightmares. Annual incidence rates have been reported as high as 6% and prevalence rates as high as 17% among children aged 13 years and younger. Most non-REM parasomnias are first noticed by parents of affected children. Although a large percentage of children have at least one incidence of somnambulism, far fewer present with recurrent and disruptive somnambulism. Sleep terrors follow a similar trend, although they are less common than sleepwalking. Numerous studies have demonstrated a connection between anxiety levels and parasomnias in children, showing that increased anxiety correlates with an increased prevalence of sleepwalking and sleep terrors.

Although the treatment of non-REM parasomnias has received minimal formal study, there are numerous measures that have been shown to be effective. In addition to safety measures, the use of

scheduled awakenings and naps, and in severe cases, clonazepam or tricyclic antidepressants, may be effective. In addition, a formal sleep study may be helpful in revealing SDB as a comorbid disorder for which treatment may reduce the apparent severity of the parasomnia.

Sleep talking, or *somniloquy*, is considered the most common parasomnia, with a reported prevalence of greater than 50% in children between the ages of 3 and 13 years. Somniloquy is often comorbid with sleepwalking and sleep terrors, suggesting a common pathophysiology among the three disorders. Nightmares are common among children and adolescents and are only considered abnormal when they are recurrent and cause excessive distress. Although sometimes associated with post-traumatic stress disorder (PTSD), up to 70% of children report that the content of their nightmares is influenced by media seen on television or at the movies. Effective treatment for nightmares generally includes CBT and rescripting but can also include hypnotherapy and medication. REM sleep behavior disorder, in which subjects become aroused during REM sleep and “act out” their dreams due to loss of body paralysis, is not generally observed in children and is more closely associated with brain damage and dementia.

RLS is characterized by an irresistible urge to move the legs, commonly associated with discomfort and pain, which is partially relieved by movement. In the adult population, RLS has an estimated prevalence of 10% to 15%. PLMD, no longer classified by DSM-5-TR, is characterized by episodic limb movements during sleep, generally involving the leg along with the extension of the ankle and toe.

Only recently has the presence of RLS in children and adolescents been elucidated, with studies generally demonstrating a prevalence rate of RLS among the general pediatric population to average around 2%. There is considerable interest in the relationship between RLS, PLMD, and ADHD. The prevalence of RLS in patients with ADHD is estimated to be between 10.5% and 44%, emphasizing the need to consider both diagnoses and the possible interrelationship between them in children and adolescents.

Prior to the diagnosis of RLS, a child often presents with sleep disturbances and daytime impairments, including extreme fatigue, irritability, and hyperactivity, and the discomfort in the extremities that accompanies the disorder is often confused with growing pains. Other qualitative signs suggestive of RLS include an urge to move the legs with a worsening sensation when sitting or lying down, the alleviation of discomfort through movement, and worsening symptoms in the evening. Several studies have demonstrated an autosomal-dominant inheritance for early-onset RLS. Family history, therefore, is an important indicating factor in diagnosing RLS in children and adolescents.

Most treatments for RLS/PLMD include a pharmacologic component, although proper sleep hygiene is also very important. Children and adolescents with RLS/PLMD should reduce caffeine intake, eliminate alcohol and tobacco use, avoid stimulating activities prior to bedtime, and minimize sleep deprivation. Correlation among low ferritin levels, iron deficiency, and RLS symptoms has been identified in both children and adults. Providing ferrous sulfate supplementation for those children who are deficient has been demonstrated to reduce PLMD symptoms. Other medications have also demonstrated efficacy in reducing symptoms. One randomized, double-blind, placebo-controlled study of children with RLS aged 7 to 12 years found a combination of carbidopa/L-DOPA to be safe and effective. In adults with RLS, dopaminergic medications, including levodopa, pramipexole, and ropinirole, are most often used. Gabapentin has also been shown to improve RLS symptoms in children. Although these medications are prescribed to children and can be effective in reducing symptoms, none has been approved by the FDA for the treatment of RLS/PLMD in children. As a result, the medications should be administered with great caution and intensive monitoring of potential side effects.

Circadian Rhythm Sleep–Wake Disorders. Circadian rhythm sleep–wake disorders occur due to a misalignment between the internal circadian rhythm and the sleep–wake schedule. Over 10% of children are thought to be affected by circadian rhythm sleep

problems. Delayed sleep phase type occurs in as many as 5% to 10% of adolescents, while advanced sleep phase type is more common in the elderly and occasionally in preschool children.

A delay in the normal sleep phase is typical in the peripubertal period, leading to later bedtimes. Extensive homework and extracurricular obligations coupled with early school start times frequently result in excessive daytime sleepiness, academic difficulties, irritability, mood instability, attention and memory impairment, and family conflict. Recognizing the detrimental effects of delayed sleep phase on adolescents, the American Academy of Pediatrics has published a policy statement urging a delay in the school start time so that high school students can achieve adequate sleep.

Treatment of delayed sleep phase typically involves sleep education and hygiene, along with gradual advancement of the sleep phase. Bright light morning therapy (5,000 to 10,000 lux), along with low-dose melatonin (approximately 500 mcg) about 4 to 5 hours before the desired bedtime, have both been found helpful in advancing the sleep phase after several weeks. Chronotherapy, or the gradual delay in bedtime by 3 hours each night until the desired bedtime is achieved, can also be effective, although the schedule is very difficult to maintain.

Nocturnal Enuresis. Although no longer classified by DSM-5-TR as a sleep–wake disorder, *nocturnal enuresis* is a frequent occurrence, affecting approximately 30% of 4-year-olds, 10% of 6-year-olds, 5% of 10-year-olds, 3% of 12-year-olds, and 1% of individuals aged 15 years or older. *Primary nocturnal enuresis* (never consistently dry at night) is likely to have a multifactorial etiology and may be due to difficulties with bladder musculature stability, central nervous system arousability, pontine reflex function, internal sphincter tone, functional bladder capacity, nocturnal urine production, and a maturational delay in antidiuretic hormone (ADH) secretion. *Secondary nocturnal enuresis* (previously dry for at least 6 months), by contrast, is typically caused by urinary tract infections, diabetes mellitus, and psychological factors.

The first step in treatment is to educate the family and patient regarding proper sleep hygiene. All caffeine and alcohol intake should be discontinued because both decrease ADH secretion, and late-night fluid intake should be strictly limited. On occasion, the introduction of an afternoon nap will be beneficial by virtue of decreasing the quantity of nighttime deep sleep, thereby making it easier for the patient to awaken to the internal cues of bladder fullness. Finally, parents sometimes find that briefly awakening the child after 2 or 3 hours of sleep and sitting them on the toilet will decrease the frequency of enuresis without significant impairment in sleep efficacy. Should these educational strategies be ineffective, both behavioral and pharmacologic treatments exist for nocturnal enuresis.

Behavioral treatment most commonly involves the use of an enuretic alarm, which has the highest cure rate and lowest relapse rate. Other behavioral interventions include bladder training to increase the number of micturitions during the day or to enlarge bladder capacity. The use of reward systems, such as star charts, has also been shown to be useful. Finally, cognitive therapy (e.g., explaining the enuretic process and maintaining a daily diary), motivational therapy, pelvic floor muscle training, and biofeedback also have some reported utility.

The two medications most commonly accepted as an appropriate pharmacologic treatment for pediatric nocturnal enuresis are desmopressin acetate and imipramine. The use of amitriptyline and anticholinergic agents, such as oxybutynin and tolterodine, however, has also been described.

Sleep Disorders in Children with Psychiatric Disorders

Sleep problems often occur in the context of mental illness, either as primary concerns (e.g., primary insomnia) or secondary concerns (e.g., as a consequence of depression or anxiety). All sleep problems identified early in childhood have been later correlated with anxiety, depression, attentional difficulties, family or parental distress, continued sleep problems, aggression, delinquency, and

social problems. Some of the more common psychiatric disorders among children and adolescents and their effect on sleep (and vice versa) will be reviewed here.

Attention-Deficit Hyperactivity Disorder. Numerous studies based on parent reports have demonstrated the prevalence of sleep disorders among children with ADHD to be higher than that for healthy controls, controls with other psychiatric illnesses, and healthy sibling controls by up to fivefold. Actigraphy has shown children with ADHD to have greater variation in sleep onset time, wake time, and single-night sleep duration than controls, and in at least one study, there were significantly more bedtime struggles and longer total sleep duration in the ADHD group. Although children with ADHD often have difficulty settling down to sleep and may sleep more total hours than controls, restricting the amount of sleep a child receives in an experimental setting can also result in symptoms of ADHD, including inattention, hyperactivity, impulsivity, and poor cognitive performance.

ADHD is also associated with snoring during sleep. Habitual snoring has been reported to be three times more common in children with ADHD than in control children drawn from child psychiatry and pediatric clinics. In addition, children with ADHD have been found to have a greater frequency of PLMD while maintaining normal sleep architecture. Children with ADHD also suffer from SDB at a greater rate than expected. SDB has been associated with poor memory performance on standardized psychometric tests and lower academic achievement in children, whereas in adults, deficits in attention, concentration, memory, and verbal and nonverbal intelligence have been noted.

Children with ADHD may also suffer circadian rhythm abnormalities. Among children with ADHD, there is greater inconsistency or instability in time to sleep onset, wake time, and sleep duration than in controls. Furthermore, a high prevalence of ADHD has been shown among children with chronic sleep-onset insomnia, and sleep-onset insomnia in children with ADHD is associated with later dim-light melatonin release. The use of

melatonin near bedtime often improves sleep-onset delay among children with ADHD.

Fragmented or disrupted sleep, rather than lessened TST, may be the true culprit behind the daytime behavioral changes and disruptions seen in some children. To that end, recommendations to families with a disruptive or hyperactive child should include an emphasis on basic sleep hygiene. Many children with ADHD take medication regularly, which can further complicate an understanding of their sleep cycle. Much investigation, however, has suggested that children with ADHD still demonstrate more sleep disturbances than controls regardless of medication use, particularly with regard to sleep-onset latency, sleep efficiency, and TST.

Opinions vary greatly on how to manage insomnia due to either ADHD or the stimulant medications that are used to treat it. Typical recommendations include lowering the dose of the stimulant, changing to a shorter-acting preparation, adding a low dose of stimulant (if the insomnia is believed to be secondary to hyperactive "rebound"), or changing to an entirely different stimulant or treatment, such as atomoxetine. If adjunctive pharmacotherapy is used, typical medications include melatonin, clonidine, antihistamines (e.g., diphenhydramine, cyproheptadine), and antidepressants (e.g., trazodone, mirtazapine).

Autism Spectrum Disorders. Children with ASDs are also susceptible to sleep difficulties, with prevalence estimates ranging as high as 90%. Younger children and those with more severe cognitive or intellectual disabilities tend to demonstrate increased sleep problems, which often persist over time. The most frequently reported sleep problems among those with ASD include difficulty falling asleep, restless sleep, frequent awakenings with difficulty falling back to sleep, early-morning awakenings, irregular sleep–wake patterns, shortened duration of sleep, dyssomnias, and parasomnias.

Numerous hypotheses have been put forth to explain the reported sleep difficulties among children with ASD, including failure to recognize environmental and social cues, poorly developed circadian

rhythms secondary to social deficits, altered melatonin production, and abnormalities in the hypothalamic–pituitary–adrenal axis and serotonin systems. Many treatments have been proposed for children with ASD with comorbid sleep difficulties.

Various behavioral treatments have been used with varying success in the ASD population. Most favorably, the use of proper sleep hygiene techniques, stimulus control, graduated extinction, scheduled awakenings, and daytime nap restriction have all shown utility among children with autism and intellectual disability. Light therapy, in combination with chronotherapy, may also be useful in children with autism who have circadian rhythm abnormalities. Pharmacologic treatments also have proven to be useful for many, but not all, children with ASD.

Various prescribed medications have reported utility in the treatment of sleep difficulties in the ASD population, including antihistamines, sedating antidepressants, α-2 agonists, benzodiazepines, and antipsychotics. Melatonin has also demonstrated utility in treating children with neurodevelopmental disabilities and autism.

Mood Disorders. Sleep complaints are among the most prevalent symptoms of major depression in children and perhaps the most prevalent symptom among adolescents. Insomnia has been reported to affect nearly 90% of depressed adolescents, whereas *hypersomnia* affects a considerably smaller proportion, perhaps around 25%. Some adolescents—around 10%—continue to experience insomnia even after the remission of depression. The use of actigraphy in diagnosing sleep problems among depressed children and adolescents highlights the compromised sleep quality and abnormal circadian rhythms these individuals experience while depressed. PSG studies in children with depression often demonstrate decreased REM latencies, increased total REM, and increased sleep-onset time. A recent meta-analysis of PSG characteristics among children and adolescents with major depression demonstrated, in fact, that increased sleep-onset latency was collectively the strongest PSG marker of depression in youth.

A number of large prospective population-based and cross-sectional studies have been conducted in the past decade among adolescents, demonstrating a strong association between sleep problems and suicidality. A close relationship between sleep problems and suicide attempts has also been shown in adolescents who have already engaged in nonsuicidal self-injury. A curvilinear dose–response was observed such that those adolescents with reported TST of 8 to 9 hours per night had the lowest risk for suicidal ideation and attempts. Insufficient sleep duration has emerged as one of the most salient risk factors for suicidality, illustrating the importance of sleep screening as part of a suicide assessment.

Many children who are or will be later diagnosed with bipolar disorder present with sleep-related symptoms. When depressed, these children may experience exhaustion, distractibility, irritability, and impulsivity at levels significantly greater than at baseline. In contrast, children experiencing mania may present with unusual amounts of energy and a decreased need for sleep. Such extremes of sleep behavior warrant clinical assessment.

Seasonal affective disorder (SAD) has a reported prevalence of 3% to 4% in children and adolescents, for whom more than 20% of their parents report that their children are sleepier and generally more tired during winter months. Studies of children with a diagnosis of SAD have found that they did not differ from controls in the level of nocturnal activity but did experience significantly lower diurnal activity levels and had less robust circadian rhythms, with a reduction in amplitude.

There have been a small number of studies examining the effects of pharmacologic and behavioral interventions in depressed children and adolescents suffering from sleep problems. A combination of improved sleep hygiene and cognitive behavioral therapy (CBT) has been shown to be effective in managing the insomnia and awakenings associated with depression. In those cases that require further treatment, the most effective drug therapy appears to be a combination of an antidepressant with the short-term use of a sedative or hypnotic. As noted previously, however, some children

and adolescents experience a paradoxical reaction to these medications, which severely limits their utility.

Anxiety Disorders. Although it is difficult to establish causality between early sleep problems and the later onset of anxiety and depression, it is clear that anxiety and sleep problems are intimately connected in childhood and that the presence of a sleep problem at age 4 years is significantly correlated with the development of depression and anxiety by age 15 years. Fears at nighttime are common among children, with up to 75% of those aged 4 to 12 years reporting such fears, which generally take the form of animals, fictitious characters (e.g., witches, monsters), being kidnapped, or being teased by peers. Although no specific numbers are available, for the majority of children with DSM-5-TR anxiety disorders, sleep problems typically follow. In addition to the aforementioned concerns, anxiety is also believed to predispose children to parasomnias and nightmares.

The effects of anxiety on sleep are profound, and the clinical presentation depends largely on the specific disorder. Individuals with *generalized anxiety disorder* (GAD) have a wide range of sleep disturbances, which can include insomnia and hypersomnia. These GAD sleep symptoms may be due to central nervous system hypervigilance and hyperarousal such that the individual is unable to relax sufficiently to fall asleep and maintain good sleep quality. Patients with panic disorder tend to present with insomnia, restless and fragmented sleep, and nocturnal panic attacks. These symptoms often result in trouble initiating and maintaining sleep, increased sleep latency, and reduced sleep efficiency.

Children and adolescents with PTSD may experience significant sleep difficulties. Individuals with PTSD often have trouble initiating sleep and experience significant nighttime arousals and disruptive nightmares. Because children with PTSD may have flashbacks to their traumatic experiences, bedtime can become a stressful time in which they experience increased anxiety and are unable to relax sufficiently for restful sleep. The accompanying nightmares, which are a characteristic symptom of PTSD, and increased limb

movements, which are associated with nightmares, lead to disrupted REM sleep.

Some research suggests that early trauma may exert a sustained impact on sleep persisting into adulthood. Bader and colleagues demonstrated that childhood trauma was the strongest predictor of delayed sleep-onset latency, poor sleep efficiency, and high nocturnal activity during adult years, even after controlling for stress and depression. Similar data has been derived from studying sleep in females who experienced sexual abuse as children, suggesting that traumatic exposures, more so than a diagnosis of PTSD *per se*, are closely associated with persistent sleep disturbances.

Cognitive and behavioral techniques, systematic desensitization, and imagery rehearsal therapy have demonstrated efficacy in decreasing nightmares and are integral parts of treating the sleep disturbances accompanying obsessive-compulsive disorder (OCD), PTSD, and GAD. CBT, along with systematic desensitization, has been demonstrated to improve the sleep disturbances associated with OCD. In cases that are particularly severe, serotonin-specific reuptake inhibitors such as fluoxetine, sertraline, and paroxetine further aid in the reduction of symptoms. Children and adolescents with PTSD generally have a complex constellation of symptoms, and the primary psychiatric diagnosis must be treated first before the sleep disturbances will resolve. CBT and play or expressive therapies, in which the children process the traumatic events triggering the PTSD, have been shown to be very effective, and antidepressants and anxiolytics may hasten the recovery process in combination with other therapies.

54.14 Internet Gaming Disorder in Youth

Michael Feldmeier, M.D., Michael Ogata, M.D., Caroly Sue Pataki, M.D., and Roxy Szeftel, M.D.

The first commercially available video and computer games for children and adolescents emerged in the 1950s and were played by one or two players sitting together at a single computer. In the 1970s, home and handheld video game consoles became available, including the popular Atari Home Pong and the Magnavox Odyssey 2. By the 1990s, the internet gaming industry emerged with an explosion of online games able to be played by multiple players across the globe and available as a commercial network.

Internet gaming disorder (IGD) was proposed in the United States in 2013 and included in the Diagnostic and Statistical Manual (DSM-5) as a "condition for further study." Clinicians conceptualized it as a potentially impairing psychiatric disorder that might merit inclusion in future revisions of the DSM. At about the same time, the World Health Organization (WHO) began consideration of game addiction as an important public health issue. In 2018, the WHO proposed game addiction as gaming disorder (GD) which was included in the 11th revision of the International Classification of Diseases (ICD-11).

In the United States, given the paucity of evidence-based clinical studies on GD and the lack of consensus on diagnostic criteria, clinicians and researchers decided to delay its inclusion in the DSM-5.

PREVALENCE

Due to variability in screening measures as well as different uses of the diagnostic criteria of IGDs in the ICD-11 and the DSM-5, the prevalence of this disorder in youth and adults remains difficult to determine. Barriers to acceptance of a unified screening tool for IGD include a lack of consensus on symptom identification, variation in clinician view of how much gaming

is impairing, and how cultural and national social norms may play a role in identifying IGD as a disorder. One analysis of four survey results conducted in the United States, Canada, United Kingdom, and Germany showed clinically significant impairment due to internet gaming behaviors or disorders with a prevalence between 0.3% and 1% in adults. Most existing gaming rating tools focus on screening for impairment in relationships, school, or work due to internet gaming addiction and gaming behaviors.

DIAGNOSTIC CRITERIA: GAMING DISORDER (ICD-11) AND INTERNET GAMING DISORDER (DSM-5 CONDITION FOR FURTHER STUDY)

The DSM-5 (Internet Gaming Disorder—condition for further study) and ICD-11 (Gaming Disorder) list similar but not identical diagnostic criteria for these disorders. Similarities include a pattern of repetitive or persistent gaming behavior that impairs functioning in multiple domains (e.g., educational, occupational, interpersonal) for a period of at least 12 months (Tables 54.14–1 and 54.14–2).

Table 54.14–1.
DSM-5: Diagnostic Criteria for Internet Gaming Disorder (proposed as a condition for further study)

Persistent and recurrent use of the Internet to engage in games, often with other players, leading to clinically significant impairment or distress as indicated by **FIVE** *(or more)* of the following in a **12-month** period:

1. **Preoccupation with internet games.** *(The individual thinks about previous gaming activity or anticipates playing the next game; Internet gaming becomes the dominant activity in daily life.)*
2. **Withdrawal symptoms when Internet gaming is taken away.** *(These symptoms are typically described as irritability, anxiety, or sadness, but there are no physical signs of pharmacological withdrawal.)*
3. **Tolerance**—the need to spend increasing amounts of time engaged in Internet games.
4. **Unsuccessful attempts to control the participation in Internet games**.
5. **Loss of interests in previous hobbies and entertainment as a result of, and with the exception of, Internet games**.
6. **Continued excessive use of Internet games despite knowledge of psychosocial problems**.
7. **Has deceived family members, therapists, or others regarding the amount of Internet gaming**.
8. **Use of Internet games to escape or relieve a negative mood** *(e.g., feelings of helplessness, guilt, anxiety)*.
9. **Has jeopardized or lost a significant relationship, job, or educational or career opportunity because of participation in Internet games**.

Note: Only **non-gambling Internet games** are included in this disorder. Use of the Internet for required activities in a business or profession is not included; nor is the disorder intended to include other recreational or social Internet use. Similarly, sexual Internet sites are excluded.

Specify current severity:

Internet gaming disorder can be mild, moderate, or severe depending on the degree of disruption of normal activities.

Table 54.14–2.
ICD-11: Diagnostic Criteria for Gaming Disorder

- **Description**
  - Gaming disorder is characterized by a pattern of persistent or recurrent gaming behaviour ('digital gaming' or 'video-gaming'), which may be online (i.e., over the internet) or offline, manifested by:
    1. impaired control over gaming (e.g., onset, frequency, intensity, duration, termination, context)
    2. increasing priority given to gaming to the extent that gaming takes precedence over other life interests and daily activities; and
    3. continuation or escalation of gaming despite the occurrence of negative consequences.
  - The pattern of gaming behaviour may be continuous or episodic and recurrent.
  - The pattern of gaming behaviour results in marked distress or significant impairment in personal, family, social, educational, occupational, or other important areas of functioning.
  - The gaming behaviour and other features are normally evident over a period of at least 12 months for a diagnosis to be assigned, although the required duration may be shortened if all diagnostic requirements are met, and symptoms are severe.
- Exclusions
  - Hazardous gaming (QE22)
  - Bipolar type I disorder (6A60)
  - Bipolar type II disorder (6A61)

BENEFITS AND RISKS OF ONLINE VIDEO GAME PLAY IN YOUTH

Benefits

Most children, adolescents, and adults who play online games identify distinct benefits to (moderate) video gameplay. Most individuals can

identify the negative health outcomes of substance use, for example, but negative health and mental health outcomes due to video gameplay are more difficult to determine and differ based on one's psychosocial situation and needs. Most video game players may never experience clinically significant negative outcomes from their video game use, but those that do can experience very significant impacts on their lives. Benefits of internet gaming for youth include promoting problem-solving, cooperation, and connection with peers all over the world.

Educational—Inherent to all video games is a process of learning the rules and objectives of a game. Typically, this is done either through a tutorial preceding the core of gameplay or concepts that are gradually introduced as a player progresses through the initial sections of a game. Game designers must balance a difficulty curve while maintaining engagement–a game should not be so easy that it becomes boring a predictable, but it should not be so difficult to frustrate a player into quitting the game. It is our observation that through video gameplay, like "real-life play," children can acquire prosocial skills such as frustration tolerance, winning and losing gracefully, cooperating with others, and in some cases, delayed gratification (such as when completing a game despite challenges arising).

Social—There are palpable benefits of internet gaming for youth seeking social connections to peers. Especially for youth who are isolated or lonely, the medium of video games may provide a need that is otherwise unmet. Online video gaming may be perceived as a safe space that allows for peer-to-peer self-disclosure and social exploration.

Risks

Avoidance—In some cases, children may rely on video gameplay as a way of avoiding social and academic challenges. Children may delve into gaming instead of schoolwork or in-person social interactions with peers to shield themselves from emotional stress.

Anger—Some gaming environments can lead to hostile environments or intimidation of younger children who are playing with players who are older or who bully less experienced players. Some children, as well as adults, may express their anger during gaming through verbal altercations or through private messaging. There is no data to support those violent video games lead to violent in-person behaviors in youth.

Financial—Children and adolescents have anecdotally been reported to utilize parental credit cards to make large in-game purchases.

BIOLOGIC CORRELATES OF INTERNET GAMING DISORDER

Proposed Neurobiology of Internet Gaming Disorder

IGD shares neurobiologic alterations that are typical for other addictions, such as:

1. Activation in brain regions associated with reward as evident from cue exposure and craving studies and neurotransmitter systems studies that indicate an involvement of dopamine-mediated reward mechanisms
2. Reduced activity in impulse control areas and impaired decision making
3. Reduced functional connectivity in brain networks that are involved in cognitive control, executive function, motivation, and reward

Structural changes, mainly reduction in gray-matter volume and white-matter density, have been found in groups of individuals with IGD.

Executive control networks in ADHD may increase the susceptibility to developing IGD.

COMORBIDITY

Several comorbid psychiatric disorders have been identified to be associated with youth who present with problematic or impairing video game use. The strongest associations are found with anxiety, depression, and ADHD.

Major Depressive Disorder

Depressive symptoms are frequently associated with youth and adults who present with impairment from internet game use. Depressive and IGD symptoms are hypothesized to be bidirectionally related, consistent with findings in other addictive disorders. Depressive symptoms have been shown to be more prevalent in those with IGD compared to healthy

controls. Conversely, a reduction of depressive symptoms has been reported in individuals after remission of IGD.

A 17-year-old male presents to a community psychiatric outpatient clinic with worsening performance in school, especially in subjects that he does not enjoy, and withdrawal from friends and family activities. He spends most of his time in his room with the door closed. He performs best in math, his favorite subject, but he ignores class assignments, and he rarely turns in homework. His parents report that prior to becoming a teenager, he was friendly and outgoing and did well in school without studying. His parents believe that he did so well in school as a child because of his high native intelligence. His parents are concerned that he may have attention-deficit/hyperactivity disorder (ADHD) because to complete homework now, he requires them to sit right next to him and repeatedly verbally redirect him. He is aware of his poor performance, and his goals still include going to college and possibly graduate school to focus on mathematics. Recently he has started to have crying spells at night and reports self-deprecating thoughts, which make it difficult to sleep. During an interview with him, he reports that he plays online games and watches YouTube videos about gaming for many hours during the day and late into the night, which is news to his parents. Psychiatric evaluation does not reveal a diagnosis of ADHD, but he meets the criteria for major depressive disorder (MDD). He and his parents agreed to a trial of antidepressant medication, and after a month of treatment with sertraline, his symptoms of depression improved. However, his academic performance is largely unchanged. He discloses when asked that when he sits down at his computer with the intent of completing his homework assignments after working for about 15 minutes, he plans to take a short break which usually extends to several hours. Once he becomes involved in gaming, he is unable to stop because he wants to continue to make gains in his game, and he loses all interest in completing his homework for the day. He agrees to a family session in which he reveals how many hours per day he spends gaming and his inability to control it. His parents are surprised, but they are pleased that he is willing to discuss his gaming in the session. His psychiatrist recommends that his parents enroll him in a 2-hour after-school homework program so that he can focus on homework without the option and temptation of playing online games and that he begins weekly therapy to help him monitor and control his cravings for games.

Attention-Deficit/Hyperactivity Disorder

ADHD is commonly comorbid with problematic internet gaming and maybe a mediating factor for IGD. It has been reported that features of ADHD in undiagnosed individuals with IGD are a significant predictor of comorbidity of these two disorders. Neurologic reports studies have suggested overlap between the pathways involved in ADHD and IGD. Compared to pure-IGD, when ADHD is comorbid, recovery of IGD is less likely, and there is a higher likelihood of recurrence of IGD.

A 9-year-old boy with a history of well-controlled ADHD and intermittent explosive disorder presents to the psychiatric outpatient clinic due to recurrent severe tantrums when his parents limit his time on the computer and insist that his online game be turned off. His parents are concerned about his significantly increasing cravings for online gaming and his out-of-control reactions when limits to his gaming are set. His reactions to his gaming being curtailed have escalated from screaming and crying to hitting and kicking his parents, to throwing household objects to recently physically attacking his mother. The boy feels sad and guilty after his tantrums and often apologizes to his parents, yet the same thing happens the next day. His parents report that there is a noticeably more intense pattern of tantrums occurring after longer and more frequent gameplay sessions, especially when he is playing online with friends and classmates. His parents are unsure of how to limit his online gaming while still supporting his social engagement with peers, especially since online gaming has become the main avenue for social interaction in the context of the COVID-19 pandemic. His parents helped to create a behavioral token economy that provides rewards for social nonvideo game engagement with friends and allows him to earn reasonable online gaming time. Consistent time limits were necessary and implemented by his parents, and after struggles and resistance for a few weeks, the boy was able to accept the limits, enjoy other online activities with peers that do not involve video gaming, and his reactions to limits on his gaming time lessened without escalating to physical aggression.

Anxiety Disorders

Anxiety has been frequently reported as comorbid with IGD. When anxiety is present with IGD, the risk of developing depression is increased. Correlations have also been reported between IGD, generalized anxiety disorder, and social anxiety disorder.

A 13-year-old boy presents at a psychiatric outpatient clinic with resistance to engage in online school and refusal to give presentations by Zoom. His parents brought him to the clinic for evaluation to find out if his online gaming is interfering with his school participation. He has a history of discomfort with meeting new people, speaking in public, worrying more than his peers about what others think of him, and potential natural disasters that may occur. He has had one episode of a panic attack in school after he gave a wrong answer in front of his class, requiring his parents to come and pick him up. He has been diagnosed with generalized anxiety disorder and, in the past, has demonstrated some improvement with cognitive behavioral therapy and fluoxetine medications. He has never had significant depressive symptoms or suicidal thoughts. Currently, he is not on any medication and is not in therapy. His performance in school has been consistently good, usually getting As and Bs. In his spare time, he plays a popular online game and then takes game footage and edits it in a creative way, and uploads those videos to YouTube. He has a following of several hundred subscribers. His parents have been wary of this activity and set firm limits and monitor what he is uploading. His parents emphasize that they have set a family rule that he is not to show his face or swear and that he blocks hostile viewers (trolls) who leave demeaning comments on his videos. He spends about four hours per day online gaming, but he continues to finish his homework, go to sleep at a reasonable time, and participate in family activities. Even though he spends up to four hours on weekdays and up to six hours on weekends either playing games or editing gaming footage, he is accomplishing the tasks required for his age. During the psychiatric evaluation, he reveals that he agrees with his parents' limits on his online gaming, and he feels that he can control it without distress. He discloses that over this past year of Zoom school, his fear of speaking in front of the class has escalated, and especially his anxiety when doing online presentations has made school problematic. In a feedback session with him and his parents, his parents are reassured that his online gaming is not contributing to his trouble with school and that his performance anxiety pertaining to public speaking in the classroom is the source of the anxiety for him. He and his parents agree to a trial of propranolol which he takes on days that he must give a Zoom presentation in school.

TREATMENT OF INTERNET GAMING DISORDER

Evidence-based, gold-standard treatments for IGD have not yet been demonstrated. There is anecdotal evidence for efficacy with modalities including parent training, motivational interviewing, group therapy, and cognitive-behavioral therapy. Currently, several residential therapeutic treatment programs for IGD are in operation in the United States and abroad, which offer “digital detox,” however, long-term outcomes have yet to be verified through evidence-based or randomized clinical trials. Pharmacologic treatment for IGD has been reported only anecdotally, including a case report of efficacy with bupropion. There is no evidence currently to recommend the use of psychopharmacologic agents for IGD other than in the treatment of comorbid psychiatric conditions.

Impact of Treating Comorbid Disorders on IGD

There is currently no evidence-based data to demonstrate the impact of treating comorbid disorders on IGD. It has been reported anecdotally, however, that behavioral interventions in youth with comorbid depressive symptoms and IGD symptoms may be effective in reducing the severity of both disorders. IGD is believed to be a behavioral addiction that is not affected by the concurrent effects of substance use or its treatment.

CLINICAL CONSIDERATIONS

Parent Recommendations on Gaming Limit Setting in Children and Adolescents

Age-appropriate game choice and boundaries are important considerations for parents and an essential skill for clinicians to be able to identify signs of problematic gameplay and provide guidance for parents. Clinician consensus suggests that among other risk factors for developing IGD in youth is many hours of video gameplay per day. Consequently, it is beneficial for clinicians to screen for excessive use in their child and adolescent patients and counsel parents to set age-appropriate playtime limits for gaming. While there is no known specific time-dependent exposure to online gaming hours that would lead to a given child being susceptible to IGD, clinical observation and monitoring of a child’s overall

functioning is important. Parents' familiarity with and understanding of expectations of schoolwork and other balanced tasks of childhood (exercise, socializing with peers, extracurricular activities, enrichment) at different developmental ages will help them to determine how much gaming and screen time would be appropriate for their child's circumstances.

Clinical Recommendations

As the potential for online gaming impairment may rise along with increased accessibility of video and the current ubiquitous nature of online gaming in the lives of youths, screening for IGD is a worthwhile part of age-appropriate screening questions during mental health evaluations and during clinical follow-up sessions. Video gameplay in youths, especially problematic use, may be under-reported by youth and often unknown to parents, which makes it even more important for clinicians to ask youth as well as parents for detailed information on their child's online gaming habits. It is suggested that clinician screening questions for youth begin with open-ended, plain-language questions such as "Tell me about what gaming means to you," "What happens when you find yourself gaming too much"?, and "What does gaming get in the way of for you"?

A social media screening questionnaire created by the authors. Michael Feldmeier pertaining to online use in youth, The Social Media Initial Questionnaire-revised (SMIQ-r), can be helpful in systematically evaluating a child's online activities, including video game use. The SMIQ-r is included in this book in Chapter 55.15, "Social Media in Youth." The SMIQ-r may aid clinicians in elucidating a more nuanced picture of a child's gaming internet use experience.

Many families find it helpful to view video game use as a privilege for their children and use video time as a reward to motivate and inspire their children to accomplish their necessary tasks (homework, chores, and fitness). It is important that children and adolescents have a variety of in-person as well as online activities to engage in, including physical fitness activities. The American Academy of Pediatricians lists recommended time limits based on age (see https://services.aap.org/en/patient-care/media-and-children/)

Video game abstinence is not usually recommended since it may promote avoidance of issues rather than help a child learn self-regulation. Gaming is often a coping strategy for many children. In moderation,

gaming can represent a beneficial activity allowing children an opportunity for emotional processing, social play, learning, and a reprieve from life stressors. Excessive gaming, however, can become a negative behavior that may block opportunities for emotional development. It is important for clinicians to understand that although video game use is ubiquitous in today's youth, addiction to video gameplay leading to impairment is rare.

Public Policy Impact on Clinical Sequelae of IGD

Emerging worldwide public health awareness of GDs and the impact of problematic gaming behaviors in youth leading to impaired functioning has made it an important public health concern for further investigation. The following questions come to mind: "What can be done to reduce GD prevalence"? and "Who should take responsibility"? Currently, in the United States, the Entertainment Software Ratings Board provides oversight within the video game industry regarding transparency of the content within video games. Outside of age restrictions on online gambling platforms, however, there is no oversight pertaining to the content within the game design used to attract players to initiate and continue the game. As gaming has become more widespread, increased data sets are accessible to gaming companies to use for market research to expand the popularity of a given game and increase players' overall playtime. Clinicians can be helpful to their child and adolescent patients once they understand their patients' video game use and its impact on their lives.

FUTURE DIRECTIONS

Randomized controlled studies investigating online gaming in children and adolescents are lacking in the United States. Available international data by Na Rim Kim and colleagues and Cheng-Fang Yen and colleagues (see References) provide trends about international gaming in adult and adolescent patients, but generalizability and study power are varied given the inconsistencies in self-report tools used in these studies. An internationally recognized screening tool would be instrumental in allowing research to progress. A published review by Daniel L King (see References) compared 32 different forms with no clear clinical tool standing out among the rest in assessing for GD/IGD.

54.15 Social Media and Youth

Christina Guest, M.D., Yeun J. Lim, M.D., Michael Feldmeier, M.D., Roxy Szeftel, M.D., and Caroly Sue Pataki, M.D.

Social media is defined as "electronic communication including websites for social networking and blogging through which users create online communities to share information, ideas, personal messages and other content such as pictures and videos." Social media, as we know it, originated in the 1990s when groups began forming on the newly accessible internet. This was a novel way for many people, near and far, to share thoughts, social networking, support, and ideas. This was the start of online communities.

Then, social media evolved to chat room formats, such as AOL and Yahoo messaging, in the late 1990s. It later transitioned into blogging websites, online gaming sites, and dating websites. The first social media site, Six Degrees, was created in 1997, allowing users to create profiles and make online friends. MySpace and LinkedIn became prominent in the early 2000s, and LinkedIn became the first job- and career-based social media platform. YouTube emerged in 2005, creating an innovative way for people to communicate from great distances. In 2006, Facebook and Twitter emerged and continue to be among the most popular social media sites. A whole host of additional sites, including Reddit, Tumblr, Foursquare, Snapchat, and Instagram, have emerged to fit specific social networking needs in various subcultures of youth and adults.

The proliferation of social media and media technologies has made it a mainstay of daily life for today's children and adolescents. Millennials, born between 1977 and 1995, were the first generation of social media natives who grew up with the transition and development of many social media sites and increased access to daily internet technology. Generation Z, born between 1996 and 2015, have incorporated social media as one of their primary forms of communication and social development. These

youth have grown up with social media technologies which have seamlessly been integrated into their development, communication styles, and social schemas.

According to the Pew research report of 2021, at least 60% of today's U.S. youth have interacted with a smartphone or other media technology before the age of 5 years, and over 90% of teens in the United States have access to a smartphone device. A primary purpose of social media in youth is to increase their sense of social connectedness and belonging with peers, friends, and family and increase social interactions while also being used for educational purposes and, of course, entertainment. Among children and adolescents, the most popular social media platform is YouTube, as reported by up to 80% of parents interviewed by Pew researchers in 2021.

According to the 2021 Pew Research survey, after YouTube, U.S. youth most often use Instagram, WhatsApp, and TikTok. Of the 95% of U.S. adolescents who report having a smartphone, 45% endorse being "constantly online" and with the primary reason to "just pass time" (57%). Male and female adolescents equally report the use of smartphones and social media to connect with others and to learn new things. Female adolescents, however, report that they are more likely to use smartphones to avoid in-person social interactions compared with males.

In younger school-aged children, according to the Pew Report in 2021, YouTube, TikTok, and Snapchat are the most popular. Young children are often exposed to digital media by the age of 1 year. Some parents report that they rely on social media to calm or "babysit" their children when they are busy with other tasks. Among school-aged children, the vast majority of them use their parents' devices, making it easier for parents to monitor and control their social media use compared to adolescents.

BENEFITS OF SOCIAL MEDIA USE FOR YOUTH

The ubiquitous nature of social media and media technology in the daily lives of children, adolescents, and adults leads to examining and recognizing its benefits. Today's children and adolescents have social media and media technology integrated into their lives from very early on, often within the first year of life. It is therefore understandable that youth would integrate social media and media technologies into their social schemas, that is, a natural way that they communicate with peers and

play online recreational games. With the explosion of applications for cell phones and computers and the easy accessibility of the internet, social media and media technology are here to stay and have identified themselves as beneficial tools for many youths. Social media and media technology are now used regularly by youth for increased social connectedness, including for emotional support and building of social circles and support systems, as well as for increased access to resources, such as mental health resources and education. However, the benefits of social media and media technologies continue to seem endless, and the aforementioned benefits are just a small subset of some applicable benefits for youth with mental illness.

Social Media to Increase Social Connectedness in Youth

With the seamless integration of social media into youths' lives, it is without surprise that it is used as a tool for constant communication with their social circles, including family and friends. Applications such as Facebook, WhatsApp, Instagram, TikTok, and YouTube are just a small subset of the numerous social media and media technology programs that youth use to stay connected. Having social connectedness without needing to be physically present with others can increase a sense of community and friendships for some youth. In addition, social media and media technology enable youth to connect to peers and other youth in far-away neighborhoods, cities, and even countries, enabling youth to find more friends and peer connections.

Noah, a 13-year-old male with social anxiety disorder and attention-deficit hyperactivity disorder (ADHD), presents to the outpatient child and adolescent psychiatry clinic with his mother for a follow-up visit. Since kindergarten, he had been extremely shy, quiet, and worried about being judged by other kids, especially in a large group. He has only one close friend at school. His mother was conflicted when he asked for a smartphone for his 13th birthday, as she worried that having a smartphone may steer him away from social interactions further. During this visit, the mother shared that he had been using TikTok and Instagram with his mother's permission and supervision. Noah sheepishly tells the psychiatrist that he had made several new online friends on TikTok and Instagram. They were all following and commenting on other teenagers' accounts that post funny skits about their favorite Japanese Manga characters. He is often sharing funny videos and memes with them. He no longer feels alone anymore because he realizes there are others with the same interests in many different cities and states. He is excited that soon they will meet online and play video games together.

Social Media for Youth Seeking Support

A frequent scenario among youth experiencing emotional distress without adequate support at home or who don't have clinical support, caregivers, or peers in person in place is to seek support through social media. This modality may be more desirable, especially for those youth who are not in danger of harming themselves or others and feel embarrassed or ashamed to ask for help in person. A youth's increased ability to seek support online from peers may help them feel less alone and, at times, help them to access useful resources and online education about their distress and available interventions. These can lead to positive outcomes for youth. An example of youth using social media for support can even take the form of posting photos or content related to feeling lonely and depressed and receiving empathic responses. Youth who are lonely or isolated often lack other support. Thus having the social media platform as a potential for a new sense of community and support that otherwise does not exist for them in person can be beneficial. See case report.

An adolescent female, Lena is a 15-year-old teen with a history of depression who has been feeling isolated and tearful. She turns to social media for support by posting pictures of herself looking wistful, lonely, and depressed on Instagram. Soon, she discovered that there were many other adolescents on Instagram who began to follow her with similar struggles who felt lonely, isolated, and unable to access camaraderie in person. Although Lena feels isolated because she does not have an in-person support system of peers, through her Instagram posts, she is able to share her feelings online and gain a sense of support and community, resulting in feeling less alone and her spirit lifted. Although Lena continues to feel lonely, the positive reactions and encouragement she receives online feel supportive, she is not in danger of harm, and she finds this modality of support very helpful.

Social Media for Youth to Seeking Mental Health Information

Social media is often used by youth to seek information on mental health and potentially to learn about mental health treatments. Youth from Generation Z (born 1996 to 2015) exhibit a strong preference for social media and media technology communication to learn about mental health and potentially receive online mental health treatments. This preference appears to be especially prominent in at-risk youth with emotional vulnerabilities or a history of mental health problems. Clinicians who can use social media platforms to connect with at-risk youth may increase the likelihood that these youths will access mental health interventions. Some youth report a sense of reassurance and security from online support, such as online support groups. An increasing number, albeit still a small percent, of mental health professionals are joining online support groups to provide information and guidance for youth in distress with the goal of increasing youth emotional well-being.

A 17-year-old female, Ricka, joined a clinic WhatsApp chat group for support, information, and potential linkage for treatment. According to the clinician who led the group, Ricka often posted questions about sexual abuse. The social worker was able to respond to such posts with a private message back and an offer to help Ricka find an in-person evaluation in her own city. Through these confidential and private communications, Ricka felt connected to the social worker and developed enough trust to accept her guidance and seek mental health treatment in her own city.

Surveys indicate for some youths, online modes of communication with mental health providers offer less shame, increased youth engagement, as well as an increased sense of control over their sense of emotional stability.

In addition, social media and media technology are now available to some youth around the globe, increasing access to mental health treatment for those who otherwise might not have access. For example, an African study shows an increase in retention, education, and support for youth in human immunodeficiency virus (HIV) treatment programs within Africa by having a social media platform for all to join. This allowed for support, education, and increased access to treatment guidelines and recommendations to a larger group than otherwise would be able to join due to limitations on travel or inconvenience that in-person support groups and education would require. Similarly, digital interventions have been utilized for the treatment and prevention of substance use disorders in youth, another topic that often has stigma associated with it, like HIV, potentially limiting those who would reach out for help. By integrating advertisements within social media directed at adolescents, researchers were able to imbed a substance use and addiction scale, along with digitized adaptations of motivational interviewing to help increase acceptance of substance use treatment and recovery programming. The anecdotal successes of remote engagement for youth, teachers, and clinical providers suggest that online computer-based educational settings and clinical modalities of mental health can be effective and, in some cases, increase access to education and mental health care.

RISKS OF SOCIAL MEDIA USE FOR YOUTH

Parents and caregivers may or may not be aware of what their children are viewing on social media and how much time they are spending on it, especially if they use mobile phones when caregivers are not home or at night in their rooms. Youth of all ages who use social media may be exposed to violence and risk-taking behaviors, videos of stunts or challenges that may inspire unsafe behavior, sexual content, negative stereotypes, substance use, cyberbullies and predators, advertising, misleading or inaccurate information, identity theft, or hacking.

While adequate screen time may increase social connectedness in youth, excessive screen time may lead to impairment in everyday life, has been linked in some youth to sleep problems, lower grades, less time with family and friends, lack of physical activity, weight problems, mood problems, poor self-image, and a fear of missing out (FoMO). Surveys of youth suggest that excessive social media may be contributing to increasing mental distress among youth. Some researchers have hypothesized that problematic social media use occurs with greater frequency in youth with a diminished ability to regulate impulses, display stress or anxiety when social media is restricted, and demonstrate constant thoughts about social media. The potential risks of social media are also associated with increased time spent on social media.

Data from a survey of adolescents from 29 countries showed that adolescents' intense social media use was, in some cases, positively associated with well-being and, in other cases, negatively associated with a reported sense of well-being. Factors associated with a positive or negative response to intense social media use include the prevalence of social media in the country and the level of vulnerability of the youth. In countries with a lower prevalence of intense social media use, those youth with intense use reported more frequent psychological complaints, lower life satisfaction, and lower levels of family support than youth with less social media use. In countries with a higher prevalence of intense social media use, however, intense social media use was predominantly positively correlated to family support and life satisfaction.

It is important to consider that intense use of social media is not as universally correlated with negative well-being in youth. Rather, negative outcomes of intense social media use are based on youth vulnerability due to the contributions of many possible factors, including lack of family support, poor school achievement, and prior mental health challenges. Thus, risks to a sense of well-being in youth with intense social media use

may arise not simply from the time spent on social media but perhaps due to many factors, including an inability to monitor and mediate their own use and a preoccupation with social media use.

Bidirectional Association between Social Media Usage and Depressive Symptoms

Social media use appears to be increased in youth with depressive symptoms, loneliness, and high levels of stress. Loneliness reported by youth is also a predictor of more intense usage, and in some cases, it may help to alleviate the depressed mood. Depressive symptoms, and sleep problems, have been shown to be a predictor of excessive social media use.

Negative impacts of social media on depressive symptoms are endorsed more frequently in adolescents with high levels of social isolation and low levels of in-person interaction. In contrast, youth with higher levels of in-person socialization appear to be protected against the negative consequences of excessive social media use and report negative outcomes less often.

Depressive symptoms such as rumination and brooding appear to exacerbate the negative effects of social media, according to surveys in youth. Surveys of college students report that those who tend to compare themselves with others more often also report higher rates of negative affect, such as feelings of low self-esteem after browsing the Facebook profile of an acquaintance, relative to students who infrequently compare themselves to peers.

A 2021 systematic review of the literature suggests that passive social media usage (browsing others' content or comments) may aggravate depressive symptoms, such as loss of interest or low mood. High social media use appears to be predictive of depressive symptoms and low offline social support from both family and peers. Addictive attitude toward Facebook is found to be positively correlated with depression, regardless of age (age range 10 to 18) and gender.

Social Media Impact on Youth Body Image and Risk of Self-Harm

It is well known that many social media platforms showcase images of "ideal" and idealized notions of beauty and body image. Surveys of youth and adults indicate that frequent and prolonged social media use is associated with body image concerns and disordered eating in both

females and males. This effect is more pronounced in youth who tend to frequently compare their appearance to others in person. Social media is also often used by youth to join others with similar concerns or beliefs either for support or to become a persuasive group for a specific belief or cause. On social media, eating disorders are common themes. Some online groups that attract mainly adolescent girls who are interested in extreme weight loss and are seeking guidance regarding the best ways to starvation diets provide this information. Online groups such as these provide videos and coach users on how to pathologically lose weight. Although there is some censorship by these sites to monitor the content provided, there are also groups that offer opposing viewpoints, for example, officially aimed to raise awareness of the negative consequences of anorexia.

Ashley, a 16-year-old female with no psychiatric history, went to an appointment to see her pediatrician with her mother. Her mother says that ever since Ashley started to spend 3 to 4 hours a day scrolling through fashion influencers' Instagram posts, she has been trying to skip breakfast and dinner often. Ashley does acknowledge that she has felt like she is "fat" compared to the fashion influencers who often show off their thin bodies in tight clothes or swimsuits. The pediatrician suggested that Ashley cut down on social media and non–school-related electronic use time to 1 hour a day. Her mother started using a timer for social media use, and Ashley agreed to unfollow the influencers who posted photos of their bodies often. In a couple of months, she started to eat breakfast and dinner again.

RISKS OF INTENSIVE SOCIAL MEDIA USE IN YOUTH

Associations Between Social Media Use and Anxiety

Some social media features, such as the ability to receive or post online approval through the number of "likes," have been found to be associated with excessive social comparison, rumination, and increased anxiety symptoms. Youth with pre-existing traits of "perfectionism" may be more vulnerable to reacting to other users' "likes" and "dislikes" of their posts. Social anxiety is a topic that is discussed frequently online by youth in the

United States. Online socializing can be attractive for youth with fear of being negatively judged by others during real-life social interactions. Some youth feel that by communicating and posting online, they will avoid being judged negatively. When youth with fears of in-person social interactions receive symbols of “like” to their online posts, it may reinforce their online choices and thereby replace opportunities to engage in social activities in person that promote socioemotional development. The more that youth share about their lives online, the more they are at risk of being afraid of missing updates and an urge to constantly check their profiles for feedback. This pervasive anxiety and urge to be constantly in fear of not being included is known as the “fear of missing out” (FoMO). This FoMO in youth is marked by worry that other people might be enjoying fun or satisfying experiences without them, pushing them to be constantly on social media to check. High levels of FoMO seem to promote a sense of addiction to online social media platforms.

Intensive Social Media Use and Cyberbullying

Cyberbullying commonly involves cruel messages or postings made online as well as sharing of unflattering or inappropriate pictures online without permission. A study of 181,000 adolescents in Europe and Canada found that youth who engage in social media all day long and with diminished ability to regulate their social media impulses are at increased risk of being cyberbullying perpetrators. Girls and young women tend to spend more time on social media than boys and thus are exposed to the risk of cyberbullying and its negative impacts on mental health than their male counterparts. Youth who have been victims of cyberbullying are at risk for long-standing negative emotional impacts. In some cases, the odds of suicidal ideation, plans, and attempts are higher in youth who have experienced cyberbullying.

Poor Sleep With Excessive Social Media Use

Excessive smartphone use in youth on a regular basis is frequently associated with less sleep at night and compromised mood, school achievement, and relationships with peers and family. Poor sleep may mediate the relationship between nighttime smartphone use and subsequent depressed mood, according to a longitudinal study.

CLINICAL CONSIDERATIONS

Schools, family, and clinical settings are all potential arenas for the detection of adolescents with problematic social media use, as well as for providing guidance and initiating interventions aimed at monitoring and reducing it.

Parent and caregiver media literacy can help families monitor social media and set helpful goals and limits for youth. Youth who are nurtured by positive parental influence and a supportive school environment are more likely to be open to limits placed on their social media usage and recognize its challenges.

Encouragingly, youth are increasingly recognizing the negative impact of social media on their lives and starting to take steps to mitigate this. According to a recent poll, 54% of teens felt they spend too much time on their cell phones, and about half reported cutting back on the time they spend on them.

A Clinical Tool for Clinicians to Explore Social Media Use in Youth

Clinicians may benefit from a structured instrument to explore the positive and negative aspects of a youth's social media use. One targeted tool: **Social Media Initial Questionnaire-revised (SMIQ-r)**, created and revised by the authors, is a self-report questionnaire that can be offered to youth at clinic visits or electronically by using an online link. See Figure 54.15–1.

Social Media Use in Psychiatric Clinic Youth Before and During the COVID-19 Pandemic

When the authors initially offered the SMIQ-r to clinically assess social media use in a Los Angeles County, California, youth psychiatric clinic outpatient population in 2019, youth reported the following:

- More than half reported that social media interferes with homework
- More than half reported that social media interferes with sleep
- More than one-third reported that social media interferes with school
- Most reported that social media interferes with overall functioning

The COVID-19 pandemic has accelerated the consideration of utilizing digital and social media platforms in mental health evaluation and

treatment in the recent period. During the COVID-19 pandemic, clinics, schools, and social activities were forced to discontinue in-person interactions leading to gaps in usual social connectedness, education, and treatment for youth, caregivers, and clinicians. Although most youth and adults expressed concern, in some ways, digital and remote platforms increased the ease of connectedness with those who are far away and not able to be reached in person.

During COVID-19, the following addendum questions were added to the SMIQ-r:

- Since school went online, when do you begin your online school? Earlier, later, about the same time.
- Since school went online, when do you go to sleep? Earlier, later, about the same time.
- Since school went online, when do you wake up? Earlier, later, about the same time.
- Since school went online, how many hours do you sleep at night? Less, more, about the same.
- Since school went online, how hard is your schoolwork? Easier, harder, about the same.
- In what ways is schoolwork different than before?
- Since school went online, I am feeling: more anxiety, less anxiety, about the same amount of anxiety.
- Since school went online, I am feeling: more sad, less sad, no change in my mood
- I prefer to have appointments with my psychiatrist: online (with video or phone), or in person.
- What is the biggest change in your life since the COVID-19 pandemic? And did it make your life harder or easier?
- In what ways did the change from the coronavirus make your life harder or easier?

In comparison to before the pandemic, reassessing social media and media technology use in outpatient psychiatric clinic youth from the same clinic during the pandemic, some differences were observed. Compared to the SMIQ-r data in 2019, youth endorsed an even stronger preference for in-person friends, in-person school, and in-person psychiatrist appointments. There was a trend for increased isolation and depression in youth reports during the COVID-19 pandemic. This suggests that an

inability to see friends and/or go to school in person was associated with increased levels of anxiety symptoms and sadness in youth.

Electronic SMIQ-r Use

SMIQ-r electronic survey format that most youth filled out on their smartphones appeared to be user-friendly and more efficient than the in-person paper version and reinforces the appeal of electronic and digital formats for patient engagement and as a communication method for youth going forward (Table 54.15–1).

Johnny is an 8-year-old boy being seen in an outpatient mental health clinic for routine medication management of his ADHD. He has been asking his mother about using the family iPad to go on YouTube and "watch videos like my friends." Johnny's mother is concerned about allowing Johnny to use the iPad and social media and asks the clinician for advice. Johnny's mother is reminded of the importance of setting good boundaries with social media use, modeling good social media behaviors herself, and discussing social media safety concerns. Her questions were answered, and boundaries were discussed with Johnny as part of the conversation to encourage collaboration in creating social media family rules. Both Johnny and his mother felt comfortable with the plan for his social media use by the end of the appointment.

CONCLUSIONS

There are many benefits of social media for youth, including enhancing their connectedness and ability to communicate with other youth around the globe, enabling them to seek support for important personal stressors, and seeking education and resources on limitless topics. There are some potential associated risk factors that may arise with excessive social media use: exposure to inappropriate content for a youth's developmental age, and engaging with strangers who have harmful intent. It is critical to note that most youth continue to spend the same amount of time in person with friends while engaging in reasonable or even high levels of social media and technology use compared to youth who use little social media. Overall, with some guidance and review of the risks and benefits

of social media use and media technology, clinicians can work with youth and their families to have a safe and beneficial social media experience as an integrated part of a youth's development.

SOCIAL MEDIA INITIAL QUESTIONNAIRE (SMIQ-r)

NAME: _____ **SEX: M__F___ AGE_____ TODAY'S DATE_____**

What do you frequently use:

For all ages: Instagram ____ Facebook ____ Tik Tok____ Twitter ____ Snapchat ___ YouTube ___What's app ___Texting apps ____

For teens: Tinder ____ Dating apps ____

Other apps? _____

Where do you spend most of your time online? _____

Favorite Electronic media/app site _____

Favorite Character, celebrity or content creator_____

What do you like best about him/her _____

Other Online Activities:

- ☐ Entertainment: Netflix, Hulu, Disney +; what shows? _____
- ☐ Music: what singer/group?_____
- ☐ Sports
- ☐ Shopping: Amazon, Ebay, Craig's List, OfferUp, etc...
- ☐ Information: Newspaper, news
- ☐ Entertainment News/TMZ
- ☐ Other_____

Check the games you play (listed below):

- ☐ Shooting games (Call of Duty, Battlefield, Overwatch, Fortnite, Grand Theft Auto)
- ☐ Building/User created (Minecraft, Roblox, Mario Maker 2)
- ☐ Action/adventure/platformer (Lego Star Wars, Sonic, Super Mario, Skylanders)
- ☐ Strategy/MOBA (Starcraft, League of Legends, DOTA)
- ☐ Sports (Madden, FIFA, NBA2K, MLB2k, etc.)
- ☐ Racing (Forza, Need for Speed, Mario Kart)
- ☐ Fighting/Martial Arts (Street Fighter, Mortal Kombat, Super Smash Bros., Injustice, Tekken)
- ☐ Single-Player RPG/Fantasy (Elder Scrolls, Dragon Age, Pokémon)
- ☐ Mobile Games (Angry Birds, Clash of Clans, Pokémon Go)
- ☐ Open World/Sand Box Games (Minecraft, Terraria)
- ☐ Sci-fi/Space/Futuristic (Mass Effect, Destiny)
- ☐ MMORPG (World of Warcraft)
- ☐ Horror Games (Resident Evil, Friday the 13th)
- ☐ Puzzle (Tetris, Candy Crush)
- ☐ Other game types _____

What is your favorite game? _____

What do you like best about it? _____

Who is your favorite character? _____

What do you like best about him/her? _____

What is your favorite way to play by myself ____ w/ friends in person ___ w/ friends on line ___ w/ family ___ other____

How do you contact friends to play text message ___ message in game ___ phone call ____ other ____ I don't___

Where do you play the most my bed/room___ family room ___ Other ___

How are your skills compared to others worse____ same ___ better____

How often do you have problems w/ players never ___ Rarely___ A lot ___

Do you get into arguments online? Yes ___No__ Rarely ___ Sometimes ___ Always____

Do you have bad experiences on line? Yes___ No__ Scary videos___Mean encounter____Other____

Have you ever been cyberbullied Yes___ No__ Explain _____

Do you feel left out when you view others' posts (FOMO)? Yes___No__

Do you feel bad about yourself on Social Media/gaming ? Yes___No __

What friends are easier to make Online ___in person__

What friends do you prefer Online ___in person__

What friends are better? Online ___in person__

Are mobile devices distracting? Yes__ No__ It distracts you from what ?_____

Do you use a mobile device in bed? Yes__ No__ Before you sleep?_ __When you wake up?___

My screen time can get in the way of: Homework___School___Friends/family ___Sleep___Other___

In what way? _____

After school activities (sports, music,) etc Yes___No __ What?:_____

Community activities (YMCA, church, volunteer) Yes___No__ What?_____

Job Yes___No__ What?_____

SMIQR-r *This Questionnaire is to be used for clinical, educational or research purposes only* *FINAL 11/25/2019*

FIGURE 54.15–1. Social Media Initial Questionnaire (SMIQ-r). (Reprinted with the permission of Michael Feldmeier, MD. https://levelupmentalhealth.com/resources/.)

Table 54.15–1.
Clinician Social Media Guidance for Youth, Parents, and Families

1. **Encourage discussion of safety rules**
   - The most widely used social media sites such as Instagram, TikTok, Facebook, and YouTube, all require account holders to be 13 years or older
   - Review privacy settings on all sites and apps with children to make sure they're keeping photos and personal information private
   - Utilize parental controls that limit access to inappropriate content
   - Do not give out personal information online
   - Tell a parent or other trusted adult if they or their friends are being bullied or disrespected online
   - For younger teens, do not befriend, chat with someone without a parent's permission
   - Parents may friend or follow their child's social media accounts with an agreement between the parent and child
2. **Discuss known risks of social media use in an open, nonjudgmental way**
3. **Encourage caregivers to proactively set boundaries for social media in youth**
   - Limit the amount of time that children and adolescents spend on social media so that it does not interfere with functioning
   - Do not use any electronic devices 1–2 hours before bed, and do not have any smartphones in the bedroom overnight
4. **Remind caregivers that children model social media use on caregiver behavior**
   - Caregivers who follow similar rules with their social media and smartphone use as they expect out of their children will model appropriate use

RESOURCES FOR FAMILIES

54.16 Gay, Bisexual, Transgender, Queer/Questioning, Intersex, and Asexual (LGBTQIA) Youth

Natalia Ramos, M.D., M.P.H., Serena Chang, M.D., B.A., and Mikiko Thelwell, M.D., M.P.H.

Today's youth are increasingly comfortable with gender and sexuality in the context of greater societal awareness and acceptance of diverse gender identities and sexual orientations. Relatedly, there has been a notable increase in child and adolescent patients seeking gender- and sexuality-related care and support. In order to provide effective evidence-based care to their gender-diverse and sexual minority patients, psychiatrists can increase their knowledge and comfort with key terminology and concepts and learn to implement trauma-informed LGBTQIA-affirming care models, as discussed in this chapter.

In this chapter, we utilize the term *LGBTQIA*, which stands for Lesbian, Gay, Bisexual, Transgender, Queer/Questioning, Intersex, and Asexual, to refer to gender and sexual minority patients except where data refer to specific subgroups therein. Some of these specific terms represent gender identities, while some represent sexual orientations. It is also worth emphasizing that different LGBTQIA patients use different terms to describe themselves and their identities, and the acronym used by the authors encapsulates a limited number of identities. For example, many youths identify with nonbinary, genderfluid, and/or genderqueer identities. A best practice for the clinician is always to ask the youth what term(s) best describe them and what terms they would like the clinician to use.

SEXUAL ORIENTATION

Many Western cultures take a heteronormative approach to socialization—in other words, many youth are taught that heterosexuality is one's expected sexuality. Parental expectations and assignations of gender begin even prior to conception and birth and can shape parenting. Hence, LGBTQIA youth often identify a sense of not belonging, a challenge to personal development during adolescence, when norms and fitting in seem to be the social task at hand. As a result, numerous large national studies have found notable mental health disparities between LGB youth and their heterosexual peers, including increased rates of depression, anxiety, suicidality, and substance use (Kann et al., 2016). It has also been noted that family support and acceptance are strong mitigating factors in reducing these risks for LGB youth.

Table 54.16–1.
Sexual Orientation Terminology

Heterosexual (“Straight”)	Attracted to the “opposite” sex/gender
Lesbian	Female-identified attracted to female-identified
Gay	Male-identified attracted to male-identified
Bisexual	Attracted to “both” sexes/genders
Pansexual	Attracted to all sexes/genders
Queer	Denotes identities outside of traditional cisgender heteronormativity. Historically used as a derogatory term but also feels supportive to some.
Allosexual	Having the capacity to be attracted to others in a sexual way
Asexual (“ace”)	Not attracted to anyone in a sexual way
Aromantic (“aro”)	Not attracted to anyone in an emotional/romantic way

An individual’s sexual orientation describes to whom they are physically, romantically, or emotionally attracted (see Table 54.16–1). Sexual orientation is independent of one’s sex or one’s gender. Sexual orientation has three main components:

1. Identity: how one sees themself
2. Attraction: to what gender(s) is one attracted emotionally, romantically, or physically
3. Behavior: in what acts does one engage and with whom

The Diagnostic and Statistical Manual of Mental Disorders (DSM) has a long history of pathologizing LGBTQIA identities, leading to a mistrust of the field of psychiatry and an avoidance of care. Homosexuality was first included in *the Diagnostic and Statistical Manual of Mental Disorders (DSM), First Edition (DSM-I)* (1952) and the original DSM-II (1968) as a “sociopathic personality disturbance.” It was later recategorized as a “sexual orientation disturbance” (as opposed to a mental disorder) in a

1974 edition after years of protests. The diagnosis was changed again to "ego-dystonic homosexuality" in the DSM-III (1980) before being revised yet again to remove the word homosexuality (substituted with "sexual disorder not otherwise specified") in the DSM-III-R (1987).

SEX AND GENDER

Although often conflated with each other, sex and gender are distinct concepts. An individual's *sex* is typically *assigned at birth* based on visualized genitalia and, less often, on other physical characteristics and chromosomes. *Sex assigned at birth* is typically described as female, male, or intersex. Of note, intersex is an umbrella term that describes differences in sexual development (DSD), or a range of traits and conditions in which individuals have naturally occurring variations in chromosomes, gonads, or genitals. Differences in sex development are discussed in greater detail later in this chapter.

An individual's *gender* refers to both one's internal identity and the expression of their gender within their social context (see Table 54.16–2).

Nonbinary Identities

Among Western cultures, much of the population is raised using the gender binary as the social norm. Thus, the concept of gender existing on a continuum or a spectrum can be surprising. In fact, many cultures and societies embrace diverse gender identities outside of Western colonization. In the modern day, many children and adolescents embrace nonbinary identities. In other words, many youths express gender identities that fall outside of the typical "masculine" or "feminine" descriptors. In the United States, several states legally recognize nonbinary identities.

Table 54.16–2.
Gender Terminology

Gender binary	The division of gender into two separate and "opposite" categories (i.e., male and female)
Gender identity	How one thinks about their own gender (i.e., masculine, feminine, both, neither)
Gender expression	The way one dresses, behaves, and "expresses" oneself
Gender roles	The norms that one's culture creates around male and female identities
Cisgender	One's gender identity coincides with the sex assigned at birth
Transgender	One's gender identity differs from their sex assigned at birth. Umbrella term that can encompass other descriptors such as agender, bigender, gender expansive, gender diverse, gender nonbinary, genderqueer, and genderfluid.
Nonbinary	Describes one's identity as neither fully male nor female.
Transition	The process of changing one's gender expression to match one's gender identity.

Gender Dysphoria

Similar to its approach to pathologizing homosexuality, the DSM's approach to transgender identities has been stigmatizing and mar ginalizing to many. The DSM-III (1980) listed "transsexualism" for the first time. This term was replaced by "gender identity disorder," categorized under Sexual Dysfunctions and Paraphilic Disorders, in the DSM-IV (1994). In the DSM-5 (2013), "gender identity disorder" was replaced by "gender dysphoria" (APA, 2023).

The Diagnostic and Statistical Manual of Mental Disorders, fifth edition, text revision (DSM-5-TR) (2022) defines gender dysphoria in children as "a marked incongruence between one's experienced/expressed gender and assigned gender, lasting at least 6 months, as manifested by at least six of the following [criteria]" (see Table 54.16–3). The first criterion, "a

strong desire to be of the other gender or an insistence that one is the other gender," is required for the diagnosis. Note that the criteria for gender dysphoria in adults and adolescents varies slightly. Similar to the diagnosis in adolescents and adults, "the condition is associated with clinically significant distress or impairment in social, school, or other important areas of functioning."

Treatment for gender dysphoria consists of gender-affirming care, which may include therapy or psychiatric treatment for gender-linked distress and co-occurring conditions. Youth and adults with gender dysphoria experience higher rates of co-occurring anxiety, depression, suicidality, trauma, and substance use disorders. Research has not shown correlations between gender dysphoria and rates of schizophrenia or bipolar disorder diagnoses. Recent research also points to a strong correlation between autism spectrum disorder (ASD) incidence among gender dysphoric youth.

Gender Transitions

Gender diversity in children and adolescents has become highly politicized in the United States. Anti-LGBTQIA legislation and lawsuits have focused particularly on bathroom access, youth sports team participation, and access to gender-affirming health care. However, studies show that transgender youth who are supported in their identities experience lower rates of negative mental health outcomes than those who are not. In the TransYouth Study, investigators found that prepubescent youth who socially transitioned—meaning they lived as their experienced gender, with parental support—demonstrated the same rates of depression as matched cisgender peers. Accordingly, many mainstream medical organizations, including the American Psychiatric Association, the American Psychological Association, the American Academy of Child and Adolescent Psychiatry, the American College of Gynecology, and the Endocrine Society, have published statements and guidelines supporting gender-affirming care.

Table 54.16–3.
DSM-5 Criteria for Gender Dysphoria in Children

The DSM-5-TR defines gender dysphoria in children as a marked incongruence between one's experienced/expressed gender and assigned gender, lasting at least 6 months, as manifested by at least six of the following (one of which must be the first criterion):

- A strong desire to be of the other gender or an insistence that one is the other gender (or some alternative gender different from one's assigned gender)
- In boys (assigned gender), a strong preference for cross-dressing or simulating female attire; or in girls (assigned gender), a strong preference for wearing only typical masculine clothing and a strong resistance to the wearing of typical feminine clothing
- A strong preference for cross-gender roles in make-believe play or fantasy play
- A strong preference for the toys, games, or activities stereotypically used or engaged in by the other gender
- A strong preference for playmates of the other gender
- In boys (assigned gender), a strong rejection of typically masculine toys, games, and activities and a strong avoidance of rough-and-tumble play; or in girls (assigned gender), a strong rejection of typically feminine toys, games, and activities
- A strong dislike of one's sexual anatomy
- A strong desire for the physical sex characteristics that match one's experienced gender

Many, and not all, youth with gender dysphoria will wish to transition, which is the process of changing one's gender expression to match one's gender identity. Transitioning *may* include various social, legal, and medical changes (see Table 54.16–4).

Table 54.16–4.
Gender Transitions

Social	Changes in name and pronouns, appearance, dress, grooming (e.g., clothes, hair, make-up); nonmedical changes; may include “coming out” to family, school, peers, or others
Legal	Legal name or gender marker change, resulting in the reissuing of government documents (e.g., birth certificate, driver’s license, passport)
Medical	Gender-affirming procedures with medical doctors; may include: puberty blockers (i.e., Gonadotropin-releasing hormone agonists, like leuprolide), hormone therapies (e.g., estradiol or testosterone), testosterone blockers (e.g., spironolactone), and gender-affirming surgical procedures such as: ▶ For transmasculine/nonbinary patients assigned female at birth: chest masculinization (bilateral mastectomy with chest reconstruction), hysterectomy, phalloplasty, metoidioplasty ▶ For transfeminine/nonbinary patients assigned male at birth: breast augmentation, orchiectomy, vaginoplasty, electrolysis, tracheal shave, facial feminization surgery

There is no single protocol for a gender transition; every gender-diverse individual has unique needs and goals. For example, some people opt solely for social or legal transition. Others may wish to engage in any number of medical transition options with their doctors. Of note, many gender-diverse individuals face legal, social, and financial barriers that prevent access to medical-affirming care. Furthermore, the above medical procedures have developmental prerequisites and may not be readily accessible to minors. The Standards of Care for the Health of Transgender and Gender Diverse People, Version 8 (SOC8) published by the World Professional Association for Transgender Health (WPATH) provides specific guidance around medical transitions and the treatment of gender dysphoria (see https://www.wpath.org/publications/soc for details).

Mental health clinicians have historically been pushed into a "gatekeeper" role in the medical transition process, as standards of care often require patients to pursue psychological evaluation and obtain surgical readiness evaluation letters from psychiatrists or therapists. Insurance carriers or surgeons mandate these evaluations in some cases. This process can create a complicated relationship between mental health clinicians and their gender diverse patients. For example, patients may feel pressure to deny mental health symptoms or pursue care to be accepted or "approved" for gender-affirming medical care. Like many individuals who experience social stressors, gender-diverse individuals may benefit from therapeutic or psychiatric treatment. The best clinical practices allow the clinician to support the youth and family before, during, and after the transition process. Clinicians can help youth target mental health symptoms, manage stressors, seek support, and better understand their goals while providing developmental guidance and skills to caregivers to improve youth well-being.

Differences of Sex Development (DSD) and Intersex Youth

While the literature on the specific mental health needs of intersex youth remains limited, the first national survey of intersex adults in the United States revealed a high prevalence of lifetime anxiety disorders, post-traumatic stress disorder (PTSD), and depressive disorders. Intersex youth face unique stressors and related mental health symptoms across developmental stages due to the medicalization and pathologization of their bodies from a young age. Some intersex traits present clearly at birth, such as those involving external genitalia, while others manifest during puberty.

Intersex youth experience intense stressors with lifelong consequences, including medically unnecessary surgeries, a lack of support around gender identity development, and the loss of autonomy and agency. Parents, meanwhile, may contend with a sense of urgency around sex assignment, including pressure to consent to genital surgeries without understanding the potential long-term effects on their child and regret about irreversible decisions. Often the justification for an early surgical procedure is to improve long-term mental health by helping the child live a "normal" life—a justification made without evidence and typically by clinicians who do not specialize in mental health. Additionally, early medical interventions reinforce sociocultural norms around male and

female gender stereotypes, often before the development of the youth's own gender identity.

Overall, there is a great need for increased mental health research, programs, and developmentally appropriate guidelines in caring for youth with DSDs. Mental health professionals can support youth and families in gender identity exploration, navigating challenging health care decisions, and recovery from traumatic stress. Additionally, new parents may experience intense and conflicting emotions in deciding on their child's health care plans. Child and adolescent clinicians can also advocate using psychologically sound evidence to determine care for intersex youth at all developmental stages and seek inclusion in pediatric teams who manage DSDs. Finally, they can assist youth and families in identifying community resources and supports that promote mental well-being.

YOUTH TRAUMA AND RESILIENCE

LGBTQIA youth are more likely than cisgender heterosexual youth to experience traumatic stress due to discrimination, harassment, marginalization, and victimization across social systems, including family, school, and health care settings. Examples of common social stressors include family rejection and neglect, harsh discipline and bullying in schools, and anti-LGBTQIA legislation. Youth who experience multiple forms of psychosocial stress are especially susceptible to trauma sequelae across their lifespan. The stage of development during which the stressors occur may also influence their long-term impact. Youth with chronic or pervasive social stressors, particularly unsupportive, rejecting, or dangerous home environments, are at a higher risk for unhealthy behaviors. Consequently, they experience higher rates of the leading causes of morbidity and mortality in adulthood, including ischemic heart disease, cancer, lung disease, and liver disease, than peers without adverse childhood experiences.

Mental Health Inequities Among LGBTQIA Youth

Despite an increase in the number of youths identifying as LGBTQIA, data continue to demonstrate clear inequities in mental health outcomes among LGBTQIA youth compared to their cisgender heterosexual peers. LGBTQIA youth report disproportionate rates of depression, anxiety, suicidal ideation, and suicide attempts. Nearly two-thirds of LGBTQIA

youth report symptoms of generalized anxiety disorder, and more than half report symptoms of major depressive disorder. For many LGBTQIA youth, mental health challenges emerge earlier in the life course and persist over time.

Clinicians can understand these disproportionate mental health outcomes by examining the interlocking systems of marginalization and discrimination that compound to produce a variety of unique mental health challenges for LGBTQIA youth living in cis-sexist heterosexist social environments. Intersectional and minority stress approaches, which have strong empirical support in LGBTQIA health disparities research, explain how structural inequities like a lack of access to stable housing and interpersonal anti-LGBTQIA discrimination lead to increased rates of mental health symptoms among LGBTQIA youth. In addition to the negative outcomes stemming from the external stressors themselves, experiences of anti-LGBTQIA stereotypes and messaging influence internalized psychological processes, such as the perception of the external world as threatening, concealment of identity, and poor self-image. Clinically, providers may observe symptoms related to anxiety, depression, and somatization, in addition to more externalizing symptoms like impulsivity and substance use.

CLINICAL APPROACHES FOR LGBTQIA YOUTH AND THEIR FAMILIES

Intersectional Care for LGBTQIA Youth

In order to provide effective care, clinicians must thoughtfully explore and assess each youth's unique experiences of stigmatization and support, as LGBTQIA youth do not share a universal experience by any means. For example, asexual adolescents report significantly higher rates of internalized LGBTQIA-phobia than adolescents with other sexual minority identities while experiencing less interpersonal prejudice and engaging in fewer risky behaviors. Notably, LGBTQIA youth of color experience profound inequities across school, juvenile justice, and social welfare settings due to compounding marginalization based on both race/ethnicity *and* gender identity or sexual orientation. Gender-diverse youth of color report more school victimization based on gender identity *and* race/ethnicity than cisgender peers of color, while multiracial Black

LGBTQIA students experience more victimization than LGBTQIA students who identify only as Black.

Clinicians must thoughtfully examine connections between observed symptoms and identity-linked social stressors. Like cisgender heterosexual youth, LGBTQIA youth experience an array of mental health challenges, which can be additionally compounded by their experiences of marginalization and social rejection. Existing evidence-based treatments can be tailored to a youth's unique stressors and strengths. For example, cognitive behavioral therapies (CBT) can address LGBTQIA identity-related stressors and promote adaptive coping strategies. Modified CBT has been shown to reduce depression symptoms, alcohol use, and human immunodeficiency virus (HIV) risk behaviors among gay and bisexual young men. Trauma-focused cognitive-behavioral therapy (TF-CBT) has been formally adapted to LGBTQIA youth and their families. Additional interventions, such as the Family Acceptance Project, target caregivers' accepting and rejecting behaviors and family caregiver–child communication to improve outcomes among LGBTQIA youth and can be adapted to diverse families.

Addressing Risk Factors and Building Resilience

In addition to experiencing more social stressors, LGBTQIA youth are also less likely than cisgender heterosexual peers to have access to key protective factors that mitigate traumatic stress, including family support, stable housing, and social support networks. In working with LGBTQIA youth, clinicians can focus on family, school, and community support that strongly impact the psychosocial well-being of LGBTQIA youth.

Family support is a key factor in the mental well-being of LGBTQIA youth, while family rejecting behaviors detrimentally impact youth mental health. Accepting and supportive parental behaviors related to gender identity and sexual orientation reduces the risk of depression and risk behaviors among LGBTQIA youth, buffering the effects of identity-related stressors. Among prepubescent transgender youth, those who socially transition with parental support demonstrate rates of depression and anxiety comparable to cisgender peers. In working with families, the best practice is to align with caregivers around the shared goal of supporting their child's wellbeing rather than challenging deeply held beliefs.

Experiences of acceptance and support in the school setting also greatly impact LGBTQIA youths' mental health, as do bullying and

discrimination. School connectedness and school safety are associated with better mental health and decreased risk behaviors. Unfortunately, the vast majority of LGBTQIA youth experience verbal harassment and discrimination in school settings. Clinicians can help youth recover from traumatic stress, manage co-occurring conditions, build coping strategies, and locate safe spaces and supports. Caregivers can also advocate in the school setting for inclusion policies and support for their youth and help youth connect to affirming activities in their community.

Table 54.16–5.
Key Trauma-Informed LGBTQIA-Affirming Practices in Clinical Settings

- Collect accurate data on sexual orientation and gender identity, including names and pronouns used
- Use the youth's name and pronouns consistently
- Screen for trauma symptoms and experiences of abuse, discrimination, marginalization, and bullying
- Utilize open-ended questions to discuss sexual orientation and gender identity/expression
- Ensure confidentiality and privacy pertaining to identity
- Engage the youth in collaborative decision-making when feasible
- Avoid gender stereotypes and comments based on appearance
- Make the clinical care space more supportive (e.g., access to gender-inclusive bathrooms, open-ended intake forms)
- Refer to Standards of Care and Continuing Education to stay up-to-date with LGBTQIA care practices

Trauma-Informed Affirming Care for LGBTQIA Youth

By implementing trauma-informed affirming care, clinicians can play key roles in recognizing and targeting psychological symptoms that stem from social stressors and marginalization experienced by LGBTQIA youth. Research consistently shows that social support and positive coping strategies can mitigate stress experienced by LGBTQIA youth. Clinicians who practice from a trauma-informed perspective recognize and support the youth's strengths and contextualize symptoms and challenges stemming from lived experiences. Additionally, in practicing affirming care, clinicians fundamentally presume that gender and sexual orientation: (1)

exist on a natural spectrum where no gender identity or expression or sexual orientation is pathologic; (2) can be fixed or fluid and, in regards to gender, binary (male/female) or nonbinary; and (3) may evolve or change over the life course for some individuals. LGBTQIA-affirming care also recognizes that gender and sexual orientation vary across cultures and throughout history. Clinicians can follow specific practices to deliver trauma-informed affirming care to LGBTQIA youth (Table 54.16–5).

ACKNOWLEDGMENT

The authors would like to acknowledge Dr. Suegee Tamar-Mattis, DO, for graciously offering to consult and review our content related to caring for intersex youth and youth with DSD.

54.17 Racism and Discrimination's Impact on the Health and Well-Being of Developing Children and Adolescents

Wanjikũ F.M. Njoroge, M.D., Ewurama Sackey, M.D., Nana Asabere, M.D., and Eraka Bath, M.D.

Researchers have always been interested in understanding the way the social construction of race has impacted health. While several well-known and foundational researchers were investigating the impact of "race" on

the health and well-being of children, adolescents, and adults, it was not until 2002 that the Institute of Medicine (IOM)'s Committee on Understanding and Eliminating Racial and Ethnic Disparities in Health Care produced a seminal document titled "Unequal Treatment: Confronting Racial and Ethnic Disparities in Health Care." This report definitively highlighted the decades-long impact that unequal health care access and treatment had on the health, lives, and well-being of generations of people of color (BIPoC) in the United States. Specifically, the report highlighted the ways in which communities of color have been historically marginalized by health care providers and the health care system or, worse, brutalized with experimentation (e.g., Sims on Black women of reproductive age, the Tuskegee experiment on Black men, women, and children in Alabama, forced sterilization of Native American and Black women, and even more recently immigrant women in 2020). The IOM's 2002 nuanced report not only outlined the harm done to communities of color but also gave specific recommendations on how to mitigate the injustices that had occurred in and by the health care system and practitioners. However, in spite of the cogent and clearly outlined recommendations, these systems, structures, and institutions continue to operate as created, with the resultant disparate health care outcomes still evident in every aspect of medicine, including psychiatry.

Around the same period, Dr. Camara Jones, former president of the American Public Health Association (APHA), launched a National Campaign Against Racism, one of the largest professional organizations to do so. While at the Center for Disease Control and Prevention (CDC), she led the development and integration of a standardized assessment tool on racism within the Behavioral Risk Factor Surveillance System. Almost two decades later, during the midst of the global COVID-19 pandemic and after the murder of George Floyd launched uprisings around the world for racial justice, the CDC officially recognized the ongoing impact that racism has had on the health of historically marginalized BIPoC in the United States in that race and ethnicity *still* remain significant predictors of access, quality, and type of care that patients receive. Secondary to these pervasive health inequities, in the spring of 2021, the CDC director declared in the midst of the global COVID-19 pandemic, "Instead, the pandemic illuminated inequities that have existed for generations and revealed for all of America a known, but often unaddressed, epidemic impacting public health: racism. What we

know is this: racism is a serious public health threat that directly affects the well-being of millions of Americans. As a result, it affects the health of our entire nation. Racism is not just the discrimination against one group based on the color of their skin or their race or ethnicity, but the structural barriers that impact racial and ethnic groups differently to influence where a person lives, where they work, where their children play, and where they worship and gather in community. These social determinants of health have life-long negative effects on the mental and physical health of individuals in communities of color."

DEFINING TERMINOLOGY

As we begin this discussion, it is important to understand the historical significance of the classification of peoples into "races." While this particular terminology has been used in medicine specifically to categorize the risk of disease, surveillance methods, prognostic predictions, and even specific treatment modalities, questions have long existed about the scientific validity of this type of framing. It is important to recognize the myth of race(s) and recognize it as a social construct developed to justify and explain structural and interpersonal/personally mediated racism that has no scientific merit. Carl Linnaeus's 1735 taxonomy of humans created the underpinnings of scientific racism that persist to this day, reflecting Eurocentric classifications of groups by the myth of "race." Because of the longstanding use of "race" as a proxy to attribute differences in health and well-being, health disparities have long been framed using race as the construct rather than racism. "Race" has been confounded with social determinants, such that phenotypic appearance has been designated as a key factor in illness and health rather than understanding how the context in which people live, work, and play influences their experiences and their health and well-being, which are in fact not determined by "biologic race" but rather secondary to structural systems and barriers put into place by the social construct of race. But more simply, these systems and structures have determined access and quality of care and, ultimately, the health of people rather than personal choices and decisions.

This chapter specifically interrogates the ways in which race, ethnicity, racism, and discrimination have impacted children and adolescents' developmental trajectories, behavioral health, and well-being. We highlight ways to prevent and disrupt the various forms of racism and

discrimination embedded in the health care system, other systems in which children find themselves, as well as the practice of medicine, specifically child and adolescent psychiatry, thus ensuring all children and adolescents receive equitable psychiatric assessment, treatment, and care. However, any thorough discussion of race, ethnicity, racism, and discrimination must first begin with diagnosing the problem and this requires critical examination of the language and nomenclature that have been historically used to buttress and support different ideologies and beliefs. Thus, to ensure shared understanding throughout the chapter a definition of terms that are frequently used when discussing health equity will first be discussed. Throughout the chapter, Black has been used to describe African American/African peoples from the African diaspora, Latinx has been used to describe Latino/Latina/Latine/Hispanic peoples, Asian American and Pacific Islander (AAPI) has been used to describe Asian American/Asian/Native Hawai'ian/Pacific Islanders, and Native American has been used to describe Indigenous, First Nations, Alaskan Natives, Native tribes—federally recognized, and not.

An important undergird of the American health system, and thus the practice of psychiatry in the United States is the existence of systemic, structural, or institutional racism. All of these terms have been used to explain the systems, structures, and institutions that were put into place during and after slavery, particularly during the Jim Crow era to ensure an inequitable and unjust system in the United States. With respect to psychiatry, this has resulted in not only disparate treatment for Black, Indigenous, and BIPoC, but also defined the ways in which we diagnose psychiatric illnesses which cascades to potentiate inequitable treatment and care. An understanding of the multiple forms of racism is important in being able to both dismantle and correctly diagnose the problems. To that end, it is helpful to understand that most theorists divide racism into multiple buckets including larger systems or structures down to the more nuanced and personalized forms of racism that we see operating between and within individuals (see Table 54.17–1). Understanding these differing forms of racism as operating at all times is also important when understanding the ways in which racism impacts the physical and mental health of individuals, particularly children and youth. When discussing systemic or structural racism, the link to the deliberate construction of neighborhoods, schools, and other foundational systems is incredibly important in understanding how these systems continue to function and

negatively impact the lives of BIPoC Americans. While the government purposefully constructed these inequitable systems, they have been maintained and reinforced via other actors. The result has impacted the health of generations of children and families of color.

Table 54.17–1.
Levels of Racism

Levels of Racism	Structural/Institutional Racism	Interpersonal/Personally Mediated Racism	Internalized Racism	Impact
Definition	▸ Systematic and historic racial inequities that are embedded into interconnected social, political, cultural, and economic systems such as health care, education, housing, economic, imprisonment ▸ Historically has privileged whiteness and disadvantaged people of color	Face-to-face or covert actions expressing racial prejudice, hate, or bias. These acts can be intentional, unintentional, and include acts of omission and commission	Acceptance by members of the stigmatized races of negative messages and stereotypes affecting self-esteem and self-worth	Psychiatric development morbidity and mortality

In 2019, the American Academy of Pediatrics (AAP) published a policy statement which at the time was revolutionary simply stating, “Racism has a profound impact on the health status of children, adolescents, emerging adults, and their families.” In this chapter, we will focus not only on systemic, structural, and institutional forms of racism and the impacts on Black, Indigenous, and children of color, but we will also highlight how other forms of racism including interpersonal/personally mediated and internalized forms of racism continue to have deleterious impacts on developing children and adolescents. Understanding the multiplicative ways in which developing children differ in their cognitive, regulatory, and emotional developmental trajectories, the impacts of racism on children will be presented along specific developmental ages and stages: early childhood, preschool age, school age, adolescence, and transitional age youth. This chapter will nest the experiences of these developing children and adolescents within the larger supports and systems in which they live and grow including their parents and primary caregivers, schools and childcare facilities, neighborhoods, and communities (see Fig. 54.17–1). Finally, this chapter will speak to the role of the child and adolescent psychiatrist as well as future research, policy, and clinical directions, highlighting culturally appropriate prevention and intervention models to ensure equitable care for all children and youth with behavioral health challenges.

CONTEXTUALIZING RACE-BASED TRAUMATIC STRESS AS AN ADVERSE CHILDHOOD EXPERIENCE

Racial Stress and Trauma

In 2009, the American Psychiatric Association (APA) Presidential Task Force on Traumatic Stress Disorder and Trauma in Children and Adolescents first recognized discrimination as a contributing factor to stress in the lives of youth of color. *Racial Trauma* is defined as "dangerous or frightening race-based events, stressors, or discrimination." Most of the time racial trauma is not a major, isolated episode but results from an accumulation of sometimes daily, covert acts of racial discrimination. Children and adolescents may experience direct racial trauma through structural inequities (neighborhood environments, lower quality schools, health care, family resources, and the like) or via interpersonal/personally mediated racist experiences. Racism and discrimination have been long considered not only a social determinant of health but also increasingly considered as an adverse childhood experience (ACE) initially described by Felliti and colleagues identifying certain experiences that occurred in childhood as having direct impact on adult health. Following this seminal work, the impact of racism and discrimination is being acknowledged on health surveys designed to identify ACEs; an example would be the National Survey for Children's Health [NSCH], Philadelphia ACE Survey. For example, due to racism in the adult carceral system, a significant proportion of Black and Latinx youth have parents who are incarcerated. Youth with incarcerated parents are at increased risk of poverty, criminal activity, drug use, and emotional distress.

In addition, youth of color are also vulnerable to direct, indirect, or vicarious racialized trauma such as personally experiencing police harassment or witnessing police killings of unarmed Black or Latinx citizens. Resulting symptoms of racial stress and trauma include anxiety, depression, hopelessness, and cognitive distortions about self-esteem and safety. Racial trauma has a detrimental effect on the physiologic, emotional, social, and psychological development of BIPoC children and adolescents. Ongoing racial discrimination and incidents of racial trauma can lead to a range of behavioral health disorders, including post-

traumatic symptoms such as hypervigilance and avoidance, and can lead to the development of a post-traumatic stress disorder (PTSD) diagnosis, as well as generalized anxiety disorder (GAD), and/or major depressive disorder (MDD) diagnoses.

EMERGING RESEARCH/NEUROBIOLOGY/NEUROPLASTICITY

The health and development of children and adolescents is shaped by a dynamic process of adaptation (at the molecular, cellular, organ system, and behavioral levels) that begins at conception and extends throughout the life course. Importantly, the underlying plasticity that influences that adaptive capacity (known to decrease with age) can lead to a wide range of outcomes that are influenced by the interactions among individual genetic predispositions and the environments in which pre- and postnatal

development unfolds. Crucially, as children's brains develop, the cortical lining thins. Cortical thinning occurs in a typical pattern that begins in primary sensory cortices, then extends to the motor cortices, and finally ends in the association cortices occurring late in adolescence or in early adulthood/transitional age youth. Importantly, cortical thinning reflects myelination, and myelination reduces plasticity, thus early cortical thinning may shorten windows of developmental plasticity. Cortical thinning has also been linked to synaptic pruning, which has the potential to limit the plasticity at later developmental windows. Recent examination of cortical changes throughout development has shown that in adolescence, there are cortical thickness differences between individuals from lower and higher socioeconomic backgrounds across much of the brain. When further articulating when these changes first begin, data has shown that in early childhood (ages 4 to 7), the cortex is thinner (reflecting that of an older child) in individuals from lower socioeconomic backgrounds, suggesting that cortical thickness differences may be influenced by a variety of environmental circumstances, and likewise may also be preventable with appropriate evidence-based interventions. The theory that stress accelerates aging is well established, and the theory that early life stress accelerates maturation has been gaining ground.

STRESS, CORTISOL LEVELS, HYPOTHALAMIC–PITUITARY–ADRENAL AXIS

Racial discrimination and the chronic stress associated with racism and poverty have direct effects at the microcellular level and can lead to physiologic dysfunction. Racism increasing cortisol levels reflects the phenomenon of stress neurobiology. With increased stressors, there is a related increase in sustained release of stress hormones, which is critically important not only for all adults but also for pregnant women and their developing fetuses. We now know that not only does early exposure to maternal responses to stress shape the developing fetuses' later stress responsivity, but also early postnatal exposure can have similar adverse effects. We are increasingly learning more about the mechanisms involved leading to these alterations such that now agreement exists as highlighted in a technical report issued by the AAP to increase the depth of surveillance. Unceasing stress hormones directly impact cortical structures with neuronal shrinkage of specific areas including the

amygdala, hippocampus, and prefrontal cortex. Reductions in these areas can lead to specific behavioral challenges including emotional and behavioral dysregulation, as well as later executive function deficits. With greater elucidation of the science around early neurodevelopment, much is now known about the ways in which these unrelenting, pervasive amounts of stress impact these early developing systems with resultant increasing levels of earlier detection of mental health and behavioral challenges leading to increasingly complicated psychiatric presentations later in childhood.

In the past 20 years, this level of sustained exposure to specific stress hormones (cortisol, corticotropin-releasing hormone [CRH], adrenaline, norepinephrine) has often been labeled “toxic stress” secondary to the harm it produces on children’s developmental trajectories. This intimate intertwining of systemic racist environments impacting developing brains speaks to the need to not only understand the mechanisms of action involved, but also to better understand ways to mitigate these interactions in order to prevent, intervene, or buttress children of color who are disproportionately bearing the brunt of these disparate endemic conditions. All of this evidence speaks to the importance and understanding that early experiences matter greatly, as these very early experiences can alter neuronal development leading to lifelong consequences. With growing evidence of the impact that early, repeated, and pervasive stress leads to later physiologic and psychological changes, understanding racism as an important early adversity that can be mitigated is critical.

IMPACT OF RACISM AND DISCRIMINATION ON DEVELOPMENT

The health and development of young children are shaped by a process of ongoing, interactive adaptation from the cellular through to cortical systems beginning at conception and extending throughout the life course. The underlying plasticity that influences adaptive capacity (which decreases with age) can lead to a wide range of positive or negative outcomes influenced by the inextricable interactions among individual genetic/biologic predispositions and the environments in which pre- and postnatal development unfolds. Disparities in physical and mental health impose substantial human and economic costs on societies—and the

relation between early adversity and lifelong well-being presents a rich scientific framework for fresh thinking about promoting health and preventing disease broadly, augmented by a deeper focus on how racism exacerbates inequities more specifically.

With increasing longitudinal research, we are beginning to understand the impact that racism and discrimination specifically have on child neurodevelopment at different ages. Secondary to the differing forms of racism as described earlier in the chapter, as well as the differential impacts on developmental stages, this section unpacks the ways in which these specific forms of racism and discrimination impact children and adolescents across five developmental stages: infancy and toddlerhood, preschool age, school age, adolescence, and transitional age youth.

Infant and Toddler

There is increasing evidence that environmental exposures including, but not limited to—intrauterine conditions, poverty, environmental toxicants, psychosocial stressors, maternal ACEs, racism, and traumatic life events—confer significant neurodevelopmental risk prenatally. Furthermore, there is increased evidence that maternal stress–related aberrations in utero are associated with a child's later risk for neuropsychiatric disorders and stress responsivity, as discussed earlier in the chapter. When thinking about the impact of racism on early childhood, it is critically important to understand that pregnant women's experiences of racism and discrimination impact not only their health and well-being but also that of the growing fetus. Crucially, evidence suggests that early environmental influences including racism impact children's outcomes including their behavioral health. Importantly, the multiplicity of factors has a worsening impact on early childhood development.

Data reflects that very young children experience both institutional/structural racism, as well as interpersonal or personally mediated racism (indirectly) through their mothers' or primary caregiver's experiences, with evidence identifying that racism created inequities for Black and brown mothers and children even before birth. Strikingly, Black babies have been shown to have the highest incidence of ACEs—more than 1.5 times the national average of two or more. Public health researcher, Geronimus developed the analytic framework of weathering, which essentially describes the ways in which the health of Black people is harmed by early deterioration secondary to exposure to

structural/institutional racism. Her studies have demonstrated that racial discriminatory experiences lead to negative impact on telomeres. The length of telomeres, the end caps of chromosomes that shorten with cellular division, has been used as a marker of epigenetic age. Individuals who have experienced more stress have shorter telomeres. Geronimus has shown that exposure to stressors, such as racism and discrimination, can increase allostatic load, leading to faster aging or “weathering.” There is mounting evidence that disparities in the pace of aging begin early in life: children from racially and socioeconomically disadvantaged groups mature faster than their socially advantaged and non-Latinx White peers.

Preschool Age

Recent research has reflected the impact of structural racism and discrimination on early maturation noted by early molar development in preschool-aged children. There is mounting evidence that disparities in the pace of aging begin early in life with children from racially and socioeconomically disadvantaged groups, Black, and Latinx children, all maturing faster than their socially advantaged and non-Latinx White peers. Along with these early signs of early maturation as a consequence of racism and discrimination, further evidence reflects that as children age, they become increasingly aware of racism, specifically interpersonal or personally mediated racism, and even begin to struggle with internalized racism. Recent data has shown that Black and non-Latinx White children show pro-White biases by age 4, and that children have preferential play partners and this can be based on skin color or gender. But, importantly for young children, these biases are based solely on phenotypic differences or skin color NOT racist stereotypes. What becomes increasingly clear is that young children have clear in-group preferences. But, as these children aged, they focused on individual characteristics, such as shared interests, to determine in-group and out-group membership.

By age 5, Black children attribute social exclusion to their identified race. Less is known about how young children process interpersonal racism and social exclusion, or about individual differences in their sensitivity to these experiences. Kenneth and Mamie Clark discussed these issues in the 1940s with the seminal doll study showing the impact of structural racism in the form of school racial segregation and its impact on Black preschoolers in the South. Importantly, this data was so

compelling that it was used over a decade later in 1954 when Thurgood Marshall and colleagues argued the landmark desegregation case of Brown *v* Board of Education citing the research as evidence of the direct harm segregation was having on young Black children.

As described earlier in this chapter, race is a social construct and very young children initially identify differences in skin color, however as they age they learn that there is a value attached to different skin colors. Theory and research has suggested that implicit intergroup attitudes emerge early in life at levels that are comparable to that of adults.

School Age

School-aged children have a different understanding and experience of racial dynamics. Research has demonstrated that non-Latinx White children can exhibit anti-Black bias by the age of 6. Research studies have also demonstrated that non-Latinx White children are more likely to choose other non-Latinx White children as friends over Black, Latinx, Asian, and Native American children. This can cause racial bullying at school and the exclusion from academic, school-related (sports, arts, groups), and social activities. This results in racial trauma and negative associations with school, learning, and education for non–White-identifying students. Moreover, research proves that children who are the only Black children in their class or school are more likely to experience more racist incidents while having less support from teachers, administration, and their peers at school. At 7 years old, most children have developed racial permanency, the understanding that their skin color is unchangeable, and in-group bias. By 9 years old, most children have an understanding of the status that their racial and/or cultural group holds in the broader society.

Children of color are often able to notice when preferential or oppressive racial dynamics play out at school, in their community, and in society at large. School-aged children are also able to recognize that racial violence in the form of police killings of citizens, xenophobia against immigrants, and race-based attacks are based on White supremacy. Dr. Alvin Poussaint hypothesized that Black people are not able to express appropriate rage in response to the racial violence that they experience which results in repressed anger and internalized psychological self-hatred. Elementary school children of color can internalize racism and racial stereotypes, leading them to unconsciously perceive people as

having negative or positive characteristics based on race. This can further result in children of color internalizing White supremacy and believing in White superiority. Academic and social rejection in school by teachers and peers may lead students to avoid school for fear of traumatic school experiences which then affects students' academic participation and performance in school. In addition, children of color are often aware that their non-Latinx White peers are often given preferential treatment and access to additional resources. Accordingly, despite racial permanency, children of color can unconsciously desire to attain Eurocentric physical features to receive equal treatment at school and in broader society.

10 to 12 Years Old

Research has shown that Black children as young as 10 years old are routinely perceived to be older and less innocent than non-Latinx White children of the same age. This stereotyping leads to differential treatment, with Black children being labeled as aggressive, culpable, and needing to be watched and feared. In addition, in Black boys (aged 10 to 15 years), experiences with perceived interpersonal and institutional racism were related to increased internalizing symptoms such as depression and anxiety, and increased externalizing symptoms, such as anger or aggression. School-aged children of color are also able to identify that racial discrimination threatens safety and security. Direct and indirect experiences of race-based trauma can cause typical trauma symptoms such as fear, helplessness, and worry about the physical safety of children and their family members based on race. Race-based trauma can also affect caregivers' emotional availability, attachment, and ability to help children manage their psychological responses to racial stress and trauma. Racial trauma in school-aged children is associated with distractibility, problems in school, phobias, and other anxiety symptoms.

Dr. Kenneth B. Clark hypothesized that racism creates an unconscious hypervigilance in its victims. Accordingly, as school-aged children age, they are able to identify differential treatment based on race, but may not have the ability to recognize that their problems with mood, behavior, and self-image may be secondary to racism. Consequently, children tend to avoid settings in which they are made to feel "othered." A loss of safety and sense of belonging can result in decreased self-esteem and children losing a sense of hope, optimism, and belief in a future filled with endless possibilities. Research has shown that by age 12, there is increased

pressure for youth to conform to racial in-group beliefs as evidenced by the tendency to shun nonconforming in-group members.

Early Adolescence

Adolescence is a crucial developmental stage in the life cycle that encompasses numerous physical and psychosocial changes. During this phase, youth become more attuned to their social standing within peer groups and increasingly separate from their family. In addition, adolescence is characterized by an exploration of one's sense of self and personal identity. For minoritized youth, this normative process becomes exceedingly more complex when confronted with increased exposure to institutional, interpersonal, and internalized forms of racism which threaten central parts of identity and may have deleterious effects on developmental pathways and adolescent mental and physical health.

Several studies have reported higher rates of internalizing disorders among Black, Native American, and Asian American adolescents compared to non-Latinx White adolescents. In a longitudinal, school-based epidemiologic study of adolescent depression encompassing a diverse range of adolescents in grades 7 through 12, minoritized youth were more likely to report higher baseline levels of depression. Secondary analyses identified several factors that predicted a higher risk for the onset of a depressive episode, including Black/Latinx ethnicity, female gender, and low-income socioeconomic status (SES). Latinx children and adolescents reported the highest levels of depressive symptoms of all ethnic groups across three separate waves of data collection. Asian Americans reported similarly high levels, followed by Black adolescents. Non-Latinx White adolescents had the lowest depressive scores over time, whereas depression scores for all other ethnic groups converged, despite initial differences.

Black youth are disproportionately impacted by traumatic events (i.e., physical, sexual abuse, witnessing violence). One study demonstrated that 65% of Black youth report traumatic experiences compared to 30% of their peers from other races. In addition, Black youth were more likely to report adverse emotional and behavioral sequelae to trauma exposure, including poor mental health, substance abuse, decreased well-being, and risky sexual behavior. The disproportionate rates of trauma and the associated outcomes observed among African Americans were thought to be moderated by unique race-based toxic stressors.

Late Adolescence/Transition Age Youth

The transition to adulthood has become a critical window in the life course, directing some young people on trajectories of increasing advantage and solidification and others on pathways of increasing disadvantage. In a seminal study of 422 patients independently observed over 5 years in a psychiatric emergency room (ER), it was found that after adjusting for psychotic disorders, the severity of disturbance, dangerousness, psychiatric history, use of restraints, time spent in ER, and other factors, compared to other patients, Black patients received, on average, more antipsychotic doses. In addition, data reflected that clinicians spent less time evaluating Black patients than non-Latinx White patients.

RACISM IN SYSTEMS OF CARE

Children and adolescents spend the majority of their time interfacing with different systems of care including schools, early intervention (EI) programming, child welfare, juvenile justice, and services for those with developmental disorders. However, data reflects that these systems, much like other systems in which children spend their time, may also be impacted by structural/institutional racism and/or interpersonal/personally mediated racism and discrimination. This section explores challenges that BIPoC children and their caregivers may face vis-a-vis experiences of racism and discrimination both within and outside of these systems which reflect long-standing, structurally, and racialized inequities that may adversely impact their developmental trajectories. Furthermore, when thinking of barriers or access to care, institutional/structural racism again plays a role in that the creation of redlining or residential segregation in the 1930s in over 200 cities across the United States has left neighborhoods in the 21st century bereft of certain services and infrastructure, thus placing patients farther away from quality care, as well as barriers around the costs of affordable care.

We posit that antiracist, culturally and trauma-informed approaches that focus on systemic inequities can create more equitable frameworks benefitting the children and adolescents they serve.

Racism in Early Care and Early Intervention

A greater understanding of the mechanisms of early stressors, including racism and discrimination on neurodevelopmental pathways, and how these stressors cause impairment of these critically developing systems has led to more work substantiating the importance and efficacy of early care and EI programming. The EI system was created to ensure that high-quality preventive and EI programming is accessible to very young children in order to prevent adverse outcomes. Several EI programs have shown efficacy in longitudinal assessments of a variety of various health, behavior, development, and educational outcomes. For children participating in high-quality EI programs (e.g., Perry Preschool Program, Carolina Abecedarian Project ([BC], Early Headstart, and the like) in the first 5 years of life, the impact of these programs is notable.

As more is known about the criticality of the first 5 years of life and neurodevelopment, understanding the benefits and challenges inherent in early childhood intervention, and prevention systems are incredibly important. Evidence shows that implicit racial bias and exclusionary discipline against children begin as early as preschool. Dr. Walter Gilliam's work in preschools highlights how teachers' biases and stigmatized beliefs directly impact young children's (particularly young Black boys with an expulsion rate of 3.6 times more than their non-Latinx White age-matched peers) ability to remain in early educational programming. Understanding how to buttress healthy caregiving to ensure that even when children are living in inequitable systems, institutional and federally funded supports exist to level the playing field.

Racism in Educational System

Children of color experience structural/institutional and interpersonal/personally mediated racism on a daily basis. A large portion of children's time is spent in school; a system purposed to facilitate healthy socioemotional development and equip children with knowledge while serving as a safe, nurturing, and affirming environment. Unfortunately, schools have often served the opposite role for children of color who experience repeated, daily structural and interpersonal racial discrimination in school settings from as early as preschool. Structurally, Black, Latinx, and Native American children are more likely to be educated in school systems with less experienced teachers, less advanced courses, and lower resources than their non-Latinx White peers. Multiple studies have shown that children of color perform better

academically in school when they share the same cultural background as their teachers, yet youth of color are less likely to have a teacher, counselor, or principal of the same cultural background compared to their non-Latinx White peers. In addition, due to racial bias, Black and Latinx children score lower on standardized testing than their non-Latinx White peers. Subsequently, these factors impact students' engagement and investment in school, compelling many children of color to mentally and physically "check out" of school at an early age, which impacts their educational attainment, income, and status as adults.

In controlled preschool classroom simulations, teachers were more likely to have increased surveillance of Black children and expect misbehavior from them, especially Black boys, even when no behavioral issues were present. Studies have demonstrated that continual correction of students by teachers in front of peers has a negative effect on the peers' perceptions of students. Black and Latinx children are viewed as more aggressive than non-Latinx White students. This bias has resulted in Black preschoolers being suspended at a rate of more than three times their White peers. Black girls are six times more likely to be suspended from school than non-Latinx White girls. At school, similar behaviors in Black and White children, such as inattention, talking back to a teacher, or defiance, are often interpreted differently and can result in additional attention and resources for non-Latinx White students versus punishment for Black students.

In addition to disproportionate punishment, academic enrichment, leadership opportunities, and extracurricular opportunities are structured by racism and bias. Black students are less likely to be recommended for gifted education programs than their non-Latinx White peers, because teachers have been shown to have lower expectations for Black students. Moreover, children of color who are not academically challenged but may experience attentional and behavioral issues in school, are more susceptible to racially biased exclusionary disciplinary practices. Multiple studies have shown that Black students are disproportionately punished with suspension and expulsion. Factors influencing suspension include being Black, being male, and being perceived as looking older than their classmates. Black and Latinx youth are also less likely than their non-Latinx White peers to receive a referral by school professionals for an attention deficit hyperactivity disorder (ADHD) evaluation.

Exposure to racism in schools can render them unsafe spaces for children of color. This, in addition to other institutional forms of racism (family economics, neighborhood environment, nutrition), contributes to educational inequalities. By high school, Black, Latinx, and Native American youth were more likely to have higher rates of absenteeism and lower graduation rates than their non-Latinx White counterparts. This further exacerbates racial disparities as advanced educational attainment is a major predictor in life outcomes such as health and economics.

Racism in Special Education

As stated earlier in the chapter, secondary to the impacts of structural racism, youth of color are more likely to have experienced a variety of adverse outcomes, including low birth weight, exposure to lead and environmental pollutants, and living in unsafe neighborhoods, all of these are structural risk factors for developing disabilities. In addition, significant bias and structural racism has been shown in the rates of disability identification, evaluation, categorization, and access to and utilization of services rendered for Black and Latinx children in the special education system. Children diagnosed with one or more disabilities, such as autism spectrum disorder (ASD), emotional disturbance, and hearing impairment, qualify for special education. Black children are more likely to be diagnosed with emotional disturbance or intellectual disabilities; they are underrepresented in ASD and speech and language delay categories. Missed diagnoses mean that instead of receiving accurate diagnoses and appropriate services, Black youth with disabilities are more likely to be suspended than their non-Latinx White peers with disabilities.

Overall, Black and Latinx children are less likely to be enrolled in special education compared to children who are identified as non-Latinx White. However, when placed in special education programs, youth of color are more likely to be placed in the most restrictive educational settings. This means that they are more likely to spend 100% of their educational time in segregated, special education settings and are less likely to have access to general education curricula, teaching, and resources. Black and Latinx children in the high school special education system are more likely to be placed in tracks where they earn high school certificates instead of traditional high school diplomas, which prevents them from considering postsecondary education as a possibility. These exclusionary practices for Black and Latinx students in special education

have significant repercussions because they restrict Black and Latinx youth to a future of limited job opportunities, income/economics, health, and life trajectories.

Racism in Juvenile Justice System

Importantly, challenges that children of color face in schools are also linked to their involvement in the juvenile justice system, a system that reflects larger societal structural racism. Students who experience exclusionary and punitive disciplinary measures in school are more likely to drop out of school and more likely to become involved in the juvenile justice system. Black, Latinx, and Native American youth are disproportionately represented in the juvenile justice system. According to 2021 data, youth of color comprise 49.8% of the U.S. population but make up 62% of the youth charged in the juvenile justice system. Racially minoritized teens have higher arrest rates for nonviolent, low-level offenses, and for noncriminal misbehaviors such as truancy and curfew violations. Research has also shown that race is a strong predictor of youth commitment to facilities where Black youth were more likely to be sent to boot camp or wilderness programs, while their non-Latinx White peers were committed to therapeutic programs such as drug/alcohol diversion programs and mental health facilities. In addition, Black children are five times more likely to be detained in juvenile justice facilities and are more likely to be sent from juvenile to adult court than their non-Latinx White peers.

During incarceration, youth experience solitary confinement, abuse, possible inadequate access to mental health care or education. Evidence has shown that involvement in the justice system “can lead to lower family functioning, impaired social networks, decreased high school graduation, decreased employment rates, increase in violence and victimization, and poorer mental health outcomes.” Subsequently, youth involved in the juvenile justice system are more likely to continue involvement in the justice system throughout adulthood.

Child Welfare

The child welfare system is another system characterized by inequity, racial disparity, and racial disproportionality across multiple levels. Oversurveillance of and overinvestigation of families of color reflect systemic, implicit, and explicit biases that are racialized and extend across

every stage of decision making in the child welfare system, from reporting, investigating, intervention, and the placement process. This includes the types of services to which families are referred, are accessible, the degree of placement instability, and engagement with caseworkers. All of these reflect disparities where Black families have disparate contact and outcomes. It is documented that biased decision making contributes to the fact that caseworkers are more likely to substantiate claims of abuse and neglect for Black and Indigenous families resulting in disproportionate separation of Black and Indigenous youth from their families. From entry to placement or exit out of the child welfare system, Black children experience more harm, longer lengths of stay, protracted reunification periods, and slower rates of exit compared to other children.

Specifically, the mental health implications of structural racism within child welfare are significant. Researchers have shown how racism impacts mental health access for youth of color in the child welfare system and that despite having similar presentations in symptoms and diagnoses, youth of color have a higher likelihood than non-Latinx White youth to receive psychotropic medication and behavioral health diagnoses. Solutions proposed by researchers, advocates, and policy members include the development of culturally responsive practices, recruiting and retaining foster families of color, and understanding and addressing bias at various decision points.

Developmental Disabilities

Another system in which disparities exist for children of color is within developmental disabilities services. Proper and timely identification, access to treatment, and care are all challenges for BIPoC families. Multiple studies have identified that there are significant racial/ethnic disparities in the identification of ASD. Historically, there were lower rates of identification in Black and Latinx children compared to their peers. Recently, the CDC has shown an improvement in the identification of ASD in Black children. However, lower identification rates for Latinx children still persist. Black and Latinx children are still more likely to receive ASD evaluations at later ages and stages of severity than their non-Latinx White peers. Studies indicate that this delay in assessment and diagnosis occurs years after Black parents have voiced concern for their child's development to teachers and pediatricians. Black parents are also more likely to experience difficulties getting ASD evaluations for their children

and, on average, visit multiple providers before finally receiving a diagnosis of ASD. This delay in diagnosis denies children of color access to EI (which is related to longitudinal outcomes, including morbidity and mortality), services, and accommodations that are essential in their developmental trajectories and quality of life. Moreover, these children ultimately experience worse health outcomes.

Even when diagnosed with developmental disabilities, children of color are more likely to receive certain diagnoses that reflect racist stereotypes. Black students are twice as likely to be identified as having emotional disturbance and intellectual disabilities as their peers. Native American students are twice as likely to be identified as having specific learning disabilities and four times as likely to be identified as having developmental delays. In addition, children of color with disabilities are more likely to be placed in more restrictive learning environments than their non-Latinx White peers. After diagnosis, research has shown that Black and non-English speaking families receive fewer services for their children with developmental disabilities than non-Latinx White families who have children with developmental disabilities. These differences have also been identified at the state level, in that studies have shown that regional centers in California, which provide services for children with developmental disabilities, spend less funding on Black and Asian children than on non-Latinx White children.

RACIAL INEQUITIES IN MENTAL HEALTH TREATMENT AND OUTCOMES

The data reflects how BIPoC patients not only have less access to care, but when they do receive care, it is consistently poorer quality than that received by their non-Latinx White peers. Racism and racial bias are woven into the foundation of the American practice of psychiatry and mental/behavioral health care. In the 18th century, Dr. Benjamin Rush created the concept of *negritude*—the belief that having black skin was a disease only curable by a patient becoming White. In the 19th century, Dr. Samuel Cartwright invented the concept of *drapetomania,* also known as runaway slave syndrome, which believed that enslaved Africans who attempted to escape slavery had a mental disorder that could only be treated with physical punishment or amputations; he also invented *dysaesthesia aethiopica,* the theory that it was a mental illness for

enslaved Africans to refuse to do manual labor. Mirroring the sociopolitical climate of American society, psychiatric institutions intentionally participated in racial segregation. Even when psychiatric institutions were "integrated," they provided different standards of care and treatment for Black and White patients, resulting in significant inequities in mental health care. During the 1960s and 1970s, there was a shift in the definition and racial demographic of schizophrenia. More Black men were diagnosed with schizophrenia, and the diagnostic criteria began to include characteristics such as aggression, violence, agitation, and stereotypical terms often attributed to Black men. Per psychiatrist and historian Dr. Jonathan Metzl, these racially coded words were added to the definition of the disorder in order to discredit the mental fitness of many Black people who were involved in the Civil Rights Movement. This racialization and criminalization of mental illness also resulted in mental health care and treatment transferring from psychiatric institutions to the carceral system, which disproportionately imprisons BIPoC. To this day, psychiatrists are more likely to diagnose Black patients with schizophrenia and prescribe them higher doses of antipsychotic medications.

Adults of color are also more likely to have worse mental health outcomes than their non-Latinx White counterparts, which is of particular importance when recognizing that the health of the parents or primary caregivers directly influences the healthy development of their child. Child mental health prognosis is directly dependent on the mental wellness of their adult caregivers. In addition, inequities in mental health care extend to children of color. Psychiatrists' racial bias and differences in access to mental health care have resulted in mental health disparities along color lines. Research has shown that implicit and explicit personally mediated racism can affect mental health care delivery and outcomes.

With respect to psychiatric and behavioral health care, recent literature reviews have indicated that ethnic/racial minority children with mental health difficulties are underserved relative to their non-Latinx White counterparts for prevention, access, quality treatments, and outcomes of care. Mental health care systems perpetuate racism and racial bias through the underdiagnosis and misdiagnosis of common pediatric psychiatric disorders and, moreover, the limited exploration and identification of the manifestations of racial trauma in children. Children and adolescents of color have experienced disparities in mental health care access, diagnostic variability, and treatment availability, resulting in

differences in outcomes. Due to structural racism, Black and Latinx youth are more likely to live in areas with a shortage of health providers and, most likely, child psychiatrists. Systemic racism influences treatment seeking and the experience of mental health care for BIPoC children and youth. Studies from the United States cite experiences of racism, discrimination, and culturally incompetent care as barriers to help-seeking behaviors and retention in treatment. Studies in Canada demonstrated that youth are less likely to access outpatient levels of care voluntarily and more likely to initiate treatment in crisis settings or through the criminal justice system. When minoritized youth ultimately access mental health treatment, they are more likely to express dissatisfaction with their care due to experiences of race-based discrimination. In addition, attitudes toward help seeking are further complicated by cultural background (i.e., first- vs. second-generation immigrants) and views of mental health treatment as a westernized construct.

According to the 2006 to 2012 Medical Expenditure Panel Surveys, Black and Latinx children had fewer visits to psychiatrists and other mental health professionals and less substance use care than their non-Latinx White peers, even when controlled for mental health impairment, income, and health insurance. This may also show lower identification of mental illness in minority youth and decreased referral rates to psychiatrists from pediatricians and educators. Psychiatric and behavioral problems in youth of color are more likely to result in increased school punishment and incarceration than increased referrals for mental health care. Black adolescents diagnosed with MDD received mental health treatment at a much lower rate than non-Latinx White adolescents. Black and Latinx adolescents, even when severely impaired, were less likely than non-Latinx White adolescents to receive medication or therapy for mood and anxiety disorders. Once care was initiated, youth of color had fewer follow-up mental health appointments than their non-Latinx White peers.

A large portion of all diagnostic processes allows for clinician subjective evaluation, which leaves room for unconscious racial bias. ADHD is prevalent in children of all races and genders. However, non-Latinx White boys are more likely to be diagnosed with ADHD than any other group. By kindergarten, Black children are 70% less likely to receive the diagnosis of ADHD compared to non-Latinx White children, and by high school, non-Latinx White children are almost twice as likely to receive the diagnosis of

ADHD as Black children. Further studies have shown that Black and Latinx youth are more likely to receive the diagnosis of oppositional defiant disorder (ODD) and conduct disorder (CD) than the diagnosis of ADHD and are more likely to be diagnosed with ODD and CD than their non-Latinx White peers. These diagnoses make youth more vulnerable to adverse punitive disciplinary action in school, poor school performance, and involvement in the juvenile justice system. Failing to diagnose youth of color with ADHD can significantly alter one's life trajectory; it denies youth`s essential medications, therapy, and support services, further perpetuating or exacerbating professional and socioeconomic inequalities. Compounding overreporting of ODD and CD and underreporting depression, anxiety, and ADHD in youth of color is the fact that racial trauma is likely underreported in youth of color due to clinician's lack of awareness, bias, and discomfort surrounding racial topics and the narrow and exclusive scope of the PTSD criteria.

Disparities in mental health diagnosis and treatment have resulted in worsened mental health outcomes for children and adolescents of color. Research from Leventhal et al. showed that self-reported concern about increasing societal discrimination was associated with a higher frequency of substance use, a greater number of substances used, and higher odds of depression and ADHD symptoms. The suicide rate for Black youth has increased from 2.55 per 100,000 in 2007 to 4.82 per 100,000 in 2017, which is the fastest rate increase for any racial/ethnic group. Compared to their non-Latinx White peers, Black youth under 13 years are twice as likely to die by suicide. Research investigating the impact of perceived racial discrimination among children and adolescents found that exposure to perceived discrimination predicted poorer mental health care outcomes.

THE ROLE OF THE CHILD AND ADOLESCENT PSYCHIATRIST

Child and adolescent psychiatrists are poised to leverage both developmental and structural approaches to understand and respond to structural racism and the resultant adverse mental health outcomes in BIPoC children and youth. By acknowledging the role of racism in child and adolescent mental health, psychiatrists and other mental health professionals can proactively engage in systems-level interventions to identify, mitigate, and prevent the adverse effects that stem from

structural, systemic, interpersonal/personally mediated, and internalized racism, thus improving the health and well-being of all children, adolescents, emerging adults, and their families. By using innovative strategies, including having an antiracist approach to clinical practice, engaging not only the family but also community partners, and building resilience through supporting racial–ethnic socialization and racial pride, child and adolescent psychiatrists can improve the equitable care of diverse children.

Intentionally antiracist practices, trauma-informed care, and culturally informed care are important factors in ensuring the healthy and optimal development of BIPoC children and youth. Psychiatric treatment of minoritized and marginalized youth should fundamentally be strength based, emphasizing creating safe spaces that foster trust, autonomy, and self-advocacy. Understanding the neighborhoods, schools, and communities in which children live and grow is an important part of child psychiatric practice. Optimizing clinical care includes understanding the lives and experiences of diverse children and adolescents and their families, ensuring that prevention and intervention programs interdigitate with real life. Screening for mental health and behavioral issues should always be nuanced and thoughtful, taking into account differential experiences as well as taking into account diverse cultural practices and beliefs.

Building Resilience

Importantly, many children and adolescents are able to thrive even in the face of racist systems and structures that directly impact their lives, neighborhoods, communities, and, ultimately, their development. As important as it is to describe how racism and discrimination can negatively impact developing children, equally important is recognizing that families have support systems that help to mitigate the impacts of racism and discrimination.

As has been noted, several studies have identified racism as impacting youths' psychosocial functioning and emotional well-being, particularly around anxiety, depression, and academic functioning. Literature that examines protective and resilience-promoting factors highlights the importance of racial–ethnic socialization and racial pride in decreasing negative mental health outcomes. As described by Stevenson, Hughes, and colleagues, racial/ethnic socialization (R/ES) represents a diverse set

of individual coping skills across various psychosocial domains to mitigate experiences of racial-related tension and stress in interpersonal relationships. R/ES, which includes affirming messages passed on between youth and their caregivers around racial pride and identity, has been shown to be particularly important for the academic and socioemotional well-being of Black children. Racial ethnic connectedness is also a form of cultural affirmation and pride that can positively impact academic achievement and decrease conduct and emotional problems.

Research and Antiracism

Despite a considerable increase in the number of studies on racism and health in recent years, relatively few have focused on children, adolescents, and transition age youth. Furthermore, much of the work has focused on the experiences of Black and, to a lesser extent, Latinx children and adolescents, excluding the experiences of Asian Americans, Hawaiian, Pacific Islanders, and Native/Indigenous children and adolescents. The sparse evidence from studies that draw on longitudinal data draws a correlation between racial trauma and poor health but provides few insights about the sensitivity of early exposure, the importance of duration of exposure, clear mechanisms of action, or the latency period between exposure to racism and discrimination and the onset of illness; as a result, the causal pathways through early childhood and later adolescence are not fully understood. What is known is the impact of perceived and observed experiences of discrimination and racism on child and family health outcomes can be profound. Future research efforts should (1) focus on nuanced tools to measure perceived racism and its impact on all BIPoC children and adolescents at different developmental ages and (2) explicitly focus on BIPoC youth as they are underrepresented in research, thereby ensuring that prevention and intervention strategies that are created will be as effective in diverse communities.

By ensuring that the research undertaken recruits and includes diverse families and youth, we will ensure more equitable care, access to treatment, and more holistic preventive strategies. Secondary to the increasing recognition of the dearth of inclusive research on children and youth of color, federal and state agencies are creating legislation to ensure these limitations cease in future funded research mechanisms. Allied organizations are also changing the language they use with youth

and their families, enhancing their guidelines to identify and address racism and discrimination and its impact on developing children and youth. Both the AAP and the American Academy of Child and Adolescent Psychiatry (AACAP) have created resources for clinicians, children, and families that highlight the importance of addressing issues of racism and discrimination often and early, recognizing the detriment they have on child and adolescent mental health and well-being.

As this chapter comes to a close, the salient points highlighted throughout the sections include the growing evidence of the significant ways in which multiple forms of racism and discrimination can adversely impact developing children and adolescents. Also highlighted are the burgeoning evidence-based modalities and system changes that, once generalized, will ensure equitable care and treatment for all children. Increasingly, the role of the child and adolescent psychiatrist is to be able to understand emerging principles of neuroscience as they relate to child development and then integrate this understanding with information about the social determinants of mental health. A comprehensive appreciation of child development must include the impacts of racism and discrimination on child health. This chapter has taken a developmental perspective to articulate the myriad ways in which racism and discrimination harm children and youth while also ensuring that the science around prevention, intervention, and discussion of systems and practices to prevent, intervene, mitigate, and ultimately treat if necessary are also clearly understood.

54.18 Forensic Evaluations of Child and Adolescent Migrants

Olivia Shadid, M.D., and Shawn Singh Sidhu, M.D.

Forensic psychological evaluations of child and adolescent asylum seekers are a rewarding, meaningful, and effective way for health care providers to engage with a unique population while providing a valuable service. The presence of an objective and independent medical evaluation may increase the likelihood of receiving asylum from 37.5% to 89%. Asylum hearings can have life or death significance for migrants seeking humanitarian relief. An official report from Human Rights Watch documents that hundreds of migrants have been murdered shortly after deportation from the United States to their country of origin, while others have reported being tortured, raped, or sexually trafficked after deportation to their country of origin.

MENTAL HEALTH PREVALENCE IN ASYLUM-SEEKING POPULATIONS

According to the United Nations High Commissioner for Refugees (UNHCR), 82.4 million people were forcibly displaced from their homes in 2020, 42% of whom were children. Premigration (armed conflict, disasters, abuse, and neglect), migration (treacherous conditions, trafficking, sleep deprivation), and postmigration (detention, family separation, racism and immigration stress, resettlement stress) trauma result in elevated rates of mental health diagnoses in migrants. Children show high rates of developmental regression and attachment difficulties in

detention, while parents show high rates of anxiety, psychosis, and suicidal ideation. Both groups show alarmingly high rates of depression, anxiety, and post-traumatic stress disorder (PTSD).

OVERVIEW OF THE EVALUATION PROCESS

While there can be considerable variation in the asylum evaluation process, most cases follow a typical approach. Initially, an immigration attorney requests a mental health evaluation for their client. Once connected, the attorney assists in arranging an evaluation for their client. This evaluation may take place in the community, at the evaluator's office, within a detention center or other forensic center, or through a telehealth evaluation. As in clinical interviews, it is helpful to collect collateral from caregivers, and, with very young children, caregivers may be present with the client throughout most of the interview. However, youth should always be given the opportunity to be interviewed without the caregiver present. The length of evaluations can vary considerably depending on the complexity of the case. Following the assessment, the evaluator will submit their written and signed document, or legal affidavit, to the attorney, who can then use this document in court to advocate for their client.

Evaluators

A broad range of mental health and medical professionals can conduct mental health evaluations for asylum-seeking immigrants. Trainees and professionals without an independent license may still conduct these evaluations if they have a co-signer who is independently licensed.

Preparing for the Psychological Evaluation

Prior to the interview, it is important to review any initial documentation, such as the client's Declaration or Statement of Facts, I-589 Application, Credible Fear Interview, medical records, or any other documents provided by the attorney for accuracy and pertinent details. The evaluator should work with the attorney to discern whether the evaluator is a good fit for the evaluation based on their identifiable characteristics.

Conducting the Psychological Evaluation

Context, Introductions, and Confidentiality. Given the whirlwind of procedural meetings and interactions that asylum seekers may have with multiple individuals, it is of the utmost importance that the evaluator introduces themselves to the client and their caregiver as someone working with their attorney, clearly state their profession, and explain their role as an evaluator to the client. The evaluator should also introduce and explain the role of anyone else at the interview, such as the certified medical interpreter or if a trainee is present. Once the client and their caregiver are comfortable with information about the evaluator, notify the client that the evaluation may take several hours, that the client is in control of the interview, and that they can take breaks or stop at any time. Communicate also that this interview is completely voluntary, and their autonomy will be respected. Notify the client and caregiver that they should feel free to express how they are feeling throughout the interview and to ask questions at any time. To further elucidate the nature of the evaluation, it is useful to state clearly that while the evaluator is a mental health professional, they will not be providing the client with specific treatment plans after the evaluation or treating any mental health problems going forward. The client should also be informed about the confidentiality of the affidavit. The affidavit will be visible to legal authorities and representatives within the court setting, and thus its contents will not be confidential within the legal system. However, the contents of the affidavit are not to be shared in any capacity outside of the hearing with the federal immigration judge.

Interviewing the Client. It is common for asylum seekers to exhibit a broad range of emotions while telling their story and answering very detailed and specific questions about their traumas. The evaluator must carefully gauge the client's readiness to continue in these circumstances. Above all, it is important that the evaluator take a trauma-informed approach to the interview to avoid potential retraumatization—which consists of attending to psychological and physical safety, transparency, collaboration, empowerment, and understanding cultural, gender, and historical issues—given the high prevalence of trauma among asylum seekers. Evaluators should also take a stance of cultural humility, reflecting and remaining cognizant of potential interviewer biases, privilege, and power dynamics in the interview. It is also essential to allow the client time to feel, process, and ground while discussing traumatic

memories. Younger children, in particular, may benefit from the evaluation being conducted over multiple interviews to avoid overwhelming or risk dissociation or retraumatization. Evaluators can make empathic statements and give clients a sense of control if they experience symptoms, with necessary adjustments for telephonic and telehealth interviews. For young children, it can be helpful to start the evaluation with drawing, asking about hobbies, or playing a short game to establish rapport. Throughout the interview, offer breaks for the child to check in with their caregiver.

Developmental level and culture can play a significant role in how a client engages with an evaluator and, ultimately, how a client testifies. The evaluator should not hesitate to ask the client openly about their affect and note this in the affidavit. Child and adolescent clients are much more likely to display an incongruent affect when discussing traumatic or emotionally difficult topics, and even more so if the child has a history of developmental delays. Similarly, a client's culture or socioeconomic status can largely shape how they present for the interview. For example, a client from a culture in which the expression of negative affect is considered rude may display incongruent responses, such as smiling when recalling trauma. Such changes in affect and the topics precipitating them should be noted in the mental status examination. Understanding this dynamic more fully at the outset will help to inform the evaluator's interview and write-up.

Contextual History. While there are many ways to effectively conduct a psychological evaluation, one logical starting point is contextual history, particularly when interview time is limited. This is an opportunity for the client to express in their own words what life was like in their country of origin for individuals who shared the same identifiable characteristics as them. For example, if a family reports they were tortured and persecuted on the basis of belonging to a minority political group, it would be helpful for the court to understand how the predominant political group typically treated political opposition. Was the client's family the only family who was treated unfairly, or was this common among their associates as well? Personal stories and detailed examples help to illustrate the circumstances for the immigration judge and frame the narrative for the remainder of the evaluation. Starting with a contextual history also helps

the youth ease into the interview and helps establish rapport with the evaluator.

Focused Trauma History. Given the importance of trauma in the psychological evaluations of asylum seekers and the link between trauma and claims for humanitarian relief, the evaluator should obtain a focused trauma history during the evaluation. This is one of the most critical sections of the affidavit, and high-quality reports have detailed trauma histories. If a client has endured multiple traumas, it can be helpful to ask initially about the traumas that impacted them the most, potentially including traumas during migration and following migration. While qualitative details can be helpful, quantitative details with specific numbers, dates, and times can sometimes cause a client's case to lose credibility erroneously. However, qualitative details can be important in describing how the client was harmed and demonstrating the degree of torture or damage inflicted on the client. This type of detail could include the type of trauma, who the attackers were, the instruments used, the type of injuries, how the client was injured, the type and duration of the pain, and whether or not there was any bleeding, bruising, burning, broken bones, or other forms of physical damage. In the case of sexual trauma, it can be important to ask potentially uncomfortable questions in a gentle manner, such as whether there was bleeding or lacerations, the type of any penetration, any resultant difficulty urinating or defecating, or persistent scarring. Occurrence and symptoms of a potential traumatic brain injury are also necessary to include, such as blows to the head, bleeding and/or bruising to the head or face or neck, whiplash, loss of consciousness, dizziness, unsteadiness, gait abnormalities, decreased reaction time, and short- or long-term headaches or memory difficulties. It is helpful to ask about short- or long-term impairments in function.

It is essential to note whether a client or client's family member's life was threatened or if they feared for their life during an event. Also important is to ask about what was said by perpetrators during the torture, as this ties the trauma into the client's legal claim (e.g., if the perpetrators of the torture mention political parties, and the client is claiming asylum on the basis of political persecution, such statements would be highly relevant to the client's case because they convey a motive for the torture).

In line with a trauma-informed approach, it is helpful for the evaluator to normalize and validate any potentially distressing emotions or physiologic

symptoms that may come up during the interview. Evaluators should strive to maintain a supportive and nonjudgmental approach to the interview and avoid asking questions in a manner that may seem like a forced exposure or risk retraumatization. Evaluators should also explain why questions—particularly sensitive ones—are asked.

Social History. There are several elements of the social history that could impact the client's testimony and case. For example, the level of education can have a significant impact on testimony. If a client has little formal education and the judge is asking complex questions, the likelihood of a reliable or consistent answer is low, given the client's likely level of skill in rhetoric and vocabulary. The client should be asked about their school, occupational, and social goals and dreams following resettlement in the United States, as these small personal details can help paint a complete and holistic picture of the client.

Substance Use History. The implications of substance use in humanitarian relief cases are multiple and complex. Most evaluators will include at least a basic overview of the most commonly used substances in their report. If the client was either forced to use or had access to substances as a minor, this could be useful to note, as it could aid in characterizing their social and developmental history. It is important to note if the client was under the influence when the trauma occurred, if the substance was forced upon them, and if the substance was an attempt to self-medicate a significant mental health condition.

Past Mental Health History. A fairly standard past mental health history is warranted in a forensic psychological evaluation for asylum seekers. This should include prior counseling, inpatient hospitalizations, substance use treatment, suicidal and/or homicidal ideation, self-harm, auditory or visual hallucinations or delusions, a history of violence, and psychotropic medication trials. It is relevant to include any treatment that the individual received while in detention or in the community while awaiting their immigration hearing. If the client reports acute psychiatric symptoms, such as suicidal ideation with a plan and intent, or if the client is observed to be experiencing hallucinations and delusions to the extent that it impacts their safety, this should be reported to the attorney, caregiver, and/or detention center immediately. If the client presents with subacute symptoms, such as passive suicidal ideation, the inability to

perform basic activities of daily living, or severe weight loss, the attorney, caregiver, and relevant authorities should be made aware that these symptoms are to be followed closely.

Past Medical History. A basic medical history should be included in the psychological evaluation. Developmental issues should be listed. A history of traumatic brain injury or concussion is especially important in this section, as is the documentation of any significant injury or impairments in functioning from past torture or persecution. Seizures must always be ruled out in a mental health evaluation. Current medications should be noted. If the individual required treatment and this was neglected, this should be noted.

Physical Examination. While a full physical examination is contraindicated as part of a mental health evaluation, some mental health evaluators choose to document scars in easily visible areas and the mechanism by which the patient reports that such injuries were obtained. For example, if a client was struck on the forehead and has a scar, the evaluator can document a "*hypopigmented lesion on upper right temporal legion, which the client states is from being struck with the butt of a rifle*." Similarly, regarding functional impairment, the evaluator could document that "*the client reports that they are unable to sit for long periods of time after being struck in the knee with the butt of a rifle, which could impact testimony*." Scars in less visible areas of the body can be described verbally by the client, and this verbal description can be included in the report.

Targeted Diagnostic Screening. A thorough diagnostic mental health screening is arguably the most important portion of the entire psychological interview of asylum seekers. The presence of a mental health diagnosis can be a way of demonstrating objective harm experienced by the client at the hands of the alleged perpetrators. At the same time, a mental health diagnosis can also explain why the client's presentation in court might vary based on their experiences.

While a thorough diagnostic interview based on criteria outlined in the Diagnostic and Statistical Manual–5 Text Revision (DSM-5-TR) remains the gold standard, providers may use diagnostic scales with which they are familiar to add an objective measure to the report. However, note that most scales and screening tools have not been studied in migrant

populations. Limiting reported diagnoses to those that are most impairing removes the impression that a client may be overendorsing symptoms to the judge.

When screening for mental health disorders, it is important to proceed criterion by criterion and provide additional detail whenever possible. For example, stating "*Client screens positive for PTSD*" provides far less detail and evidence than "*Criterion B1: client endorses recurrent distressing dreams of the event in which they will dream that they are being physically attacked and awaken in a cold sweat, with the feeling that they were being restrained again and not remember where they are*."

The most common diagnoses in youth asylum seekers are PTSD, major depressive disorder, and anxiety disorders. Anxiety secondary to PTSD, an other specified trauma- and stressor-related disorder such as traumatic stress, or an adjustment disorder should be ruled out before diagnosing an additional anxiety disorder. Less common diagnoses include a psychotic disorder, bipolar disorder, cognitive disorder, or a developmental disorder/intellectual disability. Unaccompanied minors separated from both parents have been shown to have higher scores of PTSD and depression compared to youth asylum seekers who are not separated from their parents.

Aside from directly experiencing trauma, which would also include threats of harm or death, PTSD also can be diagnosed if a client saw a trauma happening to someone else or found out about a trauma happening to a loved one. For children, recurrence symptoms may be more likely to manifest in play, such as imagining facing monsters or acting out the trauma repeatedly, emotional dysregulation, or disrupted attachment.

Assessing psychosis in the context of an asylum evaluation can be complex and requires astute clinical skills. Psychotic symptoms most often result from trauma, PTSD, and/or mood disorders. The presence of multiple simultaneous voices, negative symptoms, disorganized speech, disorganized thought, or disorganized behavior is concerning for a primary psychotic disorder, such as schizophrenia.

The Mental Status Examination

The mental status examination is an important component of the assessment wherein the clinician documents objective findings of the client's presentation, including the client's demeanor, evidence of

tearfulness or overwhelming emotion, incongruent or constricted affect, and need for breaks, thus providing insight into the patient's emotional and cognitive state.

If the client is wearing an item of jewelry or has a tattoo that aligns them with certain social groups, these might be noted. Gender presentation may be important to note, particularly if the client was persecuted based on gender or intersectional identity.

Behavior is important to describe, particularly gestures of distress such as when a client holds their head in their hands, fidgets, looks at the ground, takes deep breaths and sighs, requires multiple breaks, clenches their fists, sweats, talks in either a loud or soft manner, the nature of eye contact, and attempts to avoid discussing distressing content or trauma. Affect may shift throughout the interview, and such alterations may be instrumental in acquiring a more nuanced, dynamic formulation of the client. When assessing cognition, such as attention, memory, orientation, insight, and judgment, it is important to factor in developmental age, educational history, and culture.

The following is a completely fictional sample mental status examination.

Alejandra is a 15-year-old transgender girl appearing younger than her stated age. She is feminine presenting. She wears a rosary necklace which she clutches during the interview, particularly during times of stress. She is well groomed, wearing pink lip gloss, and casually dressed. Alejandra is highly cooperative and engaged with the interview. She has good eye contact but will lower her eyes when talking about her traumas. She was observed being tearful throughout several portions of the interview, ranging from brief tearfulness to outright sobbing. During some portions of the interview, she laid her head down to rest, while at other times, she stared blankly off into the distance when discussing difficult elements. Her speech is very soft and slow, almost a whisper. Her motor examination is significant for psychomotor retardation or slowing. Her mood is, “I feel like I lost a piece of soul that I never got back after I was attacked.” Affect is tearful, dysphoric, and anxious. Thought process is linear and logical. Thought content is without any hallucinations, delusions, suicidal ideation, or homicidal ideation. Insight and judgment appear good for age and developmental level.

GENERAL TIPS FOR WRITING AN EFFECTIVE PSYCHOLOGICAL AFFIDAVIT FOR ASYLUM SEEKERS

In the majority of cases, the contents of the affidavit are ultimately the only information from the mental health evaluation that will be available for use in the client’s case; thus, what is written is crucial. Psychiatric terminology may be employed when making an official diagnosis or explaining medical phenomena, but consider also explaining such terms in lay language, as most judges and attorneys are not familiar with the technical language of psychiatry and medicine. Words such as “torture,” “persecution,” and “competency” should also be avoided, as these are legal determinations. If collateral information is obtained, such as from a caregiver, sources of information should be noted in the affidavit.

A few disclaimers can be helpful to note in the affidavit. For example, given the limitation in time, the focused trauma history may not be a comprehensive list of every trauma experienced by the client. This is helpful in the event that the client shares different traumas with immigration authorities than they do with the psychological evaluator. It is also helpful to note that quotations are paraphrased and not exact quotes if the client had used slightly different quotations elsewhere.

Assessment

The assessment and discussion sections of the affidavit are most likely to be of direct benefit and utility to the attorney and the client. The purpose of the assessment is to state whether the evaluator found the client's reported history to be consistent with a history of traumatization. An assessment of whether the psychological findings the client reported are typical reactions to extreme stress may also be documented in this section. The evaluator may also use the qualities of the interview in their assessment of consistency. For example, the evaluator may find that the emotional responses the client exhibited during the interview and the ways in which they described vivid details of certain traumatic events are consistent with the experiences the client reported. This section also offers an opportunity to note whether the evaluator feels the client endorses symptoms indiscriminately or if they endorse some, rather than all, symptoms when they are queried.

Diagnosis

Following the assessment, the evaluator should include whether the client meets the criteria for any diagnoses described in the DSM-5-TR. Although not all youth will meet the full criteria for a disorder, such as PTSD, they often exhibit symptoms of a disorder, such as several symptoms of PTSD, which should be detailed and explained clearly. Youth may describe symptoms of a disorder in the past, but symptoms may be currently in remission, especially if they are living in a supportive, safe environment without ongoing exposure to the trauma. Diagnoses should be clearly labeled with the accompanying ICD-10 F-Codes (e.g., "*Post-Traumatic Stress Disorder–F 43.10"*).

Discussion

In the discussion section, the evaluator can offer the attorney and judge information on the client's ability to testify, particularly noting findings or framings that may lead to impairment in this ability. Aspects that can affect the ability to testify range from the effects of psychiatric or physical symptoms to cognitive or educational status to cultural factors to qualities of resilience.

If the client is found to have suffered from trauma, the evaluator can discuss how impaired memory is not only a symptom of trauma disorders but also consistent with neurobiologic understandings of the neurotoxic effects of chronic stress, via cortisol elevation, on the hippocampus, the brain's memory center. Similarly, impaired concentration, memory, sleep, and cognition are also associated with many mental health diagnoses. Multiple cognitive domains, including memory and executive functioning, may also be affected by any traumatic brain injuries suffered by the client. If there is a concern for baseline neurocognitive deficits, such as in a client with an intellectual disability, this should also be noted as a possible impairment in the ability to testify.

Clients suffering from trauma may also have difficulty testifying should they experience "intrusion symptoms" such as flashbacks, distressing memories, or dissociation while testifying. This risk can be mitigated by acknowledging triggers of intrusion symptoms and minimizing their presence in the courtroom. Clients may also have physical conditions that may impair their ability to testify secondary to pain or other difficulties.

For children, the evaluator may discuss why a child may not recall particular events or symptoms or avoid talking about events or symptoms by discussing the impact of developmental stage, trauma, language, and mental health diagnoses on memory and recall.

For children and for any client with developmental or intellectual disabilities, it can be useful to describe what developmental stage they are in, noting the competencies they have attained and those that they have not yet likely mastered. If a client, whether child or adult, has not completed high school, the client may have difficulty with both vocabulary and rhetorical skills possessed by those who have completed higher years of formal schooling.

An evaluator may discuss how the affect displayed by the client during testimony may appear incongruent with the topics they are discussing. In addition, the evaluator may discuss the mental health impacts of detention and family separation on a client. Finally, the evaluator may cite literature

that explains why parents may remember or experience certain events differently than their children.

Conclusion and Signature

The affidavit should conclude by restating the mental health diagnoses and explaining that there are highly effective, evidence-based treatments available for the client within the United States for said diagnoses. If the client is in need of urgent treatment, that should also expressly be stated here. If the evaluator has knowledge of mental health care availability in the client's country of origin, they can note whether the availability of such treatments may be limited in the client's country of origin, which could lead to psychiatric decompensation. Finally, the evaluator will write that they swear by penalty of perjury that all information contained in the affidavit ("herein") is truthful to the knowledge of the evaluator and sign and date the affidavit for submission.

Follow-Up

Once drafted, the affidavit should be sent to the client's attorney for review. The attorney may ask clarifying questions or comment on potential issues the affidavit may pose that are unique to the courts in which they practice. Following this revision process, the evaluator will finalize, sign, and date the affidavit. In the majority of cases, this will conclude the asylum evaluation process.

CONCLUSION

Conducting forensic psychological evaluations can be a meaningful and rewarding experience for health care providers and can significantly improve the likelihood of receiving asylum or other forms of humanitarian relief for children and families fleeing torture and persecution. Prior to evaluating the client, the clinician should carefully review all legal documents and arrange for a safe interview space and high-quality interpretation. The evaluator should bring a trauma-informed, culturally sensitive, and developmental lens to the interview and conduct the interview empathically by conveying that the client is in control, meanwhile obtaining a detailed trauma history, contextual history, and mental health review of systems. The mental health status examination should be used as a tool to convey the experience of being in the room with the client.

The evaluation should conclude with a thorough and nuanced assessment and discussion, in which the diagnosis, consistency with trauma, and factors affecting testimony are described completely for legal authorities. The affidavit concludes when the evaluator states that they swear the aforementioned is truthful to the best of the examiner's knowledge and that the document is signed, dated, and submitted.

Finally, as they are at risk for vicarious trauma, evaluators should monitor their own countertransferences and responses to hearing, engaging with, and carrying the stories of often severely traumatized children and adolescents. Evaluators may find solace and integration by debriefing with colleagues and by consciously noting not only the traumatic experiences of clients but also their remarkable resilience despite their traumas.

55 Geriatric Psychiatry

55.1 Overview

55.1a Introduction to Geriatric Psychiatry

Dilip V. Jeste, M.D., Dylan J. Jester, Ph.D., M.P.H., and Ellen E. Lee, M.D.

The population of the United States is aging rapidly, with both an increased number and an increased proportion of older adults. The number of Americans aged 65 and over has increased from 3 million (4% of the total population) in 1900 to 54 million (16% of the population) in 2019. Yet, this historical rise will continue to be dwarfed by that which started in the year 2011 when the first baby boomers (those born between the years 1946 and 1964) reached the age of 65—the traditional definition of "old age." The number of people over 65 will rise to 81 million in 2040 and 95 million (24% of the population) by 2060 (Fig. 55.1a–1).

The average life span in the United States has increased from 47 years in 1900 to 79 years today. The more optimistic estimates project an increase in life expectancy at birth from the current figures of 76 years for men and 81 years for women to 86 years for men and 92 years for women by 2050. Men and women who are 65 years old today are expected to live an average of 16 and 19 years, respectively. By 2050, the average life span at age 65 would have increased to 25 and 30 years, respectively. Thus, reaching age 65 would not indicate imminent death but rather many

more years of life. One of the unwelcome scenarios that could torpedo such an age wave would be a continuation of the current epidemic of obesity in younger and middle-aged individuals leading to a rising incidence of diabetes and other metabolic and vascular diseases that may shorten life spans.

FIGURE 55.1a–1. Number of Americans 65+ (in millions) (U.S. Census Bureau, 2019). (From U.S. Census Bureau. 2020 Profile of Older Americans; 2021. https://acl.gov/sites/default/files/Aging%20and%20Disability%20in%20America/2020ProfileOlderAmericans.Final_.pdf)

The fastest-growing segment of the population in the United States is that of individuals over the age of 85. The 85-and-over age group is expected to increase from about 6 million today to more than 18 million in 2050. Also striking is the growth of the centenarian population. While there were about 5,000 centenarians in the United States in 1900, today, there are around 53,000 people in that age group in the United States or 1.73 centenarians per 10,000 people in the total population. By 2050, that number will have gone up to about 835,000. A particularly notable fact is that whereas most of the centenarians in the United States today are White, nearly half of those in 2050 will belong to ethnic minority groups.

The aging of the population is not restricted to the United States but is a global phenomenon. The world is getting older at a pace that has taken demographers by surprise and presented governments with economic, environmental, and social challenges. Whereas there were about 605

million people over age 60 in the year 2000, that number will reach 2 billion in the year 2050. Two-thirds of all the people in the entire history of the world who have reached the age of 65 are alive today. The number of centenarians in the world will increase from approximately 316,000 at the present time to an incredible 2.2 million by 2050. To put the latter number in perspective, presently, the entire population of countries such as Kuwait, Latvia, Macedonia, and the United Arab Emirates is roughly 2 million people each.

The rates of aging of the population vary widely by region. In some developed countries today, the proportion of older persons is close to 20%—that is, one in five. During the next several decades, that proportion will reach one in four and, in a few countries, as high as one in two (i.e., 50%). Highly developed countries have more stable populations and will experience proportionately less growth in their older populations than developing countries that are undergoing a rapid increase in the number of aged individuals.

We may need to revise our definitions of middle age and old age as well as some of our traditional thinking about chronologic versus biologic aging as well as psychological aging (“felt age” that indicates how old one feels). It has been suggested that middle age be defined as age between 51 and 70 years, “younger old” between 71 and 90 years, and “older old” over age 90. With increasing longevity, the timetable for brain aging may have changed as well.

Table 55.1a–1.
Population by Age and Sex: 2019 (Numbers in thousands. Civilian noninstitutionalized population.[a])

	Both Sexes		Male		Female	
Age	Number	Percent	Number	Percent	Number	Percent

From U.S. Census Bureau. The older population in the United States: 2019; 2020. https://www.census.gov/data/tables/2019/demo/age-and-sex/2019-older-population.html

The growth of our older population during the 20th century is attributable to several factors. During the first half of that century, the main factor responsible for the demographic change was a progressive and dramatic decrease in perinatal and infant mortality due to enhanced sanitation efforts, the advent of antibiotics and vaccines, improved nutrition, and better prenatal and postnatal care. In the latter half of the last century, the greater longevity resulted primarily from an increase in average life span—that is, adults lived longer as a result of declines in mortality from pneumonia, heart disease, and other chronic diseases.

Aging is associated with increased heterogeneity. Tables 55.1a–1 to 55.1a–6 show numbers of people over age 55 in the United States by age and gender, marital status, educational attainment, earnings of full-time workers, types of household, and monetary income. The wide range of diversity in socioeconomic status in older adults is remarkable. Factors such as education, marital status, and income have a potential bidirectional relationship with a number of mental illnesses. For example, adults with schizophrenia are likely to have lower levels of education, be unmarried, and have lower incomes than the general population. These variables could be considered potential risk factors for the illness; it is more likely, however, that these factors are secondary to the development

of a serious mental illness. In either case, they are of considerable importance in the management of persons with schizophrenia.

WHAT IS NORMAL AGING?

"Normal" aging, which reflects typical or average (rather than illness-free) aging, must be differentiated from disease. Some bodily functions decline with age, but health problems are not inevitable. Most diseases of old age, such as heart disease, cancer, and dementia, result from pathologic processes rather than from normal aging. Disabilities resulting from diseases can usually be treated and sometimes prevented. For example, most hearing problems can be at least partially corrected with hearing aids, while the risk of heart disease can be reduced by healthy habits with respect to diet and exercise. The same applies to mental health and many mental illnesses in older people.

One point to stress is that aging is associated with more, and not less, diversity. It is a common misconception that older adults look, think, and behave alike. Indeed, there are more differences among older people than among younger adults. Even in the same person, different organs "age" at different rates. It has been suggested that we should abandon the notion of chronologic age ("how old are you?"), and instead, consider the stages of aging that a given individual exhibits in different areas of functioning. Furthermore, just as a child may be at different stages of development mentally and physically, an older adult may have divergent aging of their brain, liver, kidneys, and heart. As a matter of fact, not even all the parts of the brain age at the same rate in a person. Thus, an aged person may have relatively intact memory while having deficits in motor function.

We must recognize that although we need age cut-offs for defining old age for societal purposes (e.g., the qualifying age for starting Medicare or for Social Security), such cut-offs are artificial and arbitrary. No magical change occurs overnight on the 65th or any other birthday. Also, with increasing longevity, the age cut-offs used currently will need to change.

There is often a tendency to confuse the effects of old age with those of its common, but not inevitable, associations. Thus, medical morbidity increases with aging, but many physical diseases can be managed better, and some (e.g., nutritional deficiencies) can be prevented. The diverse treatment of various physical illnesses by different specialists resulting in polypharmacy has an adverse influence on the treatment of mental

disorders in older adults. Similarly, psychosocial stressors such as financial hardship and lack of appropriate community services impact the management of older people with psychiatric symptoms.

DEMOGRAPHICS OF OLDER PEOPLE WITH MENTAL ILLNESSES

Aging and aging-associated disorders (e.g., metabolic and vascular diseases) may influence the expression and management of mental illnesses. Yet, psychiatric epidemiologic studies have tended to exclude older adults. The common notion that psychiatric disorders are rare among older individuals is just plain wrong. This misconception, prevalent even among nongeriatric mental health experts, is based on studies such as the Epidemiologic Catchment Area (ECA) study conducted by the National Institute of Mental Health in the early 1980s. The ECA study was one of the largest epidemiologic investigations of psychiatric disorders

using, what was at that time, state-of-the-art methodology, including then-new DSM-III criteria. The ECA study reported that the prevalence of any psychiatric disorder (excluding dementia), either over the previous year or over the entire lifetime of the individuals, was considerably lower among older compared to younger adults. This decrease in the prevalence of mental illness with aging was thought to be due, in part, to higher mortality associated with serious mental illnesses. Yet, an important explanation for this ECA finding could be that psychiatric disorders were underdiagnosed among older adults for a variety of reasons, indicating differences due to a "cohort effect" (i.e., different rates of an illness in people from different generations).

According to the ECA study, 13% of people over age 65 would meet the criteria for psychiatric disorders other than dementia. This is, however, likely to be a serious underestimate because of factors such as misattribution of psychiatric symptoms (by patients, caregivers, and raters) to other causes such as cognitive impairment, physical disorders, or "normal aging"; a lack of age-appropriate diagnostic criteria for major psychiatric disorders including substance abuse or dependence; and underreporting of psychological symptoms due to forgetfulness and social or gender-based stigma. The "real" prevalence of psychiatric disorders other than dementia in older adults is probably at least 25% higher—that is, over 16%. In addition, over 10% of older adults have dementia, usually of the Alzheimer type; neuropsychiatric behavioral disturbances are common in patients with dementia, with at least a third of them (i.e., about 3% of the total older adult population) exhibiting psychotic and/or depressive symptoms. Thus, a total of nearly 20% of persons over age 65 would have diagnosable psychopathological symptoms.

Figure 55.1a–2 shows the prevalence of mental illnesses among younger and older (>50 years) adults. While the overall prevalence of mental illness among young adults has increased in recent years, it has remained relatively stable among older adults. Mood disorders, anxiety disorders, substance use disorders, and personality disorders tend to decrease in prevalence as age increases. However, there may be sex differences between the octogenarian and nonagenarian years of life. Older men who survive to age 85 years or older have a higher prevalence of mood disorders (e.g., major depression, dysthymia), posttraumatic stress disorder, and other anxiety disorders (e.g., panic disorder, specific

phobias, generalized anxiety disorder) than older men aged 65 to 74 and 75 to 84.

Furthermore, psychiatric symptoms that do not meet the traditional criteria for psychiatric disorders (that had been developed for use in younger adults) but are nonetheless quite disabling are much more common in older adults than the ECA study suggests. For example, a diagnosis of major depression requires the presence of at least five symptoms from a list of nine symptoms included in the DSM-5. If a person has four of those symptoms, they would not meet the criteria for major depression but may still be quite disabled. Such subsyndromal depression is much more common than major depression in older adults, yet the patient may not receive the necessary therapeutic attention because the patient was not diagnosed with major depression.

There is expected to be a disproportionately greater increase in the numbers of mentally ill older adults than that of the overall older population. There are several reasons for this demographic change. Excess mortality (from suicide, nonintentional injuries, or physical comorbidity) in early life among seriously mentally ill patients such as those with schizophrenia, bipolar disorder, unipolar depression, and substance dependence is likely an important reason for a lower prevalence of nondementia psychiatric disorders in older compared with younger adults. With an improved overall standard of living, better treatment for physical disorders, and more effective treatments for psychiatric illnesses, the high mortality in mentally ill young adults should begin to decrease, resulting in a greater number of those who will reach old age. Unfortunately, this scenario has not materialized yet. As a matter of fact, the longevity gap between people with schizophrenia (and other serious mental illnesses) and the general population has increased in recent decades. The likely reason is that persons with mental illnesses have not been able to benefit from the health and medical advances that have led to increased longevity in the community at large. Also, with the general increase in the numbers of people older than 65 years, there will be more older adults in the community at risk of developing late-onset psychiatric disorders. Furthermore, aging baby boomers are expected to have a higher risk of depression, anxiety disorders, and substance use disorders than those born before World War II. For all these reasons, it is estimated that the number of older mentally ill adults in the population will increase by at least 10% from 2000 to 2030—that is, it will be about 22%. Thus, the numbers of psychiatrically ill older adults will rise by 275%—from 4 million in 1970 to 15 million in 2030, while comparable numbers for those aged 30 to 44 years will increase by only 67%—from over 9 million to 15 million. These estimates are educated crude guesses; nonetheless, they provide some understanding of the magnitude of the challenge facing psychiatry.

It is also to be noted that not only will the numbers of older adults with mental illness increase dramatically over the next few decades, but also the types of patients we see will change to some extent. For several disorders, there will be higher proportions of patients at the two ends of the severity spectrum. For example, expected advances in the ability to detect Alzheimer disease (AD) in earlier stages and to decrease the rate of decline via the use of effective neuroprotective agents may result in greater numbers of patients who are more mildly affected and who will present different management problems from patients with advanced dementia. Issues regarding employment, financial planning, driving, home care, and daycare will become more prominent. At the same time, reduced mortality from severe forms of physical illness (e.g., strokes, heart disease) will lead to increased numbers of severely demented patients with comorbid medical conditions living longer, raising different clinical, research, and ethical issues.

GERIATRIC PSYCHIATRY AS A SUBSPECIALTY

There are unique diagnostic and therapeutic considerations in the management of older adults with mental illnesses. Just as children are not small adults, older adults are not merely chronologically more aged people. There are important bio-psycho-social differences that have an impact on the diagnosis, course, and treatment of mental (and physical) illnesses in different age groups. Because of age-related changes in the functioning of the liver, kidneys and brain, older people may only tolerate lower doses of most medications and are at a greater risk of developing a number of side effects. They also have special needs for psychosocial treatments (e.g., they are less likely to be living with their families and more likely to have financial difficulties). Additionally, they may have major physical illnesses and disabilities, visual and hearing impairments, and even less access to health care than younger adults (e.g., due to transportation issues and financial limitations). As a result, fewer than half of older Americans with mental illness receive the needed mental health services. They face the dual stigma of mental illness and aging. These problems are further compounded by therapeutic pessimism (and even nihilism) fostered by rampant societal as well as professional ageism.

FIGURE 55.1a–2. Prevalence of psychiatric disorders over time by age. Note: Any mental illness (AMI) is defined as a mental, behavioral, or emotional disorder. AMI can vary in impact, ranging from no impairment to mild, moderate, and even severe impairment (e.g., individuals with serious mental illness as defined below). Serious mental illness (SMI) is defined as a mental, behavioral, or emotional disorder resulting in serious functional impairment, which substantially interferes with or limits one or more major life activities. The burden of mental illnesses is particularly concentrated among those who experience disability due to SMI. (From Substance Abuse and Mental Health Services Administration. Key substance use and mental health indicators in the United States: Results from the 2019 National Survey on Drug Use and Health [HHS Publication No. PEP20-07-01-001]. Center for Behavioral Health Statistics and Quality, Substance Abuse and Mental Health Services Administration; 2020. https://www.samhsa.gov/data/sites/default/files/reports/rpt29393/2019NSDUHFFRPDFWHTML/2019NSDUHFFR1PDFW090120.pdf)

Old-age psychiatry has had a long and distinguished tradition in the United Kingdom and other countries in Europe. In recent years, it has started to come of age in the United States too. Geriatric psychiatry became the second subspecialty of psychiatry (after child psychiatry) recognized by the U.S. Accreditation Council for Graduate Medical Education and by the American Board of Psychiatry and Neurology. There are several geriatric psychiatry organizations, such as the American Association for Geriatric Psychiatry and the International Psychogeriatric Association. There are also several peer-reviewed journals devoted to geriatric psychiatry, including Aging & Mental Health, the American Journal of Geriatric Psychiatry, the International Psychogeriatrics, the International Journal of Geriatric Psychiatry, the Journal of Geriatric Psychiatry and Neurology, Psychogeriatrics, and Psychology & Aging. In basic sciences, there is a growing interest in the molecular biology of aging and the neuroplasticity of aging.

Table 55.1a–7.
Overview of the Education and Training of Professionals in Geriatrics in the United States

Discipline	Progress
Geriatricians	Geriatricians are doctors that specialize in older adults. As of 2016, the number of geriatricians with up-to-date certifications had remained flat at 7,000 for the past 10 years. Approximately 300 geriatricians are trained each year, and many fellowship positions are not filled.
Geriatric Psychiatrists	There were less than 2,000 certified geriatric psychiatrists, and many fellowship positions remain unfilled each year.
Gerontology Advanced Practice Registered Nurses (APRN, NP, and CNS)	In 2013, the certification in gerontology for NPs and CNS was phased out and combined with adult primary and acute care certifications. In turn, the number of adult-gerontology certified APRNs significantly increased to 12,000.
Registered Nurses Certified in Gerontology	From 2013 to 2014, the number of RNs certified in gerontology increased by 1.7%. In 2014, 7,874 RNs were certified out of 3.1 million RNs nationwide.
Gerontologic Social Workers	There is no certification in gerontology for social workers. In 2009, 1,318 individuals in a Master of Social Work program specialized in aging.
Certified Geriatric Pharmacists	Between 2010 and 2015, the number of pharmacists certified in geriatrics increased from 1,210 to 2,158 (a 78% increase).
Geropsychology	In 2010, the American Psychological Association recognized professional geropsychology as a special area of psychology and started accrediting a geropsychology postdoctoral program. In 2014, the American Board of

	Professional Psychology added geropsychology as a boarded specialty.
Geriatric Physical Therapy	Between 2010 and 2015, the number of physical therapists certified in geriatrics increased from 1,006 to 1,936 (a 92% increase). The number of residency programs expanded from 6 to 13.
Gerontology-Certified Occupational Therapists	As of 2015, there were only 18 occupational therapists certified in gerontology.

Reprinted from Substance Abuse and Mental Health Services Administration. Older adults living with serious mental illness: the state of the behavioral health workforce. 2019. https://store.samhsa.gov/sites/default/files/d7/priv/pep19-olderadults-smi.pdf; originally adapted from Warshaw GA, Bragg EJ. The essential components of quality geriatric care. *Generations*. 2016;40(1):28–37.

Unfortunately, the increasing need for a geriatric mental health workforce is being met with a diminishing availability of experts in the field. There is a severe shortage of workforce trained to provide the necessary mental and physical health care for the growing numbers of older adults (Table 55.1a–7). Despite an urgent need for a trained workforce with expertise in geriatric mental disorders, the number of American Board-certified geriatric psychiatrists, who have maintained their subspecialty certification, has dropped from over 2,200 a decade ago to fewer than 1,800 today. This number is projected to decrease further to 1,650 by the year 2030, amounting to less than one geriatric psychiatrist for every 6,000 older adults with mental health and substance use disorders. Out of more than 40,000 psychiatrists in the United States, only about 5,000 list “geriatric or gerontologic psychiatry” as one of their three primary areas of interest.

The Health Resources and Services Administration (HRSA) and the Substance Abuse and Mental Health Services Administration (SAMHSA) have reported that we have passed the “tipping point” of an inevitable shortfall in geriatrics-trained providers and highlighted the urgency of expanding and strengthening the geriatrics health care workforce. Yet, little is being done to address this challenge. Already geriatric psychiatric services are in high demand, and specialists are in short supply. The trainee pool is a critical issue. Currently, there are over 100 geriatric

psychiatry fellowship training slots available nationwide, but the number of slots filled has declined from more than 80% in 2000 to under 50% today. Psychiatry residents, often struggling with large student loans, are drawn away from geriatric psychiatric fellowship, at least partly because of financial concerns. Rates of Medicare reimbursement are decreasing, and the reimbursement system as a whole makes psychiatric care difficult to access for older patients. The dual stigma against aging and mental illness also makes geriatric psychiatry less attractive to many trainees.

COMMON MENTAL ILLNESSES IN OLDER PEOPLE

A brief description of a few of the mental disorders of late life is provided below. A detailed description of each illness, its causes, and treatments are provided in subsequent chapters of the book.

Alzheimer Disease (AD) and Other Dementias

AD is the most common form of dementia. It is a progressive brain disorder that results in cognitive deficits such as memory loss, impaired thinking, and abnormal behavior. The number of older persons with AD will increase substantially over the next three decades for several reasons. The prevalence of dementia doubles every 5 years after the age of 60. Thus, 1% of the people aged 60 to 64 years are affected; 2% of those aged 65 to 69, 4% of those between 70 and 74, 8% of those 75 to 79 years old, 16% of those aged 80 to 84, and 30% to 45% of those age 85 years and older. These figures provide a reasonable guide to the number of patients with AD and other dementias anticipated over the next three decades. From a different perspective, one of the “hottest” areas of research is developing drugs that delay the progression of brain degeneration in patients with dementia. AD and other dementias are seriously under-recognized at present. In various studies, investigators have found that primary care practitioners recognize only a minority of the AD patients identified by researchers using a structured diagnostic interview. We can expect greater awareness of the need for early detection of AD among professionals as well as among the lay public. Currently, many researchers are working on developing biologic markers to detect early AD. Reliable and valid biologic markers will diminish the present dependence on clinical (largely subjective) judgment in diagnosing early AD and enhance the rate of detection of AD even before

obvious dementia has set in. Furthermore, as new therapies for the treatment of very early AD (even before dementia is obvious) become available in the coming years, improved recognition of patients before they manifest the disease clinically will increase the number of identified cases in the population.

Interestingly, there are also factors that could serve to reduce the incidence of AD in future cohorts of aged individuals. One such factor is education. The prevalence of AD is lower among those with more years of formal education or greater "cognitive reserve." There will be greater numbers of older baby boomers with a high school diploma compared to the current cohort of older adults. Education also has a variety of secondary effects that may reduce the frequency of dementia. For example, head injury has been identified in several studies as a risk factor for AD, and head trauma is less common among those with more education who are more likely to wear safety belts, use protective headgear in contact sports, and avoid driving while intoxicated. Such factors associated with a reduced risk of AD point to the way in which we may be able to lower the incidence of AD by proactive societal actions.

Neuropsychiatric behavioral disturbances such as agitation, psychosis, and depression are common in patients with AD and are frequent causes of institutionalization. About a third of the patients with AD have depressive symptoms, whereas the prevalence of psychosis is about 50%. Agitation is even more frequent, especially in later stages. A number of intervention studies of pharmacologic as well as psychosocial treatments have been performed for these neuropsychiatric symptoms, with variable results.

Dementias other than AD, such as Lewy body dementia, frontotemporal dementia, and vascular dementia, are also receiving increasing attention, mainly in the areas of brain imaging and neuropathology. Again, behavioral disturbances and psychotic symptoms are common phenomena in these patients.

Anxiety Disorders

Anxiety disorders are the most common disorders among older adults, with the exception of dementia. There are a number of differences between younger versus older adults in terms of the psychopathology of these disorders. For example, older phobic patients tend to have a fear of situations or inanimate stimuli, such as heights or lightning, whereas

younger individuals are more likely to have a fear of animals. Because of physical and psychosocial changes associated with aging, it might be difficult to distinguish between phobias or agoraphobia and nonpathologic avoidance behaviors in older patients, such as avoiding leaving home due to arthritis or fear of crime. Older adults might be more likely than younger patients to manifest a mixture of anxiety and depression. Such comorbidity could be a result of the cooccurrence of two common conditions or could reflect one being an epiphenomenon or a complication of the other. A syndrome of “mixed anxiety– depressive disorder” might have both heuristic and clinical utility for older patients.

Depression

Numerous studies have shown that depression goes undiagnosed in sizable proportions of older adults. This is due, in part, to frequent denial of depression with its associated social stigma and attributing the symptoms of depression to “normal” aging or to physical illnesses. In the past three decades, some SSRIs have become nearly household names, leading to more recognition and acceptance of depression in the public at large. This trend will continue, resulting in reduced social stigma associated with depression. Another important reason for the underdiagnosis of depression in the primary care setting, where most older persons are seen, is the inadequacy of geriatric mental health training at the medical school level. With improvements in medical education, this situation will change in the years to come, resulting in greater detection of depression in older adults.

Major depression manifests somewhat differently in older compared to young adults. Physical symptoms such as a change in appetite and body weight, constipation, and sexual dysfunction are more common in older adults; on the other hand, the physical symptoms in older adults could be a result of an undiagnosed physical illness (e.g., pancreatic cancer). While the point prevalence of subsyndromal depression in younger adults is comparable to or lower than that of major depression, the prevalence of subsyndromal depression (18%) is three times that of major depression (6%) in people aged 65 years or older. Thus, the predominant form of depression in older adults appears to be subsyndromal depression. Notably, subsyndromal depression is also associated with significant increases in psychosocial impairment in major domains of everyday functioning.

A number of large epidemiologic investigations in several different countries have shown that the risk of depression, as well as depression-related suicides, alcoholism, and substance abuse, is significantly higher in the baby boomers than in those born before World War II. The reasons for this type of "cohort effect" are not known but could be related to several different factors: Genetic factors such as new mutations among recent generations. A number of environmental factors may also contribute to greater stress and increased risk of depression among the baby boomers; these include changing family structure with nuclear families, higher divorce rates, changing roles for working women, greater urbanization, and a decrease in "social connectedness" due to geographic mobility and job changes. Detection of depression in older age has likely increased due to improved psychometric tests, the development of the DSM, and reduced societal stigma around seeking treatment for mental illness. Finally, depression is known to be much more common among those with physical illnesses than in physically healthy people. This observation leads to the development of preventive interventions in individuals with physical disorders such as heart disease and cancer.

Schizophrenia and Other Psychotic Disorders

The century-old concept of schizophrenia, based on Kraepelin's definition of dementia praecox, is that this is a disorder with onset in early life—that is, adolescence and early adulthood ("praecox") and progressive deterioration ("dementia"). Yet studies in older patients show that schizophrenia can have onset in middle age (late-onset schizophrenia). Late-onset schizophrenia is more common in women and is usually of the paranoid type but may present initially as brief psychotic disorder or delusional disorder. In terms of its course in late life, schizophrenia is typically not associated with a dementing course. Indeed, a small minority of patients with schizophrenia have a sustained remission of their illness in old age.

Psychotic symptoms may manifest for the first time after age 65. This is generally not schizophrenia but is best labeled as very late-onset schizophrenia-like psychosis.

Substance Use Disorders

As better treatments become available for substance use disorders (including alcoholism), the focus on the war on drugs during the coming

decades will shift from punishment to treatment. Studies using currently available diagnostic criteria for substance abuse have underestimated the prevalence of drug abuse in older adults because these criteria were developed and validated only in young and middle-aged samples. For example, DSM-5 criteria for substance use disorders include the development of tolerance to the effects of that substance (e.g., a given amount of a stimulant produces less stimulation than it used to), resulting in a need for increased consumption over time. Yet, liver and kidney damage common in old age would produce higher concentrations of that substance in the blood, while age-associated brain changes would serve to enhance the effects of the substance on the brain. Hence, there is likely to be decreased tolerance to that substance in an older individual (i.e., a given amount produces more effect than it used to), leading to a need for decreased consumption. This older person, although still dependent on the substance, may not meet the “official” criteria for diagnosis. One DSM-5 criterion for substance use disorders is a report of being repeatedly unable to carry out major obligations at work, school, or home, such as absences or poor work performance, suspensions or expulsions from school, and neglect of children. Such adverse consequences are much less likely to occur in older adults who often live alone and are unemployed or retired, resulting in the underestimation of substance use disorders.

It is generally believed that aging is associated with reductions in and changing patterns of drug use (i.e., reductions in illicit drug use). One theory posits that factors associated with “maturation” associated with aging processes, increased numbers of individuals who have been dependent on illicit drugs would become abstinent as they age. This is, however, not entirely supported by empirical data, which suggest that there may be increasing numbers of older addicts and that persons who have been dependent for more than 5 years do not become abstinent as they age. An alternative theory posits that those with the most severe substance use behaviors would die prematurely and, therefore, never reach old age. In addition to increased numbers of aging “life-long” drug abusers, we are also likely to see greater numbers of individuals who, after decades of abstinence, return to drug or alcohol problems. Psychosocial stressors, including isolation, various types of losses, loneliness, and the onset of illness, have been related to late-onset drug use.

There is greater use and acceptance of psychotropic medications among the baby boomers than among those born before World War II. In contrast to younger substance abusers who most often abuse illicit drugs, substance abuse problems in older adults may result from misuse or abuse of over-the-counter (OTC) and/or prescription drugs. Older individuals use prescription drugs three times as frequently as the general population, and the use of OTC medications by this group is even more extensive. The estimated expenditure on prescription drugs by older adults in the United States is $15 billion annually, a fourfold greater per capita expenditure on medications compared to younger individuals. Psychoactive drug use (most often sedative-hypnotic, anti-anxiety, and analgesic) is particularly problematic, including long-acting drugs not recommended for older adults and especially those at risk of falls and inappropriately high doses of benzodiazepines.

Comorbid physical, as well as psychiatric disorders appear to be important predictors of prescription drug use. As greater numbers of people with chronic physical and psychiatric disorders survive into older age, there will be an increased prevalence of substance use disorders in the older population. Moreover, the deceptive marketing and overprescription of narcotics (e.g., Dilaudid, fentanyl, methadone, Oxycontin, oxycodone) for chronic pain have led to a drastic increase in their use and abuse in older adults.

The jury is still out whether the legalization of marijuana for medical use or adult recreational use in a growing number of states may negatively affect the health of older adults. Marijuana is the most commonly abused drug in the United States and around the world, but it is likely that by legalizing marijuana, the number of marijuana users would increase.

POSITIVE SIDE OF AGING

Contrary to the concept that aging is synonymous with progressive and inevitable deterioration of the brain and mind, a number of recent studies across the world show that psychological well-being and happiness increase with age, especially after middle age. Some studies have found that subjective feeling of well-being (a sense of contentedness) is high at the beginning of our adult life, then declines progressively until it hits rock bottom in middle age, producing the so-called mid-life crisis, but then starts to rise again. Other investigations report a progressive rise in well-

being from age 20 to 80+. Interestingly, the level of happiness in the early 80s is similar to that in the early 20s. The increase in happiness after middle age occurs even as physical, cognitive, and fertility functions decline. This finding has been reported by researchers from several different countries and cultures. Notably, perfect physical health is neither necessary nor sufficient to feel happy as we grow older. Research shows a paradox of aging: physical health and some aspects of cognitive function (for instance, memory for names and faces) decline with age, while happiness, mental health, and management of interpersonal relationships improve.

What are the possible explanations for this counterintuitive result? Suggested factors include changes in attitude such as greater acceptance of one's physical limitations, contentedness with past accomplishments in life, reduced preoccupation with peer pressure, a more realistic appraisal of one's own strengths and limitations, and increased emotional stability. Intriguingly, a recent study, based on the reports by the individual caretakers of chimpanzees and orangutans in zoos and other protected areas, found an increase in these great apes' well-being after middle age. Thus, better well-being in older age might be rooted, in part, in biologic changes in the brain.

Several aspects of aging can be aided significantly by improved health care, the greater societal value placed on older adults, and a more positive conceptualization of old age. Most psychiatrists today would not agree with Freud's assertion in 1924 that near or above the age of 50, the elasticity of mental processes is lacking, and, therefore, older individuals are "no longer educable." The so-called problems of aging should become opportunities for a better understanding and improvement of the entire life process.

The aging of the population is generally viewed with concern and alarm about its impact on social security, healthcare (including Medicare), housing, jobs for younger generations, etc. Yet, this is also a grand opportunity to make positive use of the growing older adult population so that the new era, dubbed inappropriately by some as "Silver Tsunami," can be labeled the "Golden Wave." The most important advance in neuroscience in the past two decades has been the demonstration of neuroplasticity of aging—the fact that brain growth and development continue into old age. Furthermore, such a positive outcome is related not so much to the genes we inherit from our parents but to our behavior,

attitude, and environment. With appropriate physical activities, targeted nutrition, and psychosocial stimulation along with necessary healthcare and social support, successful aging need not be a dream but can become a widespread reality. As the quality of life of older adults improves, they become more productive and contribute more to the rest of society, and their healthcare costs go down. The seniors who learn and teach can be wonderful and wise mentors for younger generations. Older citizens can lead efforts at social entrepreneurship in a collaborative manner.

One of the positive traits that have received increasing attention in recent years is wisdom. Wisdom is comprised of several specific components—*viz*., prosocial behaviors (empathy and compassion), emotional regulation, self-reflection, acceptance of diverse perspectives, decisiveness, and possibly, spirituality. Research has also shown a neurobiologic basis of wisdom, mainly involving the prefrontal cortex and limbic striatum. A number of studies have found higher levels of several components of wisdom in older compared to younger adults. Investigations have also demonstrated that intergenerational activities are useful for both generations. A meta-analysis of 57 randomized controlled trials reported that about half of these trials resulted in significant improvement in a component of wisdom, such as empathy and compassion, emotional regulation, and spirituality, with moderate to large effect sizes. Importantly, wisdom is associated with greater well-being, happiness, resilience, and better health. Recent research has shown an opposite relationship between loneliness and wisdom, especially its compassion component. Whereas loneliness is associated with worse physical, mental, and cognitive functioning, the reverse is true for wisdom and compassion. Thus, wisdom-enhancing interventions can potentially curtail loneliness in older adults and thus contribute to better health and, perhaps, greater longevity.

SUCCESSFUL COGNITIVE AND EMOTIONAL AGING

Research on aging has typically focused on disease and disability. However, during the past two decades, this focus has slowly begun to expand to incorporate studies of “successful or healthy aging.” Understanding why some people seem to adapt to challenges they encounter in late life when others cannot facilitate the development of

interventions and policies geared toward older populations. Yet, there are many times as many studies of aging-related disorders as there are on successful aging. One problem in research on successful aging is that it involves multiple components (e.g., physical health, psychological well-being) that extend beyond longevity, and as a result, there are numerous criteria for defining it but no consensus. In 1987, Rowe and Kahn proposed that successful aging involved three components: (1) absence/low probability of disease and disease-related disability, (2) high cognitive and physical functioning, and (3) active engagement with life. According to this model, however, many cognitively intact and socially active older adults would not be categorized as aging successfully because of the presence of chronic physical diseases and disabilities. Also, such criteria fail to take into account the perspectives of older adults themselves about what defines and determines successful aging. Whereas researchers tend to focus on physical health as a critical factor to successful aging, older adults tend to stress the role of psychological factors such as adaptation and acceptance, along with emotional well-being. One focus group study indicated that older adults viewed successful aging as involving a foundation of health and security, along with attitudes and adaptive behaviors that can compensate for difficulties with that foundation and enable engagement in meaningful activity and stimulation. It is particularly noteworthy that a number of aspects of successful aging identified by older adults in this study (e.g., attitude, healthcare, financial security) are potentially modifiable.

Successful aging is a complex and multidetermined trait and state, with numerous genes and environmental factors making small contributions to the overall presentation of the phenotype. No single factor is either necessary or sufficient to determine the outcome in a specific individual. Cognitive preservation may, however, be a prerequisite of independent living, positive adaptation, mastery, and growth, all of which seem to be the major determinants of “success.”

IMPLICATIONS FOR FUTURE PROGRESS

The impending crisis in geriatric mental health with the projections of dramatic increases in the numbers of mentally ill older people as the baby boomers reach old age should be a cause of great concern. However, the good news is that we can do something about this issue. We should begin

by recognizing the fact that the expected increases in the ranks of older mentally ill adults are not necessarily a bad thing. It is better for us to diagnose illnesses that are treatable rather than keeping them from being detected in older adults. Advances in the pharmacologic and psychosocial management of psychiatric disorders over the past two decades have already improved the treatment of several serious mental illnesses in older people. Previously unimaginable advances are taking place in the understanding of brain function in normal aging as well as in various neuropsychiatric disorders. New lines of investigations are pointing to possible ways of not just managing but even possibly curing and preventing several diseases for which there was little hope in the past. Brain stem cell implants, gene therapy, and vaccines for AD (despite the initial disappointing results) are among a host of therapies that are moving from the realm of science fiction to reality in a matter of years instead of decades. Early diagnosis of disorders such as depression or AD is important in order to start treatments that will prevent or at least slow their progress. Similarly, it is better that young adults with schizophrenia who currently have a shorter life span than the general population live into old age. Hence, an increase in the numbers of older adults with mental illnesses will be, in part, a welcome development.

At the same time, some of the increased prevalence of mental illness in older people may be preventable. For example, a proportion of cases of late-onset depression or substance use disorders could be prevented by appropriately treating individuals at high risk of developing these disorders. Thus, support groups for bereaved persons could lower the risk of developing major depression. Similarly, persons with stroke or myocardial infarction are at a high risk of depression, and the incidence of poststroke and postmyocardial infarction depression could be reduced with the use of suitable antidepressant treatments and/or psychosocial interventions following strokes or heart attacks. There are now emerging neurobiologic data suggesting that physical exercise may be as beneficial for the brain as for the body. Research also needs to be conducted to determine if engaging in specific types of mental activities may lead to the delayed onset of dementia.

The less developed regions of the world will undergo proportionately larger demographic shifts in the decades ahead than the more developed ones that have had a stable population base for many years. Yet, the less developed nations also have fragile economies and will have limited

opportunities to increase health services and treatment for aged individuals. This global situation places a premium on developing diagnostic technologies and treatments that are sufficiently inexpensive and can be widely applied.

Reducing the social stigma associated with aging is as critical as reducing the social stigma associated with mental illness. Mental illnesses are brain disorders and, as such, should receive the same consideration in terms of insurance coverage.

We can change the age-old stereotype that late life is a gray and dark period of life and try to make it a “golden” one for our senior citizens. There are several aspects of aging that can be aided significantly by improved healthcare. If the societal value placed on the older population becomes more positive and the scientific openness to conceptualizing old age increases, it will become clear that the so-called problems of aging are actually opportunities for a better understanding and improvement of the whole life process. To quote Alex Comfort, “No pill or regime known, or likely, could transform the latter years of life as fully as could a change in our vision of age and a militancy in attaining that change.” The same applies to our attitude toward mental health and mental illness in old age.

55.2 Assessment

55.2a Psychiatric Assessment of the Older Patient

Davangere P. Devanand, M.D., and Andrea Delgado-Peraza, M.D.

In the older adults, there is an interplay between biologic, psychological, and social issues in the presentation of mental illness. Therefore, a thorough evaluation, including an assessment of the patient's internal and external environment, is necessary for accurate diagnosis and treatment. In neuropsychiatric disorders, localization of signs and symptoms to specific brain regions should also be attempted to improve understanding of the patient's condition and facilitate clinical management.

The advent of a variety of brain imaging techniques, genetic testing, and other developments have helped enhance diagnostic assessment, but these approaches are not adequate substitutes for comprehensive history taking and clinical assessment of older patients. Structured and semi-structured interviews and rating scales can be used to supplement the diagnostic interview process.

Input is often required from the family and significant others. Collateral information becomes essential in most cases as some older adult patients can minimize symptoms, partly because of fear of losing independence or becoming a burden to their families. Another factor can be shame about developing psychiatric problems, especially in those who never previously

suffered from mental disorders, which is related to the broader issue of stigmatization of mental illness. When evaluating a patient for possible dementia diagnosis, it is critical to involve a reliable informant as patients with dementia may have difficulty providing history due to language problems, memory loss, or anosognosia (lack of insight).

In older adult patients, the fear of aging and its effects are common. They often state that since they are getting old, their symptoms, for example, depression or cognitive impairment, are normal and to be expected. In such a patient, it is useful to point out that among people in their own age group, only a small minority has their specific condition and that most people function well. The evaluation should aim at obtaining a comprehensive assessment of the patient's mental and physical state. The historical background and values of the older adult patient within a social class and culture, and occupational background influence the perception and presentation of illness and disease.

HISTORY TAKING

The principles in gathering history are similar to those in adults generally: establish rapport, make the patient comfortable, and maintain privacy and confidentiality. Older people have lived a long time, have undergone many stresses, are resilient, and expect to be treated with respect. The older adult patient expects direct inquiry and examination. Hand contact and reaching out and touching the patient are often useful in establishing rapport. A medical approach is often expected and respected by the older patient. This is important even in the age of telehealth that has been amplified by the COVID pandemic.

The psychiatrist needs to take an active role and involve the family and significant others whenever feasible. The psychiatrist should clearly explain the nature and purpose of the evaluation and inquire about the patient's complaints and the patient's and family's goals for the evaluation. The patient's limitations may require modification in the interview technique. In a patient with hearing impairment, the psychiatrist may need to move close to the patient's good ear and speak slowly, loudly, and clearly. If necessary, conducting the interview by writing questions for the patient to read could be done to obtain the essential information. Cognitively impaired patients may find it very stressful to perform cognitive tasks in the mental status examination and may refuse to complete the

tests. It is important to explain the nature and purpose of the cognitive tests before administering them, and frequent breaks between tests can help the patient complete the cognitive assessment.

Details about medical illnesses and medications taken are important in older adult patients. Information from other physicians, hospitals, and therapists should be obtained whenever needed to supplement the evaluation. Getting a complete medication list is imperative as older adult patients tend to have polypharmacy, and occasionally cognitive symptoms can improve when inappropriate medications are discontinued. If medication nonadherence occurs, simple techniques like introducing pillboxes are often useful. In severely impaired patients, particularly patients with dementia, information from caregivers and professionals involved in social support and related services is important. Most older adult patients first see their primary care physician for their psychiatric symptoms, and this is the setting where the majority of them are treated. Therefore, primary care physicians may refer their patients to a psychiatrist if diagnosis and management become difficult.

The history should include the following components: identifying data (name, age, sex, education, marital status), chief complaint, history of present illness including onset, duration and symptom course over time, past psychiatric history, medical history and medications are taken, alcohol and substance use history, work history and living situation, and family history of psychiatric, neurologic and other medical disorders.

The initial evaluation session may be long in an older patient, especially if extensive information from collateral sources needs to be obtained, which may be necessary to confirm the information provided by the patient and evaluate reliability. Further, a second visit may be necessary to provide enough time to gather all the additional information from the results of all the tests and procedures conducted with the goal of making an informed diagnosis. In a patient with cognitive decline, laboratory tests to identify potential causes (e.g., syphilis, vitamin B12 deficiency, folate deficiency, hypothyroidism, medication toxicity) of cognitive impairment, and neuropsychological testing and structural/functional brain imaging procedures (CT or MRI, SPECT or PET) may need to be ordered at the first visit. In these cases, the second visit becomes an informing visit at which the patient and family receive an opinion about the diagnosis and likely prognosis. Some diagnostically puzzling cases may need more visits and follow-ups to help clarify the patient's condition. In particular, the

psychiatrist needs to keep an open mind about the possibility that the initial diagnosis may need to be revised based on the patient's clinical course and response to treatment, for example, change in cognitive status after initiation or withdrawal of medications that have an adverse impact on cognition, including benzodiazepines and medications with anticholinergic properties.

History of Present Illness

The patient should be encouraged to describe the history of the current illness in an open-ended interview. The chief complaint might provide additional information as to whether that patient came of their own volition or was forced to come by a family member, with more structured questions following this initial inquiry. The onset and course of symptoms should be evaluated in relation to other changes, including loss of loved ones, retirement, loneliness or isolation, relation to daily activities, medication usage, response to treatment if applicable, and intercurrent medical illnesses. Many older adult patients consider insomnia and fatigue to be a normal part of the aging process, and these impairments may require explicit inquiry. The time course of development of the present illness is very important in older adult patients. In a patient with cognitive decline, a history of gradual deterioration suggests dementia, episodic cognitive deficits with confusion suggest delirium, focal neurologic symptoms or signs suggest cerebrovascular disease, and a short, downhill course may indicate rapidly progressive dementia like Creutzfeldt–Jakob disease.

Ascertaining age and age at onset of symptoms is critical in the older adult patient. There is considerable evidence that patients with late-onset (onset after 50 to 60 years of age) major depression are less likely to have a positive family history of affective disorder and more likely to have evidence of cerebrovascular disease and cerebral atrophy than older adult patients with early-onset depressive illness. Late-onset schizophrenia differs in some respects from early-onset schizophrenia, with a greater preponderance of females, paranoid subtype, and some differences in neuropsychological test profiles. Patients with early-onset Alzheimer disease (onset in the 40s or 50s) typically have presenilin I or presenilin II gene mutations, whereas late-onset Alzheimer's patients usually do not have these gene mutations though a large proportion may have the

apolipoprotein E e4 genotype that increases risk and some have a positive family history of Alzheimer disease.

Based on the clinical presentation, the inquiry should focus on pertinent symptoms to make a diagnosis of major depression or psychosis or anxiety disorder or other primary psychiatric disorder. Potentially serious symptoms that should be reviewed with the patient include depressed mood, suicidal thoughts, lack of interest, agitation/aggression and impulsivity, delusions, hallucinations, and an assessment of functioning, including ADLs and social functioning.

Insomnia is common in the older adults. During the aging process, there is a small, gradual decline in the number of hours slept per night. Therefore, any change in sleep pattern that occurs over a short period of time should alert the psychiatrist to the presence of an underlying psychiatric disorder, most commonly a depressive illness. Some patients may downplay insomnia, anorexia, and lack of interest as normal features of the aging process, but this constellation of symptoms should trigger a thorough evaluation for the presence of a depressive disorder. Insomnia, apathy, and anhedonia also occur in early dementia, and the presence of these symptoms should lead to a systematic assessment of cognitive abilities. A gradual decrease in libido and sexual functioning occurs in some older adults, but a rapid deterioration in sexual interest should trigger an investigation into the underlying cause. Diabetes, hypertension, and the iatrogenic effects of medication are common causes of sexual dysfunction, but so is depression. Somatization is typical of older adult depressed patients, but there are cultural differences in the degree to which this occurs.

Older adults face a variety of stresses: medical illnesses, physical disability, sensory impairments in vision and hearing, loss of family and friends, loss of social supports, changes in relationships with children and significant others, alterations in living situation, and loss of income. One or more of these factors may be related to the onset of the clinical syndrome. Although many psychiatric disorders are biologically driven, psychosocial precipitants play an important role in causing or exacerbating psychiatric disorders. The death of a spouse is extremely stressful, as is the death of an adult child. Patients with major depression perceive the significantly greater negative emotional impact of the same life events than patients with dysthymic disorder and healthy controls, particularly for interpersonal conflicts.

In the older adults, there is a high rate of delirium after admission to a hospital. This may be related to the lower “cognitive reserve” of older compared to young adults. If there is a suspicion of delirium, potential risk factors should be evaluated, including fever, urinary tract infection, urinary retention, fecal impaction, changes in medications or dehydration.

The following symptoms need to be asked of patients with cognitive decline: difficulties in memory or thinking or concentration, forgetting of recent events, forgetting where things are located, forgetting to take medications or keep appointments, problems in finding the right word to say, getting lost in familiar places, making mistakes with commonly used gadgets that include cell phones and kitchen equipment, and difficulty in managing finances like balancing the checkbook or paying for items in a store. These symptoms may be the first indicators of dementia. However, the isolated symptom of forgetting names is common during the normal aging process and by itself is not indicative of dementia.

A specific inquiry should also be made about pain, visual and hearing impairment, and possible drug toxicity. For patients in institutional settings, interpersonal interactions with other residents are important.

Psychiatric History

Evaluation of psychiatric history should include the course of illness and types of treatment, that is, psychotherapy, medications, and ECT, and history of response or lack of response to these treatments. Treatments that worked well before in the patient, or worked well in family members, should be given priority.

History of depression, anxiety disorders, and psychosis/schizophrenia, and treatments received in prior and current episodes, should be obtained. Personality disorders are less common in older adults depressed patients compared to young adults with depression. Obsessive-compulsive and avoidant personality subtypes are more common than borderline, histrionic, narcissistic and antisocial personality disorders in older adults. Leading questions should be asked about alcohol or substance abuse, history of head trauma, infections like meningitis or encephalitis, stroke, seizure disorder, and other neurologic disorders such as restless leg syndrome or REM sleep behaviors.

Family Interview and History

In the cognitively impaired patient, it is advisable to see the patient alone first as older adults abuse is more prevalent than is reported to the authorities, then the informant (usually a family member) and/or the patient together with the informant. Studies show that 1 in 10 Americans above 60 years old are abused by a family member, which translates to 5 million elders abused per year in the United States. When interviewing both the patient and the family member, assessing the interaction based on verbal and nonverbal communication might provide additional information. The informant interview provides an independent assessment of the patient's environment, for example, the cognitively impaired patient may have allowed the home to become disorganized or left the stove on with adverse consequences. In severe dementia, interviewing the informant (or informants) both separately and in a joint interview with the patient is often necessary. In these patients, impairment in memory and other cognitive functions may be so severe that nearly all the history needs to be obtained from the informant. Even at the stage of mild cognitive impairment, the informant's report of the patient's function has been shown to be a stronger predictor of dementia on follow-up than the patient's self-report of functional ability.

Patients may minimize symptoms in the presence of other people but may be more revealing about symptoms like depressed mood and suicidal ideation when interviewed alone. Paranoid ideation may not be revealed when family members are also present in the room. A joint interview with the patient and family (or another informant) may become necessary if there are conflicts about the patient's habits and behavior that need to be resolved, for example, the patient wants to continue driving after developing dementia. However, the family member's report may not always be accurate. For example, in patients with dementia, there is consistent evidence that the informant's report that the patient is depressed often reflects the informant's own depression rather than the patient's mood state. Studies show that caregivers of older adult patients with dementia are more prone to develop financial, emotional, and physical difficulties and receive treatment with psychotropic medications compared to caregivers of older adult patients without dementia; depression affects 20% to 40% of caregivers.

A genogram is helpful in delineating the familial relationships and the important psychiatric, neurologic, and other medical illnesses in different generations. An inquiry should be made about a family history of

psychiatric hospitalization, unipolar depression or bipolar disorder, schizophrenia, anxiety disorders, alcohol or substance abuse, suicide, Alzheimer disease, stroke, epilepsy, Creutzfeldt–Jakob disease, Huntington disease, Parkinson disease, and other neurologic disorders. Interviewing more than one family member, and preferably more than one generation of family members, improves accuracy regarding family history.

In older adult patients with functional impairment, family and other caregiver support need to be assessed. The time spent by family members, services provided by family members, perception of family support, and tolerance by family members of changes in behavior are elements that need to be assessed and considered in the development of a treatment plan. Services that may be needed include transportation, nursing services, physical therapy, continuous supervision, homemaker, and household services, meal preparation, administrative, legal, and protective services, financial assistance, and coordination of the delivery of services. These issues may be of greater concern to the patient and family than the clinical symptoms and usually require coordination with nurses, case managers and social workers in the health support system for the older patient.

The patient and family usually find the transition to assisted living or nursing home to be very difficult. Guilt, frustration, anger, helplessness, isolation, depression, and demoralization on the part of the caregiver can reduce caregiver effectiveness and adversely impact the patient. This can lead to an accident like falling and fracturing a hip, inappropriate nursing home placement, or, in some instances, elder abuse. It is important to inquire how the caregiver is coping with the stress of having to take care of the patient, and an appropriate referral for the caregiver to seek evaluation and treatment may become necessary.

Personal History

Details should be obtained about the patient's marital status, living situation, educational background, work history, and the nature of relationships that are important to the patient. Premorbid personality does carry into old age, but its impact on illness in the older adults varies considerably. Personality itself may change with aging. This change is believed to be environmentally determined, but it could also be based on changes in neurobiology, for example, catecholaminergic neurons in the locus coeruleus decay markedly with aging and this change may be

related to the relatively low rate of late-onset anxiety disorders in the older adult population. Religion is often important to the older adult patient and needs to be included in the history as it is a protective factor when suicidal thoughts or hopelessness are present.

The interviewer may be embarrassed to ask about the sexual history of the older adult patient, but many older adults do have symptoms of sexual dysfunction and want to talk about it. Inquiry about sexual orientation and sexual dysfunction should cover any history of sexually transmitted diseases, erectile dysfunction (including impotence) in men, and anorgasmia in men and women. Sexual dysfunction can be a side effect of medication, particularly SSRIs and related antidepressants. Diabetes and hypertension are also common culprits.

Medical History

The older adult patient typically suffers from several medical illnesses and takes a large number of medications. Patients may not keep track of all the medicines they are taking, and their list often excludes medications obtained over-the-counter or alternative medications sold in health food stores. Therefore, it is important to inquire about all these categories of medications, and it is a good idea for the psychiatrist to ask the patient to bring all the current medications in a bag to the visit. Benzodiazepines, steroids, and anticholinergics can lead to cognitive impairment and even delirium, L-dopa and dopamine agonists prescribed for Parkinson disease can lead to psychosis, and the use of some antihypertensives and steroids has been associated with depression.

Medical history should cover all major illnesses, surgery, hospitalizations, trauma, and treatments. A variety of medical disorders can first present with disturbances in mood, cognition, or psychotic features, including infections, electrolyte and metabolic imbalances, cardiovascular and cerebrovascular disease. Depression can lead to weight loss and malnutrition. Dietary history is important in this regard; the older adult living alone may not obtain adequate nutrition and develop vitamin and other deficiencies.

Alcohol and Substance Abuse

Alcohol abuse is not uncommon in the older adults, and explicit inquiry is usually necessary to elicit this history. Even when alcohol consumption has been constant in amount for many decades, it can lead to cognitive

decline in susceptible patients as they grow older because of decreased cognitive reserve due to neuronal loss in the brain. Neuropsychiatric complications of alcohol abuse and dependence, now subsumed under alcohol use disorder in DSM-5, include varying degrees of amnesia, Korsakoff syndrome, malnutrition, and intention tremor and ataxia due to cerebellar damage. Other substance use disorders are less common in older adult patients, but some do use marijuana and tobacco regularly. Even with the advent of new hypnotics, benzodiazepine use remains fairly widespread. This is of particular concern in the older adults because benzodiazepines can contribute to excessive sedation, unsteady gait and falls, and cognitive deficits. Patients with chronic pain, particularly back pain, may be dependent on narcotics.

MEDICAL EXAMINATION

If a medical examination has not been conducted recently by the patient's primary care physician, the psychiatrist needs to complete this component or arrange to have it done by another physician. The neurologic examination is particularly important and needs to include evaluation of sensorium, cognition, motor strength and function, gait, sensation, reflexes, extrapyramidal signs, vision, and hearing. Neurologic deficits, endocrine disorders, cardiovascular disease, occult malignancy, and infections are potential causes of cognitive impairment, agitation, depression, and occasionally psychosis. Urinary tract infection, which can occur without fever, is a common underlying cause of cognitive decline and delirium, particularly in the nursing home.

Mental Status Examination

The mental status examination is essential. Serial mental status exams may be necessary, especially if mental functioning fluctuates over time.

Observation of Behavior. The first part of the mental status examination is a general observation of the patient's appearance, personal hygiene, motor activity, any unusual behaviors, speech, attitude toward the examiner, and the presence of hearing and visual aids. Poor hygiene suggests dementia, but commonly the patient with dementia may look well-groomed because of the caregiver's efforts.

In older patients, paranoid delusional thoughts occur not only in schizophrenia and delusional disorder but also in dementia, particularly Alzheimer disease, and during the course of delirium. Apathetic, withdrawn behavior is common in both depression and dementia. Disturbances of motor activity are frequent in older adult patients, and bradykinesia with slow gait is common in the eighth to tenth decades of life. A slow shuffling gait with mask-like facies, resting tremor and rigidity indicate Parkinson disease or extrapyramidal side effects of antipsychotic medication. Older adult patients are particularly prone to the neurologic side effects of antipsychotics. Lip-smacking and involuntary Bucco facial movements suggest tardive dsykinesia in patients with prior antipsychotic exposure, though this has become less common since the advent of second-generation antipsychotics. Impulsive, disinhibited behavior with minimal to mild cognitive impairment may be the first signs of frontotemporal dementia, though increasing apathy is, in fact, more common than disinhibited behavior in frontotemporal dementia.

Language and Thought Disorder. Speech and language are important to assess in older adults. The quality, quantity, and fluency of speech need to be assessed. Speech can be normally responsive, rapid, pressured, loud or emotional, slow, monotonous, lacking spontaneity, or slurred. Aphasia or slurred speech occurs in stroke and in a variety of neurologic disorders. Mutism occurs in the late stages of primary progressive aphasia, dementia from a variety of causes, and amyotrophic lateral sclerosis. Repetitive speech with perseveration on the same topic is common in patients with dementia and tends to be secondary to the loss of recent memory, which is a hallmark of the illness.

The patient should be able to understand and answer questions appropriately and think in abstract terms. The paucity of speech with long latency is characteristic of major depression, particularly the melancholic subtype. Tangentiality and looseness of associations are characteristic of schizophrenia. The patient with Alzheimer disease may display repetition, perseveration, and fragmented ideas. In contrast, patients with subcortical dementias like Huntington or Parkinson disease usually do not show these patterns of thought process.

Thought content abnormalities include preoccupations or obsessions, including preoccupation with health problems in the older adult depressed patient. Delusions can be persecutory, grandiose, somatic, erotic, guilty, or

nihilistic. Hypochondriacal delusions are common in delusional depression, for example, bowels are not working or have been destroyed. Delusional depression in the older adults is associated with a high suicide risk. Bizarre, fixed delusions are common in schizophrenia, but they are rare in dementia where transient persecutory ideas are more common. Distinguishing fact from fiction can be difficult in the older adult patient, who may have had personal effects stolen and may not have a persecutory delusion as the evaluation may suggest.

Perception. Perceptual disorders include hallucinations and illusions. Hallucinations can be simple or complex and organized. Hallucinations can occur in dementia and in patients with hearing or visual deficits. In these patients, it is important to distinguish an illusion, that is, perceptual distortion of a real sensory stimulus, from a hallucination that may indicate more severe psychopathology. Memory loss and disorientation help to identify the problem as being related to dementia. A number of other perceptual abnormalities occur in a variety of neurologic disorders involving damage to specific brain regions. These syndromes include micropsia, which occurs when objects look smaller than their real size, macropsia, which occurs when objects look larger than their real size, visual agnosia, which is the inability to recognize visible objects, prosopagnosia, which is the inability to recognize familiar faces, astereognosis, which is the inability to recognize objects by touch, and autotopagnosia, which is the inability to recognize parts of one's own body.

Mood and Affect. Mood is the subjective and affect the objective emotional state. Many older adult patients describe their mood accurately as depressed or anxious, but some tend to deny and suppress it. For example, an older adult woman who is crying may say that she is not depressed. Somatization is common in older patients, particularly gastrointestinal symptoms like constipation. Some patients are not sure if they are depressed because they have begun to lose interest in activities but do not experience a clear-cut depressed mood. Many of these patients have dysthymia or minor depression. Depression is common in a variety of other neuropsychiatric syndromes, including dementia, stroke, and Parkinson disease. Mania is not common in the older adults but can occur as a primary late-onset mania or secondary to dementia or stroke, or other neurologic insults. Labile affect is believed to be typical of

vascular dementia, but it remains unclear if labile affect is more common in vascular compared to other forms of dementia. Pseudo-bulbar affect is uncontrollable laughing or crying in the absence of the corresponding subjective mood experience and occurs in neurologic disorders like amyotrophic lateral sclerosis and frontotemporal dementia, and less commonly in Alzheimer disease. Medication side effects or toxicity need to be considered as possible etiologies for depression. Of note, late-onset anxiety disorders, including panic disorder, are relatively rare.

Suicidal and Homicidal Ideation. An inquiry should be made about suicidal and homicidal ideation. Suicidal ideation should be probed by first asking whether the patient thinks that life is not worth living. A positive response should lead to follow-up questions about whether there is a suicide plan or history of a suicide attempt. If this line of inquiry indicates suicidal risk, further questions should focus on whether a gun or other means to commit suicide are easily available, and the appropriate clinical intervention with the patient and family members should then be made. Studies consistently show that older adult males, particularly white males, living alone are the demographic group with the highest risk of committing suicide and that they often use guns as the method of suicide. Of note, the majority of patients who commit suicide have visited their primary care physician a few days to weeks before they act. Patients with a new recent diagnosis of dementia may have an increased risk of suicide.

Sleep. Approximately half of older adults complain of sleep difficulties. Careful assessment of sleep habits, including factors such as alcohol and caffeine intake that can disrupt sleep, is important. Other factors contributing to sleep impairment include age-related changes in sleep architecture and circadian rhythms, sleep disorders including sleep apnea, dementia, depression, other medical illness, and polypharmacy. The impact of treatment, or withdrawal of treatment, for example, benzodiazepines, needs to be assessed in the context of these factors that can underlie sleep disorders.

Sensorium and Cognition. Evaluation of sensorium and cognition is critical and essential in older adult patients. Whenever there is suspicion of cognitive impairment by history, it is important to administer a screening test like the Mini Mental State Examination (MMSE) or Montreal Cognitive Assessment (MOCA). Both are adversely affected by low educational

attainment, particularly the MOCA, and this fact should be taken into account during the assessment.

At the start of this portion of the exam, the patient should be told that some of the questions are easy and some more difficult and that people score across a wide range on these tests. This instruction is important because patients with significant cognitive deficits may not agree to complete the test if they feel that they are taking an examination and that their deficits are being judged critically. Skills that can be tested in this component of the evaluation can be assessed more thoroughly by detailed neuropsychological testing, including tests of attention and concentration, learning, recall, recognition after a delay (memory), comprehension, verbal fluency, repetition, naming (language), visuospatial abilities, calculation, praxis, and the executive functions of initiation, perseveration, response control, synthesis and integration, and changing mental sets (frontal lobe functions).

A patient needs to be able to focus and be attentive in order to complete the tests. If a patient is distractible and unable to concentrate, the subsequent components of the test may not be valid. Educational achievement and the patient's primary language are important variables to consider in the interpretation of cognitive tests. A patient with low education or a patient for whom English is not the primary language is likely to score poorly on some components of the cognitive assessment, but memory is affected less by these factors. Therefore, a patient with low education who scores 25/30 on the MMSE but recalls 3/3 objects at 5 minutes is less likely to be developing dementia than a patient with a post-graduate degree who scores 28/30 on the MMSE but recalls only 1/3 objects at 5 minutes.

Cognitive Testing. A brief evaluation of cognitive ability can be performed with the MMSE. A score of less than 24 out of 30 is considered indicative of a cognitive deficit. A variety of conditions, including major depression, can be associated with low MMSE scores. In patients with mild cognitive impairment, deficits in recall of three objects after a 5-minute delay, and impairment in the orientation items, suggest an increased likelihood of developing dementia. However, the MMSE by itself is not sufficient to make a diagnosis of dementia, especially in patients with mild impairment. The MMSE has limitations in evaluating executive function. The Clock drawing test can be used instead to evaluate

executive function. In the early stages of dementia, attention is preserved, but short-term memory is impaired. In contrast, attention is impaired in depression, but short-term memory is relatively intact, that is, what is registered in the brain is generally retained. Delirium is characterized by disorientation, which also occurs in the mid to late stages of most dementing disorders. The rapidity and duration of disorientation are useful indicators of delirium versus dementia in the differential diagnosis. If the results of the cognitive screening leave the diagnosis in doubt, which is often the case, a referral for detailed neuropsychological testing is usually indicated. Neuropsychological testing is useful in making the diagnosis of dementia in its early stages, but its utility in differentiating subtypes of dementia, for example, Alzheimer's versus vascular, or in diagnosing depression in patients with dementia, is not as well established.

Insight. Insight refers to the ability of patients to understand their own symptoms and their potential causes. Insight is impaired in most forms of moderate to severe mental illness and can disappear in severe dementia. Judgment can be assessed during the course of the interview by inquiring about the patient's opinion and proposed course of action in incidents that they describe in their own history or in a hypothetical incident. Judgment is compromised in psychotic disorders and dementia.

DAILY FUNCTIONING

Assessment of daily functioning is essential in the evaluation of the older patient, unlike the situation in most young adults. Activities of daily life (ADL) can be classified into basic ADL (e.g., eating, dressing, toileting), instrumental ADL (cooking, shopping, laundry) and more complex social and cognitive functions requiring greater mental effort, for example, handling finances and doing taxes. Basic and instrumental ADLs need to be assessed in older adult patients. The Pfeffer functional activities scale is widely used in large-scale studies of patients with mild cognitive impairment and Alzheimer disease. Other scales for ADL and instrumental ADL include the Katz Index of Independence in Activities of Daily Living and Lawton-Brody Instrumental Activities of Daily Living. The Clinical Dementia Rating (CDR) incorporates cognitive, functional, and social-cognitive items, and is widely used as an overall indicator of the level of cognitive impairment and dementia severity.

NEUROLOGIC EVALUATION

Psychiatric, cognitive, and neurologic examinations overlap considerably in older adults. While patients with manifest neurologic disorders need a consultation with a neurologist, the geriatric psychiatrist needs to be able to perform the neurologic examination because many patients present with syndromes that overlap between the two specialties. In patients who have cognitive disorders or focal neurologic symptoms or signs, a neurologic examination is essential. All components of the neurologic examination are important, but in the older adult patient presenting to a psychiatrist, the areas of frontal lobe function, basal ganglia function (examination for extrapyramidal signs), motor and sensory function, reflexes, coordination, and evaluation of vision and hearing are essential. A neurologic evaluation could help determine parkinsonism's symptoms that characterize Parkinson disease and Lewy body dementia.

RATING SCALES

Although rating scales are used primarily in research studies, they can serve several possible functions in clinical practice: address specific clinical problems and document change, teach, communicate with colleagues, and strengthen the chart or electronic medical record for medicolegal and insurance purposes. The SCID can be administered to make comprehensive DSM diagnoses, but it requires special training and takes too long to be recommended for routine clinical practice. Some of the widely used scales to assess specific domains of psychopathology and cognitive and daily functioning will be summarized here.

Depression

The Hamilton Rating Scale for Depression (HRSD), Montgomery-Asberg Scale (MADRS), Geriatric Depression Scale, and Center for Epidemiological Studies-Depression Scale (CES-D) have been used in a variety of research studies. The Hamilton Rating Scale for Depression and the Montgomery Asberg Depression Rating Scale are particularly useful in patients with severe depression. Another widely used instrument is the Beck Depression Rating Scale, a self-report instrument. Epidemiologic studies have typically used the self-report CES-D. The Geriatric Depression Scale, which can be self-rated or observer-rated, is quick to

administer and can be quite useful. To assess depression in patients with dementia, the Cornell Scale for Depression in Dementia has been developed.

To assess cognitive impairment, a plethora of rating instruments are available. The most widely used instrument is the MMSE, and the MOCA is comparable in its utility. Education and cultural background can affect performance on these tests, which is one reason why the score obtained should be evaluated in the context of the entire clinical picture. MOCA is available in multiple versions, including a version for blind people and in different languages. Of note, the MMSE is copyrighted, and using the MOCA requires first taking a 1-hour training course.

To assess psychosis, the Brief Psychiatric Rating Scale (BPRS) is commonly used in young adults and can also be used in older adult patients. To address the unique features and methods of assessment of psychosis in dementia, a variety of scales have been developed. These include the Neuropsychiatric Inventory (NPI), the Columbia University Scale for Psychopathology in Alzheimer's Disease (CUSPAD), CERAD Behavior Rating Scale, and the Behavioral Pathology in Alzheimer's disease (BEHAVE-AD) rating scale. The Cohen-Mansfield agitation inventory is available for use in nursing home patients. Currently, the NPI, which uses a time-efficient, decision-tree approach, is the most widely used scale to evaluate the effects of pharmacologic treatment of psychosis and agitation in patients with dementia.

The standardized Confusion Assessment Method (CAM) can be used to assess for delirium. To assess the neurologic side effects of antipsychotic medications, the Unified Parkinson's Disease Evaluation Scale and the AIMS scale can be used.

BIOMARKERS FOR A DEMENTIA DIAGNOSIS

A biomarker is a measurable parameter that reflects a physiologic or pathologic process. It should be reliable, reproducible, and measurable, preferably in a noninvasive way. Alzheimer dementia continues to be the most common type of neurocognitive disorder, accounting for the majority of patients with dementia in the United States. Structural imaging with MRI shows decreased hippocampal and entorhinal cortex volume in Alzheimer disease, but these measures show only moderate accuracy in differential diagnosis and estimation of prognosis. The brains of Alzheimer disease

patients are characterized neuropathologically by the aggregation of extracellular β-amyloid (Aβ) peptides into plaques and intracellular hyperphosphorylated tau into neurofibrillary tangles. Studies show that AD biomarkers, particularly PET imaging showing increased amyloid in the brain, can be detected several decades before the clinical onset of cognitive impairment. Imaging using PET for tau biomarkers may also indicate abnormality during the preclinical stage of AD, though perhaps at a later stage than amyloid. Amyloid and tau biomarkers can also be measured in the CSF with decreased amyloid AB42 and AB42/40 ratio, with an increase in tau and phospho-tau being indicative of AD. These biomarkers can be utilized in clinical practice together with neuropsychological testing and neuroimaging to increase diagnostic precision and earlier diagnosis. One limitation of amyloid and tau biomarkers is lack of specificity, for example, similar abnormalities can occur in Lewy body dementia. Another approach is to use FDG-PET imaging that can reveal distinct regions of low metabolism and hypoperfusion and could differentiate between AD and frontotemporal dementia. Some limitations to CSF or PET/SPECT biomarkers are that they are invasive, time-consuming, and expensive, and each biomarker by itself does not have greater than 75% diagnostic accuracy.

New studies have proposed that AD biomarkers can be measured in the plasma, which would be less invasive, cost-effective, and easily accessible. These include Aβ42/ Aβ40 ratio, NfL, T-tau, and more recently, P-tau181 and possibly P-tau217. Other noninvasive biomarkers include olfactory identification deficits that occur because the brain regions subserving olfactory neuronal projections to limbic regions are affected early in the course of Alzheimer disease.

COMPETENCE

The psychiatrist may be asked about the patient's level of competence to give consent for medical treatment, power of attorney, sign or change a will, or manage personal finances. Competency is a legal term, and the criteria for judging it have never been precisely defined. Competency needs to be judged in a specific framework and context, that is, a patient may be competent to execute one task but not another and may be competent at one time but may change shortly thereafter. There are some specific measures to evaluate financial abilities, but testamentary capacity

remains a judgment call. Both cognitive abilities and general functioning need to be evaluated before making this judgment.

SYNDROMES SPECIFIC TO GERIATRIC PATIENTS

There are several syndromes common in geriatric patients that do not fit easily into the current diagnostic nomenclature. These syndromes, cut across medical and psychiatric diagnoses, are widely recognized and need to be incorporated into the evaluation. Apathy is common, and it can be difficult to separate from depression. Frailty is a syndrome that is associated with increased morbidity and mortality, and gait and grip strength are important metrics in the evaluation of frailty. Technology-based assessments that can monitor activity levels and sleep to inform diagnosis are now used mainly in research studies, but over time they are likely to be included in the standard clinical assessment of patients. Similarly, telemedicine can be extended to telepsychiatry, particularly given the aging of the population and the need to provide psychiatric assessment and treatment to the homebound older adults.

SUMMARY

The evaluation concludes with a summary of the key findings and differential diagnosis, which leads to an overall diagnosis. An etiologic formulation using the biopsychosocial model is the next step. Finally, these conclusions are built into the treatment plan and management strategies for the patient. Holistic management through an integrated healthcare model is warranted most of the time for older adult patients. Improving the social support system, engaging that patient in social and cognitive activities, and encouraging a healthy diet and exercise routine, especially for patients with hypertension, diabetes and obesity, should also be part of the treatment plan.

55.2b Complementary and Integrative Geriatric Psychiatry

Sarah A. Nguyen, M.D., Hanadi Ajam Oughli, M.D., Harris A. Eyre, M.B.B.S., Ph.D., and Helen Lavretsky, M.D., M.S.

Although the terms “alternative,” “complementary,” and “integrative” are often used interchangeably, the National Center for Complementary and Integrative Health (NCCIH) defines these terms as follows: “Alternative” medicine refers to a set of practices of medicine (e.g., traditional, oriental, mind–body, etc.) without sufficient evidence base that is used in place of conventional medicine, whereas “complementary” medicine refers to nonmainstream practices that are used together with conventional medicine. “Integrative” medicine refers to the use of conventional and complementary approaches in a coordinated way targeting specific disorders or underlying neurobiologic processes.

Complementary and integrative medicine (CIM) emphasizes a holistic, patient-focused approach to health care and wellness. CIM targets the whole person rather than one organ system, and historically, these practices are oriented toward a harmonious rebalancing of mind, body, and spirit. CIM approaches incorporate the belief that well-being is a state of balance, encompassing the spiritual, physical, and mental/emotional functioning achieved by leading a balanced, healthy lifestyle. This is achieved by proper nutrition, exercise, sleep habits, and the ability to regulate stress response through meditation or other mind–body practices. The NCCIH identified three categories for complementary and integrative approaches: (1) mind and body practices (massage therapy, meditation, yoga, acupuncture, chiropractic/osteopathic manipulation, hypnotherapy, tai chi, qi gong, healing touch, and relaxation exercises); (2) natural products (herbal medicines, botanicals, vitamins, minerals, probiotics, and other dietary supplements); (3) other complementary approaches (indigenous healing practices, Chinese medicine, Ayurvedic medicine, homeopathy, and naturopathy). In general, CIM practices aim to achieve a greater balance and well-being, making them especially valuable strategies for disease prevention. Because CIM is often considered to be a natural and safer option compared to conventional medicine in addressing common health conditions, these interventions are rapidly gaining popularity in the United States; the top practices include mind–body practices like yoga and meditation and the use of prayer for

health and multivitamin supplementation. The baby boomer cohort and subsequent birth cohort are particularly high utilizers of CIM.

Mind–body practices refer to practices that emphasize mind–body connection awareness in order to achieve well-being, stress reduction, or reduction in stress-related disorders. These can be mindful exercise practices rooted in ancient traditions (e.g., yoga, tai chi, and qigong) or meditation-based practices (e.g., mindfulness meditation). The shared feature of mindful activities is putting attention and raising awareness of bodily sensations (e.g., breathing, muscle relaxation) and the ability for self-regulation by rebalancing autonomic nervous system functioning to offset the deleterious effects of chronic stress.

Other integrative interventions are based on improving lifestyle using diet, exercise, and sleep regulation. Dietary interventions address the effect of dietary choices on health and may include Western, traditional, and Mediterranean dietary patterns, as well as caloric restriction, among others. Natural products and supplements include herbs, vitamins, minerals, natural supplements, and probiotics. Body-based practices may include spinal manipulation (e.g., chiropractic, osteopathic medicine), aromatherapy, and massage therapy. Whole medical systems include traditional Chinese medicine (including acupuncture), Ayurvedic medicine, or homeopathy. These CIM interventions are largely based on therapies that have been utilized in many civilizations and religions for hundreds and thousands of years. In the more recent decades, empirical science has begun to explore the evidence behind these therapies. For a graphical representation of the CIM subtypes, refer to Figure 55.2b–1.

There are a number of major reasons why geriatric mental health providers need to recognize the importance of these interventions. (1) *CIM therapy use is high and rising*. Research suggests the 12-month prevalence of any CIM usage (excluding prayer) in the United States is around 35% to 50%; baby boomers (adults born from 1946 to 1964) report significantly higher rates of use than the Silent Generation (born from 1925 to 1945) for chronic conditions. (2) *The global population is aging*. The number of older persons (aged ≥60 years) globally is expected to more than double, from 841 million people in 2013 to more than 2 billion in 2050. (3) *CIM therapies are increasingly cited in clinical guidelines*. It is now commonplace to note the use of therapies like conventional exercise in the management of psychiatric conditions. (4) *CIM therapies are a source for innovative interventions and have a growing, quality empirical*

research basis. Empirical research into these therapies is exploring their clinical efficacy in trials and the neurobiologic mechanism underlying their effects. (5) *CIM therapies can help to lower the utilization of conventional medicines*. CIM therapies may be used in replacement of conventional medicines for the management of mild illnesses (e.g., relaxation techniques for mild anxiety instead of benzodiazepines which are known to have adverse effects on older adult populations). (6) *CIM therapies can have significant side effects and CIM–drug interactions*. With the high use in geriatric populations, this is, therefore, an important reason why clinicians need to better understand CIM therapies.

FIGURE 55.2b–1. Types of complementary, alternative, and integrative therapies.

This chapter aims to provide an overview of the importance of understanding CIM therapies in geriatric psychiatry.

THE EPIDEMIOLOGY OF COMPLEMENTARY AND INTEGRATIVE MEDICINE USE

To appreciate the importance of CIM therapies in geriatric psychiatry, it is important to explore the epidemiology of and drivers behind usage. This section will explore these topics in general, aging and psychiatric populations.

CIM Use in Geriatric Populations

CIM usage in general adult populations appears to be high. However, there is variability within studies. In a joint survey conducted by the American Association of Retired People (AARP) and the NCCIH, the use of CIM was reported to have increased rapidly, exceeding a prevalence of 53% among those aged 50 years and above. Previously, studies had shown that older adults were more likely to use prayer for health and spiritual practices than younger adults and were less likely to use other forms of CIM. However, a recent study comparing the baby boomers cohort (1946–1964) to the pre-boomer cohort (those born prior to 1946) demonstrated that a higher proportion of baby boomers used CIM (27.7%) than pre-boomers (16.4%). This data, therefore, suggest that given baby boomers are already using 30% more CIM than their older counterparts, with the aging baby boomer population across the world and associated increases in chronic and painful conditions, CIM therapies will only continue to increase. By 2030, more than 6 in 10 baby boomers will be managing at least one chronic disease. National estimates of CIM use were highest in East Asian countries such as Japan, South Korea, and Malaysia. Studies consistently show that “average” CIM users are more likely to be female, better educated, middle aged, and report poorer health status than nonusers.

The use of CIMs appears to be influenced by a complex mix of economic and sociocultural factors. First, it appears CIM use is tied to the movement for self-care. Therefore, CIM use may provide people with a better sense of control and responsibility over their illness. CIM therapies such as tai chi and yoga appear to improve patients’ quality of life (QoL). CIMs can be used in addition to, or in replacement of, pre-existing pain medications. CIM therapies can offer a less harmful way to manage chronic pain by avoiding unnecessary complexity, polypharmacy, and side effects. In low-resource environments where access to biomedical services is poor, there is evidence of a pervasive reliance on traditional healers, even for severe diseases. Delayed medical care—more likely in low-resource environments—is associated with CIM use in the United

States. In high-resource settings where biomedical services are more readily available, a significant amount of CIM therapies are used for health promotion and illness prevention. CIM therapies are often used as adjuncts to conventional therapies for severe diseases like cancer and to self-manage chronic health complaints like lower back pain. It appears CIM usage is driven more so by values and beliefs rather than dissatisfaction with biomedicine. The influence of increasing marketing of CIM therapies is anecdotal but must be considered.

Persons with Mental Illnesses

Persons with mental illnesses appear to use higher numbers of CIMs than the general population. In national samples of general adult populations, persons with depression and anxiety symptoms use CIM therapies more than persons without such disorders. One study indicated that over half of such persons reported CIM use within the prior year. The presence of psychiatric illness also increases the odds of visiting a CIM practitioner. The use of CIM therapies for anxiety and depression was often in conjunction with traditional treatments, raising concerns about how these treatments interact with conventional psychiatric treatments. Using the 2002, 2007, 2012, and 2017 National Health Interview Surveys, there has been a robust increase in the use of yoga, tai chi, and qigong from 2002 to 2017 (5.8% to 14.5%, respectively) by the general population typically for stress, anxiety, and depression. Relatively less information exists specifically about CIM use among older adults with mental illnesses. Therefore, clinicians treating older adults need to be informed of the efficacy and potential side effects of various CIM therapies to better assist their patients in making health care decisions.

Mind–Body Therapies

Mind–body therapies (MBT) are varied and are also rising in popularity, according to the 2017 National Health Survey, with a 5% to 10% increased use of yoga, meditation, and chiropractic care. A growing body of research evidence supports the use of MBTs (including meditation, yoga, tai chi, and qigong) as minimally invasive, cost-effective approaches for the management of stress, late-life mood, and cognitive disorders. In contrast to pharmacologic approaches, MBTs aim to teach patients life-long skills that may continue to confer benefits long after formal training has ended.

MBTs can be best divided into physical and nonphysical exercise-type practices. Mind–body physical exercise practice includes yoga, tai chi, and qigong. Mind–body nonphysical exercise practice includes relaxation, mindfulness, meditation, and acceptance therapies. Mind–body physical practices are often defined as “physical activity executed with a profound inwardly directed contemplative focus.” Mindful physical activity contains the following key elements: (1) a noncompetitive, nonjudgmental meditative component; (2) mental focus on muscular movement and proprioceptive awareness combined with a low to moderate level of muscular activity; (3) centered breathing; (4) a focus on anatomic alignment (i.e., spine, trunk, and pelvis) and proper physical form; and (5) energy-centric awareness of the individual flow of intrinsic energy, vital life force, qi, etc. Mind–body nonphysical practice does not emphasize the physical activity component of the above. More recently, MBTs such as mindfulness yoga have taken a combined approach, integrating yoga practices with interventions from mindfulness-based stress reduction (MBSR) programs. In cases of mind–body practices, individuals go through training to develop life-long skills for self-regulation in the face of adversity and stress and health-promoting practices.

Mind–Body Physical Practices. Mindful exercise interventions have shown promise in addressing depressive symptoms in older adults. A more recent review including 1,282 older adults aged 62 to 83 years with depressive symptoms, frailty, or chronic medical illnesses showed that qigong exercise resulted in significantly improved physical ability compared with active control or usual care (standardized mean difference [SMD] = 1.00 and 1.20, respectively). Although qigong exercise showed favorable effects on depression, balance, and functioning, the overall effects did not reach statistical significance. However, no significant adverse events were reported, suggesting that the qigong exercise may be an option for older adults to improve physical ability, functional ability, and balance and lessen depression and anxiety.

The practice of yoga typically benefits from instruction by expert instructors and requires participant commitment to multiple weekly sessions and ongoing maintenance practice for maximal benefit. Yoga is commonly used in combination with other treatments for depression, anxiety, and stress-related disorders. A prior review of published randomized controlled trials (RCTs) of yoga for depression in adults

revealed that all trials found benefits. However, the trial methodologies have generally been weak with a lack of blinding, short duration of the intervention, variable outcome measures, limited information about subjects, randomization procedures, compliance, and dropout rates. Comparative studies of yoga have likewise been limited to older adults. In an RCT of 98 older adults, aged 65 to 92 years, participants were randomly assigned to chair yoga, chair exercise, and control groups and assessed preintervention, postintervention, and 1-month follow-up. Yoga participants improved more than both exercise and control participants with regard to depression, anxiety, well-being, anger, general self-efficacy, and self-efficacy for daily living. Another study of 69 older adults in India did compare the impact of yoga to Ayurveda or a wait-list control condition on sleep and depressive symptoms. Participants in the yoga group practiced physical postures, relaxation techniques, regulated breathing, and devotional songs and attended lectures for more than 7 hours a week during the course of the 6-month trial. The practice of yoga significantly impacted the quality of sleep and level of depressive symptoms when compared to the two control conditions, neither of which demonstrated significant effects. In particular, depressive symptoms, as measured by the short form of the *Geriatric Depression Scale (GDS)*, decreased in the yoga group from a baseline average of 10.6 to 8.1 by 3 months and 6.7 by 6 months. The average time to fall asleep decreased in the yoga group by 10 minutes, while the total number of hours slept increased by 60 minutes and resulted in a greater feeling of being rested after 6 months. A recent study compared the effectiveness of laughter yoga, group exercise therapy, and control in decreasing depression in older adult women (60 to 80 years). In this study, 70 depressed women were chosen if their Geriatric Depression Score was >10. This study went on for 10 sessions and found a significant improvement in depression scores with both yoga and group exercise therapy as compared with control. While the evidence supporting the use of these therapies in the treatment of late-life mental illnesses is not strong, there are some interesting early results that require further high-quality research.

A recent meta-analysis critically evaluated the effects of tai chi on individuals aged 60 years and older with and without cognitive impairment. In this study, 20 eligible studies with a total of 2,553 participants were identified that met inclusion criteria for the systematic review; 11 of the 20 eligible studies were RCTs, 1 was a prospective

nonrandomized controlled study, 4 were prospective noncontrolled observational studies, and 4 were cross-sectional studies. The overall quality of RCTs was modest, with 3 of 11 trials categorized as high risk of bias. Meta-analyses of outcomes related to executive function in RCTs of cognitively healthy adults indicated a large effect size (ES) when tai chi participants were compared with nonintervention controls (g = 0.90; p = .04) and a moderate ES when compared with exercise controls (g = 0.51; p = .003). Meta-analyses of outcomes related to global cognitive function in RCTs of cognitively impaired adults, ranging from mild cognitive impairment (MCI) to dementia, showed smaller but statistically significant effects when tai chi was compared with nonintervention controls (g = 0.35; p = .004) and other active interventions (g = 0.30; p = .002).

A recent review of 13 RCTs examined the impact of yoga on cognition and mental health. Yoga-based interventions have had some positive evidence on attention, executive functions, and memory among cognitive variables. These studies are limited by the small number and the need for more validated modules of yoga intervention with longer-term follow-up and standard study methodology in future trials. In addition, the impact of yoga on depression was comparable to active control among older adults.

For patients with mild to moderate Parkinson disease (PD), a 2016 meta-analysis concluded that mind–body exercises, including yoga, dance, and tai chi, had immediate moderate-to-large beneficial associations with motor symptoms, postural instability, and functional mobility. A more recent RCT of 138 participants with mild-to-moderate PD also showed that a mindfulness yoga program was found to be as effective as stretching and resistance training exercise (SRTE) on psychological distress, physical health, spiritual well-being, and health-related QoL.

RECOMMENDATION AND SUMMARY. We recommend the use of mind–body therapies as a stand-alone or adjunctive treatment in the management of geriatric disorders based on individual preference and the severity of the disease. The majority of studies to date have focused on younger and middle-aged adults, but the overall impact of MBTs has been positive despite the proposed mechanisms by which MBTs improve mood, sleep, and well-being in geriatric populations being less understood. Further high-quality data is needed to better inform these recommendations

oriented toward promoting well-being and resilience in this vulnerable population.

Mind–Body Nonphysical Practices and Stress-Reduction Techniques. Existing evidence suggests that, on average, both meditative movement (e.g., yoga) and multicomponent mindfulness-based interventions can be as effective as other active treatments for disorders such as major depression, anxiety, and substance use disorder. Results of studies with healthy adults suggest that multicomponent interventions such as MBSR have the potential to increase empathy, self-control, self-compassion, relationship quality, and spirituality, as well as decrease rumination. Research has also begun to evaluate the neurobiologic mechanisms by which meditative therapies enhance resilience to mental health disorders, and several promising mechanistic domains (neural, hormonal, immune, cellular, and cardiovascular) have been identified.

Relaxation techniques, such as breathing exercises, guided imagery, and progressive muscle relaxation, are designed to produce the body's natural relaxation response. These relaxation therapies are shown to lower stress levels in older adult subjects and so are recommended for clinical use. Two of the most commonly available and widely studied forms in research are MBSR and mindfulness-based cognitive therapy (MBCT). These mindfulness-based treatment protocols are usually brief (typically eight in-person individual or group sessions), multicomponent interventions incorporating both education and practice.

An RCT including 103 adults aged 65 years or older with an anxiety or depressive disorder (diagnosed according to DSM-IV criteria) and subjective neurocognitive difficulties were recruited and randomly assigned in groups of 5 to 8 to MBSR or a health education control condition matched for time, attention, and credibility. The primary outcomes were memory (assessed by immediate and delayed paragraph and list recall) and cognitive control (Delis–Kaplan Executive Function System Verbal Fluency Test and Color Word Interference Test). Other outcomes included clinical symptoms (worry, depression, anxiety, and global improvement). The mindfulness group experienced greater improvement on a memory composite score ($p = .046$), measures of worry ($p = .042$), and depression ($p = .049$) at posttreatment and on worry ($p = .02$), depression ($p = .002$), and anxiety ($p = .002$) at follow-up. However, the groups did not differ on changes in cognitive control. Participants

receiving MBSR were more likely to be rated as much or very much improved as rated by the Clinical Global Impressions-Improvement scale (47% vs. 27%, $p = .03$). Cortisol levels decreased to a greater extent in the mindfulness group, but only among those participants with high baseline cortisol.

In another study, **13 participants with PD** experienced depression, anxiety, stress, or difficulty coping with PD. Six completed the full, 8-week MBSR course. The MBSR group reported significant improvements in levels of depression, anxiety, and stress at weeks 8 and 16, as measured by the Depression Anxiety and Stress Scale, short version (DASS-21). This small study supports previous preliminary findings that mindfulness-based interventions could benefit people with PD experiencing nonmotor symptoms. Further research using larger sample sizes, a control group, and a longer follow-up period is required.

Another RCT examining the effects of MBSR on chronic insomnia demonstrated that the MBSR program could be a beneficial treatment for chronic insomnia in adults aged 75 years and older. Sixty participants were included, ages 75 and older, over with chronic insomnia. They were randomly assigned to the 8-week MBSR group or the wait-list control group. Assessments using the Pittsburgh Sleep Quality Index (PSQI), Self-rating Anxiety Sale (SAS), and GDS were taken at baseline and posttreatment. There was a significant time × group interaction for the PSQI global score ($p = .006$); the MBSR group had a decrease in the PSQI global score (Cohen's d = 1.12), while the control group did not (Cohen's d = –0.06). Among the sleep PSQI components, there was a significant time × group interaction for daytime dysfunction ($p = .048$; Cohen's d of the MBSR group was 0.76, while Cohen's d of the control group was -0.04). There was no significant time × group interaction for the anxiety SAS score ($p = .116$). However, for the depression GDS, there was a significant time × group interaction ($p = .039$; the Cohen's d value for the MBSR group was 1.20, and it was 0.12 for the control group).

Another randomized pilot trial with MBSR aimed to test the safety and feasibility of MBSR in older adults with MCI. The study found that adults with MCI can safely participate and adhere to an MBSR program. The qualitative interviews revealed that most enjoyed the program and described improved mindfulness skills, well-being, interpersonal skills, acceptance/awareness of MCI, and decreased stress reactivity. Most data

suggest a trend toward improvement for measures of cognition and well-being, but a more formal, large-scale RCT is needed.

RECOMMENDATIONS AND SUMMARY. The evidence is growing for the efficacy and underlying mechanisms of complementary and integrative interventions. Given the low cost and relative safety, we recommend mind–body therapies as useful stand-alone or adjunctive therapies for the management of mild–moderate neuropsychiatric and cognitive symptoms (e.g., psychological distress, anxiety, depression, pain, insomnia, and MCI) and physical health (e.g., improving balance, strength, coordination). Care must be taken to create age- and physical- and mental-function–appropriate prescriptions. Our recommendations are based on existing evidence and clinical experience, as well as growing patient preferences for the use of integrative medicine.

Conventional Physical Activity

Conventional physical activity is one of the most promising therapy for the treatment and prevention of age-related cognitive decline and dementia. Importantly, there are a variety of subtypes of physical activity, from aerobic activity to resistance, stretching, and toning. Currently, the American College of Sports Medicine recommends that exercise programs for older adults include both aerobic and nonaerobic physical activities, such as resistance training, balance training, and stretching, for optimal general health. See Table 55.2b–1 for the latest clinical guidelines on physical activity for older adults.

Table 55.2b–1.
Clinical Suggestions for Geriatric Populations

If 65 years or older, generally fit, and have no limiting health conditions

- At least 150 minutes of moderate-intensity aerobic activity (i.e., brisk walking) every week and muscle-strengthening activities on 2 or more days a week that work all major muscle groups (i.e., legs, hips, back, abdomen, chest, shoulders, and arms).

OR

- 75 minutes of vigorous-intensity aerobic activity (i.e., jogging or running) every week and muscle-strengthening activities on 2 or more days a week that work all major muscle groups.

OR

- An equivalent mix of moderate and vigorous-intensity aerobic activity and muscle-strengthening activities on 2 or more days a week that work all major muscle groups.

Other comments

- If there is a limiting condition, it is recommended the health professional and patient consult a qualified exercise physiologist.
- 10 minutes at a time is fine for physical activity.
- The following activities count as muscle-strengthening activities: yoga, heavy gardening.

Adapted from U.S. Department of Health and Human Services. *Physical Activity Guidelines for Americans*. 2nd ed. U.S. Department of Health and Human Services; 2018. https://health.gov/sites/default/files/2019-09/Physical_Activity_Guidelines_2nd_edition.pdf

Conventional physical exercise has received considerable attention for its potential role in the treatment of depression, based initially on the results of observational studies. A large (n = 6,828) cross-sectional study of men and women aged 20 to 88 years found that aerobic fitness and physical activity levels, as measured by a maximal treadmill test and self-report, respectively, were significantly related to the degree of depressive symptoms and emotional well-being. Interestingly, these relationships occurred in a graded, dose-dependent fashion, with progressively higher levels of fitness associated with increasingly lower levels of depressive symptoms and higher degrees of self-reported well-being. For physical activity levels, a similar dose–response relationship was observed;

however, the greatest benefit was seen at between 11 and 19 miles per week of walking, jogging, or running.

The effects of aerobic exercise in depressed adults aged 50 years and older were examined and compared to either monotherapy with sertraline as a standard antidepressant or a combination of both approaches. The study found that after 16 weeks, all three groups demonstrated equivalent significant reductions in depressive symptoms as measured by scores on the *Hamilton Depression Scale* and the *Beck Depression Inventory*. Furthermore, a 10-month follow-up study showed that participants in the exercise group who had improved to the point of remission during the initial study showed lower rates of relapse than those taking antidepressants and independent continuation of exercising related to a reduced probability of being depressed at the end of the trial. Another study of exercise for older adults found that 10 weeks of weight-bearing exercise classes provided as an adjunctive treatment significantly lessened depressive symptoms in a group of older adults who had not responded to antidepressant therapy alone when compared to a health education course. A systematic review examining the role of physical exercise in the treatment of depression in older adults was conducted in 2009. This study noted 11 RCTs with a total of 641 participants aged >60 years. The study noted short-term (0 to 3 months) positive outcomes were found in nine studies, although there was variation in the type, intensity, and duration of exercise. The efficacy of exercise in the medium and long term (3 to 12 months and >12 months, respectively) was less clear. Issues were noted, with only five studies showing appropriate allocation of concealment, five studies showing intention to treat analysis, and blinding occurred in seven studies. The effectiveness of a number of lifestyle interventions promoting increases in conventional physical exercise has been recently reviewed. Overall, interventions were relatively successful in initiating increased levels of physical activity in the short run; however, maintenance of these gains was diminished over time, and there was no convincing evidence that behavioral reinforcement strategies were beneficial. Another review of exercise interventions found that while many older adults increase physical activity levels in response to a wide variety of interventions, the amount of increase is seldom enough to convincingly impact health outcomes in a positive manner.

In a recent randomized controlled study, 28 participants with MCI and 28 participants with Alzheimer disease (AD) were randomized to a control

group and exercise group and evaluated before and 3 months after the intervention on physical and cognitive abilities. MCI is a well-recognized risk factor for dementia and represents a critical window of opportunity for intervening and altering the trajectory of cognitive decline. The intervention included a 12-week multimodal physical exercise program on global cognition, executive function, and mobility in older adult people with MCI or AD. Results in this small study suggest that the 12-week multimodal physical exercise program contributed to improvements in the mobility and executive function of older adult individuals with MCI but not of those with AD. Currently, several larger-scale RCTs are underway, but this suggests that physical exercise should be recommended to those in the early stages of neurocognitive disorder for more preventative measures.

Another RCT examined the efficacy of resistance and aerobic training in the improvement of cognitive functions in subjects with MCI. The study occurred over 6 months and involved 86 community-dwelling women aged 70 to 80 years. Physical activity protocols included twice-weekly resistance training, twice-weekly aerobic training, or twice-weekly balance and toning (BAT) training (i.e., control). Resistance training improved selective attention/conflict resolution and associated memory compared with BAT. In contrast, aerobic physical activity improved general balance and mobility and cardiovascular capacity. The study also found aerobic physical activity improved verbal memory, and both resistance and aerobic physical activity improved spatial memory. A recent stringent meta-analysis has examined the efficacy of exercise on cognition in older adults with MCI. MCI was diagnosed on documented criteria or via the Mini-Mental State Examination (MMSE). Fourteen RCTs with 1,695 participants aged 65 to 95 years were utilized. These studies had a duration of 6 to 52 weeks. Overall, 42% of effect sizes (ESs) were potentially clinically relevant (ES > 0.20), with only 8% of cognitive outcomes statistically significant. The meta-analysis revealed negligible but significant effects of exercise on verbal fluency (ES: 0.17 [0.04, 0.30]). No significant benefit was found for additional executive measures, memory, or information processing. The authors critically appraised RCT methods and concluded on a moderate quality, with the majority of trial samples being too small for sufficient power. There is clearly some effect for exercise at moderate to high levels of exertion. In addition, nowadays, there is emerging evidence for the effect of low levels of physical activity

or “sedentary behaviors” like sitting. Physical inactivity may increase the risk of AD by 82%. Approximately 13% of AD cases worldwide may be attributable to sedentary behavior. A 25% reduction in sedentary behavior could potentially prevent more than 1 million AD cases globally. Sedentary behaviors may contribute to the risk of AD and dementia by an increased risk of cardiometabolic risk factors—diabetes, hypertension, obesity—diseases associated with an increased risk of dementia.

Our own studies of yoga and memory training in older adults with MCI and tai chi in older adults with depression have demonstrated changes in mood, psychological resilience, brain connectivity, and memory and executive functioning, leading to improved QoL.

Recommendations and Summary. Our clinical recommendation is physical activity should be encouraged for all members of society and particularly older adults. Evidence points to exercise as having a significant potential to lessen symptoms in depressed older adults and, furthermore, to prevent relapse of depression and/or development of depressive symptoms in older adults experiencing acute stressors associated with aging. We recommend physical aerobic and mindful exercise as a stand-alone therapy in the treatment of mild depression and as an adjunct in moderate depression. Recommendations for engagement are given in Table 55.2b–1. More work is required to understand if physical activity recommendations or dementia prevention are the same as generic “healthy aging” recommendations (as in Table 55.2b–1). While shorter-term interventions are useful in the research setting, care must be taken to ensure a sustained engagement in physical activity. Care must also be taken to create age- and physical-function–appropriate prescriptions, given the risks of adverse health effects (e.g., falls, cardiovascular events).

Diet and Use of Herbal and Nutritional Supplements

Several lines of investigation have pursued the role of diet and nutrition in the management of mental disorders. These include targeting increased oxidative stress and inflammation; reduced essential nutrients in psychotic and mood disorders; and gut microbiome dysfunction, all of which have been linked to mental disorders. Over half of all U.S. adults take some form of nutritional supplement. Older adults aged 70 years and older suffering from disorders such as stroke, cancer, obesity, breathing

problems, and arthritis are more likely to use herbal and nutritional supplements. Despite the popular belief that natural supplements are safer, their use can be associated with important adverse effects and supplement/herb–drug interactions, which are only minimally regulated by the Food and Drug Administration (FDA). In addition, excessive consumption of certain supplements may be harmful, underreported in consumer reports or media, and underappreciated by patients and health care providers. This next section will discuss the limited evidence available for herbal and nutritional supplements.

Diet. The emerging field of nutritional psychiatry focuses on the consequences and associations between what you eat, how you feel, and, ultimately, how you behave. The focus shifts from single nutrients or supplements to a comprehensive, cohesive, and scientifically rigorous evidence base to support a shift in thinking about the role of diet and nutrition in mental health. In particular, the Mediterranean diet gained attention after a large, multicenter, randomized controlled PREDIMED study showed that adherence to a Mediterranean diet could be a primary prevention strategy for cardiovascular disease. The Mediterranean diet consists of plentiful use of olive oil; high consumption of fruit, vegetables, legumes, cereals, and nuts; regular but moderate intake of wine (especially red wine) with meals; moderate consumption of fish, seafood, fermented dairy products (yogurt and cheese), poultry and eggs; and limited consumption of red and processed meats and sweets. Two RCTs found significant improvement in depression with Mediterranean diet interventions in adults compared to social support controls, with the dietary support group demonstrating significantly greater improvement between baseline and 12-week Montgomery–Åsberg Depression Rating Scale (MADRS) scores compared to social support alone. There was also a noted greater reduction in depression (p = .03) and improved mental health QoL scores (p = .04) at 3 months with sustained effects at 6 months follow-up with Mediterranean and fish oil supplementation compared to social support alone. Another observational cohort study examined the relationship between the Mediterranean-DASH diet on depression in older adults, demonstrating adherence to the Mediterranean-DASH diet was associated with lower rates of depression while Western diets had a positive association with depression. Beyond mood effects, the Mediterranean diet has also been shown to be

beneficial for cognition. One of the first RCTs examining dietary patterns on global cognitive function demonstrated nutritional intervention with the Mediterranean diet supplemented with either extra virgin olive oil (EVOO), or mixed nuts is associated with improved global cognition. It is likely that a combination of emphasizing foods that contain multiple beneficial nutrients, as well as a reduction in saturated and unsaturated fats, has a stronger, combined effect on mental disorders than single supplementation alone. Despite the popularity of supplements and herbals, the data has been less consistent than the stronger, reproducible evidence of certain dietary patterns in supporting geriatric mental health.

Natural Products. Natural products may include herbs, minerals, natural supplements, vitamins, and probiotics. A range of these products has been explored with regard to the treatment and prevention of cognitive impairment. There are too many of these products to thoroughly review in this chapter, so only the main products, with a larger body of research and/or epidemiologic usage, are reviewed here with further reading recommended.

ST. JOHN WORT. St. John Wort (SJW) (*Hypericum perforatum*) is a wildflower that has been used for medicinal purposes for thousands of years. Various standardized extracts of this natural dietary supplement have been studied for the treatment of depression. There are around 40 published clinical trials comparing SJW with various antidepressants, including tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs), as well as many systematic reviews and meta-analyses. A Cochrane review by Linde et al. examined 5,489 patients with 18 trials comparing SJW with placebo and 17 trials comparing SJW with standard antidepressants. Overall, the results were heterogeneous, but SJW was found to be superior in efficacy to placebo and equivalent to standard antidepressants. Another meta-analysis led by Ng et al. studied 3,808 patients and 27 clinical trials comparing SJW with SSRIs for the treatment of mild to moderate depression. SJW demonstrated comparable response (pooled risk ratio (RR) 0.983, 95% confidence interval [CI] 0.924–1.042, $p < .001$) and remission (pooled RR 1.1013, 95% CI 0.892–1.134, $p < .001$) rates with a significantly lower discontinuation/dropout rate (pooled OR 0.587, 95% CI 0.478–0.697, $p < .001$) rate. In addition, the pooled SMD from baseline scores on the

Hamilton Depression Rating Scale (HAM-D) supported the efficacy of SJW in ameliorating depressive symptoms. In older adults, the available evidence for the use of SJW as an antidepressant is limited. A small RCT comparing SJW (800 mg extract LoHyp-57) and fluoxetine (20 mg) in moderately depressed older adults (60 to 80 years old) found equivalent efficacy for these agents in reducing depression over 6 weeks. Therefore, there is a strong evidence basis for SJW in treating the general adult population suffering from depression.

SJW contains more than 150 chemicals, some of which have psychotropic properties. Hypericin and hyperforin are two compounds that are best understood, and SJW preparations tend to be standardized to one of these compounds. SJW's mechanism of action appears to be multifactorial and includes interaction with the hypothalamus–pituitary–adrenal (HPA) axis leading to decreased cortisol levels. In addition, SJW has a slight monoamine oxidase inhibitor activity, which needs to be taken into consideration when combined with SSRIs as it could result in serotonin syndrome. Other mechanisms include direct serotonergic activity, decreased serotonin receptor density, and synaptic neurotransmitter reuptake.

Classic doses of SJW range from 300 to 1,800 mg/day, which are usually divided into three times daily basis. The standard therapeutic dose is typically 900 mg daily. SJW tends to be well tolerated. Side effects commonly include dry mouth, constipation, dizziness, phototoxicity, and cycling to mania in bipolar disorder patients. SJW is also an inducer of the cytochrome P-450 3A4 liver enzyme system, which leads to decreased activity of multiple medications such as warfarin, methadone, benzodiazepines, zolpidem, olanzapine, clopidogrel, cyclosporine, oral contraceptives, theophylline, digoxin, indinavir, Camptosar, irinotecan, phenprocoumon, and verapamil. Thus, extreme caution is needed for patients with HIV who are treated with protease inhibitors, cancer patients who are receiving chemotherapy, and transplant patients who are taking immunosuppressive drugs while using SJW.

Thus, the evidence concludes that SJW can be used as a natural remedy for the treatment of mild to moderate depression. For an older adult who would rather not take conventional western medications, SJW can be considered an alternative natural treatment. However, all patients using SJW should be informed about potential side effects and be monitored for drug–drug interactions.

S-ADENOSYL-L-METHIONINE. S-adenosyl-L-methionine (SAMe) is a naturally occurring compound normally synthesized in the body formed from the amino acid L-methionine as part of a multistep metabolic pathway involving folic acid and vitamin B_{12}. SAMe is thought to play a role in depression since it is a necessary cofactor for the synthesis of serotonin, norepinephrine, and dopamine. In addition, cerebrospinal fluid levels of SAMe have been shown to be decreased in depressed patients, and levels rise in response to treatment.

The literature so far supports the efficacy of parenteral and oral SAMe preparations as compared to placebo. In addition, SAMe was deemed to be equivalent to TCAs in terms of efficacy. Over 50 clinical trials using SAMe for depressive disorders, including 19 RCTs, 17 open-label trials, and 21 comparison trials with other antidepressants, exist. Among the trials, the oral doses of SAMe ranged from 400 to 1,600 mg/day, with most trials showing benefits with dosing between 800 and 1,600 mg/day. However, dosages up to 3,600 mg/day have been used with success and safely in older populations, supporting the notion that higher dosages may be necessary for clinical benefit.

A meta-analysis by Hardy et al. comparing SAMe to placebo showed a significant improvement of approximately six points in the score of the HAMD. Comparisons with other antidepressants showed no differences in risk ratios and ESs, which supports equivalence between SAMe and other agents. However, there was some concern regarding publication bias, small samples, heterogeneity of the doses used, and delivery systems, and thus, the authors were cautious regarding their interpretations of the results.

A recent systematic review by Sharma et al. determined that relatively few new studies of SAMe have existed since 2002, thereby noting that the meta-analysis by Hardy et al. remains highly relevant. Furthermore, they found promising but limited evidence of efficacy and safety to support the use of SAMe as monotherapy and as augmentation for other antidepressants.

SAMe can be beneficial for depression. However, the data are lacking for the geriatric population. It is generally well tolerated, yet important safety concerns such as increased anxiety, mania, and hypomania have been reported in patients with bipolar disorder. Patients with bipolar disorder should not take SAMe without concomitant administration of mood stabilizers coupled with clinical monitoring. Other side effects may

include insomnia, anorexia, dry mouth, sweating, dizziness, and nervousness.

SAMe has a faster onset of action than standard antidepressants, with some patients exhibiting improvement in depressive symptoms within 2 weeks. It could be combined with antidepressants, thereby accelerating the onset of action in many cases. SAMe is a particularly good choice in patients with methylene tetrahydrofolate reductase (MTHFR) deficiency, as it would bypass the steps in folate metabolism that are dependent on this enzyme. An ideal candidate for a trial of SAMe could include a mildly symptomatic patient who would not have serious effects if there was a delay in treatment or a person who has failed multiple trials of conventional antidepressants and/or is unable to tolerate side effects.

VALERIAN. Valerian (*Valeriana officinalis*) is an herbal sedative and mild hypnotic that has been used for over a thousand years worldwide. Its tranquilizing effect is due to its active compounds, including valepotriates and sesquiterpenes, which have gamma-aminobutyric acid (GABA)-ergic activity and function similarly to barbiturates and benzodiazepines. Valerian also appears to promote natural sleep after a few weeks of regular use instead of treating insomnia acutely.

There are over 40 published controlled trials of valerian that include both healthy and symptomatic individuals. Some studies have shown that valerian is comparable in efficacy to that of benzodiazepines and is associated with lesser side effects and no tolerance. There are a few meta-analyses and systematic reviews that are not supportive of its efficacy. In addition, one 4-week pilot RCT involving 36 patients with generalized anxiety disorder (GAD) treated with valerian, diazepam, and placebo showed no significant differences between the valerian and placebo groups or valerian and diazepam groups in HAM-A total scores. The inconsistent findings in these trials could be due to the valerian's powerful smell that could lead to unmasking. However, this may be overcome by combining the inactive compounds of the valerian into placebos, which is more recently practiced.

The recommended dose of valerian is 450 to 600 mg before bedtime, with little benefit from higher doses. Overall, it is very well tolerated. The most common side effects include gastrointestinal (GI) side effects and headaches. No increased sedation or hangover effect in the morning after its use. Rare toxic reactions include blurry vision, dystonias,

hepatotoxicity, delirium, and withdrawal. It has been noted to be safe for older adults. In conclusion, valerian is a safe and effective hypnotic that decreases sleep latency and improves sleep quality and can be used in older adults.

GINKGO BILOBA SUPPLEMENTS. Ginkgo biloba leaf extract is among the most widely sold herbal dietary supplements in the United States. Its purported biologic effects include scavenging free radicals, lowering oxidative stress, reducing neural damage, reducing platelet aggregation, and anti-inflammatory, antitumor, and antiaging activities. Ginkgo's primary indication is for enhancing cognitive function, including memory and abstract thinking, in individuals with organic brain diseases such as Alzheimer dementia. No standards or guidelines regulate the constituent components of Ginkgo biloba leaf extract, nor are exposure limits imposed. Over 30 placebo-controlled, double-blind RCTs of *Ginkgo biloba* in patients with various types of dementia have yielded contradictory results. Of the studies that revealed cognitive improvement, the effect was minor and did not last more than 6 months. One RCT demonstrated the efficacy of once-daily–dosed Ginkgo biloba (240-mg extract EGb 761) in outpatients aged 50 years or older with mild to moderate AD or vascular dementia (VaD) over 24 weeks. Both types of dementia showed improvement in cognition and neuropsychiatric symptoms compared to placebo. In addition, a recent meta-analysis by Hashiguchi et al. examined 9 out of 13 studies lasting 12 to 52 weeks with doses >120 mg/day in 2,381 participants. In seven out of the nine studies, Ginkgo overtook placebo. The advantage was preserved when examining its efficacy in dementia types, including AD, VaD, and the combination of AD and VaD. Doses of 240 mg/day appeared to be most effective with good tolerability. Ginkgo has been compared to cholinesterase inhibitors and was noted to be better tolerated, albeit less effective. The evidence does not suggest Ginkgo biloba has any clear preventative effects on dementia. In a trial of AD prevention in older adults aged 72 to 96 years, 120 mg of *Ginkgo biloba* twice a day was not effective in reducing the overall incidence of dementia in older adults with normal cognition or MCI. Therefore, *Ginkgo biloba* will not prevent the development of AD but may have a minor impact on cognitive decline in those already afflicted with dementia.

As with other natural products, Ginkgo biloba comes with risks. It is recommended to use caution when using *Ginkgo biloba* in those who are at increased risk of hemorrhage as it may potentiate bleeding by inhibiting platelet-activating factor (PAF). Nevertheless, a recent meta-analysis of 18 trials including patients with dementia and healthy volunteers, diabetes mellitus, and peripheral artery disease did not find an added risk of bleeding based on hemostatic outcomes. Side effects also include mild GI upset, headache, irritability, dizziness, or allergic reactions. The short-term use of Ginkgo biloba is acceptable under some conditions, dependent on clinician–patient discussions, with the potential risks being considered.

SILEXAN. Silexan is a potent anxiolytic composed of lavender oil. Its active ingredients are linalool and linalyl acetate which comprise 71% of the oil, while the remaining 29% is made up of trace amounts of over a hundred other compounds from the lavender plant. Its mechanism of action is multifactorial and includes potent inhibition of voltage-dependent calcium channels. In addition, it is an N-methyl-D-aspartate (NMDA) antagonist, a serotonin-1A agonist, and it has GABA-ergic effects. A recent randomized, double-blind controlled trial compared two doses of silexan 80 mg or 160 mg/day to paroxetine 20 mg/day and placebo in the treatment of GAD. The 10-week study showed that both doses of silexan worked significantly better than paroxetine and placebo ($p < .01$) on the Hamilton Anxiety Rating Scale as well as on secondary measures of depression, sleep quality, and overall QoL. The effect was dose dependent, with an ES of 0.4 and 0.5 for the 80 mg and 160 mg doses, respectively. A Cochrane-style meta-analysis found a medium-size effect of 0.67 for anxiety and a large-size effect (0.87) in studies that exclusively enrolled participants with GAD.

Silexan is generally well tolerated and has no known withdrawal effects, addictive potential, or known drug interactions. The most common side effect was burping. It is considered safe for consumption by the FDA and National Institutes of Health (NIH). However, several ingredients have weak estrogen-like properties leading to rare cases of breast development in adolescent boys and early breast development in young girls. Thus, its use in children under the age of 18 years should be avoided. There are currently no known studies looking at the anxiolytic effects of silexan in older adults.

OMEGA-3 POLYUNSATURATED FATTY ACID SUPPLEMENTS. Omega-3 fatty acids are a family of polyunsaturated lipids that include eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), both derived from oily fish such as salmon, mackerel, herring, and sardines, as well as alpha-linolenic acid (ALA) derived from vegetable sources such as flaxseed oil. Omega-3 fatty acids are essential for brain development and are a key component of neuronal membranes in the brain. They promote cognitive function due to their antioxidant and anti-inflammatory effects. They also have antidepressant properties and have previously been used for the treatment of major depression as adjunct therapy as well as monotherapy.

The evidence regarding omega-3 fatty acid supplementation is difficult to interpret due to the heterogeneity among studies, specifically regarding the omega-3 preparations, doses, and study design. Numerous meta-analyses examined their efficacy in the treatment of dementia. A recent Cochrane review looked at the effects of omega-3 fatty acids on the treatment of cognitive dysfunction. Six hundred and thirty-two participants with mild to moderate AD were examined over 6, 12, and 18 months. However, there was no evidence of an increased benefit from omega-3 fatty acids supplementation on cognitive function when measured at 6 months with the MMSE or the Alzheimer's Disease Assessment Scale-Cognitive subscale. Another Cochrane database systematic review explored the effects of omega-3 fatty acids on the prevention of dementia and cognitive decline in cognitively healthy older people. Information was available from three RCTs, including 3,536 participants in total. This meta-analysis found no evidence to support a preventative effect following 24 or 40 months of intervention. Other RCTs suggest that selected patients with an MMSE score >27 were more likely to identify a positive effect of omega-3 fatty acids supplementation.

In terms of depression, a meta-analysis showed that omega-3 fatty acids supplementation with ≥60% of EPA was beneficial, with evidence supporting a role for their use. The data supporting omega-3 fatty acids supplementation in geriatric depression is less extensive. There are currently no meta-analyses available for the geriatric population; however, some RCTs looking at the antidepressant effect of omega-3 fatty acids exist. A small RCT of clinically depressed females aged 66 to 95 years living in a nursing home found that omega-3 fatty acids supplementation improved depression and QoL. These findings are consistent with previous studies on the general adult population.

Typical doses range from 1 to 2 g/day with the use of preparations ≥60% EPA in omega-3 fatty acids combinations. Potential side effects include mild nausea and a fishy aftertaste. Previous concerns regarding the increased risk of bleeding associated with omega-3 fatty acids were disproved. However, caution is recommended in patients taking anticoagulants. There have been some cases of cycling to mania in bipolar patients who were depressed, and therefore, individuals with bipolar disorder should be on concomitant mood stabilizers. More placebo-controlled trials with large samples in older adults with depression are needed to further confirm their effectiveness.

VITAMIN SUPPLEMENTS. Antioxidant compounds such as vitamins A, C, and E have a significant role in the regulation of oxidative stress, a pathway associated with neurodegeneration and cognitive impairment. However, the use of vitamin E supplementation has not been found to have a protective effect against progression from MCI to dementia or cognitive function. Likewise, vitamin B is linked to cognitive impairment during the aging process. It is considered a standard procedure to check a vitamin B_{12} level when considering a diagnosis of dementia because it is seen as a reversible cause of the cognitive decline. Moreover, various measures of vitamin B_{12}, including methylmalonate, homocysteine, and cystathionine, are associated with episodic memory deficits, slowed perceptual speed, and decreased total brain volume in adults aged 65 years and older. Interestingly, data have related elevated homocysteine levels to amyloid and glutamate toxicity and cognitive decline in animal studies. In addition, vitamin B_3 (niacin) deficiency, also referred to as pellagra, leads to the classic triad of dementia, dermatitis, and diarrhea. Therefore, it is logical that B vitamin supplementation should benefit cognition.

Table 55.2b–2.
Other Natural Products and Supplements Suggested for the Treatment of Cognitive Impairment

Herb/Supplement	Suggested Dose	Possible Mechanism of Action	Evidence Base	Side Effects
Bacopa monniera	300 mg/day	An Ayurvedic medicinal plant that acts as a free radical scavenger and in animal models reduces Aβ; may also boost cholinergic function	No convincing evidence: 9 RCTs; 518 subjects in meta-analysis. Limited evidence given poor study design	GI upset
Curcumin (yellow curry)	2,000–8,000 mg/day	Antioxidant, anti-inflammatory, induces heat shock proteins; antiamyloid effects in animals	Mixed results; no convincing evidence: 2 studies find no effect; 1 study finds beneficial effect	GI upset
Dehydroepiandro-sterone (DHEA)	100 mg/day	Adrenal steroid that declines with aging, is lower in Alzheimer disease patients, and is neurotrophic in animals	No convincing evidence of benefit. 3 RCTs	Acne, balding, insulin resistance, dyslipidemia, mood changes, hepatic dysfunction, possible effects on hormone-sensitive cancers
Hydergine	3 mg/day	Combination of 4 ergot derivatives with vasodilatory effects and possible effect on monoamine and cholinergic transmission	2,000 Cochrane meta-analysis of 19 trials found some evidence of modest efficacy but many trials conducted before standardized criteria for diagnosing dementia	GI upset, psychosis, flushing, blood pressure changes
Lecithin	3,600 mg/day	An acetylcholine precursor	Review of 11 randomized trials showed no consistent benefit	GI upset, rash, headache, dizziness
Resveratrol	Unknown (phase 1 trials 2,500–5,000 mg/day)	Polyphenol in the skin of red grapes and red wine with antioxidant and antiamyloid properties in animals	Clinical trial linking to increased cerebral blood flow. Needs further study on cognitive effects	Possible estrogen-like effects, as its chemical structure is similar to phytoestrogens
Vitamin E	800–2,000 IU/day	Free radical scavenging	No convincing evidence. Cochrane review—3 studies	High dose increases all-cause mortality

GI, gastrointestinal; RCT, randomized controlled trial.

The evidence, however, does not support a robust response in cognition with B vitamins. A multicenter RCT of adults over 50 years old with mild to moderate AD and normal vitamin B_{12} and B_9 levels showed no benefit in cognition with supplementation. Another RCT in China failed to show an improvement with supplementation in cognition with older participants, age 60 years or older, with either AD or VaD and normal vitamin levels. However, the evidence appears to be more promising in individuals without cognitive impairment. A recent RCT of older adults, aged 60 to 74 years, without dementia and normal vitamin B_{12} and B_9 levels showed a benefit in immediate and delayed recall with supplementation. The evidence does not support vitamin B supplementation in treating dementia when levels are normal. However, some data support supplementation in improving cognition prior to the development of dementia. In addition, such use of supplemental vitamins may come at a risk. The Iowa Women's Health Study demonstrated an increase in mortality with the use of various dietary supplements, including vitamins B_6 and B_9. This study supports the fact that it is important for patients and clinicians to acknowledge that being natural is not always safer than "conventional" medicine.

For further details on other utilized CIM therapies for the treatment and prevention of age-related cognitive decline, refer to Table 55.2b–2.

Table 55.2b–3.
Other Natural Products and Supplements Suggested for the Treatment of Late-life Depression

Herb/Supplement	Suggested Dose	Possible Mechanism of Action	Evidence Base	Side Effects
Inositol	6–19 mg/day	Altering serotonin, dopamine, glutamate levels	Mixed findings: 7 RCTs in depression explored (MDD, PMDD). One positive, some negative	GI upset
Saffron	30 mg/day	Serotonergic effects, antioxidant, anti-inflammatory, neuroendocrine effects, neuroprotective effects	5 trials found. Promising findings which need further, high-quality assessment	Headache, nausea, anxiety, decreased appetite
Vitamin D	600–300 k IU/ daily or weekly	Neuroprotection	Promising findings requiring further research. Meta-analysis of 7 RCTs	Fatigue, headache

GI, gastrointestinal; MDD, major depressive disorder; PMDD, premenstrual depressive disorder; RCT, randomized controlled trial.

For other natural products and supplements which may be used for the treatment of late-life depression, see Table 55.2b–3.

Potential Side Effects and CIM–Drug Interactions. As eluded to above, when encountering natural products in a clinical environment, it is important to consider potential side effects and CIM–drug interactions. Table 55.2b–4 outlines an array of clinical findings and potential pitfalls of natural products. It is important to note that CIM use may exacerbate polypharmacy in the older adults, which is a risk factor for drug interactions, medication errors, and hospitalization.

Other Therapies

Acupuncture. Acupuncture, a component of oriental traditional medicine (OTM), is a technique in which practitioners stimulate specific points on the body—most often by inserting thin needles through the skin. Several reports of positive effects of acupuncture for cognitive and psychiatric symptoms of VaD have emerged from China, but a 2007 Cochrane review found the methodologies of most of these studies to be highly problematic, leaving no convincing evidence of positive benefit. Acupuncture, however, has been further examined for the treatment of depression and was found to produce some advantages. Prior reviews of RCTs using acupuncture to treat depression have found some evidence for benefit; however, the majority of included studies have been of relatively low quality, with placebo acupuncture treatment at times yielding similar results to treatment acupuncture. The Cochrane database review

of studies examining acupuncture for depression found insufficient evidence to determine the efficacy of acupuncture compared to standard antidepressants, sham acupuncture, or wait-list controls. Another pilot study examining acupuncture as an augmentation strategy in late-life depression (LLD) showed significant overall improvement in HAM-D rating scales, well-being, and activity from baseline to the end of treatment. This suggests that acupuncture may benefit older adults if they are willing to participate actively. More clinical studies investigating the use of acupuncture are needed to further establish its efficacy.

Table 55.2b–4.
Potential CAIM–Drug Interactions Between Natural Products and Prescription Medications

Herb/Supplement	Prescription Drug(s)	Possible Interaction
Chamomile	Sedatives (or alcohol)	Oversedation
Garlic extract	Protease inhibitors	Decreased efficacy against HIV
Ginkgo biloba	Anticoagulants	Excessive bleeding
	Omeprazole (CYP2C19 substrates)	Decreased drug levels (2C19 induction)
	Antipsychotic	Priapism
Ginseng	Anticoagulants	Excessive bleeding
	Monoamine oxidase inhibitors	Mania, hypertension, headache
	Sulfonylureas, insulin	Hypoglycemia
	Stimulants	Insomnia, anxiety, mania
Kava	Sedatives (or alcohol)	Oversedation
	Levodopa	Increased Parkinsonism
Omega-3 fatty acids	Warfarin	Excessive bleeding
St. John wort	Protease inhibitors	Decreased efficacy against HIV
	Cyclosporine	Organ rejection
	Serotonergic antidepressants	Serotonin syndrome
	Oral contraceptives	Ineffective contraception
	Tetracycline	Photosensitivity
Valerian	Sedatives (or alcohol)	Oversedation
	CYP3A4 substrates	Increased drug levels (3A4 inhibition)
Vitamin E	Anticoagulants	Excessive bleeding

Aromatherapy. Aromatherapy, a therapy related to massage, has found some interesting results in small-scale studies. Aromatherapy is the use of essential oils extracted from plants for health purposes. Trials of

aromatherapy have, at times, combined the application of the essential oils with a massage, while at other times, the patients simply inhaled the aromas of the oils. One study reported the combination of aromatherapy (with lavender oil, commonly proposed to have calming effects) and massage tended to yield less agitation than either condition alone. Another small study in China was positive for simple inhalation of lavender oil versus control oil in reducing agitated behaviors. The most methodologically sound study of aromatherapy used lemon balm oil (*Melissa officinalis*) in a double-blind, placebo-controlled trial for managing agitation in severe dementia and found significant benefits for aromatherapy. Thus, aromatherapy can be used for agitation in patients with dementia.

Body-Based Practices. Body-based practices may include massage therapy and spinal manipulation. The authors are unaware of any strong evidence supporting these therapies in the prevention and treatment of cognitive disorders. However, they may have merits in stress reduction, pain management, and treatment of anxiety disorders. Massage therapy includes many different techniques in which practitioners manually manipulate the soft tissues of the body. It has found some use in dementia care populations.

Medical Systems

Chinese or Oriental Traditional Medicine. Acupuncture is a part of OTM—it is a technique in which practitioners stimulate specific points on the body—most often by inserting thin needles through the skin. Several reports of positive effects of acupuncture for cognitive and psychiatric symptoms of VaD have emerged from China, but a 2007 Cochrane review found the methodologies of most of these studies to be highly problematic, leaving no convincing evidence of positive benefit.

Ayurvedic Medicine. Ayurveda, which translates as “the science of life” and has been described as “knowledge of how to live,” is a complete natural health care system that began in India more than 5,000 years ago and has been used within the context of mental health and aging for memory enhancement and anxiety reduction. Promoting immune system function through anti-inflammatory remedies, Ayurveda is widely used contemporarily in India as a system of primary health care. With the

emphasis on developing an individualized regimen for patients that includes dietary, meditation, herbal, and other components, interest in Ayurveda is growing worldwide to treat a number of maladies, including depression. Through yoga and/or transcendental meditation techniques, Ayurveda promotes lifestyle change and education about how to release stress and tension. Furthermore, Ayurveda is geared toward treating chronic disorders associated with the aging process, and promising preliminary results related to the use of Ayurveda have been found in studies of depression, anxiety, sleep disorders, hypertension, diabetes mellitus, PD, and AD. Of concern regarding the quality of certain Ayurvedic products, in 2008, an NCCIH-funded study examined the content of 193 Ayurvedic products purchased over the internet and manufactured in either the United States or India. The researchers found that 21% of the products contained levels of lead, mercury, and/or arsenic that exceeded the standards for acceptable daily intake.

PERSPECTIVES ON THE DIGITIZATION OF SUITABLE THERAPIES

As we are living through the Fourth Industrial Revolution, where technology trends are accelerating, it is important to consider the role of the digitization of relevant therapies. Therapies can offer digitizable physical activity, meditation, and other forms of patient-empowerment/education tools. While some geriatric patients may shy away from using e-technologies, many are becoming high utilizers of technologies. There are a burgeoning number of research labs focused on technology innovations for geriatric patients, and a large amount of private sector investment capital is moving into this field.

Notable examples of digital therapies include the following. Researchers in Europe recently assessed the feasibility of delivering a Lifestyle-Integrated Functional Exercise program and evaluated the delivery of the intervention by use of digital technology (eLiFE) to prevent functional decline in 61- to 70-year-old adults. They conducted a multicentre, feasibility RCT run in three countries (Norway, Germany, and the Netherlands). Out of 7,500 potential participants, 926 seniors (12%) were screened and 180 participants randomized to eLiFE (n = 61), aLiFE (n = 59), and control group (n = 60). eLiFE participants used an application on smartphones and smartwatches, while aLiFE participants

used traditional paper-based versions of the same lifestyle-integrated exercise intervention. At 6 months, 87% of participants completed the *posttest*, and 77% completed the final assessment at 12 months. Participants were willing to be part of the program, with good compliance and adherence. Despite small errors during start-up in the technologic component, intervention delivery by use of technology appeared acceptable. Another group recently explored the effectiveness of a neurobic exercise program on memory and depression among older adults residing in old age homes. The neurobic exercise program was found to be effective in reducing depression in this population.

A commitment to responsible innovation of these technologies is paramount. For example, most dementia health apps do not have a privacy policy, so bolstered safeguards and improved communication about privacy protection are needed to facilitate consumer safety and trust in the apps. Responsible innovation is an increasingly prominent initiative. A 2020 Organisation for Economic Co-operation and Development recommendation on responsible innovation in neurotechnology proposed the first international standard in this domain. This recommendation "aims to guide governments and innovators to anticipate and address the ethical, legal and social challenges raised by novel neurotechnologies while promoting innovation in the field." It articulates "the importance of (1) high-level values such as stewardship, trust, safety and privacy in this technological context, (2) building the capacity of key institutions like foresight, oversight and advice bodies, and (3) processes of societal deliberation, inclusive innovation, and collaboration."

FUTURE DIRECTIONS

Gaining a better understanding of the clinical effect of CIMs, as well as their safety, is clearly critical for the management of geriatric psychiatry conditions. At present, there is insufficient data on the prevalence, effectiveness, efficacy, safety, and health economic benefits of most CIM treatments. This means patients, health providers, and other stakeholders are unable to access reliable and rigorous evidence on CIMs. When considering future directions for this field, it is important to consider the most recent NCCIH strategic plan for 2021 to 2025 and the ongoing emphasis on integrative health research to bring conventional and complementary approaches together in a safe, coordinated way to

improve clinical care for patients, health promotion, disease prevention, and ultimately, restoring health rather than just treating disease. The NCCIH's updated plan for 2021 to 2025 has five main objectives: (1) advance basic and mechanistic research relevant to dietary, psychological, and/or physical approaches; (2) advance research on whole person health and on the integration of complementary and conventional care; (3) foster research on health promotion and restoration, resilience, disease prevention, and symptom management; (4) enhance the complementary and integrative health research workforce; (5) disseminate objective evidence-based information on complementary and integrative health interventions. Ultimately, this expansion of the definition of integrative health to include whole person health, or helping individuals improve their health in multiple interconnected domains: social, psychological, and physiologic, including connections between organs and systems, serves as a way to bring conventional and complementary approaches together in a safe, coordinated way.

CONCLUSION

Despite the increasing use of CIM by individuals and a growing body of research examining the efficacy of CIM for treating mental disorders, research and scientific support for its efficacy for older adults remains limited for most practices. Overall, there is stronger and more consistent evidence about the benefits of dietary interventions and mind–body therapies for mood and cognitive disorders, while the evidence for most herbal and nutritional supplements remains mixed and inconclusive. The noninvasive nature of mind–body therapies and Mediterranean diet modifications also make these CIM interventions more favorable over supplementation use due to the variability in formulations available, as well as potential drug–drug interactions. However, studies have consistently faced limitations, such as small sample size, heterogeneity of outcome measures, lack of an active control group, and absence of long-term follow-up, particularly in older adults. Additional research is needed to determine predictors and biomarkers of response that would allow the identification of individuals who are more likely to respond to CIM. Implementing CIM interventions in the communities will represent the next phase of CIM research as preventive, well-being–oriented interventions.

Neuropsychiatric disorders in older adults, such as mood, anxiety, sleep, and cognitive disorders, are among the most common reasons for older adults to use CIM therapies. The use of CIM therapies in geriatric psychiatry is promising, with a growing body of empirical research. There is a wide range of research quality within this field, making firm conclusions difficult. More high-quality research is needed to establish efficacy and safety. When promoting the safety of various natural products, clinicians can offer important information to those patients who are less comfortable with "conventional" medicine and prefer alternative "natural" therapies, such as advising on drug–CIM interactions and directing them toward evidence-based indications. It is clear that CIM use is significant in older adult populations and will likely increase, so empirical research is essential.

55.2c The Aging Brain

Robert J. Boland, M.D., and Iqbal Ahmed, M.D., F.R.C.Psych.

Aging is an essential factor in health and disease. Over the adult life span, the body undergoes changes that generally result in loss of functional capacity. Fundamental processes underlying aging drive these changes, and lifestyle factors and diseases can influence them. The brain is not unique in experiencing changes associated with aging that tend to decrease its capabilities. These changes occur at different levels, including clinical evaluation, risk, and protective factors, biomarkers such as brain imaging, and underlying mechanisms and pathophysiology. Although the current understanding of the mechanisms that underlie brain aging is incomplete, there has been much progress in identifying the contributions of aging and disease processes to changes in cognition, mood, and behavior in older adults. Many myths about aging have arisen, and many of us tend to view old age as a time of physical and mental decline and infirmity—however, recent research on successful aging challenges this bias. We have made much progress at defining the cognitive strengths and abilities preserved in healthy brain aging and teasing out contributions of diseases to loss of ability. By delineating the clinical features, biomarkers, and pathophysiology of conditions that are not part of healthy brain aging and impair brain function, such as Alzheimer disease (AD) and vascular pathology, we can, hopefully, develop specific treatments that target these conditions age-associated diseases disease processes. In addition, factors that may limit age-related impairment in cognition and other aspects of brain function and result in greater resilience in the face of aging are also receiving attention; these include cognitive stimulation, social and physical activity, and nutrition. This chapter provides an overview of concepts and challenges in studying and measuring brain aging and its effects on brain anatomy. First, we will review tools and approaches to

measure cognitive aging and neuroimaging studies that have revolutionized how brain aging is studied. Next, we will describe the nature and impact of common age-associated brain pathologies and diseases. We will also consider the burgeoning area of identifying factors that may modulate the effects of brain aging, and we will consider what may mediate those effects. Finally, we will summarize the approaches that may help to promote healthier brain function during aging.

CONCEPTS AND CHALLENGES IN STUDYING BRAIN AGING

How are metrics for brain aging defined and established? Table 55.2c–1 lists some essential questions and issues that are critical to this measurement. First, is it helpful to define approximate stages in brain aging based on transitions at specific ages, even though the underlying processes are likely to be continuous and cumulative? Although it is easy to identify age by time, we do not have biologic markers of the aging processes. By default, “milestones” used to define aging are thus measured by chronologic age and may impose artificial divisions and definitions. For example, many aging studies set a cutoff of 65 or older as older adults. Even disease definitions, such as dementia, have considered onset before the age of 65 as presenile and after 65 as senile. This arbitrary cutoff at 65 was selected based on the age for retirement benefits, established in 1889. In developed countries, the average life expectancy now exceeds 75, and many people live into their ninth and tenth decades. In addition, in the United States and Europe, we see a steady increase in centenarians. So, the concepts of young-old, aged 65 to 75, and oldest-old, aged 85 and older, have arisen. However, no agreed-upon measures or markers other than the passage of time distinguish groups of people in their eighth, ninth, and tenth decades. Studies have not yet shown clearly whether the age-associated decline of brain abilities accelerates at particular ages. Indirect support for acceleration comes from epidemiologic

studies of age-associated syndromes such as dementia, which show an exponential increase in incidence after 65. Therefore, the inadvertent inclusion of some subjects with preclinical dementia influences many “normal aging” studies with a likely outcome that cognitive decline will appear to accelerate in very old age.

Another question about staging is how to develop benchmarks for “normal” brain structure and performance against which to measure effects related to aging and disease. One approach is to collect normative data for groups of apparently healthy individuals of varying ages, that is, to age adjust. This approach may have clinical utility, for example, to define laboratory test cutoffs or identify suboptimal performance as a likely indicator of disease. Clinical, pathologic, and imaging research studies across the life span suggest that the human brain matures, establishes connectivity, and achieves optimal function by the time people reach their mid-to-late 20s. There is some measurable decline beginning as early as the 30s. Should brain structure and performance at age 30 be used as a benchmark to calibrate the magnitude of changes associated with many years of aging? This cutoff may help estimate relative changes in the number of neurons in particular brain regions or changes in connections between neurons and may also shed light on how human cognitive performance changes. Many studies have followed people aged 60 or older to derive data on brain structure or performance and compare subjects in later decades to people in their 60s. However, this may underestimate the magnitude of changes across the adult age span. This underestimate may particularly affect pathology studies, where studies across the age span have indicated that a disorder such as AD expresses itself clinically only after decades of slowly emerging pathology.

Table 55.2c–1.
Important Questions Regarding Brain Aging

1. Should benchmarks or reference ages be used to calibrate the extent of age-related changes? Are there biomarkers of chronologic age?
2. Is brain aging a steadily progressive process or does it accelerate?
3. How can “normal” aging be distinguished from disease-related changes?
4. Are some brain pathologic changes inevitable?
5. What factors are associated with more or less severe age-associated brain changes?
6. Are some brain regions more susceptible to age-related changes than others?
7. Do plasticity and cognitive reserve attenuate the loss of function associated with brain aging?

Secular changes that may exaggerate differences between younger and older individuals may also inflate cross-sectional comparisons across the age span. For example, levels of education, nutritional habits, and the widespread use of medications such as statins and antihypertensives have changed markedly over the past 50 years. These changes may result in differences between cohorts born decades apart when assessed through cognitive testing during life and even in studies of postmortem brain tissue. Longitudinal data relating measures of clinical performance of the brain to the underlying structure are becoming available from imaging studies, but we usually measure serial imaging over a few years rather than decades. However, secular changes do not inevitably result in better brain health. For example, inactivity, obesity, and increasing rates of type 2 diabetes, as well as effects of air pollution, climate change among adults in Westernized societies, as well as global problems such as pandemics, may counteract improvements in education and cardiovascular management.

Almost any physiologic index shows an increase in its variability in association with aging. This increase holds for many aspects of cognitive and motor performance in older adults. The reasons for increased variability are not well understood, but both genetic and environmental factors may contribute. Identifying factors that contribute to decline in brain performance associated with aging, particularly those that may be modifiable or preventable, may lead to interventions aimed at forestalling or attenuating the degree of age-associated decline that falls within what we consider normal.

Are there boundaries between brain aging and disease? Can disorders like AD be demarcated from normal or optimal brain aging? Aging is associated with an increased prevalence of lesions such as senile plaques (SP) and neurofibrillary tangles, vascular brain changes, and neuronal loss. Even though the clinical syndrome of progressive dementia associated with AD is different from the lesser degrees of cognitive change associated with aging, the key pathologic features of AD are present to some extent in most individuals aged 90 or older. If Alzheimer pathology is an inevitable feature of aging, it is possible that extending life span will lead to the inevitable development of clinical AD. Even if AD pathology is an unavoidable part of the aging process, the pathology builds up slowly, over a decade or longer, and the task of understanding factors that may lead to earlier or later age of onset of clinical dementia and the quest to delay the expression of clinical dementia for as long as possible remains extremely important. Because of the high frequency of AD lesions in older adults, it is difficult to carry out studies of brain aging in which the definition of normal requires the exclusion of any degree of AD pathology. Nevertheless, it may be possible to dissect the impact of aging from that of AD. In this quest, biomarkers for AD pathology have been used in studies to illustrate differences in longitudinal cognitive performance and magnetic resonance imaging (MRI) indices of functional brain connectivity in people who test positive for amyloid and tau biomarkers compared to those who test negative.

Studying Brain Tissue: Neuroanatomy, Genomics, and Imaging

Neurons vary significantly in structure and connectivity throughout the brain. An important question is whether aging selectively affects certain neurons or specific brain regions or whether changes are relatively uniform and widespread. To provide a systematic answer to this question would require an enormous amount of work obtaining quantitative measures or neuronal numbers and axonal and dendritic structure throughout the brain from a series of tissue samples across a wide age span. Studies of neurons during aging have typically targeted brain regions whose connections or neurotransmitter circuitry relate to specific brain processes, such as hippocampal neurons with memory.

An issue that has troubled the field for years is the extent of neuron loss with aging. A series of studies by Harold Brody sparked initial interest in this question. Brody's work, supported by other investigators, suggested that the superior-frontal and superior-temporal cortices lost up to 50% of neurons between the ages of 18 and 95, and 20% to 30% losses occurred in the precentral gyrus and visual cortex. Later, investigators found that brain tissue processing caused shrinkage, and the initial studies likely overestimated the density of neurons in younger brains. After appropriate adjustment and the introduction of automated counting methods, investigators found markedly lower estimates of neuron loss. However, the number of neurons is only one of many conceivable measures of neuronal well-being. Recent studies have evaluated the dendritic arbor or synaptic density as indices of neuronal connectivity and have assessed the strength of neurotransmitter circuits by measuring levels of neurotransmitters or their receptors in the brain. These approaches, assessing structure, connectivity, and biochemistry, provide a more nuanced picture of age-associated changes.

Technology advances enable comprehensive protein and gene expression studies in discrete brain regions and even in single neurons. Large-scale omic analysis is now feasible for interrogating the mechanisms of brain aging. In particular, transcriptional analysis using arrays to measure relative mRNA expression, followed by bioinformatic approaches, allows identification and analysis of

signaling pathways. For example, the BRAINEAC project (www.braineac.org) analyzed mRNA expression in 12 brain regions in brains from over 130 people without neurodegenerative disorders covering the adult age span.

In recent years, neuroimaging studies have brought another dimension to the study of brain aging. It is possible to obtain morphologic, functional, and metabolic information about the brain in living people with excellent precision and reliability. The resolution of MRI is sufficient to obtain overall and regional quantitative measures related to the brain. Multimodal brain imaging studies, combining measures of brain structure, connectivity, blood flow, and chemistry in the same individual, are being brought into play to help to understand structure–function relationships.

Thresholds of Pathology, Clinical Disorders, and Cognitive Reserve

Investigators have attempted to define thresholds to clarify the relationship between the pathology and the clinical expression of brain disorders. For example, some have tried to define the burden of pathology or cell loss typically present when a clinical phenotype manifests. For example, studies of postmortem brain tissue of patients with Parkinson disease have suggested that motor symptoms do not appear until more than 40% of dopaminergic neurons in the substantia nigra are lost. This threshold exceeds the extent of neuron loss found in this brain region in studies of normal aging. Impaired reserve and plasticity may play a role in whether age-associated changes in the brain may manifest as disease or not. Subthreshold changes related to aging may increase vulnerability to pathology. For example, an individual with mild Alzheimer pathology may maintain intact cognitive function with aging due to sufficient brain reserve. However, the addition of one or more small strokes may be enough to impair cognition beyond a tipping point, resulting in clinically recognizable dementia. Similarly, age-related decreases in the strength of norepinephrine or dopamine, and possibly serotonergic, circuits may increase the vulnerability for developing

depression, and particular stresses may precipitate it even though they would not have done so at a younger age. Finally, brain aging, with decrease in strength of cholinergic circuits, may increase someone's vulnerability to develop adverse cognitive side effects from medications and develop delirium in the setting of systemic illness.

Cognitive reserve is, in part, a resilience that allows preserved performance in the face of damage, and it may protect against the onset of a clinical disease phenotype. Dr. Yaakov Stern has proposed two types of reserve: brain reserve refers to differences in brain structure that may result in tolerance of pathology, and cognitive reserve describes differences in task performance between individuals. Brain reserve may depend on the intrinsic richness of connections between brain structures or possibly on the total number of mature neurons that remain at the end of brain development. Factors such as education, carrying out cognitively demanding activities, or physical exercise may assist in the maintenance of these connections during aging. Neuroplasticity is an essential component of reserve. Neuroplasticity classically refers to the brain's ability to adapt and strengthen connections or potentially to form new connections between neurons and circuits. Studies of recovery after a stroke or ablative brain surgery support this possibility. However, aging generally leads to less effective recovery after injury, and the brain is no exception. Classically, we considered neurons fully differentiated postmitotic cells, making them particularly vulnerable to cumulative damage sustained over the years. Although neurons do not divide, they can form new synapses and carry out remodeling. This limited view of the regenerative potential of neurons has changed; exciting research findings over the last two decades have challenged the doctrine that mammals do not actively replace neurons. Neural progenitor cells had been identified in birds and rodents and play roles in brain plasticity.

A prominent example is neurogenesis which accompanies the acquisition of new songs by birds. In the 1990s, evidence emerged that similar progenitor cells exist in primate brains, including humans. New neurons can be generated throughout adult life in brain regions

such as the dentate gyrus of the hippocampus, as progenitor cells differentiate in its subgranular zone and in the subventricular zone of the lateral ventricle. Although we are still trying to define the roles of these progenitor cells in health and disease, their potential to proliferate, differentiate, and migrate expands the repertoire of compensatory changes within the brain. In rodent and primate models, brain injury, for example, due to stroke, leads to the stimulation of neurogenesis. Recent studies have suggested that depression may be associated with deficient neurogenesis.

Table 55.2c–2.
Mechanisms Implicated in Brain Aging

1. Oxidative stress—damage to DNA, proteins, lipids
2. Mitochondrial damage
3. Protein misfolding and aggregation
4. Decreased endocrine support (e.g., estrogen and testosterone)
5. Decreased neurotrophic factor support
6. Impaired axonal transport
7. Impaired neurogenesis

MECHANISMS IMPLICATED IN BRAIN AGING

The mechanisms and processes that lead to age-related changes throughout the body and ultimately limit life span are not well understood. Aging has been characterized by one of its leading scientists, Dr. Leonard Hayflick, as the effect of an increase in entropy on molecules such as proteins, lipids, and deoxyribonucleic acid (DNA), resulting in the accumulation of structural changes that eventually lead to impaired physiologic function at the level of molecules, cells, and ultimately the organism. Many mechanisms can contribute to the age-related damage that may impair brain function or reduce brain reserve, as summarized in Table 55.2c–2.

Oxidative stress is particularly relevant to the brain, whose long-lived neurons use oxygen more extensively than any other organ. Although there are many antioxidant defenses and repair

mechanisms, oxidative damage gradually affects the structure of DNA, ribonucleic acid (RNA), lipid membranes, and proteins. These changes may become irreversible, resulting in impaired function of the affected molecules and organelles. Mitochondrial damage associated with aging leads to less production of ATP and more production and accumulation of reactive oxygen species (ROS) may impair energy metabolism. During aging, damaged mitochondria produce less ATP, and more ROS accumulate. The ROS cause oxidative stress that accelerates aging and possible neurodegeneration; an example is the damage in substantia nigra. Proteins that undergo oxidative changes such as nitrosylation or carbonylation may be prone to cross-linking and to aggregation. In addition, they impose a load on the degradative machinery of neurons, which may be unable to remove these abnormal proteins effectively or break them down completely. Diabetes, which is increasingly prevalent with aging, may promote oxidative stress through mechanisms such as the glycation of proteins and the generation of advanced glycation end-products. Caloric restriction has been widely studied in animals as a method that may extend the life span. Decreasing oxidative damage and improving insulin signaling are two potential mechanisms that may explain these effects. However, whether this is effective for life span extension in humans is unknown, and we have not discovered whether it benefits brain health.

Misfolding of proteins, with the adoption of stable insoluble amyloid configurations, is an essential theme in many age-associated diseases. For example, aggregates of amyloid-β protein (Aβ) and the microtubule-associated protein tau form SP and neurofibrillary tangles are the hallmark lesions of AD. In families with early-onset AD, mutations in genes related to Aβ (amyloid protein precursor [APP] and presenilin 1 and 2) are associated with a relative or absolute increase in the production of longer forms of Aβ or produce mutant forms of Aβ that are more prone to aggregate. Evidence to date does not support the overproduction of Aβ in sporadic AD or with aging. Only a small change in the expression levels of specific proteins may be needed to initiate pathology, or

aging may predispose to amyloid deposition in the brain through other mechanisms. Impaired degradation or clearance of Aβ is, in part, responsible for age-associated plaque formation. Factors that modulate the misfolding, aggregation, and clearance of proteins (proteostasis) during aging continue to receive much research attention.

Another age-related factor may be the lack of trophic support of certain types of cells or their connections. Estrogen deficiency after menopause or androgen decline with aging may impair the function of neurons that respond to these hormones. Delivery of neurotrophic factors may be necessary for synaptic plasticity and specific populations of neurons. For example, in aged rodents and primates, the administration of nerve growth factor (NGF) to the brain can enhance cholinergic neurotransmitter circuits and improve performance on cognitive tasks related to memory. Axonal transport is required for neurons to convey proteins and other components needed to maintain the structure and function of their lengthy processes. Impaired axonal transport is one factor in the decrease of growth factors in the aging brain.

Inflammation is a mechanism under exquisite regulatory control throughout the life span. Peripheral inflammation is most likely one mechanism related to aging in general. For example, several cytokines and inflammatory biomarkers, such as C-reactive protein, are increased in serum with aging, and various autoantibodies increase during aging. An increase in microglial activation and other innate immunity mechanisms in the brain may damage or lack appropriate neuronal or synaptic support.

Although there is no obvious selection or survival advantage for genetic factors that influence brain aging, investigators have identified several genes that may impact brain aging. As an extreme case, rare genetic causes of premature aging syndromes, such as progeria, result in hallmarks of premature aging, such as cataract development, skin changes, increased risk of cancer, and immune alterations during childhood. However, these syndromes are not clearly associated with accelerated brain aging or decline. In addition, there are rare genetic mutations associated with early-

onset familial AD, inherited in an autosomal dominant pattern. However, these genes do not appear to have sequence changes that alter the risk or age at the onset of late-life AD. The most common variant associated with the risk of late-onset AD is the gene for apolipoprotein E (APOE), which codes for a lipoprotein involved in cholesterol transport within the brain. There are three APOE alleles, e2, e3, and e4. People who carry one copy of the e4 allele have a two- to threefold increased risk of developing AD, whereas those with two copies have a four- to eightfold increased risk. The e2 allele slightly decreases the risk of developing AD and is overrepresented in people who live into their 90s or 100s.

The ability to generate new neurons in certain adult brain regions also decreases with aging in animal studies. Although direct data are lacking from studies of human brain tissue, a decrease in the production of neural progenitor cells may play a role in brain aging. Another study developed an innovative magnetic resonance spectroscopic index of neural progenitor cells and could detect a specific signal in cultured cells and animals. Furthermore, a small group of human volunteers spanning the age range from 20 to 70 showed attenuation of this signal with age in the hippocampus, an area known to harbor progenitor cells. At present, this represents the best available evidence for the age-related decline of neural progenitor cells in humans. That said, most of the research, including the effects of aging, derives from rodent studies.

STRUCTURAL CHANGES ASSOCIATED WITH BRAIN AGING

Brain atrophy accompanies aging, but the extent to which this represents a loss of neurons is controversial. The belief that thousands of neurons are lost every day derives from studies with methodologic flaws. More recent studies indicate that neuronal cell loss is less conspicuous and may be selective for specific brain regions.

Methodologic issues are essential in brain aging studies. By design, aging studies of human brains are cross-sectional. Secular effects, for example, generational changes in nutrition, general health, and comorbidity, can complicate comparisons in brains of individuals in their 30s and 40s with those in their 70s and 80s. Height and gender influence brain weight and size. Counts of neurons should attempt to adjust for these factors. Also, brain region sizes and neuron count vary as much as two- to threefold across populations. To detect significant changes in the face of high variability requires many samples or large effect sizes. Ideally, the brains used for normal aging studies should be from people formally evaluated close to their time of death. As mentioned above, including brains with AD pathology is inevitable if an aging study includes individuals in their 80s and 90s. However, there are staging systems of AD pathology, allowing for the exclusion of people with a substantial lesion burden.

Postmortem tissue preparation is critical—early studies that claimed that extensive neuron loss accompanied aging were flawed because of shrinkage of brain tissue during its preparation. Technical approaches to imaging and counting neurons have improved in recent years, including automated counting of neurons based on profiles and the availability of cell-specific stains. Stereologic approaches to sample neurons in a relatively unbiased manner have become routine. Comparative studies of brain tissue from aging primates and rodents have the advantage of minimizing postmortem changes and optimizing brain tissue preparation. These provide valuable data that complement direct studies on human tissue.

Total brain weight reaches a maximum in young adults around the age of 20, followed by a progressive decline thought to begin around the ages of 30 to 40 and reaches its nadir after 85 (Table 55.2c–3). By that age, on average, brain weight has decreased by 11% compared to the maximum. Investigators have found similar findings of an age-associated decline in studies of chimpanzee brains. Neuroimaging studies have provided both cross-sectional and longitudinal data showing that brain volume decreases with age, accompanied by an increase in the volume of the ventricles.

Quantitative MRI studies have shown that brain volume decreases across the adult age span. Some studies have suggested that brain volume loss may accelerate with aging, with about 0.1% to 0.2% of brain volume lost per year between 30 and 50, increasing to about 0.3% to 0.5% per year after 70. Preclinical diseases related to aging, including vascular changes, amyloid, and tau deposition, may contribute to this apparent acceleration. Although the whole brain, including gray and white matter, shows volume loss, regions such as the hippocampus and frontal and parietal cortices are affected to a greater degree than the occipital cortex.

What explains the decline in brain weight or volume? Neuron loss, as discussed, has been overestimated in the past. However, after Hege Gundersen and colleagues introduced stereologic methods (including the dissector and its modification, the optical dissector), studies by Bente Pakkenberg and Gundersen reported a less substantial loss of neurons across the adult life span, representing about 9.5%. Other studies have questioned whether there was substantial loss of gray matter, attributing age-associated declines to loss of white matter.

Table 55.2c–3.
Structural Changes Associated With Brain Aging

1. Decline of brain weight
2. Neuron loss
3. Neuronal atrophy
4. Synaptic loss
5. Pruning of dendritic trees
6. Nucleolar atrophy
7. White matter changes
8. Gliosis

Neuron atrophy, rather than loss, could contribute to the age-related decline in brain weight. For example, a classic study by Dr. Robert Terry and colleagues used a computer-assisted method to estimate neuron numbers and size in the superior-temporal, medial-

frontal, and inferior-parietal cortical regions from ages 24 to 100. They found that the number of large neurons decreased in all of these regions, accompanied by a corresponding increase in the number of small neurons. In addition, investigators have documented the atrophy of pyramidal cells. In particular, pyramidal neurons in the hippocampus and cerebral neocortex show atrophy. This atrophy is associated with shrinkage in the nucleolus or loss of cell body RNA.

Regional and Microstructural Changes

Investigators are re-examining whether particular regions are vulnerable to neuron loss with aging. The hippocampus and its subregions, such as the entorhinal cortex, CA1, and CA2, have been singled out due to their role in memory and learning. The use of high-resolution MRI, for example, at 4 or 7 Tesla strength, allows for acquiring regional anatomical information in great detail. For example, in a study of healthy individuals spanning the age range from 20 to 85, the CA1 subregion of the hippocampus showed the most significant degree of volume loss with age, whereas the entorhinal cortex, CA2, CA3/4, and dentate gyrus showed much less change. How does this compare with pathology studies? Teresa Gomez-Isla and colleagues applied stereologic techniques to the entorhinal cortex and found no appreciable loss of neurons in cognitively healthy individuals in their 70s and 80s; by contrast, there was a substantial degree of neuronal loss in AD, even when clinically very mild. When they similarly studied the superior temporal cortex, an area representative of the association cortex, once again, there was no significant loss of neurons with aging. However, stereologic studies of the CA1 subfields have been inconsistent. Some investigators have found decreases in neurons in CA1 and the subiculum with age, but others failed to find these effects. The reasons for these discrepancies are unclear. Using similar stereologic methods, studies of monkeys have shown no appreciable loss of neurons with age in the entorhinal cortex, CA1, CA2, or subiculum. However, despite the intact number of neurons,

decreases in *N*-methyl D-aspartate (NMDA) receptors were evident in aged monkey brains. This finding raises the possibility that changes short of neuronal death may occur during aging and may provide a substrate that could explain the cognitive decline.

Changes in Synapses and Circuits

Neurons function by exchanging information across circuits and networks. The shape and branching of dendrites vary markedly between different neuron types and within individual neurons of a particular class. Dendrites have protrusions called spines, which contain excitatory synapses. These vary in density across the dendrite length and increase in number with successive branches of dendrites. Even in the absence of overt neuronal loss, changes in dendritic branches or spines could impair neuronal circuit function. A consistent finding in anatomical studies is age-related, prominent in pyramidal neurons in areas such as the prefrontal, precentral, and superior-temporal cortices. Studies using fluorescent dyes have revealed a marked loss of dendritic spines at all levels of dendrites in aged monkeys. Dendritic changes may link to the levels of neurotransmitters and strength of certain types of neurochemical circuits. For example, the glutamate R2 and NMDAR1 receptors show decreased expression in monkeys associated with aging, in areas such as the prefrontal cortex for glutamate R2 and projections from the superior-temporal cortex for NMDAR1. Detailed studies of postsynaptic non-NMDA glutamate receptors in monkeys have suggested that these remain functionally unchanged in primates in areas such as the prefrontal cortex. However, there appears to be an increase in the level of inhibitory synaptic input to pyramidal cells in this area. The increased release of γ-aminobutyric acid (GABA) from presynaptic neurons could explain this. In the absence of overt neuron loss, these changes in morphology and biochemistry could form a substrate for declining performance on cognitive tasks that assess memory, learning, and cognitive processing speed. Of interest, circuits that are highly vulnerable to degeneration in AD may

also display synaptic changes similar to those described above in association with aging.

Neuroimaging and electrophysiologic methods (e.g., EEG and magnetoencephalography [MEG]) can help develop functional brain maps and identify overall and regional brain connectivity. Functional MRI (fMRI) evaluates cerebral responsiveness to activation in human subjects. This approach takes advantage of the BOLD (Blood-oxygen-level-dependent) signal, which is related to a decrease in deoxyhemoglobin concentration and an increase in cerebral blood flow that accompanies local neuronal activation. Such studies can explore the activation of brain circuitry in response to cognitive tasks. Many fMRI studies evaluate neural activation of regions and circuits in the brain with aging. For example, the extent of hippocampal activation in response to episodic memory tasks decreases in cognitively intact subjects aged 70 or older compared to younger adults. Resting-state fMRI takes advantage of correlated regional blood flow changes at short time scales to investigate and map the degree of large-scale coordination between brain systems. A default network of functionally interacting anterior and posterior brain regions is associated with internally directed mental states and is vital in forming a substrate for memory acquisition and planning. Early studies exploring aging, for example, those by Buckner and colleagues reported a sizeable age-related decrease in functional connectivity between these systems that correlated with worse cognitive performance, particularly prominent after 70. The most likely structural basis for this functional decline was the disruption of white matter integrity. The ability to image preclinical amyloid pathology by amyloid PET scanning has led to a reappraisal that connectivity changes in cognitively intact older adult individuals are more significant in those with positive amyloid scans than without.

In summary, the level of understanding of structural changes in the brain that accompany aging remains descriptive. It will be a great challenge to define the mechanisms that underlie these changes. Brain imaging provides tools to study the effects of risk factors that may explain some of the variability of brain changes in later life. They also may help to interpret the effects of interventions that may

decrease the degree of age-associated decline or enhance the function of brain networks or connectivity, as discussed below.

LESIONS IN THE AGING BRAIN

Various pathologic markers are visible on microscopic examination of brain tissue from older adult individuals (Table 55.2c–4). Markers such as corpora amylacea, lipofuscin, or neuromelanin, may represent cellular responses to aging with uncertain clinical consequences because they do not correlate with clinical disorders or with a decline in function. Others such as amyloid deposits and neurofibrillary tangles are markers of AD when they exceed a threshold. In older people who lack defined disorders such as dementia, the overall burden of these lesions may likely contribute to cognitive decline attributed to aging. For example, circumscribed distribution of tau aggregates is a common part of aging in the absence of significant amyloid deposits, and some experts have proposed the acronym primary age-related tauopathy (PART). PART may be asymptomatic or associated with mild cognitive changes.

Table 55.2c–4.
Lesions That Accumulate in the Brain With Age

1. Lipofuscin
2. Corpora amylacea
3. Neuromelanin
4. Amyloid deposits, including senile plaques
5. Vascular amyloid
6. Neurofibrillary tangles and argyrophilic grains
7. Lewy bodies
8. Aggregates of TDP43 and hippocampal sclerosis
9. Vascular (ischemic) lesions

Lipofuscin is the most common age-related marker seen in tissues throughout the body. Postmitotic cells such as neurons accumulate lipofuscin more extensively than mitotic cells. Lipofuscin is

particularly evident in neurons in the inferior olive, dorsal root ganglia, anterior horn cells, the dentate nucleus of the cerebellum, and large neurons in the cerebral cortex. Lipofuscin consists of protein and lipid, mostly oxidized and contained within lysosomal membranes. Metals, particularly iron, are also present. Lipofuscin is evident as intracellular autofluorescence or can be seen using lipid stains or via electron microscopy. Lipofuscin likely represents the remnants of incomplete mitochondrial breakdown by lysosomes. The accumulation of small amounts of lipofuscin may allow cells to sequester aged mitochondria of cross-linked proteins. However, when lipofuscin occupies large cell areas, it is less clear that this is adaptive and likely adversely affects cellular processes.

Corpora amylacea are round, cytoplasmic glycoprotein inclusions most commonly seen in astrocytes, which are found in the brain after age 40. They may arise due to the effects of oxidative stress and iron imbalance within astrocytes. However, it is uncertain whether they represent a cellular defense that sequesters iron or oxidized components of mitochondria or whether their presence may impair the ability of astrocytes to function optimally. The number of corpora amylacea is increased markedly in the brain in AD.

Neuromelanin may be found within neurons as early as 3 years of age and increases throughout life. It is particularly abundant in the substantia nigra and the locus ceruleus. The function of neuromelanin is not known. However, it contains melanins, derivatives of dopamine, and lipofuscin. Neuromelanin likely forms after the uptake of extracellular dopamine and its oxidation and may represent a means to sequester potentially damaging dopamine byproducts. In addition, Neuromelanin avidly binds iron, which may be protective, but could act as a source of oxidative stress in association with aging.

Protein misfolding is a prominent feature in many body organs, accompanying aging and associated with the disease. In the brain, aggregates of Aβ form extracellular SP and deposit in the walls of meningeal and intraparenchymal arterioles. Tau forms aggregates with the ultrastructure of paired helical filaments. Its aggregates are in dystrophic neurites, argyrophilic grains, and neurofibrillary tangles.

Both plaques and tangles are associated with aging, and AD patients have them in greater abundance. Because there is no unique morphology of plaques or tangles that characterize AD but is absent from cognitively intact older adult individuals, pathologic criteria used to diagnose AD are quantitative. Both plaques and tangles are necessary for a diagnosis of AD, and the distribution and burden of tangles, as well as neuronal loss, more strongly correlate with cognitive abilities and dementia than does amyloid. There are several sets of pathologic criteria for AD. These have been updated in light of increasing knowledge of the anatomical distribution of tau lesions. National Institute on Aging and the Reagan Institute (NIA-Reagan) criteria combine the presence of abundant neuritic plaques with the anatomical extent of tau pathology (limited to entorhinal cortex, spread to the hippocampus, or spread to neocortex) to assign a low, intermediate, or high probability that AD is present. These were recently modified to also score the extent and nature of Aβ pathology as a “phase” of brain amyloidosis.

Studies of individuals with intact cognitive performance close to the time of death have reported an age-associated increase in the number of plaques and tangles. About one-third of cognitively normal subjects in their 80s meet NIA-Reagan criteria for an intermediate probability of AD. In people without dementia, tangles are usually limited to the hippocampal formation. The spread of these lesions to involve association areas in the temporal neocortex, and more widely, is more clearly linked to the development of clinical evidence of cognitive decline and dementia. In very older adult individuals with AD, there is also a lower tangle burden compared to younger individuals with AD. This finding suggests that brain reserve is diminished in association with aging so that only a small increase in tangles is necessary to lead to the clinical expression of dementia. The question of whether AD pathology contributes to age-associated changes in general cognitive performance is not clear. Autopsy studies have suggested that people in their 50s may have some degree of amyloid deposition and tangle formation. However, tau pathology does not occur through the brain but instead is usually restricted to hippocampal subregions and the entorhinal cortex and

may represent PART. Age-related declines in cognitive speed and executive function correlate weakly with plaques and tangles.

Two other lesions occur variably in association with brain aging. With the loss of neurons in the CA1 and sometimes other hippocampal regions accompanied by gliosis, we generally do not consider hippocampal sclerosis a part of “normal” aging. However, its prevalence increases with age, being in about 15% to 20% of brains of people over age 90. When present, hippocampal sclerosis contributes to cognitive loss and dementia and is usually associated with aggregates of a protein called TDP43. Another protein, α-synuclein, forms aggregates within neurons, including structures, called Lewy bodies, which are perinuclear intraneuronal inclusions. These are the identifying pathology of Parkinson disease. They occur in subcortical areas such as the locus ceruleus and substantia nigra, and cortical and limbic regions in small numbers and exist in up to 20% of elders examined at autopsy. Like hippocampal sclerosis, α-synuclein aggregates are more likely to be present in the brains of people with cognitive impairment and are more likely markers of preclinical disease processes than adaptive changes of brain aging.

Age-associated vascular changes in the brain have received increasing focus. The many faces of vascular pathology include cerebral infarcts, lacunar infarcts, microangiopathy, and amyloid angiopathy. Some of these lesions, in particular infarcts, are not inevitable accompaniments of aging but are related to vascular risk factors such as hypertension and diabetes. Cerebral amyloid angiopathy (CAA), with deposition of Aβ in the walls of leptomeningeal and medium-sized and small arterioles, is present in at least 30% of older adult individuals and can occur in the absence of the diagnosis of AD. Vessels laden with amyloid may rupture, resulting in lobar hemorrhage, which may cause neurologic deficits. MRI studies indicate that microhemorrhages, visible on gradient echo MRI sequences, may occur in association with CAA, and if extensive, are associated with impaired cognition. The widespread use of computed tomography (CT) imaging and MRI in studies of aging and cognition has led to an appreciation of white matter

changes. On CT, these appear as a periventricular halo of hypodensity. On MRI, they are easiest to detect on T_2-weighted images. They have various appearances, including periventricular hyperintensity, capping of the ventricular horns, and hyperintense spots of varying size. The hyperintense spots may coalesce to form larger cotton–wool-like confluent areas in the fiber tract projections of the centrum semiovale. Initially referred to as leukoaraiosis, many attributed these changes to incomplete ischemias affecting the white matter tracts. Capping of the ventricles is not related to ischemia, but age-related disruption of the ependymal layer increased accumulation of interstitial fluid and subependymal gliosis. Neuropathologic findings vary and often include pallor and loss of myelin. Cognitive testing in older adult individuals with white matter changes reveals decreased performance on timed tests and tasks dependent on executive function. White matter changes are more extensive on MRI in people with vascular risk factors such as diabetes and hypertension. These vascular factors may worsen the severity of age-dependent changes in the structure of long projecting tracts that extend through the white matter.

Detailed microscopic studies of blood vessel morphology have raised further questions about vascular factors in age-associated cognitive decline. For example, a decrease in the diameter of capillaries in hippocampal subregions, independent of AD-related lesions, raises the possibility that microvascular changes could contribute to neuron loss or damage. These changes might alter the available cerebral blood flow to neurons in the hippocampus, resulting in oxidative stress, damage, and eventually neuronal death. Intervention to treat hypertension and diabetes in middle and later life could help forestall some of the cognitive decline attributed to aging, although clinical trials of antihypertensive treatment have had mixed results on cognitive outcomes to date.

Another vascular measure is cerebral blood flow, which can be measured using positron emission tomography (PET). More recently, investigators have used the magnetic resonance technique of arterial spin labeling (ASL) to measure cerebral blood flow. This method

magnetically tags water protons in the carotid and vertebral arteries at the base of the brain, the major conduits of blood supply to the brain. As these tagged protons enter the brain, they alter the local magnetization state in proportion to blood flow. There have been relatively few large-scale studies of cerebral blood flow with aging. In general, total cerebral blood flow decreases with age, with studies reporting about 0.5% to 0.6%/year changes. Recent studies that have examined regional cerebral blood flow have identified heterogeneous changes: decreases with age seem to occur mainly in limbic and tertiary association cortices, with little change in regions such as the primary visual cortex. Vascular risk factors may adversely affect global and regional cerebral blood flow.

NEUROCHEMICAL CHANGES IN AGING

Many neurotransmitters and neuropeptides in the brain change with age. Two of these, dopamine and acetylcholine, will be highlighted because of their importance in cognitive and affective function and their potential importance in neuropsychiatric disorders. Much of the decline in neurotransmitter concentrations is due to presynaptic changes, often secondary to loss or atrophy of subcortical projecting neurons, for example, the pigmented cells of the locus ceruleus and substantia nigra (which produce norepinephrine and dopamine, respectively) or the nucleus basalis (which produces acetylcholine). Aging may also affect postsynaptic processes that affect transmitter function, including a decreased density of postsynaptic receptors and possible decreased efficiency of signal transduction.

Populations of dopaminergic neurons show marked changes during aging. In monkeys, neurons in the substantia nigra staining positive for tyrosine hydroxylase decreases by as much as 40% to 50%. This decrease may be associated with increased α-synuclein content in individual neurons, a potential factor related to decreased strength of dopaminergic transmission in the nigrostriatal system. These changes may account for slowing movement and possibly slowing cognitive processes in association with aging. Anatomical studies in primates show that dopamine innervation from the

midbrain projects to extensive areas throughout the cortex. There are two broad projections, ventral tier neurons that project predominantly to the striatum and the dorsal tier, whose cells express calbindin and project to limbic, cortical, and selected striatal areas. More detailed anatomical studies may be required to evaluate the specific contribution of these different types of cells with aging. A decline in the strength of dopamine transmission in the mesolimbic and mesocortical pathways may contribute to increased vulnerability to disorders such as depression in aging.

PET imaging can obtain quantitative data for indices of dopaminergic neurotransmission. Studies find age-associated declines in dopamine transporter levels, D_2 receptors, $5HT_2$ receptors, and $5HT_{1a}$ receptors. However, the patterns of decline differ. For example, dopamine transporters and D_2 receptors show a linear decline with age, but serotonin $5HT_2$ receptors decline rapidly during the fifth decade of life and then more slowly.

Cholinergic neurons in the nucleus basalis of Meynert and the septal nuclei project widely to the hippocampus and neocortex. They function to activate brain regions involving sustained attention, long-term potentiation, and memory formation. In animal studies, lesions to cholinergic nuclei result in deficits in memory abilities. Aged rodents, monkeys, and humans show a decrease in the levels of markers of the cholinergic system with age. In AD, there is a more dramatic decrease which parallels the severity of dementia. Although the mechanisms of these age-related declines are unknown, diminished neurotrophic support is one possible factor. Cholinergic neurons respond to NGF, and decreased retrograde transport of NGF from targets to the cell body may atrophy the cholinergic cell bodies. Treatment of aged animals with grafted cells genetically engineered to secrete NGF resulted in improved cognitive test performance and increased cholinergic markers. However, human studies of gene therapy with NGF in AD have been disappointing. It may be that waiting until observable symptoms of dementia emerge is too late a time for gene therapy, and focusing on detecting pathologic processes at an earlier stage will improve outcomes.

CHANGES IN COGNITIVE AND MOTOR ABILITIES ASSOCIATED WITH AGING

Much research has documented changes in cognitive abilities, particularly memory, accompanying aging (Table 55.2c–5). On tests of episodic memory, both the acquisition of new verbal or visual information and recall after a delay show decline with age. These are evident even when comparing the performance of 40-year-olds to that of 20-year-olds. On average, subjects at age 80 perform approximately 1.0 to 1.5 standard deviations below the mean for young adults. Whereas performance appears to decrease throughout the adult age span, the decline may be a little steeper after age 60. Other aspects of cognition, including working memory, perceptual speed, spatial visualization, and inductive reasoning, show a similar age-related decline. Age-related effects on different types of cognitive tests are correlated, suggesting that widespread brain changes underlie them. One such factor is cognitive slowing; if we remove time limits from specific cognitive tests and the scoring criterion is accuracy, older adult individuals improve their performance. Similarly, multitasking and cognitive control are more difficult for older persons. As demonstrated by performance on timed tests, retrieval of semantic knowledge, including words and names, is impaired in aging. However, vocabulary, semantic memory, and cumulative knowledge tend to increase with age and remain preserved in old age. Decline in social cognition has been noted in the ability of the older adult to correctly identify another person's state of mind. This appears to be related to cortical and white matter volume loss in the prefrontal, temporal, and insular regions. The ability to perceive emotion remains more intact.

Table 55.2c–5.
Brain Performance Measures That Worsen With Aging

1. Cognition
   – Mental speed
   – Fluid reasoning
   – Working memory
   – Retrieval
   – Episodic memory
   – Free recall worse than recognition
2. Movement
   – Gait slowing
   – Simple reaction time slowing
   – Upward gaze
   – Balance changes (vestibular, sensory, motor, and brain)

Many aspects of movement show evidence of slowing with aging. One of the more noticeable features is the slowing of gait and tendency to stoop, typical in the oldest. Older adult individuals also show a decline in balance: difficulty standing on one leg or performing a tandem walk usually begins after age 70. The decline is most likely multifactorial, with contributions from declines in nerve and muscle function, changes within the spinal cord, sensory systems (vision and vestibular function), and brain changes involving structures such as the basal ganglia. In addition, simple reaction time and movement time are both slowed with aging, resulting from changes to white matter tracts and neuronal networks that initiate and coordinate rapid movements.

AGE-ASSOCIATED BRAIN DISEASES

Several disorders show a predilection for the aged brain (Table 55.2c–6). Neurodegenerative diseases rank high on the list; AD is the brain disorder most intimately related to aging. Both the incidence and the prevalence of AD show an exponential increase

after the age of 60. Parkinson disease has a prevalence of approximately 1% to 2% in the general population. The prevalence of Parkinson disease increases with aging and may be as high as 4% to 5% in individuals aged 85 or older. However, the frequency of Lewy bodies—the signature pathology of Parkinson disease—in the substantia nigra in series of autopsies from people aged 60 to 90 is higher, typically around 5% to 8%. This finding is consistent with the concept that reserve may protect against the clinical expression of Parkinson disease. Amyotrophic lateral sclerosis (ALS) is much less common than AD or Parkinson disease. Its onset is more common among people aged 60 or older than in younger persons without a causative gene mutation.

Table 55.2c–6.
Age-Associated Brain Diseases

1. Alzheimer disease
2. Vascular dementia
3. Normal pressure hydrocephalus
4. Parkinson disease
5. Amyotrophic lateral sclerosis
6. Depression
7. Seizures
8. Sleep disorders
9. Essential tremor

The incidence of stroke increases with age. This increase includes clinically apparent strokes and evidence of stroke on neuroimaging in the absence of a history of stroke (silent infarcts). In population-based studies, silent infarcts are much more common than symptomatic strokes in older adults, and the overall prevalence of infarcts on MRI may be as high as 20% in older adults. In addition, the prevalence of MRI-defined infarcts is associated with aging and with cardiovascular risk factors such as hypertension.

BRAIN AGING IN THE OLDEST-OLD AND CENTENARIANS

In 2016, there were 82,000 Americans aged 100 years or older. This number will likely increase dramatically during this century. Living to be 100 or older is a milestone worthy of celebration if it includes good physical and cognitive function. Several studies have tried to determine the prevalence of dementia in centenarians. Centenarians typically have difficulty performing daily activities, often due to physical or sensory impairment. Because of marked differences in methods of cognitive assessment and incomplete sample ascertainment, estimates vary widely. However, longitudinal data from the 90+ study of nonagenarians living in Leisure World in Southern California identified a marked acceleration in the risk of dementia after the age of 90 with a prevalence of at least 50% by age 100.

In the oldest-old, correlations between pathologic lesions of AD and cognitive status are weaker than those in younger individuals. For example, the Oregon Brain Aging Study followed people aged 85 or older without cardiovascular or major age-associated diseases. Subjects who died without having shown cognitive decline or dementia had scanty SP and neurofibrillary tangles or NFTs, although there was a correlation between the increasing burden of these lesions and impaired performance on cognitive testing. The Leisure World 90+ study includes cognitive testing, clinical evaluation for the presence or absence of dementia, and a high rate of brain examination at autopsy. Whereas counts of SP weakly distinguished people with dementia from those without, the most significant discriminating features for dementia were reduction of presynaptic biochemical markers, overall tangle burden, and the presence of hippocampal sclerosis. Synaptic density may represent a dynamic and adaptive marker initially related to established connectivity during development, later remodeled according to use and plasticity, and then undermined by age- and disease-related processes. A study of more than 300 Dutch centenarians from the

100+ study between 2013 and 2019 showed no decline across investigated cognitive domains for up to 4 years, with the exception of a slight decline in memory function. Cognitive performance was associated with better physical health and cognitive reserve (e.g., higher education). While centenarian brains revealed varying loads of postmortem neuropathologic hallmarks of AD, this was not associated with cognitive performance or rate of decline.

Table 55.2c–7.
Interventions Proposed to Help Maintain Brain Abilities With Aging

1. Control hypertension
2. Treat diabetes and vascular risk factors
3. Regular physical activity
4. Mental activity, e.g., cognitively demanding pastimes
5. Social activity, e.g., friend, family, and community interactions
6. Diet: similar components to a heart-healthy diet, e.g., a diet rich in antioxidants and low in saturated fat, or a Mediterranean-type diet

PROSPECTS FOR HEALTHY BRAIN AGING

In the absence of effective treatment that slows the progression of AD, it is essential to consider how to prevent AD and preserve cognitive abilities during aging. Population-based studies of aging and dementia have suggested that there may be modifiable factors associated with the risk of dementia and or age-associated cognitive decline. These include aspects related to lifestyle and diet as well as medical interventions (Table 55.2c–7). These types of interventions are being evaluated in randomized clinical trials beginning in mid or later life. Early results from one of these studies conducted in Finland are encouraging, suggesting that cognitive performance may improve due to multicomponent intervention in people who have an unhealthy lifestyle.

Converging evidence suggests that physical activity may modify brain aging. In animal studies, maintained physical activity or exercise is linked to decreased markers of oxidative damage in the brain with aging, increased neurogenesis, increased brain perfusion, and lower expression of amyloid pathology in transgenic mice used as models of plaque deposition and AD. Epidemiologic studies have shown that regular physical activity is associated with a decreased risk of developing AD. Vigorous aerobic exercise may not be necessary, as evidence suggests that walking may be associated with risk reduction. Self-reported higher levels of exercise correlate with better cognitive test scores in older adult individuals. There have been many controlled trials of exercise intervention in older adult subjects; a meta-analysis of 18 randomized trials found that aerobic exercise training had beneficial effects for healthy older adults who did not exercise regularly. Effects were more robust for tests of executive function and reaction time than for other cognitive processes and were statistically significant only for interventions that used exercise sessions that were at least 30 minutes long. We need further research to confirm the findings of intervention studies, establish what types of exercise are beneficial, and determine how long and frequent each exercise session should be. In addition to defining a minimal amount of exercise that may show a positive cognitive effect, studies need to identify feasible exercise regimens for most older adult individuals. Along the way, it will be essential to clarify how exercise benefits the brain. Some have suggested that exercise's benefit is related to its influence on oxidative stress by improving the balance between prooxidants and antioxidants. However, much needs to be done in this area to clarify this.

Sleep may be an essential factor as well. Patients with dementia often have altered circadian rhythms, and several studies show an association between the circadian pattern and cognitive decline. Disordered sleep appears to be an independent risk factor for AD. The direction of the cause and effect is not clear—the relationship seems to be bidirectional. However, some investigators have suggested mechanisms for how circadian dysfunction can cause disease progression. For example, many molecules relevant to

memory consolidation, plasticity, and AD are under circadian control. Many clinical studies show that improving sleep can improve cognition. However, these are primarily in younger individuals without dementia, and whether interventions to improve sleep can treat or prevent dementia is an ongoing question worthy of study.

Cognitive stimulation is associated with reduced deposition of amyloid in transgenic mouse models related to AD. It uses such methods as environmental enrichment. Several human studies have found that engagement in cognitively demanding pursuits throughout adult life correlates with better cognitive performance and decreased risk of incident AD. For example, the Rush Memory and Aging Project enrolled over 1,200 people in Chicago, with an average age of 80, who were determined to be free of dementia and followed and reevaluated this cohort annually. They questioned subjects about cognitively active pursuits (such as reading books, attending music or plays, playing card games) and their frequencies. Those subjects who had a moderate or high level of cognitive activity had a lower rate of age-associated cognitive decline, which remained significant even after controlling for age, race, education, depressive symptoms, and chronic medical conditions.

Further analyses have shown that subjects with higher levels of cognitively demanding pursuits had a 2.6-fold lower risk of developing dementia than subjects with a low level. Other studies have reported similar findings, which have given rise to the “use it or lose it” hypothesis. Some fMRI studies support this, showing modifications in specific brain networks, such as attention, default mode, and visual networks. These associations do not necessarily a cause-effect relationship.

Many factors relate to higher levels of cognitive activity in later life, including general health, physical function and mobility, and differences in diet and lifestyle, that may be part of a package that contributes to brain function in aging. There are many intervention studies in this area, recent ones including computerized cognitive training. The Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE) study was a large-scale intervention that enrolled over 2,800 subjects aged 65 or older. Participants were randomly

assigned to receive specific training modules for memory, reasoning, speed of processing, or no intervention. A subset of subjects received booster training at 11 or 35 months after enrollment. Cognitive training improved cognitive performance on tasks specific to the training. This improvement did not, however, generalize into other areas. The effect persisted for the 5 years of the study. Reasoning training resulted in slightly less decline in self-reported instrumental activities of daily living; otherwise, there was no functional benefit associated with training. This rigorous study highlights a key feature of cognitive intervention, training to task. Computer-assisted training appears to influence the specific training area, and it has been challenging to show broader improvement in other cognitive abilities or an impact of training on functional abilities. Unless such evidence emerges, there is no apparent reason to recommend computer games and interventions to improve brain health and function in aging.

Nutrition and brain aging is another area of controversy. It is challenging to randomize people to different types of diet for long-term studies, so research efforts in this area have used dietary questionnaires, short-term interventions, and supplements with vitamins or other nutrients. Many components of diet link to cognitive performance with aging. Some examples of factors that may be protective include eating a Mediterranean or heart-healthy diet or consuming foods with a relatively high content of naturally occurring vitamins with antioxidant activities (such as vitamins E and C). A diet developed at the Rush University School of Medicine which combines the DASH (Dietary Approaches to Stop Hypertension) diet and the Mediterranean diet, called the MIND diet (called the Mediterranean-DASH Intervention for Neurodegenerative Delay) appears to be promising in reducing the risk for developing AD. The Rush team found that this diet lowered Alzheimer's risk by about 35% for those following it moderately well and 53% for those who were rigorously adhering to it. Subsequent studies have not confirmed the neuroprotective benefits of this diet.

Although switching to a healthy diet may have dramatic benefits, studies relying on dietary supplements are less promising.

Supplemental antioxidant vitamins have shown some promise in animal models but have not been promising in humans for improving cognitive benefits or reducing the risk of dementia. Homocysteine levels sometimes correlate with the risk of AD and stroke in several studies. In the United States, fortifying grain products with B-group vitamins has lowered the population's homocysteine levels. However, intervention studies of lowering homocysteine in people with AD had no benefits on cognition. Omega-3 fatty acids are essential nutrients for brain function and growth during development. Clinical trials that have used omega-3 supplementation have had no benefits in AD and have not shown apparent effects in altering cognitive decline associated with aging.

Cardiovascular risk factors, in particular hypertension and diabetes, are associated with worse cognitive function with aging. For example, in the ACTIVE study discussed above, participants with hypertension had a faster decline in logical reasoning tasks, and diabetes was associated with a faster decline on a test of cognitive processing speed. Population-based studies have found that midlife hypertension is a consistent risk factor for accelerated age-associated cognitive decline, stroke, and incident AD. However, although clinical trials of treatment of hypertension in older adult individuals have shown clear benefits for reducing heart attack and stroke, they have had less consistent benefits on slowing cognitive decline. Problems such as dropout during long follow-up periods and the difficulty of maintaining an untreated comparison group limit these studies. As obesity has increased in adult populations in Western societies, attention focuses on whether metabolic syndrome is associated with cognitive performance in older adults. Studies have found that components of the metabolic syndrome, such as diabetes and abdominal girth, appear to be related to poorer performance on a variety of cognitive measures in cross-sectional studies in older adults. Much of this risk appears to be due to hyperglycemia. However, inflammation may also contribute to the risk. Animal trials suggest that such diabetes treatments as metformin can improve memory impairment. Clinical trials are currently examining whether interventions to maintain stringent

control of type 2 diabetes benefit cognitive performance, with preliminary data suggesting that higher insulin doses in diabetic patients can have a protective effect.

Even in the absence of evidence from rigorous intervention studies, it seems reasonable to recommend maintaining physical and cognitive activity, controlling cardiovascular risk factors, and eating a heart-healthy diet to preserve general health with aging, with the bonus that there may be positive spin-offs regarding cognitive abilities. The Institute of Medicine included these lifestyle modifications in their recommendations. They also mentioned avoiding delirium and being cautious about using prescription medications with potential cognitive side effects. It also highlighted the essential planning roles that families, communities, and governments need to develop the environment to support healthy cognitive aging. More recently the Lancet Commission consisting of an international group of experts in dementia proposed prevention interventions incorporating potentially reversible risk factors from different phases of the life-span and not just old age, we are able to propose a novel life-course model of risk, from which population attributable fractions (PAFs) have been derived to show the possible effect on future incidence of successful elimination of the most potent factors. Using this approach, they calculated that more than a third of dementia cases might theoretically be preventable.

Our ability to describe and quantify changes in the brain associated with aging has burgeoned in the past few decades, with parallel advances in studying aging in animal models. Advances in brain imaging continue to have a massive impact on human studies of aging and cognition. Although there is significant progress at a descriptive level, researchers are still handicapped by not understanding which mechanisms are most important in driving the aging process and how they interact to result in biochemical and structural changes in the brain. Because aging is associated with a decline in brain abilities as well as an increased vulnerability to disorders such as dementia and cerebrovascular-associated cognitive impairment, continued research into mechanisms that lead to damage as well as those that support resilience and plasticity

within the brain could pay an enormous dividend by improving health and vitality as society continues to benefit from gains in longevity.

ACKNOWLEDGMENTS

This chapter represents an update and revision of previous chapters in this series, most recently by Douglas R. Galasko, M.D., from the last edition. The authors are indebted to Dr. Galasko for his work and retains much of his prose in this current edition.

55.2d Psychological Changes With Normal Aging

Tina L. Mayes, Ph.D., Maya A. Reiter, M.S., Ph.D., and Jennifer J. Dunkin, Ph.D.

Advances in medicine and improvements in living conditions over the past century have resulted in a greater and greater number of persons reaching old age. This "silver tsunami" of the population is expected to reach its peak over the next 50 years as the baby boom cohort reaches senior citizen status. Projections estimate by 2050, 2

billion people will be older than 65 years. The oldest-old group of older adult individuals—those 85 years of age and older—is expected to grow at the fastest rate. Although on the surface, these demographic trends reflect favorably on society's attempts to eradicate disease, reduce infant mortality, and improve standards of living, recent debates have focused on the "hidden costs" of these changes. For example, aging is associated with increased risks of, among other factors, physical illness, impaired function, personal losses, and cognitive impairment. If these risks translate into significant impairment for the majority of older people, then there will be increased costs to society as a greater and greater number of people reach old age. Unfortunately, current health care systems focus on ways to manage existing diseases rather than targeting healthy aging. If there is not a shift in health care, the world may not be adequately prepared to address the large number of older adults with serious disabilities in the coming years.

From both public health and quality-of-life perspectives, it is important to determine how to maximize the health and well-being of the aged population. It is with this in mind that a number of large-scale longitudinal studies have focused on the concept of "successful aging" to determine what characteristics are present in individuals who appear to reach old age with favorable outcomes. The results of such studies have been important in shaping public policy as well as changing societal views on the nature of the aging process itself. For example, although there are clearly unique life challenges that face older adults, it may be surprising that the majority of research studies suggest that most older adult people report high levels of life satisfaction, cope well with the challenges of late life, and demonstrate considerable resilience in the face of functional and personal losses. Nevertheless, recent studies suggest that even successfully aging individuals are prone to their own negative aging self-stereotypes and that these self-stereotypes cause distress and appear to be related to poorer functional health. Thus, the challenges as a society are to increase the number of older adult persons reaching old age successfully and to decrease negative views of the aging process.

DESIGN AND SAMPLING ISSUES

Design Issues

Most studies in the field of aging are cross-sectional in design, meaning that groups of individuals of different ages are sampled at one point in time. Although meaningful conclusions about differences between age groups can be drawn from cross-sectional studies, it is inappropriate to draw inferences about change over time from such studies because individuals are not studied prospectively, and there is considerable potential for mistaking cohort differences for longitudinal change. For example, there are vast differences between the average 30 year old and the average 70 year old besides age, including the average number of years of education, exposure to historical events and experiences such as the Civil Rights Movement and Vietnam War, comfort with revealing personal information, and ability to navigate technology. Thus, what may resemble change over time may instead be baseline cohort differences. In addition, cross-sectional designs tend to overestimate the relationships between variables that change with time. Another significant issue involves an overutilized of datasets in the aging literature known as the *tragedy of the commons*. A recent review article points out that researchers frequently use the same dataset to publish multiple papers, thereby creating an inherent sampling bias. Because of these issues, it is likely that different trajectories of change will be necessary for each individual age cohort and some scholars call for restrictions, both self-regulation by researchers and through regulatory systems, to guard against the overuse of datasets in aging research.

Sampling Issues

Until recently, most studies of psychological issues in aging have used predominantly Caucasian, well-educated, healthy, and financially comfortable samples of older adults. Studies have primarily used samples of subjects in the so-called young-old age group (65 to 75 years of age) or, less frequently, the old-old age

group (75 to 85 years of age), but rarely the oldest-old group (85 years of age and older). Furthermore, early longitudinal studies of personality development and adjustment used predominantly cisgender-male heterosexual samples. The result is that comparatively little is known about minority older adults, older adult women, LGBTQIA* older adults, inner-city and lower-income older adults, and the oldest-old. Psychological aspects of normal aging in persons with developmental disabilities such as autism spectrum disorder have also received much less attention, which is problematic in light of far higher prevalence rates of mental health as well as neurocognitive disorders in this population. Similarly, many psychometric and neuropsychological tests that measure cognitive functioning do not have adequate normative data for the oldest age groups. Attrition rates are also an important phenomenon: Studies rarely compare individuals who drop out of studies with those who remain in the study. This may overestimate the amount of stability and underestimate the amount of decline in psychological functions, as those who decline in functioning tend to have higher attrition rates than those who do not decline. In terms of cognitive aging, studies have varied considerably in terms of whether individuals with medical conditions known to affect brain function were included in the sample. Although such individuals may be “typical” of their age cohort, their inclusion in studies makes it difficult to determine which cognitive changes can be expected as a function of the aging process itself and which changes may be a function of epiphenomena associated with aging, such as medical conditions.

MENTAL HEALTH AND PERSONALITY

Mental Health Over the Life Span

With the exception of dementing disorders and delirium, most mental disorders are no more common in older adults as compared to younger age groups. Epidemiologic studies have found that prevalence estimates of common disorders such as major depression, anxiety disorders, substance abuse, and psychotic

disorders are generally lower for those over the age of 65 versus younger age cohorts, a finding recently replicated by newly revised prevalence estimates of mental disorders using the NIMH Epidemiologic Catchment Area Program data, as well as the National Comorbidity Survey. Furthermore, longitudinal studies that have followed individuals for up to 25 years have found no evidence that those rates of emotional distress increase with age. However, certain specific mental health disorders may be either more prevalent or more severe in adults over the age of 65. For example, the progression of hoarding disorder symptoms, although beginning in adolescence, has been shown by evidence to peak in severity in older adults. Sleep quality and duration, which negatively impact emotional well-being, cognitive functioning, and mental health, have also been shown to decline in aging. Large-scale studies have shown that adults over the age of 65 have higher rates of insomnia symptoms (difficulty initiating sleep, maintaining sleep, and higher rates of early morning awakenings), with women showing higher vulnerability to difficulties with sleep during aging than men. This could mean that assessing sleep patterns and addressing sleep difficulties may be an important aspect of medical care in older adults.

Age differences in the experience and expression of both positive and negative emotions have also been studied to determine if older adults report more negative emotional experiences than younger adults. In a study using a series of large ethnically diverse samples, older adults reported experiencing fewer negative emotions such as sadness, anger, and fear but more positive emotions such as happiness than those in the younger age cohorts. In another study, even among older persons with physical illness, more positive than negative emotions were observed, lending further support to the notion that even advanced age and illness do not necessarily lead to negativity in outlook. In addition, older adults reported a greater sense of emotional control over negative internal emotional states than younger subjects. To explain their data, the authors proposed an *emotional control* model, suggesting that aging is associated with

an increased ability to inhibit negative emotional states and maintain positive emotional states.

A study found interesting racial differences between older adult Blacks and Whites on measures of psychological distress. The study included over 1,000 high-functioning older adults between the ages of 70 and 79 and found that Blacks were less distressed than Whites, particularly at lower educational levels. The finding remained even after controlling for social support, socioeconomic status, and functional status. The authors suggest that older adult Blacks may be afforded higher status and stay more engaged within their communities than older adult Whites. If so, then the place of older Blacks within their communities could serve as a model for other ethnic or racial groups.

Stage Theories of Personality Development

Early personality theorists proposed that development was completed by the end of childhood or adolescence. One of the first developmental theorists to propose that personality continues to develop and grow over the course of the life span was Erik Erikson. Erikson believed that development proceeded through a series of *psychosocial stages*, each with its own conflict that is resolved by the individual with a greater or lesser degree of success. Erikson termed the crisis of the last epoch of life *integrity versus despair* and believed that successful resolution of this crisis involved a process of life review and achieving a sense of peace and wisdom through coming to terms with how one's life was lived. For example, Erikson proposed that a successful resolution of this crisis would be characterized by a sense of having lived one's life well, whereas a less successful resolution would be characterized by feeling that life was too short, that one did not choose wisely, and a sense of bitterness that one will not have another chance to live life over.

Erikson's theory is descriptive, and few studies have attempted to empirically validate it. However, a recent longitudinal study of approximately 500 subjects from two age cohorts found not only that the earlier age cohort scored significantly higher on a measure of

integrity than the later age cohort but also that scores for both age cohorts on this measure had declined significantly by the final time of testing. These data suggest that the conflict of integrity versus despair may have a more favorable outcome in earlier age cohorts versus later age cohorts, raising the possibility that changing societal values have negatively impacted the struggle for integrity. Although more empirical data are needed, Erikson's theory remains one of the most eloquent descriptions of the potential of late life.

Personality Over the Life Span: Stability or Change?

Although Erikson and other stage theorists focused on unique developmental tasks and stages central to each phase of life, other studies have focused on defining core personality traits within the individual and determining their course over the life span. Studies have consistently revealed five basic personality traits: extraversion, neuroticism, agreeableness, openness to experience, and conscientiousness. Further, these personality traits generally remain remarkably stable over the life span. A number of large, well-designed longitudinal studies that have followed individuals over periods ranging from 10 to 50 years have found strong evidence for stability, although with a few notable exceptions. For example, some studies have found that neuroticism decreases as individuals move from young and middle adulthood to old age, after which it remains stable. Other studies have found slight decreases in extraversion as individuals move into the oldest-old age category, possibly linked to deterioration in health and sensory loss, particularly hearing.

Personality factors may even contribute to mortality in old age. For example, recent studies have found that high levels of extraversion and low levels of neuroticism are associated with a reduced risk of mortality in individuals 65 years of age and older. One explanation for this finding may be that personality traits mediate physical, social, and cognitive activity levels that lead to less healthy and supportive lifestyles.

ADJUSTMENT AND COPING IN OLDER ADULTS

Individuals can expect to experience periods of change, disruption, and even crisis throughout their life span. There is no doubt that older adults experience significant challenges as they enter and negotiate the last phase of life, including bereavement, loss of socially valued roles such as that of workers, and chronic and accumulating health problems. How age affects the process of managing change and discontinuity has been an important research focus, with some authors proposing that people become less effective as they age due to depletion in resources, whereas others have hypothesized that people become better at managing stressful life events over time, secondary to a process of learning more effective strategies. These questions have been investigated from a wide range of theoretical perspectives.

Age Differences in Coping Strategies and Coping Effectiveness

“Coping” is a general term that refers to strategies that individuals use to manage stressful life situations that involve perceived or actual threats. It includes strategies designed to reduce emotional distress, such as distraction, passive avoidance, and positive reappraisal, and strategies designed to solve the problem, such as direct action, confrontation, and information seeking. Cross-sectional studies of age differences in coping strategies have had somewhat mixed results, with some studies finding no differences between age groups in their use of coping strategies and other studies finding that older adults preferentially use strategies designed to reduce emotional distress, whereas younger adults use more problem-focused coping, although the effect sizes are relatively small. This finding has often led to the conclusion that older adults are more passive in their coping style, yet when the type of stressor is controlled, these differences are often eliminated or reduced. In addition, older adults are often attempting to cope with situations that are less changeable than those faced by younger individuals, and therefore, the use of coping techniques that attempt to reduce emotional distress rather than solve the problem may be a more effective approach. In this vein, a study found that older adults who

modify their goals and accommodate and adapt to losses and stressors rather than attempting to exert control or deny losses have a better outcome.

Coping effectiveness across the life span has been another area of interest for gerontologists. The effectiveness of a coping strategy is defined by its outcome, usually measured by the level of distress, depression, or health symptomatology. Clearly, if individuals become less effective at coping with the demands of life as they age, this would have considerable implications for clinical practice and the kinds of interventions that might be used with older adults. However, studies of coping effectiveness have generally not revealed age differences; that is, the old appear to cope as well as the young, and their outcome, in terms of depression and other stress-related symptomatology, is just as favorable. For example, in a study investigating age differences in coping across a broad range of stressors using a sample of over 2,000 men ranging in age from the late 40s to over 90, there were no significant age differences in the reporting of negative emotional states in response to stressors or perceived efficacy in coping.

Role Transitions

Role transitions play an important part in the aging process, and there is no domain where it is more important to understand issues of coping and adaptation than during transitional phases of life. There are many transitions experienced by older adults, but older adults are especially likely to experience two major role transitions: retirement, or the transition from worker to nonworker, and bereavement, or the transition from spouse to widow. These major transitions present the individual with the challenge of having to redefine identity and create new roles to replace those that have been lost. Indeed, there is evidence that older adults who are successful in creating new roles for themselves experience a greater sense of well-being than those who are less successful at this process.

Retirement. Retirement is an age-graded event in which individuals in society are expected to retire at a particular age, regardless of health status or personal preference. It is almost entirely a phenomenon of Western, industrialized, and postindustrialized societies and, prior to the late 19th century, was largely a personal decision. The transition and adjustment to retirement have been characterized by social gerontologists as a *psychosocial crisis*, and the image of the successful executive deteriorating or dying soon after retirement has been popularized in the press. However, recent studies have suggested that most recent retirees rank retirement quite low in terms of its impact on a list of psychosocial stressors, with 17% of men and 11% of women reporting dissatisfaction with retirement. Nevertheless, there is some heterogeneity among retirees, and the factors that predict a poor adjustment to retirement include an involuntary or unexpected retirement, low socioeconomic status, health problems, a competitive and highly achievement-oriented personality (the so-called Type A behavior pattern), inability to set future goals, and general difficulty adjusting to change. Further, despite early data suggesting that there is an increased risk of death in the first 2 years after retirement, studies controlling for health status at retirement have failed to reveal any associations between retirement and mortality. In addition, when preretirement mental and physical health are controlled for, there are no clear associations between retirement and subsequent physical or mental health consequences. Thus, it is important to consider retirement in the context of an individual's life and other changes that they may be experiencing rather than in isolation.

Few studies of retirement have specifically investigated ethnic differences in adjustment. For many ethnic minority groups, retirement represents a significant loss of income because many are economically disadvantaged and earn lower wages relative to their Caucasian counterparts. Available data suggest that many continue to work past retirement age, even in the face of disability and health problems. A recent study suggests that middle-aged African American males can expect to spend, on average, 2.5 fewer years retired than Caucasian males and, therefore, can expect to spend

more time in the workforce with fewer years of retirement and leisure in their old age.

Spousal Bereavement. Demographic data suggest that 51% of women and 14% of men over the age of 65 will be widowed at least once. Bereaved spouses consistently rank spousal loss as among the most stressful of all life experiences. Early work on bereavement and older adults hypothesized that older adults might be less able to cope with the loss of a spouse than younger adults due to declining physical capabilities and subsequent decrements in the ability to manage stress. Subsequent research has revealed age differences in coping with bereavement but in the opposite direction as predicted: Younger bereaved spouses report greater symptomatology on measures of physical and mental health following bereavement than older spouses. Several factors might account for this difference, including cohort effects, with younger cohorts having a greater comfort level in acknowledging symptoms or whether the death was expected or unexpected, with unexpected deaths causing greater symptomatology and occurring with greater frequency in younger age groups.

Other data are consistent with the idea that, as a group, older adults appear to have a more favorable outcome than expected following the death of a spouse. A longitudinal study comparing over 120 older bereaved spouses with age-matched nonbereaved controls found that depressive symptoms peak within the first few months after a death but decline significantly within a year, and after 2 or 3 years of follow-up, although bereaved groups still report significantly higher levels of depressive symptoms than age-matched controls, these differences are very small. Even during the first few months following bereavement, few older adult widows (between 5% and 17%) score in the severely depressed range on depression rating scales. Interestingly, although older adult bereaved spouses report that loneliness and performing activities of daily living are factors that complicate adjustment, many older spouses also report positive feelings following a death, such as relief, in contrast to younger samples. There are nevertheless important exceptions;

studies suggest that older adult survivors of spouses who committed suicide, who have low social support, and who report greater psychopathology at the time of death are all at a higher risk of poorer long-term adjustment. In addition, older adult women who are highly dependent on their spouses for assistance appear to be at a higher risk for adverse outcomes and may require more professional intervention.

Recent data reveal an interesting relationship between bereavement and an excess risk of mortality in older adults. Most studies have revealed that actually younger bereaved spouses face a greater risk of mortality than older recent widows. In addition, older adult White widows appear to be at a greater increased risk of mortality than older adult Black widows, who may not face increased risk at all.

Resilience of the Aging Self

The above review of coping and adaptation in aging suggests that older adults appear to generally cope well with adversities and challenges despite, in many cases, the more chronic and accumulating nature of the stressors that they face. The concept of *resilience* has been offered as an explanatory factor for this phenomenon and is defined as the process of both maintaining adaptive behavior and positive emotions when presented with stress as well as recovery from adversity. Resilience may involve a process of *selective optimization* or an accommodative process of rescaling goals to match one's limitations and the demands of the environment and investing fewer resources available in personally salient activities that maintain self-esteem. For example, a study found that the psychological impact of physical disability was less for those elders over 80 than that in those younger than 80, suggesting that a process of scaling down expectations with increasing age may occur and may be adaptive.

Maintaining a strong sense of self-worth in the face of accumulating losses may be an important part of resilience in aging. For example, a recent study found that self-esteem actually declined

very little over time in a sample of elders with low socioeconomic status and low levels of education, despite experiences of personally meaningful losses. Rather, these older adults appeared to engage in cognitive strategies to protect their sense of self and well-being. In another study, even individuals over the age of 100 who experienced multiple losses in many domains report similar levels of happiness to middle-aged and young-old individuals, and attitudes such as optimism and self-efficacy are more predictive of happiness than objective resources available.

SOCIAL FUNCTIONING IN LATE LIFE

Research over several decades has consistently validated the importance of social support in “buffering” the effects of stress: Given equivalent stressors, those individuals with strong social ties appear to have better outcomes than those who are isolated or perceive that support is unavailable or unhelpful from those in their network. Yet, older adults appear to have reduced social networks, and the frequency of their social contacts is reduced as compared to those of younger adults, and this may be especially true for the oldest-old, whose social networks have been shown to be one-half the size of those of the young-old. This finding was previously thought to be evidence for the *disengagement* hypothesis of aging, that is, that aging involves a process of withdrawal from society and others and the development of a more inward focus. However, for many older adults, the reduction in social contact is not voluntary and may be more related to disability and reduced mobility than preference. The disengagement hypothesis has been recently reframed as *socioemotional selectivity*, based on the finding that although overall social contacts do decrease in late life, it is only contacted with acquaintances and other peripheral individuals that decreases; social contacts with very close friends and family remain stable, and older adults’ satisfaction with these close relationships remains high. It may be that as individuals age and resources become fewer, those resources are adaptively invested in maintaining close relationships as opposed to maintaining acquaintanceships. For older adults with

a *limited future time perspective* or a greater awareness of mortality, there is even more motivation to maintain emotionally meaningful relationships. However, this phenomenon may be at least partially dependent on the external circumstances of older people's lives. For example, in a study of over 500 older adult individuals over the age of 70, the size of social networks and the feelings of connectedness to that social milieu were related to the presence and availability of the nuclear family. Older adults with nuclear family members tended to have social networks that were both larger as well as more emotionally close than older adults without a nuclear family. However, those without a nuclear family reported greater feelings of closeness to friends than those with a nuclear family, suggesting that older adults can adapt to the absence of family by creating satisfying relationships with others.

The social structure of the oldest-old has recently been studied, and data suggest that this group may be particularly vulnerable to social isolation due to multiple losses. In a recent study, most individuals over the age of 85 had at least one surviving relative, but approximately one-quarter had little or no contact with that relative. Most social contacts were derived from children, and for those individuals without children, social contact, and support were not provided from more distant relatives, except within the African American community, where other relatives and friends were available to provide help and support. For the oldest-old, then, the family, especially adult children, appears to play a crucial role in providing social support.

Sexuality in Adults Over the Age of 65

Sexuality is an important aspect of personal life, well-being, personality, and identity. As a group, adults over the age of 65 continue to engage in sexual behavior. That is to say that they experience sexual desire, have sexual thoughts, and are sexually active (both with themselves and with partners). However, as in other life stages, there is a great deal of individual variability in sexuality and sexual behavior in adults over the age of 65. Sexuality

bidirectionally interacts with life satisfaction and mental as well as physiologic health in older adults. Indeed, research suggests that sexually active older adults view their health more positively and that a decline in sexuality in older adults is associated with poorer well-being. Although recent trends in sex positivity have somewhat dismantled the widespread myth that older adults stop enjoying and expressing their sexuality, opposite but equally problematic biases may be emerging, such as the misconception that physical sexual activity is a ubiquitously *essential* part of effective aging. Although sexual health is a highly relevant health care domain for older adults, sexuality concerns may be overlooked far too often in medical settings. Research suggests that adults over the age of 65 can experience more barriers to accessing medical care related to sexuality concerns than younger adults do. This could be related to heightened sex-related stigmas about older adults (affecting both patients and providers). Specifically, research suggests that providers inquire about sexuality-related concerns less frequently in older adults as compared to patients in other life stages. Given that it can be easier for patients to discuss concerns related to sexuality when the provider raises the topic, mental and medical health care workers can improve age-sensitive care by incorporating sexuality-related questions into their routine practice with older adults.

Numerous aspects of normal aging that differ tremendously across individuals can impact sexuality and sexuality-related concerns in adults over the age of 65. These include but are not limited to medical conditions (and effects of treatments for these conditions), life stressors, loss of a spouse and spousal illness, substance use, sexual dysfunction (in individuals with all types of genitalia), and normal endocrinologic changes (which may differ by biologic sex). While age-associated changes may be related in general to a reduction in physical sexual activity, this reduction is not necessarily related to decreased intimacy between romantic partners. Notably, evidence suggests that individuals with major neurocognitive disorders may experience multiple sexuality-related impacts, including decreased sexual responsiveness to their partners as well as increased sexually inappropriate behaviors. Spouses who

experience a role transition into providing care for their partners report a reduction of sexual intimacy with their partners.

Intersectionalities between sex assigned at birth, gender identity, sexual orientation, culture, and religious background, as well as distinct cohort-related experiences, may influence the expression of sexuality in adults over the age of 65. Attitudes about sexuality and gender-related roles and expectations about sex can vary across individuals and cohorts, necessitating sensitivity on the part of clinicians in discussing sexuality-related topics with patients. There are many specific sexuality-related concerns that impact sexuality in LGBTQIA* older adults. For example, LGBTQIA* adults over the age of 80 experience increased victimization related to gender identity and sexual orientation and have higher internalized stigma compared to adults in the 50- to 64- and 65- to 79-year-old age range. In addition, living arrangements may disproportionally impact the expression of sexuality in LGBTQIA* older adults, as fear of victimization and bias related to sexual orientation may hinder sexual behavior while living with family members or even in assisted living communities or nursing homes. Although LGBTQIA* older adults may be more predisposed to such barriers to expressing their sexuality, many LGBTQIA* individuals are thriving, maintain highly satisfying sex lives, and relate extremely positively to their sexual orientation and sexuality.

COGNITIVE AGING

The study of cognition and aging has been an extraordinarily productive area of research over the past several decades. Nevertheless, the existing literature is fraught with difficulties in interpretation, confusion, or disagreement about the inclusion, or exclusion of subjects with medical problems and multiple medications and the inadvertent inclusion of subjects with early dementia, which tends to overestimate the effects of age by lowering the overall mean of older adult groups. Furthermore, until magnetic resonance imaging (MRI) scanning was widely used, studies unknowingly included subjects with subcortical ischemic disease,

confounding the effects of age with disease. In addition, design issues are important; cross-sectional studies, in which individuals of different age groups are compared at one point in time, almost always show broader and sharper age effects than longitudinal studies due to possible confounding of age effects with cohort effects.

Summary of Age Effects on the Major Cognitive Domains

The broad domain of cognition has been divided into subdomains that include attentional processes, language functions, visuoperceptual abilities, learning and memory, processing speed, and executive functions.

Attentional Processes. Attentional processes are a complex group of behaviors by which individuals select information for cognitive processing while ignoring competing information, concentrate on information over a sustained period of time, divide attentional focus between two or more aspects of a task at a time, and shift attentional focus from one set of stimuli to another and back again. Basic attention span is the amount of information that can be apprehended at one time and demonstrates little or no relationship to age. Similarly, sustained concentration or vigilance is not affected by the aging process. However, complex attentional tasks such as divided attention that place more demand on cognitive capabilities show significant declines with advancing age.

Language Functions and Verbal Abilities. Language functions remain remarkably stable with age, with few exceptions. Vocabulary and expressive word knowledge may even increase over the life span. Verbal expression and verbal reasoning skills may demonstrate subtle changes with age, as some studies have shown that spontaneous language may become less precise and more repetitious over time, although most of these conclusions were drawn from cross-sectional studies and may be confounded with cohort effects. Finally, the ability to spontaneously retrieve names of objects from the lexicon appears to show reliable but small

decreases with age, although these effects are heavily influenced by educational achievement.

Visuoperceptual and Visuoconstructive Abilities. Visuoperceptual abilities are those functions that involve the recognition and appraisal of nonverbal relationships, specifically those involving shapes, patterns, and objects with spatial relationships to one another. Visuoconstructive abilities are those involving the reproduction of nonverbal material, such as the direct copy of simple and complex designs. Visuoperceptual abilities demonstrate relatively consistent age effects across studies, with older adults generally performing as well as younger adults on tests of simple object and pattern recognition but performing more poorly than younger adults on measures of visual closure and spatial orientation. Similarly, in terms of visuoconstructive functions, older adults perform about as well as younger adults when copying simple two-dimensional designs but more poorly than younger adults when copying complex three-dimensional designs and when planning and strategy are necessary for good performance. It should be noted that age effects are the largest on visuoconstructive tasks that are timed, and removing the speed component of the task often considerably reduces but does not remove the age difference.

Learning and Memory. Effects of age on learning and memory are among the most well-documented and well-studied effects in the neuropsychological literature. However, “memory” is an extremely complex set of functions and systems, and the aging process affects some components of memory to a greater degree than others. Sensory memory, or the extremely brief sensory record of a stimulus, primary memory, exemplified by the ability to recall a string of digits long enough to repeat them, and tertiary memory, or memories from childhood, show no significant age effects or mild and subtle effects that can be detected in the laboratory. Research studies have consistently shown that secondary memory, exemplified by the ability to learn information and recall it after a time delay, is most strongly affected by age. Nevertheless, the age-related effects on secondary

memory are relatively small: Studies suggest that performance declines at a rate of 10% per decade of life, beginning in midlife. However, once older adults learn information, it is retained well; studies suggest that older adults retain information at rates only slightly below that of younger adults. In addition, available data suggest that spontaneous recall demonstrates considerably stronger age effects than recognition memory, which is the ability to recognize information that has been previously presented.

Processing Speed. Speed of information processing and pure motor speed demonstrate the most reliable age differences and decrements with age, whether measured cross-sectionally or longitudinally. Indeed, reduced processing speed in aging may be a crucial component of many age-related effects on cognition, such that in a recent study, age effects on a number of neuropsychological tests were considerably diminished after controlling for processing speed, even on tests where the speed of performance was not measured. In addition, studies suggest that speed of processing is an important mediator of memory performance, such that some authors have proposed a speed of processing model to account for age-related decrements in memory and other cognitive processes. Evidence suggests that slower processing speed generally leads to slower reading, but typically their relative ability to contextualize what they read remains intact.

Executive Functions. The term “executive functions” refers to superordinate cognitive skills involved in abstract reasoning, problem solving, planning, response inhibition, the ability to shift cognitive set, and a working memory construct that is defined as the ability to simultaneously hold and process information. Early studies suggested that executive functions decline with age. However, studies that use carefully selected samples and exclude subjects with histories of chronic medical conditions known to affect central nervous system (CNS) functioning or documented evidence of subcortical white or gray matter lesions on MRI scanning reveal very few age differences in executive tasks. Because of the relationship

of performance on tests of executive functioning to the presence of medical conditions, especially diseases of the cardiovascular system, these studies suggest that some of these age effects may be preventable.

Models of Cognitive Aging

Taken together, studies suggest that there is a profile of cognitive changes with age that includes significantly reduced information processing speed and pure motor speed and mild decrements in spontaneous recall, executive skills, complex attentional processes, and complex visuoperceptual and visuoconstructive abilities. It should be emphasized that although age-related changes in cognition are statistically significant, most older adult persons still perform within normal limits on cognitive testing. The extent to which these observed changes are related to the process of aging itself, the effects of particular medical conditions on the brain and CNS functioning, and cohort differences in education and experience are not well understood at present, although a recent longitudinal study with a 10-year follow-up interval revealed that significant decline in cognitive functions (excluding psychomotor speed) was apparent only in individuals suffering from poor health. A number of models have been proposed to account for these changes, and these models have included both psychosocial and biologic interpretations. First, it is unlikely that all age-related effects on cognition are secondary to cohort differences because cohort-sequential studies, in which individuals from different age cohorts are followed prospectively, reveal clear longitudinal decline across age cohorts. Unfortunately, studies specifically addressing this important question are few and have only investigated intellectual abilities and not functions such as memory or other neuropsychological variables. It is likely that cohort effects exert the strongest influence on those abilities most dependent on formal education, but this hypothesis has not been formally tested. It is also unlikely that simple disuse accounts for significant aspects of age-related cognitive decline.

The Cattell–Horn model of intellectual changes over the life span proposes that age affects different cognitive processes differently. The model proposes that general intelligence can be subdivided into *crystallized intelligence*, referring to abilities, and information learned through exposure to education and life experience, and *fluid intelligence*, referring to abilities involved in novel problem solving. The model proposes that crystallized intelligence remains stable or increases over the course of the life span and may even increase into old age due to continuous exposure to information. In contrast, fluid intelligence, thought to be dependent on the integrity of brain function, was hypothesized to decline with advanced age. Available data have generally supported this model, with studies showing that there is little evidence of a decline in measures of crystallized abilities such as word knowledge or general fund of information, whereas measures of fluid abilities such as novel problem solving, as discussed above, generally reveal some decline. However, the model, as originally proposed, is limited in that it only discusses changes in intellectual functions, whereas other cognitive functions, such as learning and memory, are not included. Furthermore, the same limitations of studies of executive functions apply to the fluid intelligence concept.

The processing speed hypothesis hypothesizes that many of the observed age-related changes in cognition are, in fact, secondary to reductions in the speed of processing. The model proposes that the speed at which information can be processed limits both the quantity and the quality of cognitive operations. Slowing affects not only how much information is processed within a given period but may also dilute and weaken the associations between neural networks, leading to more impoverished cognitive processes. The model has received considerable empirical support, with most studies finding that a general speed factor is an important mediator of other cognitive processes, such as memory.

Neuropsychological models of age-related decline have attempted to integrate findings from cognitive testing with findings from brain imaging and neuropathologic studies to suggest possible etiologies of cognitive changes. The most promising of these is a model

variously termed the frontal deficit hypothesis or the executive function hypothesis, based on the finding that the pattern of cognitive performance in normal aging, although less pronounced, is similar to that seen in many dementing processes affecting primarily subcortical–frontal circuitry. In addition, neuropathologic data suggest that frontal–subcortical structures are the most vulnerable to aging, with many studies revealing that neuronal loss and degeneration of dendritic arborization are most prominent in the frontal cortex and in some subcortical areas. Further, there are definite changes in the vasculature of the brain with age that result in ischemic white and subcortical gray matter disease that predominantly affects cognitive processes mediated by frontal–subcortical circuits. Finally, one study found that age-related changes in the dopamine system, particularly declines in D_2 receptor availability in some basal ganglia structures, were related to age-related declines in performance on both motor and executive systems tasks. However, most studies have found that executive functions appear to decline at the same rate as other cognitive functions and are not among the first age-related cognitive changes to be observed. This casts some doubt on their central role as mediators of age-related cognitive decline.

Finally, some authors have proposed a “common cause” model, suggesting that decrements in sensory functions, including visual and auditory acuity, may explain age-related changes in cognitive processes. As with the processing speed hypothesis, empirical support for this idea is generally strong, with most studies finding that sensory function is an important predictor of age differences in a number of cognitive processes. Nevertheless, it is clear that an as-yet-unnamed variable or group of variables remains unexplained in accounting for variance in cognitive aging because most studies find that age-related variance remains even after controlling for speed and sensory abilities.

It is important to note that the line between a “normal” process of cognitive aging and a pathologic process is not well drawn at present. For example, there is considerable disagreement in the field

about the inclusion or exclusion of older adult subjects with medical conditions known to affect brain function or individuals with white matter lesions in studies of normal aging and cognition. Because these conditions affect such a high proportion of functional older adult persons, their exclusion may lead to erroneously high estimates of normal expectations of performance and the subsequent classification of many individuals as impaired. In addition, many older individuals without known cerebrovascular risk factors or other medical conditions have periventricular white matter lesions on MRI scanning, further confusing the line between disease processes and normal aging. At present, until this demarcation is better defined, the study of "typical" aging, which attempts to characterize the majority of older adult people, as well as the study of "optimal" aging, which attempts to characterize the ideal outcome of the aging process as well as characterize changes that are a function of aging itself and not epiphenomena of other conditions, are both important pursuits, as long as the research questions are appropriate to the sample being used.

Finally, it may be that older adults' performance on cognitive testing may be affected by their own ageist stereotypes. A recent study found that when, prior to cognitive testing, older adults were "primed" with positive images of aging, their performance improved on measures of memory, as well as measures of memory self-efficacy, in contrast to older adults who were primed with negative images of aging.

SUCCESSFUL AGING

In recent years, there has been a paradigm shift in gerontology, from a view of aging as an inevitable deterioration to one that includes the potential for development and growth. In this section, a number of studies were reviewed that, taken together, support the notion that the process of aging can be managed well by the majority of older adults. In this vein, the construct of *successful aging* was created. In the process, however, there has been considerable debate about how to define successful aging. It has become clear that if one

defines successful aging as the absence of deficits in physical, cognitive, and social functioning, then few older adults would be so classified. A recent study examined both objective and subjective indicators of successful aging and found that only 10% of their sample could be classified as “successfully aged” based on objective criteria that included quantitative assessments of physical, cognitive, and social functioning and measures of well-being. However, when successful aging was defined as a subjective sense of having adapted well to the demands of life or being self-rated, many more individuals were characterized as having aged successfully. In a recent review of data-based studies, the proportion of successfully aged individuals ranged from 0.4% to 95%, thus underscoring this ongoing debate. In general, older adults rate social engagement and positive thinking as more important than physical functioning in their conceptualizations of successful aging. It is likely that any definition should include both objective and subjective definitions of success.

Studies have found that high education, absence of alcohol abuse and cigarette smoking, absence of depression, maintaining an appropriate weight, regular exercise, and social support are all significant predictors of successful aging. Social class, however, does not appear to be an important predictor. Intrinsic psychological factors such as resilience, spirituality, and optimism have also been associated with successful aging. As more is learned about successful aging, both in terms of its psychosocial correlates and biologic correlates, it may be that this knowledge can be translated into useful interventions that can improve the overall number of older adults reaching old age successfully.

IMPLICATIONS FOR CLINICAL PRACTICE

One of the major points of this section is that, with the exception of cognitive processes, age in and of itself is rarely an important predictor of outcome. Studies of mental health over the life span, coping and adjustment, and personality often fail to reveal any significant age effects when other factors are controlled. In addition, research has revealed an often surprising degree of resilience in

older adults. Therefore, the clinician working with older adults should not expect that age itself is a risk factor for poor outcomes. Unfortunately, this notion has probably been partially responsible for the underidentification of depression in many older adult cohorts; many clinicians used to believe that depression was a “normal” response to the aging process. Similarly, in aging adults with developmental disabilities such as autism, there may also be an underidentification of mental health concerns due to a focus on the disability and not on an individual’s particular circumstances. Regardless of disability, clearly, the life themes that older adults struggle with are different from those of younger adults, and the clinician should be prepared to deal with issues of loss of family and friends, loss of independence that leads to increasing dependency, and the struggle to come to terms with the past. In addition, the concept of resilience may be useful in psychotherapeutic work with older adults by using their own strengths to address the challenges associated with aging. Clinicians can encourage patients to invest resources selectively in activities that they find especially gratifying. Moreover, clinicians can enlist the help of family members and encourage basic lifestyle choices (i.e., diet, quitting smoking, and exercise) to further support a better quality of life.

The important exception to some of these conclusions may be individuals in the oldest-old category or those over the age of 85. Research has shown that the oldest-old may be at a higher risk of social isolation than younger age groups, especially those without living children. Clinicians should be alert to the unique life situations faced by individuals in this age group, who may be especially vulnerable not only to isolation but also to increasing frailty and the cumulative deleterious effects of chronic medical conditions. Interventions that both provide social support as well as encourage alternative sources of social support, such as senior centers, may be especially helpful for individuals in this age group without living family.

In terms of cognitive processes, there are clear decrements in some but not all cognitive processes over the life span. However, with the exception of processing speed, these changes are generally

of small magnitude. The result is that the typical changes in cognition should not significantly impact the clinical situation, either the psychotherapeutic encounter or the psychiatric consultation. Some older adults may require more repetition and explanation of material, especially material that is novel and highly abstract, but this can easily be managed with modifications of psychotherapeutic approaches. The pattern of cognitive decline seen in normal aging discussed in this section should alert the clinician to changes that deviate from this pattern that might be cause for concern, especially such things as difficulties with recalling information even after cueing, problems with basic attentional processes, problems with constructing basic two-dimensional designs, or language impairment. At the same time, clinicians need to be alert to the effects of negative age-related stereotypes and their effects on both performance and self-concept.

Finally, it is worth noting that because research findings are based on the central or average tendencies of groups of individuals, the conclusions drawn often mask underlying heterogeneity. This may be especially true with older adults, as research has shown that the variability of almost every construct studied, such as personality, cognition, health status, and income, increases over the life span. It is likely that this increased heterogeneity is a complex interactive process of increasingly individualized expressions of genetic predispositions in response to accumulating demands from the environment over the life span. Thus, the clinician working with older adults may have less precise guidelines or standards for normative expectations for older adult patients because older adults can present with a much wider range of behavior, personality, and life experience than is found in younger adults.

55.2e Neuropsychological Evaluation

Gauri Savla, Ph.D., and Barton W. Palmer, Ph.D.

As medical technology advances rapidly, people are living longer and are active well into traditional definitions of "old age." Nevertheless, this particular demographic is also at the greatest risk for cognitive deficits related to cerebrovascular, systemic, and neuropsychiatric conditions, as well as long-term use of certain

medications. Comprehensive clinical care of older adults, therefore, should almost invariably include some consideration of neuropsychological functioning. Cognitive decline is a core component of neurodegenerative conditions such as Alzheimer disease, dementia with Lewy bodies (DLB), Parkinson disease, as well as cardiovascular conditions such as strokes. Chronic metabolic illnesses (e.g., metabolic syndrome, diabetes) and long-standing autoimmune diseases (e.g., multiple sclerosis) may also be associated with cognitive impairments. Some infectious diseases may also affect cognitive functioning. For example, in the wake of the COVID-19 pandemic, there have been numerous reports of "brain fog" among those experiencing "long-haul" symptoms.

Psychiatric disorders with a typically earlier onset that often extend into later life, such as primary psychotic disorders or severe mood disorders, are also often (but not always) associated with mild to moderate deficits in neuropsychological functioning. These deficits tend to remain more or less stable over the course of the illness (i.e., there are rarely sharp declines in later life without the co-occurrence of a new-onset neurodegenerative illness). An important point to consider is that cognitive deficits, rather than symptoms of primary psychopathology, in schizophrenia and bipolar disorder have a much stronger predictive relationship to the level of adaptive functioning.

Consequently, an evaluation of neuropsychological functioning can be a critical component of effective diagnosis and long-term treatment and care planning in geriatric psychiatry settings.

WHAT IS A NEUROPSYCHOLOGIST?

Neuropsychology as a field of scientific inquiry is not a profession or degree unto itself but falls within the broader field of clinical psychology. The term "clinical neuropsychologist" refers to a licensed clinical psychologist who, in addition to the broader training required for a doctorate and licensure in clinical psychology, has also completed additional training in structural and functional neuroanatomy, neuropathology, and neurobehavioral syndromes. A

neuropsychologist, therefore, is an expert in scientifically grounded brain–behavior relationships.

WHAT IS A NEUROPSYCHOLOGICAL EVALUATION?

Standardized neuropsychological tests that measure cognitive abilities and deficits form the core of neuropsychological evaluation. However, neuropsychological evaluation involves much more than administrating and scoring tests. A valid and clinically useful interpretation of test performance requires the neuropsychologist to consider the examinee's performance within the broader context of their presenting concern as well as prior medical history, psychosocial history and functioning. Thus, in addition to the standardized assessment of neurocognitive abilities, comprehensive clinical neuropsychological evaluations generally include a thorough review of available medical records as well as a clinical interview of the patient and family or other collateral information sources. Personality and emotional functioning are also generally assessed via clinical interviews, behavioral observations, clinical rating scales, and/or standardized psychological tests.

HISTORICAL DEVELOPMENT

The emergence of neuropsychology as a clinical discipline can be traced back to the 1930s and 1940s, when several pioneers of the field, such as Ward Halstead and Arthur Benton, began their studies of brain–behavior relationships using psychometric methods. Many of the tests developed or adapted by Halstead (and the extended battery of tests subsequently expanded by Ralph Reitan), as well as those by Benton, remain core components of contemporary neuropsychological testing. There were also early efforts in the psychometric testing of intelligence and other cognitive functions, as exemplified by the work of Alfred Binet, and the Army aptitude testing programs that emerged during World War I. (These are, by

the necessity of space, only selected examples of a more complex history of psychometric testing.) Another key contributor to the development of clinical neuropsychology was David Wechsler. In 1939, Wechsler published the first version of his Bellevue Intelligence Examination, followed in 1945 by its companion, the Wechsler Memory Scale. Many of the subtests in the Wechsler batteries were adapted from earlier sources. As collective batteries and with appropriate revisions and updates in the ensuing decades, the Wechsler scales have remained among the most widely used measures of cognitive functioning in both clinical and nonclinical populations.

The development of modern clinical neuropsychology was fostered by profound advances in theory and empirical knowledge of brain systems and processes, brain–behavior relationships, and the effects of various neuropathologic conditions on everyday functioning. The nature and quality of standardized normative data for valid interpretation of neuropsychological test results have also improved significantly. These advances have occurred in close collaboration with the growth in related fields, such as cognitive neuroscience, behavioral neurology, computer and information science, as well as profound advances in imaging brain structure and function.

COMMON USES OF NEUROPSYCHOLOGICAL EVALUATIONS

Neuropsychological assessment can be invaluable in geriatric mental health care settings; it can aid in the distinction between normal versus pathologic cognitive and functional changes, differential diagnosis among neuropsychiatric and neuropathologic conditions, and determination of long-term functional needs for treatment and care planning.

There have been remarkable advances in clinical brain neuroimaging over the past three decades, which can be a valuable supplement to, but not replace, the findings from neuropsychological

assessments. One of the most common concerns with older patients is distinguishing normal age-related changes from early Alzheimer disease or other neurodegenerative conditions. A second frequent presenting concern is determining whether an individual's reports of memory or other cognitive deficits are due to depression or primary neurocognitive dysfunction. Clinical neuroimaging can be helpful in identifying gross changes in brain structure, such as reduction in hippocampal volume. In May 2020, the U.S. FDA approved flortaucipir (AV-1451) to image the presence of tau neurofibrillary tangles in the brain with positron emission tomography (PET) scans. These new and emerging technologies are an important part of neuropsychiatric care and help evaluate structural changes. However, the neuropsychological assessment remains key to the examination of patterns of spared and diminished cognitive functions that are critical to everyday functioning.

As an example of the use of neuropsychological evaluation, consider a patient presenting with a report of "poor memory." The term "memory" has a variety of meanings in colloquial use, such as remembering to perform a task ("prospective memory"), finding misplaced objects (which may reflect attention or organizational skills rather than memory per se), and remembering recent events or newly acquired information ("episodic memory"). Even when the concern is narrowed down to episodic memory, it is important to distinguish between a range of underlying memory-related tasks or processes, including difficulties with initial learning or encoding information or difficulties efficiently retrieving information, and actual loss of the memory trace. Results from standardized memory tests are invaluable in making such distinctions. For instance, if a patient shows poor performance on initial learning or recall trials of a test, but after a delay, they are still able to recall most of whatever amount of information they learned, then their deficit is likely one of learning or encoding rather than forgetting. Comparison of cued recall, performance on a recognition format, or both to free recall permits identification of patients with inefficient retrieval rather than actual forgetting. These types of distinctions are key in the differential diagnostic process. Rapid forgetting, that is, the inability to retain

recently learned information, is relatively uncommon with normal aging and even in patients with depression but is quite common among patients with cortical dementias. One would not diagnose a patient based on their performance on an isolated test score (most healthy adults will manifest one or more scores in the impaired range on some measure when given a large test battery), but the presence of rapid forgetting would be an important piece of evidence more consistent with the presence of cortical dementia than with normal aging or depression.

Even when a patient's diagnosis is known, neuropsychological assessment can be valuable in the documentation of the trajectory and rate of cognitive change. For instance, there is considerable variability between patients with neurodegenerative conditions in terms of the rate of cognitive decline. Repeated evaluation with a targeted battery can be useful in determining how fast a particular person is likely to reach a point requiring a more structured or intensive level of care. Conversely, for a patient who has experienced a stroke or other acute brain trauma, repeated neuropsychological testing can be useful in documenting the rate, trajectory, and degree of recovery of cognitive functioning.

Neuropsychological evaluation in geriatric mental health care can also be useful in treatment plans involving the remediation of deficits in everyday functioning. For example, it may be known that a particular patient's "forgetfulness" is causing difficulties in everyday functioning (such as missed appointments, unpaid bills, etc.). In such instances, a key goal of a neuropsychological evaluation is to identify areas of spared cognitive functioning, in addition to documenting the type and degree of any cognitive deficits. With such information, the specific cognitive processes underlying any apparent deficits in independent functioning can be identified, and information about spared abilities can be used to arrange the environment in a way that maximally draws upon the individual's strengths and reduces the potential deleterious functional effects of impaired abilities.

ASSESSMENT DOMAINS AND COMMONLY USED MEASURES

The length and extent of cognitive testing performed by a neuropsychologist frequently vary depending on the nature of the presenting concern and the general context or purpose of the evaluation. Neuropsychological assessments range from screening procedures that can be completed in 30 minutes or less, whereas a more comprehensive evaluation generally requires several hours to complete. The latter type of testing is particularly valuable in identifying cognitive strengths and weaknesses across a range of more specific neurocognitive abilities. Some of the common constructs evaluated as well as examples of tests frequently used to assess these constructs are described below.

Cognitive Screening

The majority of brief cognitive screening measures were designed specifically to stage the severity of Alzheimer disease or other dementias, so they may be insensitive to other functionally relevant forms of cognitive impairment. They also tend to be less helpful in identifying areas of clear cognitive strengths.

One of the most widely used dementia screening measures is the Folstein Mini-Mental State Examination (MMSE). The MMSE has a potential range of 0 to 30, with scores below 24 generally considered "impaired." Advantages of the MMSE include ease of administration and scoring; it typically takes less than 10 minutes to complete, can be reliably administered and scored by trained clinic staff, and can be tolerated even by very low-functioning patients. In addition, it is so widely used that most clinicians have a tangible sense of how scores at a given range are likely to correspond with actual functioning. MMSE scores can thus serve as a useful means of quickly communicating the severity of a patient's overall deficits. Disadvantages of the MMSE include its sensitivity to education (highly educated patients with mild Alzheimer disease may perform very well on the MMSE, whereas healthy individuals with low

education may earn scores in the “impaired” range) and its relative insensitivity to mild cognitive deficits and deficits associated with noncortical dementias. Of note, the MMSE is a copyrighted test that requires purchase for legal use.

Another brief screening instrument for cognitive performance is the Montreal Cognitive Assessment (MoCA). Similar to the MMSE, the MoCA is brief (less than 10 minutes), easy to administer and score, and yields total scores ranging from 0 to 30, with lower scores representing worse cognitive impairment. It was originally designed to screen for mild cognitive impairment (MCI), rather than cortical dementia *per se*, and thus may be more sensitive to subtle impairments. Another advantage of the MoCA includes availability in multiple languages in addition to English. The test itself is free, but, except for those users in certain exempt categories, the copyright holder now requires users to complete a 1-hour for fee training/certification module (see MoCA website for current details: https://mocacognition.com/).

The Mattis Dementia Rating Scale-Second Edition (DRS-2) is another widely used scale of dementia screening; it generates a total score (maximum possible points = 144), indicating overall cognitive functioning, as well as five subscale scores in the domains of attention, initiation/perseveration, construction, conceptualization, and memory. It takes from 15 to 20 minutes (for a cognitively intact individual) to approximately 25 to 30 minutes (for an impaired individual) to administer. Like the MMSE, it is prone to age and education effects, but available age- and education-corrected norms facilitate the interpretation of DRS-2 scores. The DRS-2 is sensitive to mild dementia, although the ideal “cutoff” score seems to vary slightly among studies; one cross-validated study applied a cutoff of 129 of 144 and yielded a 98% sensitivity and 97% specificity while distinguishing patients with Alzheimer disease from healthy comparison subjects. Overall, DRS-2 scores, as well as subscale scores, have been shown to be good predictors of functional outcomes (basic and instrumental activities of daily living [ADLs and IADLs]) among patients with Alzheimer disease. The cognitive subscale of the Alzheimer’s Disease Assessment Scale (ADAS-Cog)

is another widely used screen for cognition among those with Alzheimer disease.

An intermediate option between a brief screening instrument and a lengthy comprehensive neuropsychological battery is to use an instrument such as the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS). The RBANS takes approximately 30 minutes to administer and assesses a number of domains of interest. Computerized cognitive screens, such as the MicroCog, were developed to reduce time and administration burden and are available for use.

A screening measure is useful for a quick and cursory evaluation of cognitive functioning but is limited in the extent to which it can assess the breadth and depth of neuropsychological abilities. A comprehensive neuropsychological test battery is the best way to measure more nuanced aspects of cognition across multiple domains of functioning.

Crystallized Knowledge

Crystallized knowledge refers to information and facts such as those typically learned in formal school settings. Tests that measure crystallized knowledge include the Wechsler Adult Intelligence Scale-Fourth Edition (WAIS-IV) Vocabulary subtest, in which the examinee is asked to define a common word, and the WAIS-IV Information subtest, in which the examinee is asked to answer “common knowledge” questions, and the Wide Range Achievement Test-Fifth Edition Reading subtest that measures one’s ability to recognize or read isolated words. Crystallized knowledge tends to be resistant to most forms of neurocognitive injury and may be relatively stable (or even improve) over the life span; word reading and vocabulary scores are, therefore, often used, together with educational history, to estimate levels of premorbid cognitive functioning.

Receptive and Expressive Language

Deficits in language functions may reflect specific or localized lesions (such as a stroke in the left frontal lobe) or diffuse neuropathology such as that occurs with Alzheimer disease. Common receptive language measures include such tasks as reading comprehension or comprehension of increasingly complex aurally presented instructions, such as measured by the Token Test or the Complex Ideational subtest from the Boston Diagnostic Aphasia Examination. The Boston Naming Test is the most widely used measure of expressive language functions in assessments of adults and is particularly useful with patients reporting word-finding difficulties. The task involves presenting the examinee with line drawings of objects one at a time and asking them to identify each one in succession. If the examinee cannot identify the item within 20 seconds, then they are given a cue to see if that aids in responding. Confrontational naming is often one of the first abilities to deteriorate in patients with cortical dementia, such as in early Alzheimer disease. Patients with subcortical dementias may have difficulty retrieving the names of the objects, but they tend to do better with cueing.

Another widely used set of tasks that are sometimes categorized under expressive language is the letter and category fluency (word generation) tasks. For instance, in the “FAS” test, the examinee is given three 1-minute trials to name as many words as they can think of that begin with the letters “F,” “A,” and then “S,” respectively. Category fluency involves having the examinee rapidly name words from a given category, such as types of animals. Because word knowledge tends to be organized by meaning (semantics) rather than by the initial letters, healthy individuals generally find the category fluency task considerably easier than the letter fluency task. However, with some neurodegenerative conditions, such as Alzheimer disease, the semantic links begin to deteriorate, so the typical advantage of category fluency over letter fluency performance decreases. This is another example of how considering the pattern of performance across tasks can be useful in the differential diagnostic process.

Attention and Vigilance

The construct of attention comprises a range of specific functions that include consciousness (attentional, arousal, and temporal orientation), simple attention (the ability to repeat recently presented stimuli, most commonly, strings of digits), selective attention (distinguishing target stimuli or information from irrelevant stimuli), sustained attention (ability to stay mentally “on track”), and vigilance (the ability to wait/look out for a particular stimulus or event over time). Some aspects of working memory, best described as a “mental workbench,” also fall under the larger domain of attention (with the more complex aspects constituting executive functions). This function of working memory allows for a limited amount of information to be actively held for short periods of time for further processing and requires active rehearsal or allocation of attentional resources for it to be retained; a classic example is the holding of a telephone number in one’s working memory so long as is needed to dial the telephone, and the number may be retained via active rehearsal over the delay period.

Attentional functions are among the first to be affected by a variety of neurologic and psychiatric conditions. Attentional decline may therefore be readily observed in older clinical populations. Alterations in consciousness are common in older adult patients with delirium, for example, which in turn may be caused by multiple etiologies (e.g., substance use, prescription medication, urinary tract infections). Other aspects of attention may be moderately to severely impaired in patients with dementia, especially subcortical dementias such as those associated with Parkinson disease. Dementia with Lewy bodies is also associated with impairments in both consciousness and arousal and simple and sustained attention. Mild to moderate impairments in attention are present among patients with Alzheimer disease, but they tend to be able to perform basic attention tasks fairly well even in more advanced stages of the disease. Fluctuating attention, especially within a single attention-oriented task, is often associated with geriatric depression or anxiety.

Orientation and simple attentional tasks are included in the MMSE, MoCA, and DRS-2. The MMSE and MoCA include the serial sevens subtraction task, while the DRS-2 includes some cancellation tasks.

A common measure of simple attention and working memory is the WAIS-IV Digit Span subtest, in which the examinee is asked to repeat strings of digits of increasing length and is then asked to repeat strings of digits in reverse order. Cancellation tasks are common measures of sustained attention or vigilance; for example, in the Digit Vigilance Test from the expanded Halstead–Reitan Battery (HRB), the examinee is asked to rapidly identify and cross out every time a target number appears in a much larger array of numbers. The various versions of the Continuous Performance Test (CPT), such as the "identical pairs" version, in which the examinee is shown a series of numbers rapidly flashed on a computer screen and is required to make a response after any number is shown twice in a row, is also an example of such a task.

Learning and Memory

Memory complaints are prevalent among older individuals, and there is consistent evidence that some aspects of memory, specifically episodic declarative memory, deteriorate with advanced age. The function of an objective memory evaluation is to determine whether memory decline is beyond age-appropriate memory decline. Therefore, normative data on standardized memory tests become even more important to interpret the target person's test results accurately. Also, given that memory components of episodic memory tests are typically preceded by learning new material (e.g., word lists, stories, geometric designs), it is also important to rule out the possibility of a learning disorder (which may have remained previously undiagnosed or undetected among older patients). The presence of a learning disorder is determined by performances on achievement tests (e.g., reading, spelling, simple arithmetic) and the individual's educational or occupational history (repetition of a grade, difficulties in school, special education programs, extra tutoring, and behavioral problems in school being common red flags). If a learning disorder exists, then memory test results must be interpreted with caution, and education-corrected norms will give skewed results.

Referral questions for neuropsychological evaluation among geriatric patients typically include a request for “memory assessment,” often because it is the primary cognitive complaint of patients, caregivers, or both. There are several reasons why older individuals may experience impairment in episodic learning and memory, such as dementia, depression, physical conditions, such as pain, and certain medication. Memory performance can also be hindered by primary deficits in other cognitive domains, such as attention or executive functioning. Procedural memory (e.g., driving a car or making dinner) tends to fade at a slower rate and may only be seen in moderate to severe stages of dementia. Finally, autobiographical memory tends to remain intact for the most part, except in patients with very advanced stages of dementia.

Neuropsychological evaluation typically includes measures of simple registration (e.g., asking the patient to repeat three or five words, as in the MMSE and MoCA, respectively) and both auditory and visual episodic learning and memory. Tests of episodic learning and memory typically begin with a series of learning trials followed by short- and long-delay recall trials. The time between the learning and delay trials is filled with unrelated tasks (typically, another neuropsychological test or “distraction stimuli”) so that the patient cannot rehearse the test stimuli. Delayed recall trials may include free recall, cued recall, recognition paradigms, or a combination of these. Cued recall and recognition trials help identify retrieval versus encoding deficits; in the former, the information is encoded but can only be retrieved with help (e.g., cues or recognition), and in the latter, the information is never encoded in the first place (so neither cues nor recognition will help).

The most commonly used tests of auditory learning and memory include the Hopkins Verbal Learning Test-Revised, Rey Auditory Verbal Learning Test, and the California Verbal Learning Test-Third Edition (CVLT-3), all of which are list-learning tasks, and Logical Memory (from the Wechsler Memory Scale-Fourth Edition [WMS-IV]) or the Story Memory Test in which the stimuli are stories or short passages. Visual learning is often measured with the Brief Visuospatial Memory Test-Revised, Visual Reproductions (from the

WMS-IV), and the Rey–Osterrieth Complex Figure Test. These tests require the examinee to learn and remember geometric figures by copying them or, via immediate recall, recalling them by drawing as many figures as possible from memory. These tests, therefore, also have a visuoconstructional element in addition to a visual memory component. The Visual Reproduction test also has recognition components.

Two classic distinctions made between memory test score profiles among older individuals are those of cortical versus subcortical dementia and dementia versus late-life depression. Cortical profiles of word list-learning tasks seen most often among patients with Alzheimer disease include a flat learning slope across the learning trials, rapid forgetting (i.e., little to no words in short- and long-delayed recall), high recency effect (i.e., most words recalled from the last third of the list), high number of intrusions (i.e., words not on the list, similar to confabulations seen in informal assessments of patients with Alzheimer disease), high number of repetitions, and no benefit from cueing or recognition formats. Patients with subcortical dementias, such as Parkinson disease, also have flat learning slopes and difficulty recalling any words during free recall trials but are unlikely to have intrusions or repetitions and do better with cues or on the recognition trial. The performance of patients with depression is marked by overall slowness in responding and lower output of words during free recall. They will almost never have intrusions or repetitions, and they tend to recall words from all over the list. They tend to do significantly better with cueing and recognition, often achieving scores within the normal range for their age.

Visuospatial Cognition

The assessment of visuospatial cognition or perceptual organizational skills is an important component of both screening and comprehensive neuropsychological evaluations. Broadly, these functions consist of perceptual ability (the ability to discern forms or patterns), visuospatial judgment (the location of objects in space), and constructional ability (the manipulation of objects in three-

dimensional space). Intact visual acuity is an obvious precondition to all subdomains of visuospatial cognition, and adequate use of hands is necessary for the constructional tasks. Visual field defects and hemiparesis can also cause impairments in visuospatial cognition. Some of the most common neurologic conditions affecting visuospatial cognition among older adults are vascular incidents (lesions causing contralateral hemispatial neglect), Balint syndrome (associated with bilateral lesions in the posterior parietal cortex), and dementias caused by Lewy bodies, Parkinson disease, and Huntington disease. Patients with Alzheimer disease also have impairments in visual cognition, but they are less severe compared with those among individuals with other dementias. Incipient Alzheimer disease is associated with difficulties with constructional ability, but other visuospatial abilities may only get severely impaired in the advanced stages of the disease.

Visuospatial abilities are commonly measured with subtests of the WAIS-IV such as Picture Completion (which is one of the WAIS-IV supplemental subtests), in which the examinee must identify the important missing element in a series of pictured scenes, and Matrix Reasoning, a visual reasoning task wherein the examinee must identify the missing element in a matrix by discerning the rule underlying the relationship between each of the several subparts. The Hooper Visual Organization Test is another widely used measure, wherein the examinee is shown pictures of objects that have been cut and randomly arranged in pieces; they must mentally rotate the various pieces and put them together, and then name the object. Constructional skills are measured by graphomotor tasks, such as the Rey–Osterrieth Complex Figure Test, in which the examinee is presented with a complex geometric figure, which they must copy (the order in which the figure is copied is noted by the examiner), or, most commonly, the Block Design subtest (from the WAIS-IV), in which the examinee is required to rapidly match a two-dimensional design by combining three-dimensional red-and-white blocks.

Executive Functions and Working Memory

There is wide consensus among neuropsychologists that intact executive functions are central to optimal daily functioning, yet, the precise definition of the construct remains elusive. The term “executive functions” is used to describe an array of subdomains, including abstraction and concept formation, planning, response inhibition, cognitive flexibility, and some aspects of working memory. The products of all these executive functions typically involve novel problem solving, initiating and maintaining goal-directed behavior, or disengaging from such behaviors when appropriate to the goals or in response to environmental cues. Executive functions were also previously called “frontal cortical functions” because they were thought to be mediated by the frontal cortex. However, there is now overwhelming evidence that these functions are not limited to the frontal cortex but that they involve several frontal–subcortical circuits as well. Therefore, lesions in frontal as well as subcortical brain structures can disrupt any of the executive functions.

People with Alzheimer disease often show signs of executive dysfunction even in the early stages of the disease. People with frontotemporal dementia and those with any of the several forms of subcortical dementias (such as those due to Parkinson disease) have significant impairments in cognitive flexibility, abstract thinking and conceptualization, and fluency. Executive functions may also be more sensitive to low or inconsistent effort; therefore, patients with depression may do poorly on some or all executive functioning measures.

The Wisconsin Card Sorting Test (WCST) is one of the most commonly used measures of executive functioning, specifically, concept formation and cognitive flexibility. The task involves asking the examinee to discern an unspoken rule that defines correct versus incorrect matches and requires the examinee to change strategies when appropriate. The Delis–Kaplan Executive Function System (D-KEFS) is a battery of nine executive functioning tests and has normative data for adults up to 89 years. The D-KEFS includes the Trail Making Test, Verbal Fluency Test, Design Fluency Test, Sorting, Tower Test, Color–Word Interference, the Word–Context Test, the Proverb Test, and Twenty Questions. These tests, some of

them modified from popular, existing tests (e.g., the Trail Making Test is modified from the Trail Making Test, Parts A and B, a.k.a., the Partington Pathways Test), measure a broad range of executive functions and are useful to include in a comprehensive battery for use with older adults.

Mental Processing Speed/Psychomotor Speed

The term “mental processing speed” (or information processing speed) refers to the speed with which one thinks and executes a task. As the tasks used to assess this construct generally include a motor response component, it is also commonly labeled “psychomotor speed,” reflecting the fact that test performance is determined not only by the speed with which one thinks but also by the integration of those thoughts with the motor response. Whether construed as psychomotor speed or pure mental processing speed, tests in this domain tend to be among the most sensitive to virtually any form of neurocognitive injury or dysfunction, including that caused by psychiatric conditions such as depression. Indeed, the steady, if gradual, stowing of processing and psychomotor speed is the most ubiquitous and consistent change seen with normal aging, beginning at least by the early part of the fourth decade of life. When examining an older adult patient for the possible presence of pathologic motor disorders, it is important to consider their psychomotor speed relative to that expected from an age-comparable normative sample.

The Digit Symbol (a.k.a., “Coding”) test is a prototypical example of processing/psychomotor speed tests and is among the most widely used tests to assess this domain. The Digit Symbol test consists of a stimulus key with the numbers 1 through 9, each paired with a unique geometric figure. Beneath this stimulus key is a large matrix of numbers with spaces below each number. The patient’s task is to rapidly fill in the symbol paired with each number. The stimuli used for this task appeared in largely unaltered form since the early 1900s. That is, the stimuli used in the Army Mental Test battery during World War I were almost identical to those used in the adult

versions of Wechsler intelligence test batteries, up through the 1997 edition of the Wechsler Adult Intelligence Scale (WAIS-III). The Digit Symbol subtest stimuli were substantially redesigned for the WAIS-IV, published in 2008, but the sensitivity of the task to age-related or other psychomotor slowing remains the same.

Another widely used measure of psychomotor speed is the Trail Making Test Part A (originally published as Partington Pathways Test in the 1930s), which requires the patient to connect a series of circled numbers in order as fast as possible, and measures scanning, visuospatial sequencing, and motor speed. The D-KEFS includes a number of interesting modifications of the Trail Making Test, including a Motor Speed subtest that may prove helpful in distinguishing pure motor slowing from slow mental processing.

OTHER ASPECTS OF COMPREHENSIVE NEUROPSYCHOLOGICAL EVALUATION

Assessment of Mood and Anxiety

Emotional functioning is extremely important to monitor as part of any assessment with older adults. Depression is often undetected among older adults, although increasing awareness of the frequency of psychiatric problems in this population has led to more routine assessments of depression, anxiety, and suicidality in psychiatric, neurologic, and general medical treatment settings. Some useful and quick measures of depression are the Geriatric Depression Scale, Beck Depression Inventory-Second Edition (BDI-II), and Patient Health Questionnaire-Ninth Edition (PHQ-9). The former is particularly helpful for use with older patients and is validated for use with patients with Alzheimer disease. Occasionally, if the patient has been able to tolerate a lengthy neuropsychological battery and may have potential emotional problems, they may be given the Minnesota Multiphasic Personality Inventory-Third Edition (MMPI-3). The MMPI-3 can give a detailed profile of the patient's emotional functioning as well as further highlight targets for intervention.

Activities of Daily Living/Everyday Functioning

It has been common practice in neurology and psychiatry to informally assess older patients' basic ADLs and IADLs. Basic ADLs include personal functions such as feeding oneself, showering, dressing, and using the toilet, among other things. Intake interviews as part of neuropsychological assessments tend to focus more on evaluating IADLs, such as cooking, driving, managing finances, and so forth (i.e., skills that are more complex than basic ADLs yet necessary for independent everyday functioning).

Diversity

One of the challenges in neuropsychological assessment of older adults has been and remains the fact that the majority of people in the normative samples were non-Latine White, heteronormative, and native English–speaking persons. There have been efforts to develop normative data for African Americans and Latine individuals, and there have been more recent attention to the effects of culture and cultural bias on the validity of standard neuropsychological tests. Yet, much work remains to be done in ensuring culturally appropriate and validated tests and test interpretation for individuals from diverse groups. Even the assumption that a particular test developed in one cultural context measures the same cognitive construct across other cultures needs to be considered with caution. A key distinction is between differences in test performance versus differences in the level of cognitive function. There are known effects of not just years of education but the quality of education that affect test performance without clearly representing differences in the level of cognitive functioning. Caution is also needed when testing a person in English when their first language was something other than English. There is some research suggesting that bilingualism confers some advantages in the resilience of some neurocognitive domains, but it may affect performance (not skill) on verbally focused tasks administered in English. For the purposes of readers of this overview, the key is to stay aware of the importance of considering

and addressing diversity issues in the interpretation and conclusions drawn from neuropsychologist test scores.

Telehealth Assessment

One of the byproducts of the social distancing requirements during the COVID-19 pandemic has been increased interest and reliance on remote administration of neuropsychological tests, such as via telehealth. Although there are active efforts to develop such tests, and some standard tests by necessity have been adapted for virtual administration, interpretation of scores under these conditions requires caution. At present, most normative data for neuropsychological tests were developed with 1:1, in-person assessments. There are small-scale studies that provide some preliminary evidence that equivalent performance can be obtained, but the generalizability of that normative data to a telehealth format remains less certain. Standardization on the receiving end is also complicated by the lack of uniformity in the size and nature of the device in the examinees' possession (smartphone, tablet, desktop, and monitor size) and other practical concerns that are closely related to socioeconomic positions, such as accessibility to high-speed internet and its reliability of functioning. An often-overlooked obstacle to valid assessment is the lack of privacy in home settings, where the examinee may be distracted by ambient noise and other family members and pets that can further confound results. With older adults, additional concerns arise from less comfort or familiarity with the requisite technology and visual and hearing impairments that can complicate the efficient use of remote technology. Thus, any conclusions derived from neuropsychological assessments currently administered via telehealth must be provisional and accompanied by the documentation of any of the aforementioned confounding variables.

ISSUES IN THE ASSESSMENT OF OLDER ADULTS

Sensory Impairment

Hearing impairments tend to be fairly common among older adults in general and can considerably impede verbally administered neuropsychological tests. The potential examinee's hearing should be at least informally assessed to determine whether it is adequate for the verbal neuropsychological tests. If hearing is deemed too impaired, they can still be assessed with largely visual tests (assuming they have adequate visual acuity) if it is clear that the person understands the test instructions. Visual acuity may be informally assessed, for example, using the Rosenbaum Pocket Screener. Visually impaired patients can be assessed with a variety of tests, including all verbal memory tests, some attention tests, all verbal D-KEFS tests, and the Tactual Performance Test, which is a measure of visuospatial functioning.

Interpretation of Test Results in the Context of Normal Aging

Normal aging is itself associated with some changes in cognitive functioning, including improvements (at least during the first seven decades of life) in crystallized verbal knowledge, slowing of mental processing speed, psychomotor speed, and subtle declines in some aspects of memory and executive functions. A key advantage of standardized testing is that interpretation is not solely reliant on the absolute level or content of responses (or pathognomonic signs) but also on reference to the level of performance expected from a neurologically healthy individual. The latter is determined by comparing the examinee's test scores to demographically appropriate norms. The most widely used neuropsychological tests have normative data developed and collected using standardized administration and scoring procedures. That being noted, the above-expressed caveats concerning the application of normative data to diverse cultural groups remain a concern.

55.2f Genetics of Late-Life Neurodegenerative Disorders

Seethalakshmi Ramanathan, M.D., M.P.A., and Stephen J. Glatt, Ph.D.

Genetic studies of any complex condition, including late-life neurodegenerative disorders, attempt to identify the elemental biologic underpinnings of these disorders to facilitate their early identification, early intervention, and, ultimately, prevention. In addition, the identification of genes that influence the development and/or progression of these illnesses may foster medicinal chemistry applications that target faulty DNA sequences or the altered RNA transcripts or proteins produced by such genes. Such discoveries

could usher in the long-awaited era of “personalized or precision medicine,” in which the treatment of any given late-life neurodegenerative disorder can be tailored to individual patients based on their genetic and biologic background.

The search for genes influencing late-life neurodegenerative disorders falls under the broader umbrella of genetic epidemiology, which has been defined as a science that deals with the etiology, distribution, and control of disease in groups of relatives and with inherited causes of disease in populations. Genetic epidemiologists examine the transmission of illness within families, or the distribution of disease in populations, with the goal of finding genetic and environmental causes of illness. Genetic epidemiologic research on a particular disorder such as Alzheimer disease (AD) tends to follow a series of questions in a logical progression. This sequence proceeds as follows: First, we ask, “Is the phenotype familial?” or “Does it run in families?” which can be established by family studies. Second, “What is the relative magnitude of genetic and environmental contributions to the phenotype?” which can be established by twin studies. This, importantly, will reveal the maximum amount of variance in a disease that may be attributable to heritable factors (including genes themselves, but also gene–environment interactions). Third, “How is the phenotype transmitted from generation to generation?” can be addressed by segregation analyses. Fourth, “If genes mediate this transmission, where are they located?” is a question that may be answered by linkage studies of families or extended pedigrees. Fifth and finally, with a heritable component established, we ask, “What are the specific genes and variants in those genes that influence risk for the phenotype?” which can be addressed by association studies, including genome-wide association studies (GWASs). These are difficult questions to answer for any trait, but particularly so for phenotypes as complex as late-life neurodegenerative disorders, which can often be confused or misconstrued with other medical, psychiatric, or substance use disorders. Fortunately, the wide variety, specificity, and power of available methods have allowed genetic researchers to begin to find

meaningful answers to some of these questions for each late-life neurodegenerative disorder.

GENETIC METHODS AND PRINCIPLES

Family Studies

The first question that must be asked and answered when attempting to delineate the genetic and environmental components of a complex late-life neurodegenerative disorder is, “Does the phenotype run in families?” or “Is this phenotype familial?” This question can be answered through the use of family studies. The basic design of the family study begins with the ascertainment of a group of subjects who are affected by the disorder (cases) and a comparable group of comparison subjects who do not have the disorder. Next, the biologic relatives of these index subjects, or “probands,” are ascertained and evaluated for the presence of the illness or, in some cases, subthreshold forms of the illness. The rate of the disorder or associated “spectrum conditions” among family members of affected probands is then compared to the rate of the disorder among family members of comparison probands to determine the familial risk or relative risk. If a late-life neurodegenerative disorder has a genetic etiology, then biologic relatives of cases should have a higher likelihood than relatives of comparison subjects of carrying the gene or genes that influenced illness in their relative, and thus they should be at greater risk for the illness themselves. In addition, the risk to relatives of cases should be correlated with their degree of relationship to the proband or the number of genes they share in common. First-degree relatives, such as parents, siblings, and children, share 50% of their genes, on average, with the proband. Thus, first-degree relatives of cases should be at greater risk for the disorder than second-degree relatives (grandparents, uncles, aunts, nephews, nieces, and half-siblings), who share only 25% of their genes with the proband.

Twin Studies

Once a disorder has been established as familial, it becomes necessary to determine if that pattern is attributable to the inheritance of genes or to shared familial and other environmental factors. It is also important to quantify the contribution that genes make relative to that made by environmental factors, as this may encourage or discourage future molecular genetic studies; this may also influence the decisions made by individuals seeking genetic counseling and impact the usefulness of family information in identifying high-risk individuals to target for early intervention and prevention protocols. These questions can be answered by twin studies. In twin-study designs, the ratio of concordant:discordant monozygotic (MZ), or identical, twin pairs is compared to the ratio of concordant:discordant dizygotic (DZ), or fraternal, twin pairs. If the concordance for a late-life neurodegenerative disorder is higher among MZ twin pairs than DZ twin pairs, this is a good indication that there is a genetic contribution to the disorder; if MZ and DZ twin pairs have approximately equal concordance rates, environmental factors are more strongly implicated. Concordance rates among twin pairs are then used to estimate the “heritability” of a disorder. Heritability refers to the ratio of genetic to phenotypic variances or the proportion of variance in risk for a late-life neurodegenerative disorder that is accounted for by variability in genetic factors. A heritability of 1.0 (or 100%) indicates that all variability in the phenotype is due to genetic factors alone. In contrast, a heritability of zero attributes all phenotypic variation to environmental factors.

Segregation and Linkage Studies

Knowing that genetic factors are involved in the etiology of a late-life neurodegenerative disorder—and to what degree—is essential for designing optimal molecular genetic studies to reveal the chromosomal location of the responsible or contributory genes. To determine the mode of inheritance of disease, segregation analysis is used to test the goodness of fit of various genetic models onto observed family and pedigree data. To identify regions of chromosomes that have a high likelihood of harboring risk genes for

late-life neurodegenerative disorders, linkage analysis is an appropriate strategy under certain conditions, that is, when the disease segregates strongly through families, and evidence suggests a Mendelian mechanism of transmission. Families are ascertained for linkage analysis through a proband affected with the disorder of interest; then, each individual in the family is genotyped at a series of DNA markers (not necessarily in genes) spaced evenly throughout the genome, and the co-segregation of these DNA markers with the illness is tracked in each pedigree. Evidence for co-segregation at each marker locus is summed across pedigrees to derive an index of the likelihood of the obtained patterns of marker-phenotype co-segregation, given the sampled pedigree structures. This approach has been successful in homing in on causal or major genes for some late-life neurodegenerative disorders. Unfortunately, most forms of late-life neurodegenerative disease are more complex in their etiology, involving the combined and interactive effects of numerous genes and environmental factors, and in such a scenario, linkage analysis is less effective in elucidating contributory genes.

Association Studies

Once regions of certain chromosomes have been implicated from linkage analysis as harboring a risk gene for a disorder (or, increasingly, even in the absence of such linkage information), the next step is to identify what specific gene is segregating through families or populations to give rise to the observed pattern of disease. A gene can be selected for such an analysis subsequent to linkage analysis as a means to follow up on evidence for increased genetic similarity at a locus among affected individuals in a family (i.e., a “positional candidate gene” approach). Alternatively, specific genes can be examined in the absence of linkage information if there is some compelling physiologic reason to suspect that the gene influences risk for a given disorder (i.e., a “functional candidate gene” approach). For example, dopamine-system genes, such as receptors and transporters, are commonly examined as functional candidates for Parkinson disease (PD) based on the neural

structures involved in its pathology and treatment. In contrast to linkage analysis, which uses random DNA markers as proxies for nearby risk genes, genetic association analysis is the leading method for determining if a particular gene variant has a direct effect on risk for an illness or is in very close physical proximity to and tight linkage disequilibrium (LD) with such a gene.

The familiar Mendelian model of single-gene transmission of a trait is only one of the many transmission mechanisms that can be tested in genetic association models. Mendelian diseases have recognizable inheritance patterns (autosomal dominant, autosomal recessive, and X linked) and generally are caused by mutations in a single gene within a particular family. In contrast to Mendelian diseases, complex diseases display no clear inheritance pattern, and most forms of late-life neurodegenerative disease fall into this category (rare Mendelian forms do exist, but these typically have early onset). Complex diseases are multifactorial in their etiology and are caused by an interacting web of genetic and environmental risk factors. The genetic risk factors for such complex diseases are generally referred to as *risk* or *susceptibility genes*, in which genetic variants that are common in the population act to increase the risk of developing the disease. Unlike mutations in Mendelian genes, susceptibility genes are neither necessary nor sufficient to cause disease.

Genome-Wide Association Studies

The completion of the human genome project and advancements in the genotyping of single nucleotide polymorphisms (SNPs) laid the foundation for a more broad examination of the human genome *via* the GWAS approach. GWAS, as the name suggests, examines the entire genome for genetic associations with specific traits. This broad approach accords GWAS more flexibility in exploring complex diseases with multifactorial polygenic etiologies, including late-onset Alzheimer disease (LOAD). GWAS techniques examine numerous markers distributed throughout the genome in order to understand the contribution to disease of various types of SNPs, including LD-

based markers that are highly correlated with the causal allele, markers for missense mutations associated with Mendelian diseases, and convenience-based markers that are chosen based on logistical conveniences such as cost, heterozygosity rate, and genotyping success rate.

Clearly, such a broad examination has advantages as well as disadvantages. One advantage that GWAS has over other methods is its unbiased nature; however, the examination of the entire genome requires large samples to establish relationships with adequate power due to the inflation of type-I error rate that can occur when performing millions of statistical tests. Another unfortunate constraint of most current GWAS methods is that, unlike candidate genes which are often typed on functional polymorphisms, the DNA markers included in GWASs are often intergenic or otherwise do not constitute any recognized functional motifs; thus, the biologic or clinical significance of a given disease-associated variant may not be immediately recognizable. Researchers have been following and attempting to replicate the extensive list of SNPs identified by GWASs and are now focusing not only on the most strongly associated individual SNPs from meta-analyses of like efforts but on the collective power of large numbers of contributory SNPs in a so-called genetic risk score. Furthermore, the functional outcomes associated with reliably implicated loci and pathways are objects of intensive study.

MAJOR OR MILD NEUROCOGNITIVE DISORDER DUE TO ALZHEIMER'S DISEASE

AD is a progressive neurodegenerative disorder characterized by an insidious onset and progressive loss of memory and other cognitive functions. AD is the most common form of dementia in older adults. Two broad subtypes of AD have been identified: an early-onset subtype, defined as occurring before age 65 years, which accounts for no more than 5% of cases, and a late-onset subtype, defined as

occurring on or after age 65 years, which accounts for 95% or more of cases.

Early-onset AD has been characterized as a familial, autosomal-dominant genetic disease with causative mutations in several genes. Early linkage studies of early-onset AD revealed linkage to a locus on chromosome 21q, which was later identified as the gene for amyloid precursor protein (*APP*) which encodes the beta-amyloid protein found in amyloid plaques. However, since linkage to chromosome 21 was not found in most families with early-onset AD, other potential loci were investigated. This led to the discovery of other gene mutations in presenilin 1 (*PSEN1*) on chromosome 14 and in presenilin 2 (*PSEN2*), based on homology to *PSEN1*, on chromosome 1. The net effect of the mutations in these genes is overproduction of the more pathogenic form of beta-amyloid; that is, more beta-amyloid 42 relative to beta-amyloid 40.

The less complicated genetic nature of early-onset AD paved the way for a greater understanding of the genetically complex LOAD, which is sporadic or familial with no clear Mendelian segregation patterns in families. AD has been estimated to be 60% to 80% heritable, with residual influence from nonshared environmental factors. *APOE* is the gene that has been the most reproducibly and consistently identified as a risk factor for the disease, with just a single copy of the *APOE ε4* allele (actually a haplotype of alleles at two physically close loci in the same gene) increasing the risk of AD by approximately 300%. Recent studies have also identified that *APOE* affects the age of developing dementia in a gene-dosage–dependent manner. On the other hand, the *APOE ε2* allele has been shown to reduce the risk for AD relative to the *ε3* allele. *APOE ε4*, however, does not account fully for the genetic variance in AD.

No less than 40 candidate genes have now been implicated by GWAS as reliable risk factors for LOAD; however, the effects of each variant are minimal, and there is no genetic polymorphism that is either necessary or sufficient to cause LOAD. Associated genes are strongly expressed in immune-related tissues and cell types (spleen, liver, and microglia). Gene-set analyses indicate biologic mechanisms involved in lipid-related processes and degradation of

APP. Pathway analysis implicates immunity, lipid metabolism, tau binding proteins, and APP metabolism, showing that genetic variants affecting APP and Aβ processing are associated not only with early-onset autosomal dominant AD but also with LOAD.

Beyond *APOE* ε4 and the several dozen identified genome-wide–significant common SNPs, there may be thousands of additional genetic polymorphisms that make minor nonessential contributions to the overall risk for LOAD. A polygenic risk score (PRS) can be quickly and easily derived from these myriad variants to aggregate their collective effects on risk. The scoring algorithm sums the weighted effect of numerous SNPs to identify a single "genetic load" variable that maximally discriminates cases from unaffected comparison subjects. The best PRS thus far assembled captures most of the SNP heritability for LOAD. Extensive research has indicated that the PRS can boost the accuracy in LOAD diagnosis beyond the performance of *APOE* alone and can capture LOAD phenotypic variability that cannot be explained by *APOE* status alone. Thus, from a diagnostic point of view, having access to a patient's genotypes at *APOE* and at all other reliable risk genes provides the most complete picture of the genetic architecture underlying LOAD.

MAJOR OR MILD NEUROCOGNITIVE DISORDER DUE TO PARKINSON DISEASE

PD is a neurodegenerative disease characterized clinically by a progressively worsening movement disorder and dementia in 20% to 30% of cases late in the course of the disease. Similar to AD, PD largely follows a complex pattern of inheritance with only 5% to 10% aggregating in families and showing an autosomal-dominant or -recessive inheritance. It is, therefore, not surprising that early family studies failed to find much support for familial aggregation of the disorder, causing many to suspect that the etiology of PD was largely (if not exclusively) driven by environmental factors. However, later studies ultimately supported a genetic contribution to the etiology of

the disorder. The largest family study has been the Mayo Clinic study, which established that biologic relatives of a patient with PD are at an approximately 70% elevated risk of themselves developing the disorder as compared to relatives of unaffected individuals. It appears that genes may more strongly contribute to the risk for early-onset PD (less than 66 years of age). Relatives of such early-onset PD patients are at a 2.6-fold increased risk of developing PD as compared to relatives of patients with onset of PD later than 66 years, who were not at an increased risk for the disorder. Segregation analyses further suggest that early-onset PD may be driven by an autosomal-recessive mechanism.

Late-onset PD (like AD), on the other hand, has a more complex etiology involving environmental factors and not excluding some major genes of additive or recessive effects. Linkage studies of PD have identified certain distinct loci as possibly harboring risk genes for the disorder in chromosomes 1, 2, 4, 5, and X. Numerous functional candidate genes have also been reliably implicated in the etiology of PD by association analysis. GWASs have further added to this list by identifying unsuspected candidate genes for PD, as well as other late-life neurodegenerative disorders. Genes encoding alpha-synuclein (*SNCA*, which accumulates in Lewy bodies), *MAPT* (which is a constituent of tangles in AD), and leucine-rich repeat kinase 2 (*LRRK2*) have also been repeatedly associated with PD. A recent meta-analysis of GWASs found that, together, *MAPT* and *SNCA* contribute to up to 25.6% of the population's attributable risk for PD. Mutations in parkin (*PARK2*), *PTEN-induced kinase 1* (*PINK1*), and *oncogene DJ1* have been associated with autosomal-recessive parkinsonism, which is early onset and responsive to DOPA. However, considering the significant clinical role of the dopaminergic system in PD, other dopaminergic system candidate genes, such as *DRD1* and *DRD2,* which code for dopamine receptors, are not similarly implicated. Further, genes involved in other neurodegenerative disorders, such as *APOE,* have not been implicated. Another meta-analysis of genome-wide association data of 13,708 cases with PD and 9,522 comparison subjects identified 26 loci, 7 of which were novel candidate genes (*SIPA, 1L2, INPP5F,*

MIR4697, GCH1, VPS13C, and *DDRGK1*). The genes at these 26 risk loci mediate diverse biologic processes, but collectively they are enriched with genes that bind nucleotides and genes that are involved in dopamine biosynthesis. Finally, the largest and most recent meta-analysis of late-onset PD, involving over 50,000 cases and 1.4 million control subjects, identified 90 independent genome-wide significant risk signals across 78 genomic regions, 37 of which were novel discoveries. These 90 variants explained 16% to 36% of the heritable risk of PD. Similar to GWAS in AD, these new findings are triggering new studies aimed at understanding the various functional aspects of the implicated genes.

MAJOR OR MILD NEUROCOGNITIVE DISORDER WITH LEWY BODIES (DEMENTIA WITH LEWY BODIES)

DLB is characterized by cognitive decline, parkinsonian signs and symptoms, fluctuations in cognition and attention, rapid eye-movement (REM) sleep disturbance, and visual hallucinations. Individuals with DLB can also have repeated falls, autonomic dysfunction, a heightened sensitivity to neuroleptics, disturbances in smell, systematized delusions, apathy, anxiety, and depression. Furthermore, the revised criteria also include consideration of biomarkers, such as changes in imaging studies and EEG.

DLB has a great deal of clinical overlap with both AD and PD. DLB differs from AD in that the onset of hallucinations is much earlier in DLB. Similar to PD, individuals with DLB demonstrate parkinsonian signs; however, these motor manifestations are markedly more and manifest earlier (at least 1 year before the onset of cognitive impairment) in PD as compared to DLB. DLB has been found to be largely sporadic and has been noted to be complex in nature, resulting from genetic and environmental interactions. Considering this sporadic nature, most genetic studies of DLB have been limited to family studies. Family studies have noted that DLB can be autosomal dominant or recessive. Reflecting the overlap in clinical

signs, DLB shares considerable genetic overlap with AD and PD. For example, *APOE4*, synuclein genes (*SNCA* and *SNCB*), and *PSEN1* genes have been found to be risk factors in DLB. A recent genome-sequencing effort and GWAS of a large cohort of DLB cases and controls identified five independent risk loci, with mutations particularly enriched in the gene *GBA*. Genetic risk scores (PRSs) and implicated pathways were strongly shared between DLB, AD, and PD.

MAJOR OR MILD FRONTOTEMPORAL NEUROCOGNITIVE DISORDER (PICK DISEASE AND OTHER FRONTOTEMPORAL DEMENTIAS)

Frontotemporal lobar degeneration is a progressive dementia characterized clinically by prominent behavioral, executive function, and language deficits. Frontotemporal lobar degeneration is categorized into three main clinical syndromes, including frontotemporal dementia, semantic primary progressive aphasia, and nonfluent primary progressive aphasia.

Frontotemporal dementia rarely has, if at all, been evaluated within the context of family, twin, or segregation studies; thus, it is difficult to estimate the familial risk, heritability, and mode of inheritance of this group of disorders. However, within the context of several linkage studies, it has been shown that frontotemporal dementia may be inherited in an autosomal-dominant manner with age-dependent penetrance (i.e., risk increases with age). One of the most routinely identified loci linked to frontotemporal dementia has been chromosome 17q21. Approximately 10% to 20% of familial cases are accounted for by mutations in the *MAPT* and *GRN* genes, which are located in this region. In addition to these, *C9ORF72*, genetically linked to chromosome 9p, has been recently identified as having a mutation that may singly account for the most number of cases (11.7%) of familial frontotemporal dementia (FTD). The association with 9p has been found by at least two GWASs, thus giving credence to the importance of 9p in FTD. While *MAPT* is associated with

increased deposition of phosphorylated tau, *GRN* and *C9ORF72* have been associated with deposition of the transactive response DNA binding protein of 43 kDa (*TDP-43*). GWAS has also identified associations with immune system processes and possibly lysosomal and autophagy pathways in FTD through 6p21.3, encompassing the *HLA* locus (immune system), and 11q14, encompassing *RAB38*/*CTSC* (transcripts of which are related to lysosomal biology). Like LBD, frontotemporal dementia also shares genes in common with AD and PD, as evidenced by the meta-analytic results of several GWASs, with associations converging at SNPs within the *HLA*, *MAPT*, and *APOE* genes.

MAJOR OR MILD VASCULAR NEUROCOGNITIVE DISORDER (VASCULAR DEMENTIA)

Vascular dementia (VaD) is the second most common form of dementia in older adults. VaD is caused by the effects of cerebrovascular disease and events (i.e., “stroke”) that initiate a cascade leading to central nervous system (CNS) damage and, ultimately, a dementia syndrome in some individuals.

While familial forms of VaD are uncommon (accounting for less than 10% of cases of VaD), cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) and hereditary cerebral hemorrhage with the amyloidosis-Dutch type (HCHWA-D) are among the better studied genetic syndromes of cerebrovascular disease and dementia. CADASIL is a syndrome of subcortical small vessel disease with lacunar strokes, migraine, and dementia. The discovery of linkage to chromosome 19q12 in two unrelated families and, subsequently, mutations in the *NOTCH3* gene explain the cause of most cases of CADASIL. *NOTCH3* is expressed in vascular smooth muscle cells and is important in cell proliferation and differentiation. FCAA, or familial cerebral amyloid angiopathy, is another heritable form of VaD, which is characterized by the deposition of amyloid on the vessel walls. A number of distinct forms of FCAA have been

identified. Hereditary cerebral hemorrhage with amyloidosis-Dutch type, HCHWA-D, is an autosomal-dominant syndrome primarily of hemorrhagic strokes and dementia. Since extensive deposits of beta-amyloid protein in brain vasculature had been found in HCHWA-D, linkage to the *APP* gene was tested for and was found in two unrelated families with HCHWA-D. A point mutation in the *APP* gene was found in two patients, providing evidence that *APP* gene mutations can cause HCHWA-D. Italian and Flemish types of HCHWA also are caused by point mutations in the *APP* gene and exhibit autosomal-dominant transmission. The Icelandic type of HCHWA, also with an autosomal-dominant transmission, is caused by a point mutation in the cysteine protease inhibitor cystatin C gene, while the British type of FCAA has been associated with mutations in the *ITM2B* gene (also called *BRI2*).

The genetic underpinnings of most cases of VaD, however, remain largely undetermined. This deficiency stems largely from the heterogeneity of the illness. VaD and AD frequently occur together as “mixed dementia.” *APOE* gene variants are known to affect risk for cerebrovascular disease, and presenilins have been shown to interact with *NOTCH3*—suggesting mechanistic overlap, if not the possibility of additional genetic overlap between AD and VaD, which may be driving the comorbidity. Studies examining candidate genes have noted inconsistent associations with genes coding for proteins involved in lipid metabolism, inflammation, and the renin–angiotensin system. A complex disease such as VaD warrants exploration into epistatic interactions. Studies have identified that epistatic interactions may act as a stronger risk factor for VaD. For example, the combined genotype of tumor necrosis factor (*TNF*α T-1031C) and heat shock 70-kDa protein 1A (*HSP70-1* A-110C) showed a much stronger odds ratio as compared to the individual genotypes. Similar synergistic relationships have been noted between transforming growth factor beta 1 (*TGF-β1*) and angiotensinogen (*AGT*) genes and between family with sequence similarity 134 member B (*FAM134B* [rs10041159]) and tumor necrosis factor receptor superfamily member 19 (*TNFRSF19* [rs9317882]). A recent GWAS also noted an association with a variant near the androgen

receptor (*AR*) gene on the X chromosome. While the mechanistic role of this association is unclear, this finding replicates past reports of associations with CAG repeat lengths on AR and VaD.

MAJOR OR MILD NEUROCOGNITIVE DISORDER DUE TO PRION DISEASE (CREUTZFELDT–JAKOB DISEASE AND OTHER TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES)

Creutzfeldt–Jakob disease (CJD) is one of several neurodegenerative diseases characterized by progressive dementia and ataxia, called *transmissible spongiform encephalopathies* (TSEs). TSEs are rare diseases that include CJD, kuru, Gerstmann–Sträussler syndrome, and fatal familial insomnia. The sporadic form of CJD is the most common TSE, with one to two incident cases per million people worldwide. The TSEs are unique in that they are inherited, sporadic, or acquired by infection. An abnormal isoform of the prion protein has been implicated as the causal agent in the TSEs. The prion protein exists in one of two states: PrP^{C}, for the normal cellular form of the protein, and PrP^{SC}, for the abnormal isoform isolated from the brains of individuals with TSE. The genetic epidemiologic study of this class of late-life neurodegenerative disorders has largely bypassed behavioral genetic approaches such as family and twin studies; thus, it has never been firmly established that these disorders have a familial or genetic basis. Data from Finland showed that 6 of 30 cases observed nationwide from 1975 to 1984 were familial cases, and all belonged to the same extended kindred. Further evaluation of this pedigree identified autosomal-dominant transmission of an early-onset long-duration form of the illness.

Despite the dearth of behavioral genetic data on CJD and related disorders in general, molecular genetic methods have often been used in the study of these disorders, largely due to their ease of application. Much of the focus of earlier studies had been on the *PRNP* gene, which encodes the prion precursor protein. In fact, most

of the affected individuals in the Finnish family described above also carried a nonsynonymous mutation in codon 178 of *PRNP*, whereas none of the 10 healthy controls carried the same variant. Since then, *PRNP* (specifically an amino acid polymorphism at codon 129 coding for methionine or valine) has been confirmed in a number of studies as a reliable risk factor for both variant or vCJD and sporadic or sCJD. Over the last 5 years, a number of other risk genes have been identified, although *PRNP* still remains the strongest universal factor. Variations in associations have been noted across populations for sCJD; SNPs at the *ZBTB38–RASA2* locus (a zinc finger transcriptional activator that binds methylated DNA) have been associated with CJD in U.K. populations, while an SNP in the *CHN2* gene has been found to be associated with vCJD in a German population. Some of the other associations include myotubularin-related protein 7 gene (*MTMR7)* and neuronal PAS (per-ARNT-sim) domain-containing protein 2 gene (*NPAS2*), which have been identified to increase risk independently, and β-site APP cleaving enzyme 1 (*BACE1)* which influences the risk of sCJD by interacting with *PRNP* gene.

FUTURE CLINICAL DIRECTIONS

The DSM-5 introduced a new category of neurocognitive disorder—mild neurocognitive disorder (or mNCD). The introduction of mNCD in DSM-5 helped formalize a uniform clinical definition which, in turn, has furthered our understanding of factors that drive the progression to dementia. Understanding the genetics of mNCD becomes critical for the purposes of early intervention and prevention and also furthering personalized medicine. Complementing the DSM-5 introduction of mNCD, the U.S. National Institute on Aging (NIA) has offered further recommendations to provide a standardized language for researchers. These recommendations focus on the biologic aspect of the neurodegenerative disease and position symptoms as a consequence of the underlying disease process. This introduction is aimed at two critical elements. The first is the delineation of a disease stage prior to the onset of mNCD, called cognitively

unimpaired (CU). Currently, considering that the diagnosis is driven by biomarkers and brain pathology, it has been difficult to identify individuals belonging to this category. However, as more clinical biomarkers, such as loss of smell, become defined, it can potentially lead to primary prevention efforts. A second new area the proposed research definition adds is the recognition and identification of newer biologic factors responsible for the dementia syndrome, such as limbic-predominant age-related TDP-43 encephalopathy or LATE, which shares mechanisms with both AD and FTD and argyrophilic grain disease (AGD), which has been identified as a cause for tau hyperphosphorylation, providing more information about the underlying disease process.

Identification of the CU population, in addition to the increased recognition of the role of resilience in symptomatic dementia, opens up an exciting new frontier in the prevention of dementia. Approximately 30% of individuals with the neuropathology of AD do not develop clinical symptoms; of the remaining 70%, the degree of severity of symptoms varies, highlighting a potential cognitive or neural basis for resilience. Recent studies have identified a number of candidate genes modulating the progression of cognitive decline in individuals with AD. As an example, the *BDNF* Val66Met SNP was associated with a faster rate of cognitive decline, while the *PLXNB1* gene was associated with slower cognitive decline. A more recent GWAS of around 5,108 individuals identified resilience genes located on chromosome 8, upstream of *ATP8B1*, which is involved in the bile acid metabolism pathways.

FUTURE RESEARCH DIRECTIONS

Over the last decade, significant strides have been made in understanding the genetics of late-life neurodegenerative disorders. Despite the initial successes, association studies remain plagued by limitations, including their propensity to produce false-positive results and their limited breadth in terms of identifying causal variants rather than markers. Regarding the former, genes identified as associated with a late-life neurodegenerative disorder in an initial study often

overestimate the true effect size and subsequently fall victim to the winner's curse, wherein the same magnitude of an effect cannot be replicated. Regarding the latter, association methods remain focused on the physical localization of association signals rather than on true functional or causal mutations. Thus GWAS can implicate regions of the genome that may harbor contributory loci, but much work remains to fine-map the associated region to identify the true source of its association signal. The result of widespread GWAS application has been the elucidation of a more complex profile of gene involvement. The discovery of the complexity led to the identification of newer and advanced methods, including imputation, which relies on the knowledge that certain gene sequences are usually coinherited. GWAS often identifies a large number of loci, some of which are noncoding. This has led to the identification of expression quantitative trait loci (eQTLs). eQTLs are regions in the genome that regulate nearby genes. In their attempts to integrate functionality with observations, researchers are also beginning to look into one of the limitations of GWASs—the tendency to filter out "near misses." Preliminary work in this area has led to the identification of an "inflammatory subtype" of PD, which may have greater involvement of genes associated with the immune system.

The multifactorial polygenic etiologies and heterogeneity of late-life neurodegenerative disorders have proved to be a huge challenge in the discovery of their underlying genetic bases. The multifactorial polygenic nature of these diseases dictates that the "signals" obtained in linkage and association studies will be numerous and of very low intensity, while the heterogeneity of these disorders increases the "noise" against which these already faint signals must be detected. Some of the most effective ways of combating these complexities are through the maximization of power, both by increasing sample size and by studying homogeneous groups of affected individuals. To identify the numerous genes with small effects on risk for late-life neurodegenerative disorders, various data-pooling strategies, such as continued combination of study-level data by meta-analysis or direct combination of primary data by mega-analysis, can be particularly effective. However, to overcome the

obstacles introduced by heterogeneity, delineating and studying smaller, more homogeneous subgroups of affected individuals may have the greatest beneficial effects on power. When used in tandem, the practices of pooling and splitting will yield maximal power for genetic studies and hasten the discovery of the full compendium of risk genes for each heritable late-life neurodegenerative disorder.

Other promising avenues for elucidating risk genes include the analysis of gene–gene interactions as well as the aggregation of risk genes into PRSs, which, in aggregate, account for a larger proportion of variance in susceptibility than any single variant in isolation. As an example, a genetic risk score based on *ABCA7*, *BIN1*, *CD2AP*, *CLU*, *CR1*, *MS4A4E*, *MS4A6A*, and *PICALM* was noted to predict the rate of progression (a twofold increase in rate) to AD from mNCD. But, perhaps, one of the most interesting shifts in paradigm is the recommendation to examine neurodegenerative disorders from the bottom-up; that is, identifying common biologic pathways in neurodegenerative disorders that become individualized, leading to unique clinical and pathologic characteristics. Recent GWASs have emphasized the biologic pathways that have subserved shared mechanisms between AD and PD (as well as LBD and FTD), such as apoptosis, autophagy, mitochondrial dysfunction, the ubiquitin–proteasome system, oxidative DNA damage, inflammation, lipid metabolism, and vascular changes.

CLINICAL IMPLICATIONS

Since the first draft of the human genome was produced in 2001, scientists have touted the promise of genetic analysis for identifying risk factors for common diseases and the development of personalized (or, more recently, “precision”) medicine. Yet, the vast potential of genetic studies to change the clinical practice of psychiatry is just beginning to be tapped. Recently, commercial genetic tests for (especially Mendelian forms of) late-life neurodegenerative disorders have become available to individuals with a strong family history of illness (e.g., *APP*, *PSEN1*, and *PSEN2*

for AD, *MAPT* for frontotemporal dementia and Pick disease, *PRNP* for CJD, and *PARK*s *1*, *2*, *6*, *7*, and *8* for PD). However, while individuals in the general population can be tested for the possession of particular genotypes to determine their cumulative risk of developing a particular disorder, these commercially available tests do not yield accurate or actionable estimates of risk. Similarly, over the past decade, progress has been made in understanding the factors that contribute to conversion to AD. However, despite these advances, the leads that have been generated from molecular genetic studies are simply not yet understood well enough.

Once the many and diverse genetic risk factors for these conditions become established and widely recognized, they can serve many purposes for early intervention and prevention efforts. For example, understanding risk factors involved in conversion to dementia could speed the initiation of appropriate treatments, which consequently may promote better prognoses through early intervention efforts. Needless to say, the most ideal situation would be preventing the development of cognitive impairment and, perhaps, identification of individuals at high risk of developing cognitive impairment through the development of biomarkers. The operationalization of the definition of early cognitive impairment will clearly advance the investigation into early identification and prevention. Knowledge of genetic risk factors will only help so much in the management of late-life neurodegenerative disorders; in order to fully realize the promise of genomics, linkage, GWAS, and sequencing studies must be followed by functional and mechanistic studies, enabling us to identify the biology and pathophysiology underlying these diseases. Understanding the functional biologic consequences of possessing certain risk-conferring genetic variants will allow for the development of more precise and effective therapeutics. All of this information may someday be harnessed to identify the earliest biologic changes associated with a trajectory toward a late-life neurodegenerative disorder, and this in turn, may help identify specific molecular targets around which the next wave of pharmacotherapies can be designed. Furthermore, the delineation of numerous distinct etiologies for what are now considered unitary

disorders (e.g., PD) may allow, in the future, for these disorders to become recognized as distinct and treated as such (e.g., *PARK1*-positive PD, *PARK2*-positive PD, etc.). Recent successes in identifying specific risk genes for these disorders have been encouraging. Replicating and refining these results, and translating them into meaningful clinical applications signals exciting times ahead for research on the genetics of late-life neurodegenerative disorders.

55.3 Psychiatric Disorders of Late Life

55.3a Assessment of Functioning

David J. Moore, Ph.D., Maulika Kohli, M.S., and Pariya L. Fazeli, Ph.D.

Older adults are the fastest-growing segment of the population in the United States. By 2030, the number of Americans aged 65 and older will more than double to 77 million; roughly 1 in 5 Americans will be over 65. Given that older people represent such a large part of the American population, it is increasingly important that clinicians and researchers in the field of psychiatry be prepared to work with and care for older adults. Older adults, like any other segment of the population, will require care for physical and mental health problems, and they may be at increased risk for impairment in both of these areas. A decline in everyday functioning may be associated with mental and physical health problems. Clinicians are increasingly asked to make decisions regarding patients' capacity to live independently, as well as to determine their capacity to conduct other daily tasks such as managing health care and finances. This chapter defines and reviews domains of everyday functioning and discusses factors (e.g., neurocognitive impairment) that are likely to interfere with daily functioning in older adults. Additionally, this chapter discusses various assessment methods and specific clinical populations, and we make recommendations for future instrument development. The authors hope that this chapter will serve as a resource for clinicians and spur additional needed research on everyday functioning difficulties among older adults.

WHAT IS EVERYDAY FUNCTIONING?

Before discussing the various assessment modalities and other factors related to everyday functioning, a few terms must be defined. Quite

simply, *everyday functioning* refers to all of the activities in which people engage in their daily lives. By this definition, *everyday functioning* is different for every person. The nature of one's daily activities and behaviors depends on numerous factors, including culture, socioeconomic status (SES), and the presence or absence of medical or psychiatric conditions. Despite the wide range of possible daily activities, certain basic behaviors are nearly universal. They range from basic *Activities of Daily Living (ADLs)* such as eating and grooming to more complex behaviors, often termed *Instrumental Activities of Daily Living (IADLs)*, such as managing finances and medications. Some scientists would confine the assessment of functioning to only these physical behaviors, but we take a broader view. For instance, the authors believe that social skills and quality of life (QoL), neither of which is based on physical ability, fit nicely under the umbrella of everyday functioning.

Even though many useful everyday functioning instruments exist, so far, researchers have not reached a consensus on the instrument or instruments that would represent the "gold standard." Several factors may have contributed to this. First, the assessment of everyday functioning in older adults is important to a wide variety of disciplines, such as geriatrics, gerontology, occupational therapy, psychiatry, psychology, nursing, general practice, neurology, and psychiatry, each of which has its own particular focus. This diversity of focus is apparent in the literature as well. Because of the multitude of disciplines conducting research on this topic, different terms are often used when referring to very similar constructs. As a result, no unified search term for "everyday functioning" is available in library reference databases (e.g., Medical Subject Headings, or MeSH) in contrast to such terms as "neuropsychology" or "cognition." The most widely used terms for everyday functioning are *ADL*, which refers to very basic skills needed to survive (basic ADLs or BADLs), and *IADL*, which covers higher-order tasks that represent a level of independence that may or may not be present among individuals with intact ADLs. These terms are discussed and defined in more detail below.

Many individuals experience declines in their ability to perform everyday tasks as they age. Some of these declines may be considered normal, whereas other impairments may result from a disease process. Declines in daily functioning can result from numerous factors, including physical, medical, cognitive, and psychiatric factors. Daily functioning ability is so important that it is included as a diagnostic criterion in the determination of

many psychiatric and cognitive disorders. For instance, a diagnosis of major neurocognitive disorder due to *Alzheimer Disease* (AD), according to the fifth edition of the *Diagnostic and Statistical Manual for Mental Disorders* (DSM-5), requires cognitive deficits that "interfere with the independence of everyday activities." Due to the typically late onset, many individuals who are diagnosed with AD are no longer working. The specific means used to determine "independence of everyday activities" are typically left to the discretion of the clinician making the diagnosis. Along these same lines, a diagnosis of mild neurocognitive disorder due to AD—thought to be a transition between normal cognitive functioning and dementia—requires that "cognitive deficits do not interfere with the capacity of independence in everyday activities." Again, the methods for determining whether daily living skills are intact are often left to the clinician and based upon historical clinical notes when available. Some standardized methods for assessing everyday functioning in mild neurocognitive disorder are available. For example, the Functional Activities Questionnaire (FAQ) is a widely used 10-item (e.g., preparing a meal, monitoring family occasions or personal medications) measure of performance of daily activities, which assesses difficulty ranging from no difficulty to dependent. This brief measure is appropriate for clinical settings and can be completed by the person or an informant. However, differences exist clinically and in research settings for how "independence" is defined. Conservative operationalizations require responses of "no difficulty" or "difficulty but still performing by self," whereas more liberal definitions allow responses of "performing with assistance."

DOMAINS OF EVERYDAY FUNCTIONING ASSESSMENT

Daily functioning tasks lie on a continuum that ranges from tasks that are necessary to function independently (e.g., the ability to get oneself to the toilet and use it) to tasks that are optional but common (e.g., driving a vehicle in the United States) and promote living independently. Tasks falling in between these extremes, such as managing one's finances, are not critical to living independently, but the inability to perform them requires strong environmental or personal support such as a structured living facility or a committed family member or caregiver. Although we

prefer not to classify daily functioning skills by category, several terms are used in the literature. These terms should be familiar to clinicians so that they are able to communicate effectively with other members of a multidisciplinary clinical team.

Activities of Daily Living

As discussed previously, some basic daily functions seem to cut across cultures. Termed ADLs, these are personal care behaviors and basic physical skills necessary in daily life. They include walking, grooming, bathing, and dressing.

Table 55.3a–1.
Typical Everyday Functioning Domains by Activities of Daily Living (ADL), Instrumental Activities of Daily Living (IADL), and Others

ADLs	IADLs	Beyond IADLs
Physically based ADLs Transferring ▸ Chair, bed, wheelchair ▸ Toilet ▸ Tub/shower Walking ▸ Given distance ▸ Climbing stairs ▸ Uneven surfaces **General ADLs** Grooming/hygiene Bathing Toileting Continence ▸ Bladder ▸ Bowel Dressing Eating/feeding	Financial management Medication management Cooking Laundry Cleaning Communication ▸ Written ▸ Spoken ▸ Reading ▸ Telephone Shopping Housekeeping Gardening Driving Hobbies Safety	Social Functioning Driving Quality of Life Multitasking

Some ADLs are more physically based than others (Table 55.3a–1). They are sometimes simply referred to as physical functions. The assessment of physical functioning is often left to physiatrists, physical therapists, rehabilitation specialists, and general practice physicians. Often, these practitioners will use the *Functional Independence Measure* (FIM) (later described in the Clinician Rating of Everyday Functioning section) or a similar measure to describe the level of physical dependence. Perhaps the most basic form of everyday functioning assessment is determining whether an older individual has the physical capabilities to perform basic motor tasks. Motor-based assessments such as timed gait and grip strength may provide additional information in this area. For example, the Timed Up and Go Test (TUG) tests the time it takes to rise from an armchair, walk 3 m, turn, walk back, and sit down, and has been shown to be well correlated with scores on scales of balance, gait speeds, and ADL, and is predictive of falls. Another measure of physical functions is the Short Physical Performance Battery (SPPB), which evaluates balance, gait, strength, and endurance by examining the ability to stand with the feet together in side-by-side, semitandem, and tandem positions; time to walk 8 ft; and time to rise from a chair and sit back down five times. This test has been reported to predict mortality, disability, and nursing home admissions.

Other ADLs are required for autonomous functioning at home (e.g., grooming, bathing, dressing). People incapable of conducting these basic activities require significant assistance and are likely to live in a structured setting (e.g., a nursing home) or receive assistance in completing these tasks from a full-time caregiver. A list of common ADLs can be found in Table 55.3a–1.

Instrumental ADLs

Assessments of IADLs were developed to assess certain higher-level abilities that are required for autonomous functioning within society. Examples of IADLs include managing medications, balancing a checkbook, and preparing a meal (see Table 55.3a–1). Assessments of IADLs are targeted at older people who live independently and have little problem with basic ADLs but may need some assistance with higher-order tasks. Most assessments of everyday functioning either focus on ADLs or IADLs, and assessment approaches are discussed below.

Beyond IADLs

There are several abilities that go beyond IADLs but can nevertheless be important for higher levels of daily functioning. These include social functioning, QoL, and driving.

Social Functioning. The ability to function socially can be important for many aspects of an older adult's life. For instance, social skills are essential to maintaining friendships and remaining actively engaged with other people. Social skills are also critical in many everyday situations, such as articulating an error on a recent bill or discussing health care choices with a physician. Assessments of social skills may be particularly important in conditions known to impact these abilities, including dementia and schizophrenia.

Driving. Many older adults continue to drive in later life. Although they typically drive fewer miles per year than younger drivers, they are at greater risk for accidents than all other age groups, with the exception of teenagers. The risk for accidents seems to increase most noticeably after age 75. After adjusting for miles driven per year, those over age 75 have the greatest number of fatal crashes of any group.

Given that older adults are at significant risk for driving-related accidents and even death, it is important for clinicians to understand what factors put these individuals at risk so that they can appropriately intervene. Equally important is to avoid stigmatizing older adults who are still capable of safe driving. Decisions regarding the advisability of continued driving can be difficult since driving often gives older people a sense of independence and allows them to maintain meaningful social relationships that may be otherwise hampered. The final decision regarding continued driving typically rests with each state's Department of Motor Vehicles (DMV). While many states have adopted special provisions for older drivers, such as no mail renewal after a certain age, very few states require individuals to take an exam or a road test once a certain age is reached. Some states require clinicians to report patients diagnosed with dementia to the DMV (e.g., California). The DMV then evaluates the driver to determine if they may retain driving privileges.

Neuropsychological abilities play a large role in determining whether people of any age should be allowed to continue driving; however, given that dementia is more prevalent in older adults, it is especially important in

this population. Cognitive domains that are more strongly associated with impaired driving performance include memory, executive functioning, and processing speed. Depression, which is common among older adults, can also contribute to decreased responsiveness and poor concentration and lead to an increased risk for driving accidents. Some evidence exists that cognitive training may help improve processing speed among older adults.

Quality of Life. QoL, while not in itself a functional ability, is perhaps the most important outcome affected by daily functioning. Certainly, improved QoL is an assumed treatment goal with any medical or psychological intervention. QoL can be viewed from two perspectives. The global perspective considers all aspects of a person's life; these assessments are typically both subjective and multidimensional. Alternatively, health-related QoL (HRQoL) focuses exclusively on the effects of health, illness, and treatment. HRQoL can be assessed generically or with reference to a specific disease. The most commonly used generic HRQoL instrument is the 36-Item Short-Form Health Survey. Although several HRQoL instruments are used with older adults, the authors are unaware of any specifically designed for this population. Physical functioning is often a part of HRQoL questionnaires and may unknowingly bias these instruments against older adults. A sampling of QoL and HRQoL instruments is shown in Table 55.3a–2. By nature, these instruments are primarily self-report, although some collateral-report measures are available. An expert panel of the National Institute on Aging recommended that older adults, particularly those with multiple chronic conditions, complete a brief but comprehensive (i.e., assesses physical symptoms and mental health symptoms) composite screening measures such as the SF-8/SF-36 or the Patient Reported Outcomes Measurement Information System 29-item Health Profile (PROMIS-29) in clinical settings. This recommendation was made to identify domains where additional follow-up measures may be warranted (e.g., depression, daily functioning).

Table 55.3a–2.

FACTORS INFLUENCING EVERYDAY FUNCTIONING

Given the complexity of most everyday functioning tasks, many factors may significantly affect performance. These include, but are not limited to, cognition, mood, physical health, culture and ethnicity, and the physical environment. Research on the relative impact of each of these factors indicates that each factor has shown varying levels of influence. A discussion of each of these factors and the evidence supporting its role in everyday functioning difficulties is provided below.

Cognition and Everyday Functioning

Of all the factors pertinent to daily functioning, the strongest evidence exists for cognitive impairment as a significant contributor to the decline in

many everyday functioning abilities. However, this literature discussing the relationship between cognition and everyday functioning is not as well developed and complete as one might expect. A recent comprehensive review of the cognitive correlates of functional status found that (1) the proportion of variance accounted for by cognition was modest, (2) some cognition domains had a stronger relationship to functional status than others, (3) cognitive impairments in executive control may be particularly strong correlates of impaired medication management, multitasking, and financial decision-making, and (4) global cognitive screening instruments may be relatively strong predictors of functional status. Historically neuropsychological tests have undergone a more rigorous test-development process than have everyday functioning assessments, and consequently, their reliability and validity are better established.

Many of the early researchers on functional abilities (e.g., Lawton, Brody) hypothesized that daily functioning skills would be lost in the opposite order from that in which they were acquired. Indeed, more complex daily tasks seem to be more susceptible to cognitive impairments than basic tasks.

The role of neurocognitive impairment for daily functioning in older adults is not the same for all disorders. For instance, some individuals may have cognitive difficulties that have long affected their daily functioning (e.g., an older person with schizophrenia), whereas others may have experienced recent and sudden changes (e.g., an older person who recently suffered a stroke). Moreover, the profiles of neuropsychological impairment vary greatly among the disorders found in older adults, and these distinct cognitive profiles may lead to different declines in daily functioning abilities. For instance, memory impairments offer a unique set of difficulties for everyday functioning as compared to motor impairments. A person with declarative memory impairment may have difficulty remembering to take his medications, whereas a person with motor difficulties may remember to take his medications but have difficulty opening the pill bottle.

Mood and Everyday Functioning

Depressed mood and other psychiatric difficulties appear to contribute less to everyday functioning impairment than cognitive difficulties. Obviously, people who are severely depressed or experiencing florid psychotic symptoms may experience significant impairment of daily

functioning; however, people who are only mildly to moderately impacted by psychiatric symptoms appear to suffer a less resultant functional disability than do people with comparable impairments in cognition. This issue is discussed further in the “Clinical Populations and Everyday Functioning” section. It is important to note that psychiatric disturbances may have a greater impact on reporting everyday functioning problems on questionnaires rather than performance-based tasks.

Physical Disability and Everyday Functioning

People who experience physical disabilities typically use appropriate assistive devices and compensatory strategies, allowing them to adapt better to able-bodied environments. For example, people recently confined to a wheelchair may need special accommodations installed in their dwellings. On the whole, there are more available and established compensatory strategies to improve ADL functioning in people with physical disabilities compared to cognitive disabilities, although people with a physical disability may still require assistance with ADLs. Several methods for assessing physical functioning are found in the “Assessment of Everyday Functioning” section.

Culture and Ethnicity in Everyday Functioning

Ethnicity and culture can play a substantial role in the types of everyday activities in which people engage as well as in the support that they receive in accomplishing those activities, in both normative and pathologic settings. Certainly, individualistic cultures differ from collectivist cultures in the amount of support that each offers. For example, Latinos and many Asian cultures have, comparatively speaking, a collectivist approach to functional impairment in family members. Households are frequently multigenerational, encompassing parents, grandparents, and other older relatives, as well as the householders and their children. Hence, families in these cultures often provide greater support to older family members in carrying out daily tasks than do people from families with individualistic cultural backgrounds (e.g., Caucasian Americans). Latino and Asian families, by virtue of their family-oriented support system, may be less likely to seek treatment for an older family member who is experiencing decline and may prefer to handle the matter within the family. Another consideration is the shame associated in some cultures (e.g., Japanese Americans) with acknowledging mental health difficulties in oneself or a

family member. In such cases, people may try to convey mental or cognitive difficulties by presenting with physical complaints (e.g., referring to a decline in cognitive abilities as a headache).

Given such cultural considerations, using everyday functioning assessment instruments designed primarily for English-speaking Caucasian people with individuals of other cultural backgrounds or who do not speak English as a first language can be problematic and lack ecologic validity. People from different cultures may perform poorly on assessments of a daily functioning task for cultural reasons unrelated to functional capacity. For example, in one study, Black and Latino subjects over 55 years of age who had recently been prescribed an antidepressant attributed intentional nonadherence to concern about side effects and stigma; they also attributed less importance to antidepressants than other medications. Other considerations include that within different cultures and households across socioeconomic backgrounds, certain everyday tasks may not be performed at all (e.g., online banking), and thus tasks assessing such domains would not reflect actual abilities. In some cases, everyday functioning instruments have been translated and culturally modified for use with other, non–English-speaking populations, for example, Chinese older adults, as shown in Table 55.3a–3; however, there is clearly a need for additional translations, adaptations, and culturally appropriate modifications.

Environment and Everyday Functioning

An older person's physical environment also can negatively affect every day functioning abilities. People with limited financial resources are often living in physical environments that exacerbate their everyday functioning difficulties. For instance, people with limited ability to climb stairs may live in apartments on the upper floors of buildings without elevators, or they may not be able to afford to have bars installed over the toilet to assist with transferring. Likewise, a person of lower SES may not be able to afford to hire a health care assistant (e.g., for help with managing medications).

ASSESSMENT OF EVERYDAY FUNCTIONING

Standardized assessment instruments and procedures have been developed to evaluate everyday functioning. Functional assessments

typically aim to determine the level of ability in a given domain of daily functioning. Depending on the individual being evaluated, an assessment may focus on basic ADLs (e.g., bathing or grooming), physically based ADLs like mobility (e.g., ability to walk without assistance), or IADLs (e.g., cooking, financial management). Table 55.3a–1 shows some of the domains typically assessed.

Table 55.3a–3. Multidomain Performance-Based Batteries of Everyday Functioning

Battery Name	Brief Description	Site	Scoring	Admin. Time (Minutes)	Notes
Dementia (Primarily Alzheimer Disease–AD, some dementia NOS)					
Activities of Daily Living Situational Test (AST) (Skurla, 1988)	4 subscales; 38 individual items. Item examples include making instant coffee, and finding and calling a phone number.	Clinic	Items scored from 0 to 4. Total score ranges from 0 to 152.	15–20 minutes	
Cognitive Performance Test (CPT) (Burns, 1994)	6 tasks; ratings of specific behaviors are used to place individuals into 1 of 6 levels of disability. Task examples include getting dressed, and preparing a piece of toast.	Clinic	Tasks scored from 1 to 6. Total score ranges from 6 to 33.	45 minutes	Requires training and special equipment. Available for a specific subpopulation (older adult Israelis with and without dementia).
Direct Assessment of Functional Abilities (DAFA) (Karagiozis, 1998)	10 domains; Designed to measure Pfeffer Functional Activities Questionnaire (PFAQ) IADL items. Examples include writing a check and making a sandwich.	Clinic	Items are scored from 0 to 3.	45–90 minutes	The DAFA has been translated and adapted for use with Hong Kong Chinese older adults.
Direct Assessment of Functional Status (DAFS) (Loewenstein, 1989)	7 subscales; 53 individual items. Item examples include balancing checkbook and writing out a check.	Clinic	Items scored from 0 to 2. Total score ranges from 0 to 106.	25–40 minutes	DAFS has also been used with other geriatric samples, e.g., older schizophrenia patients.
Functional Performance Measure (FPM) (Carswell, 1995)	3 subscales; 8 subsections; total of 40 items. Participants are videotaped doing tasks and then the videotapes are rated. Item examples include washing and drying hands, and putting on and taking off sweater.	Clinic	Each subsection scored from 0 to 50. Total score ranges from 0 to 400.	<20 minutes	
Refined ADL Assessment Scale (RADL) (Tappen, 1994)	5 domains; 14 individual items. Item examples include washing hands and brushing teeth.	Clinic	Tasks are broken into component parts and scored from 1 to 6.	5–60 minutes for eating subtask Total >90 minutes	
Structured Assessment of Independent Living Skills (SAILS) (Mahurin, 1991)	10 domains; 50 individual items. Item examples include zipping a jacket, and using a key.	Clinic	Items scored from 0 to 3. Total score ranges from 0 to 150. Both time and accuracy contribute to the score.	60 minutes	An abbreviated version of the SAILS is available. Eating and money subscales validated for older Mexican Americans.
Texas Functional Living Scale (TFLS) (Cullum, 2001)	5 subscales; 21 individual items. Item examples include making change and remembering to take medications.	Clinic	Items scored from 0 to 5. Total score ranges from 0 to 52.	15–20 minutes	
Bay Area Functional Performance Evaluation (BaFPE) (Houston, 1989)	2 general domains; 5 tasks in the first domain, 7 items in the second. Item examples include filling out a bank deposit slip and drawing a person.	Clinic	Rated from 1 to 4.	>45 minutes	This information is based on the revised BaFPE.
Older Psychiatric Patients (Primarily schizophrenia, some mixed psychiatric groups)					
Kohlman Evaluation of Living Skills (KELS) (Thomson, 1992)	5 subscales; 17 areas assessed. Item examples include budgeting money and recognition of dangerous situations.	Clinic	Item scores range from 0 to 1; ½ points are possible.	20–30 minutes	Test sold by publisher. KELS is a combination of self-report, observation, and performance-based tests.
Performance Assessment of Self-Care Skills (PASS) (Rogers, 1984; Holm, 1999)	In the home version, participants are observed conducting various tasks primarily with their own tools and props. Example items include sweeping and mailing bills.	Home	Most recent version is scored on a 4-point ordinal scale ranging from 0 to 3. Higher scores indicate better performance.	>90 minutes	Contains both physical, ADL, and IADL sections.
UCSD Performance-based Skills Assessment (UPSA) (Patterson, 2001)	5 subscales; item examples include shopping for items in mock grocery store and planning a recreational activity.	Clinic	Each subscale transformed to 0–20 score. Total score ranges from 0 to 100.	30 minutes	

Mixed (Psychiatric and Dementia)					
Independent Living Scales (ILS) (Loeb, 1996)	7 subscales; 68 individual items. Example items include how to use a telephone book and writing a check.	Clinic	Items scored from 0 to 2.	45 minutes	Test sold by publisher. Combination of NP and performance-based tests. ILS has been used with schizophrenia patients and older adults.
Occupational Therapy Evaluation of Performance and Support (OTEPS) (Nadler, 1993)	4 domains; 42 individual items. Item examples include making a sandwich and identifying medication dosage from a bottle.	Clinic	Items scored from 0 to 2. Total score ranges from 0 to 84.	Not provided	Also known as OTAPS.
Performance Test of Activities of Daily Living (PADL) (Kuriansky, 1976)	16 individual tasks; item examples include lifting food onto spoon and to mouth, combing hair, and drinking from a cup.	Clinic	Scored 0 (completes task with minimal assistance) to 1 (unable to complete on own).	Not provided	
St. George Hospital Memory Disorders Clinic Occupational Therapy Assessment Scale (OTAS) (Fairbrother, 1997)	8 domains; 30 individual items. Example items include using a telephone book and offering correct money in a simulated shopping activity.	Home	Items scored from 0 to 3. Total score ranges from 0 to 90. Score is based on time and the number of prompts.	30–40 minutes	
Older Healthy Individuals Activities of Daily Living Test (ADL-T) (Warren, 1989)	4 tasks; item examples include boiling an egg and writing a check.	Home and Clinic	Scores ranged from 0 to 16.	>90 minutes	
Day out Task (DOT; Schmitter-Edgecombe et al., 2012)	8 subtasks; laboratory apartment; participants told to imagine they are planning for a day out (beginning with meeting a friend at museum at 10 am and later traveling to friends house for dinner), the 8 tasks must be completed to prepare for the day; participants are told to multitask.	Laboratory	Accuracy of subtasks (i.e., complete/efficient; complete/inefficient; incomplete/inaccurate; never attempted), overall task accuracy, and task sequencing.	No specific time, but average completion times between 10 and 14 minutes.	Used in mild cognitive impairment (MCI) and healthy older adult controls.
Everyday Problems Test (EPT) (Willis, 1993)	7 domains; 84 individual items. Participants are shown printed material of everyday items. Examples include ordering merchandise from a catalog and determining amount to pay from phone bill.	Clinic	Scoring available in published test.	<60 minutes	Test sold by publisher. There is also an Everyday Problems Test for Cognitively Challenged Elderly (EPCCE).
Observed Tasks of Daily Living (OTDL) (Diehl, 1995)	3 domains; 31 individual items (21 usable items). Example items include baking a cake in a microwave oven and loading a pill reminder.	Home	Scoring available from author.	90 minutes	

Note: Tests preceded by a < or a > indicate approximation of administration time based on the text provided. Readers are encouraged to examine the literature for additional studies pertinent to their clinical or research question that may apply their candidate measures.

Modified from Moore DJ, Palmer BW, Patterson TL, Jeste DV. A review of performance-based measures of functional living skills. *J Psychiatr Res*. 2007;41(1–2):97–118. doi: 10.1016/j.jpsychires.2005.10.008.

Some assessments focus on capacity (what the person can do), while others focus on performance (what the person actually does). Glass describes three "tenses" of functioning: (1) a *hypothetical* tense representing the capacity of the person, (2) an *experimental* tense defined as what the person is capable of doing, and (3) *enacted* tense which represents what the patient actually does. Furthermore, Glass describes common errors in classifying older adults' functional status. The first occurs when people provide a low self-report of functioning but actually function at a higher level; these people are "overachievers," and their reports as compared to behavior represent a discrepancy between the hypothetical and the enacted tense. The opposite situation also occurs:

some people report high functioning but engage in few activities that would qualify for that designation. These people can be termed "underachievers" and also show a discrepancy between the hypothetical and the enacted tense.

When interpreting functional assessment data, the clinician or researcher must consider whether the person being assessed has ever done a given task before. For example, performing a financial assessment with a person who has never managed their own finances has little to no meaning.

Table 55.3a–4.
Strengths and Weaknesses of Various Functional Assessment Modalities

	Cost	Ease of Use	Reliability	Validity	Predictive
Self-report	Inexpensive	Easy	High	Weak	Weak
Collateral report	Inexpensive	Easy	Questionable	Questionable	Questionable
Clinician-rating	Moderate	Moderate	Moderate	Moderate	Moderate
Performance-based	Moderate	Moderate	High	Strong	High
Direct observation	Expensive	Difficult	High	Strong	High

There are many reasons for conducting a functional assessment. In many cases, functional assessments are used to get a "snapshot" of an individual's current level of functioning. Functional assessments are rarely done as part of routine care; rather, they are often conducted following some acute event (e.g., stroke) or referral complaint (e.g., the patient has difficulty managing medications). An evaluation in this context serves as a baseline for future evaluations and, ideally, would be sensitive to improvement or worsening of abilities over time. Functional strengths and weaknesses can be identified, and interventions can aim to improve areas of disability and utilize areas of intact functioning to compensate for deficits. In the optimal situation, improvements would be observed following a treatment intervention to improve the targeted area of functional impairment. It is important to place particular emphasis on those abilities that are critical for functioning within a given environment. For instance, medication management may not be important for an individual living in a structured living facility that administers medications, but bathing, grooming, and the ability to transfer remain important. In this way, a functional assessment can be used as a tool for discharge planning and estimating the level of functional assistance that a particular individual may need.

Often a person receiving a functional assessment has a significant preexisting cognitive or physical disability, but people with more subtle difficulties may be even more appropriate candidates for a functional assessment. For example, a person with AD is likely to have many functional impairments, and decisions regarding housing placement and the level of care may have been determined prior to the administration of a functional assessment. On the other hand, a person who is having mild cognitive difficulties and who evidenced impairments on tests of arithmetic and memory may be an ideal candidate for a financial capacity assessment (and subsequent treatment) if they are still managing personal finances. The authors argue that functional assessments should be used at earlier stages of clinical care to facilitate gradual life changes (e.g., enlisting a family member to help with finances) rather than wait for a radical upheaval of all aspects of daily life at once.

Everyday functioning assessments are not just for individual-level clinical purposes. These assessments can be used with representative samples of clinical populations to draw general demographic conclusions. For instance, research using the Social Skills Performance Assessment (SSPA) has shown that older schizophrenia patients have difficulties with social skills. As a result, Cognitive-Behavioral Social Skills Training was developed and has targeted these problems among people with schizophrenia and improved the functioning of this group.

There are several different methods for assessing everyday functioning. The most common are clinical interviews, self- or collateral reports, clinician ratings of behavior, laboratory performance-based measures, and direct observation. Several reviews in the literature provide additional information about the everyday functioning assessment instruments designed for older adults.

Each assessment method has inherent strengths and weaknesses (Table 55.3a–4). For example, some types of instruments are easily administered, but may not be reliable (e.g., self-report), whereas others may provide more reliable data but are not feasible to administer routinely (e.g., direct observation). Choosing the type of functional assessment to use is largely driven by the referral question, available resources, and the person's particular needs. In the sections below, common functional assessment methods are reviewed, and some of the instruments frequently used with each type are discussed. Of course, the gold standard consists of a multimodal approach.

Clinical Interview of Everyday Functioning

Though time is often at a premium when psychiatrists and other physicians conduct clinical interviews, a detailed clinical review of a patient's daily functioning can be extremely helpful in establishing current levels of functioning as well as for treatment planning. Understandably, a thorough assessment of everyday functioning cannot be conducted at every clinical visit; however, psychiatrists can make referrals to other disciplines (e.g., physical and occupational therapy, clinical psychology, neuropsychology) that may be able to spend more time both conducting a clinical interview as well as other assessment modalities described below.

Certain elements are essential to a thorough clinical interview designed to assess a person's daily functioning. First, it is important to get a sense of the person's daily activities. Open-ended questions such as, "Can you describe a typical day for me?" are often helpful. This puts the onus on the patient to elaborate on their daily activities. Queries should be made about difficulties with ADLs and IADLs. All assessments should include questions about other important domains such as social functioning, driving, and safety. Table 55.3a–5 lists some of the critical elements of an everyday functioning interview. Similarly, follow-up questions pertinent to any daily functioning domain of concern should be phrased in ways that give the patient the opportunity to elaborate on any possible concerns or difficulties. It is sometimes helpful to disarm patients by saying things like, "All people have difficulties managing their medications. Can you tell me about the last time that you had difficulties managing yours?"

Table 55.3a–5.
Topics to Cover in Clinical Interview of Everyday Functioning

For All Older Adults

- Current daily activities?
- Difficulties with:
  - Physical demands (e.g., climbing stairs, walking)
  - ADLs (e.g., bathing, dressing, feeding)?
  - IADLs (e.g., cooking, medication/financial management, driving)?
  - Social skills?
  - Safety (e.g., two-story house for frail person)?
  - Decision making?

Additional questions for persons with difficulties

- Experience with daily activities of difficulty?
- Onset (e.g., gradual/discrete)?
- Progression (e.g., continue to decline)?
- Decline associated with critical event (medical, change in medication, grief)?
- Availability, reliability, and commitment of support declines in daily functioning?
- Concrete plan for dealing with daily functioning difficulties?

It is also important to elicit patients' histories with particular daily tasks. For instance, some older individuals may have little experience cooking and preparing meals, while other older individuals may have little experience managing finances. If a patient has recently lost a significant other or a support system that used to perform a particular task, poor performance may not represent a decline in daily functioning ability but rather a lack of experience. Some assessment performances, however, may represent declines, and it is useful to pose questions such as the following: Was the onset of these difficulties gradual or sudden? Has there been a continued decline? Was the decline associated with any other recent change (e.g., medical problem, change in medications)?

Among patients exhibiting daily functioning difficulties, it is important to find out whether they have support for daily tasks. Clinicians should assess the availability, commitment, and feasibility of the proposed support system. Where possible, clinicians should get consent from the patient to follow up with the identified support person or network to

determine if the person or people identified are truly capable of providing support in performing daily tasks.

Self-Report of Everyday Functioning

Self-report is the most widely used modality for assessing problems with daily functioning. Self-reports are limited by the knowledge and objectivity of the respondent. Although self-report is subject to inaccuracies, particularly overestimation of functional abilities, it has several advantages, including cost-effectiveness, ease of administration, and portability. Furthermore, in people without significant psychopathology (e.g., depression, personality disorders) or health problems (e.g., chronic pain, fatigue), self-endorsement of functional difficulties is generally held to equate to actual difficulties; however, the opposite does not always prove to be true. That is, people often fail to report or minimize difficulties that they may be having. Among older people with mild neuropsychological impairment or dementia, self-reports of functional status may have little to no utility, especially among patients with amnestic syndromes. Even among older individuals without cognitive problems, overestimation of abilities is common.

Another disadvantage of most self-report measures is that they are not particularly sensitive to change over time. Individuals tend to hold fairly constant views of themselves regardless of recent personal events and tend not to report changes in daily functioning abilities until they become drastic. Self-report measures appear to elicit more accurate data and correlate more robustly with performance-based measures when queries are specific and pertinent to the individual's difficulties (e.g., about stair climbing) rather than abstract (e.g., about mobility in general).

Self-report data concerning functional abilities can be collected in several different ways, including structured, semistructured, or unstructured interviews. Interviews allow clinicians to hear, in the patient's own words, the difficulties that they are having. Clinicians can then ask follow-up questions that help specify the particular difficulty or difficulties. This is the approach most commonly used by general practitioners. Where indicated, problem areas can be addressed with more formal assessments.

Table 55.3a–6.
Self-Report Measures of Everyday Functioning

Self-Report Measures of Functional Status
Lawton–Brody IADL
Katz ADL
Functional Status Questionnaire
Health Assessment Questionnaire
World Health Organization Questionnaire
Short-Form Health Survey (SF-36)
Sickness Impact Profile (SIP)
Functional Disability Index Score (FDIS)
Older American Resources and Services (OARS)
Patients Assessment of Own Functioning Inventory (PAOFI)
Rapid Disability Rating Scale–2 (RDRS-2)
Questionnaire on Clinical and Preclinical Disability (QCPD)
Unmet Needs Indices (UNI)
Identification of Seniors at Risk (ISAR)
Instrumental Activities of Daily Living Compensation (IADL-C) Scale
Everyday Competence Questionnaire (ECQ)

Another way of assessing functional status is through the use of standardized self-report questionnaires. These instruments vary in their levels of reported reliability and validity. The outcome is generally a score that represents the level of functional impairment. Some of the most widely used instruments of self-reported daily functioning are the Katz ADL scale, the Lawton–Brody IADL scale, and the FAQ. Additional self-report assessment instruments are listed in Table 55.3a–6.

Katz ADL Index. The Katz ADL Index uses a three-point Likert-type scale to assess the ability to bathe, dress, toilet, transfer, feed oneself, and maintain bowel and bladder continence. It was designed for use primarily with older hospitalized patients who function at lower levels, and hence it is unlikely to identify functioning difficulties among most community-dwelling outpatients. Another limitation is the scale's hierarchical structure. Functional difficulties are assumed to accrue in this order: bathing, dressing, toileting, transferring, continence, and feeding.

Research has shown that alternative hierarchies of functions may apply equally as well.

Lawton–Brody Instrumental ADLs. The Lawton–Brody IADL scale is another structured questionnaire that focuses on higher-level domains needed for independent functioning at home and in the community. The scale covers eight domains: telephone use, shopping, food preparation, housekeeping, laundry, transportation, medication management, and financial management. This scale is often used in conjunction with the Katz scale to provide indicators of both basic ADLs and IADLs. Although the questionnaire is often used in self-report mode, the clinician or caregiver can also complete it.

Functional Activities Questionnaire. Another self-report instrument of everyday functioning is the FAQ. The FAQ is a 10-item questionnaire that is widely used in conjunction with neuropsychological testing. This questionnaire also has an informant form that can be administered in addition to the self-report form. Respondents rate the patient's ability to carry out IADLs, such as preparing balanced meals and managing personal finances, on a scale ranging from no difficulty to dependent. Ratings account for whether the patient has ever done the activity and their current abilities (e.g., never did [the activity] but could do now = normal). The main focus is on IADLs that require higher cognitive abilities that are observed in the earlier stages of dementia and not more basic ADLs that typically decline later in the dementing process.

Collateral Report of Everyday Functioning

Reports from caregivers, family members, or other people who are close to the individual with everyday functioning difficulties can be extremely valuable. In situations where the collateral reporter knows the patient well, is capable of providing an accurate report, and is able to maintain objectivity, collateral reports can be one of the best ways of gathering information regarding a patient's functional status. Accurate collateral reporters provide the same types of information as a self-report assessment, but they do so from the perspective of a direct observer. Unlike direct clinical observers, collateral reporters are typically part of the individual's daily routine, which obviates some of the problems common to traditional direct observation (see below). Unfortunately, collateral reports

also have limitations. Close family members or friends may have reasons for distorting their reports. For example, they may minimize the level of functional disability in an effort to protect the patient from unpleasant but inevitable transitions, or they may overemphasize the level of impairment in order to obtain medical or psychosocial assistance for the patient more quickly. The collateral reporters may also have cognitive or psychiatric impairments of their own that limit their ability to render accurate judgments. Finally, in many cases, older patients are socially isolated such that a knowledgeable informant is unavailable. Where collateral reports are available, the clinician must decide how likely they are to be accurate. Many of the self-report measures listed in Table 55.3a–6 also have collateral-report versions. Additionally, the Physical Self-Maintenance Scale (PSMS) was specifically designed for use by a person with significant knowledge of the skills of the patient, and the Specific Levels of Functioning (SLOF) was designed for caretakers (detailed below).

Specific Levels of Functioning. Another measure is the SLOF, which is a 43-item caretaker report of a patient's behavior and functioning in the following domains: physical functioning (e.g., vision, hearing), personal care (e.g., toileting, eating, grooming), interpersonal relationships (e.g., initiating, accepting, and maintaining social contacts; effectively communicating), social acceptability (e.g., verbal and physical abuse, repetitive behaviors), activities (e.g., shopping, using telephone, paying bills, use of leisure time, use of public transportation), and work skills (e.g., employable skills, level of supervision, punctuality). The SLOF rates the amount of assistance that the patient requires to perform real-world tasks (personal care, activities), and it rates levels of physical functioning and the frequency of certain behaviors (interpersonal relationships, social acceptability, work skills). An important aspect of collateral reports, such as the SLOF, is how well the caretaker or informant knows the patient. Performance-based measures of everyday functioning discussed below have been shown to predict real-world outcomes as determined by the SLOF.

Ecologic Momentary Assessment. Assessing everyday functioning in real-time has several potential advantages. Ambulatory approaches such as ecologic momentary assessment (EMA) and experience sampling methods are growing in research settings to capture everyday

phenomena. Such approaches involve sending individuals surveys via electronic methods (e.g., text messaging, email) on a set schedule, often several times a day for several days. Such an approach allows for a more nuanced and ecologically valid assessment of the performance of daily activities. Potential impeding factors can also be assessed using this method (e.g., cognitive impairments). Other advantages of EMA approaches are that they are less sensitive to recall bias (which may be particularly poor among those with memory impairments), as well as greater sensitivity of these methods to detect changes over time. Though EMA and other approaches offer potential advantages, implementing them in a clinical setting has yet to be realized. With the continued rise of telemedicine in clinical settings, the outlook of EMA for evaluating daily functioning is promising.

Clinician Rating of Everyday Functioning

Another common functional assessment approach is the clinician rating. Such an assessment is typically conducted in a clinic or hospital and can be administered by a physician, nurse, occupational or physical therapist, or a specifically trained rater. In contrast to self- or collateral reports, the clinician rating has the advantage that the clinician is generally familiar with specific daily functioning difficulties and the particular behaviors that may put individuals at risk for poor daily functioning. Many clinician-rated instruments have reported good interrater reliability, although it is likely that experienced clinicians will produce more accurate ratings and classifications. These instruments can measure both actual behavior and capacity. For instance, some clinician instruments measure what they see patients actually doing, and others ask patients to conduct a given behavior (capacity). A disadvantage of clinician ratings is that they are typically conducted outside of the patient's habitual environment (i.e., clinic or hospital) rather than in the patient's home or some other everyday setting. Therefore, they may not generalize to the patient's everyday setting (particularly if the patient still lives independently).

Barthel Index. One of the most widely used clinician-rated scales is the Barthel Index. To complete this and other similar instruments (see Table 55.3a–5), the clinician rates several different ADLs on a Likert-type scale that ranges from dependent to independent. The Barthel Index assesses more basic functions such as feeding, bathing, grooming,

dressing, bowel movements, bladder control, toilet use, transfers from bed to chair and back, mobility, and stair use. Items on the index mostly range from 0 to 10 (some from 0 to 5) and have behavioral anchors for midpoints (e.g., for the transfers item, a rating of 5 indicates major help from 1 or 2 people). The Barthel Index and the Katz ADL (which assesses bathing, dressing, toileting, transfers, continence, and feeding) are most appropriate for individuals who have significant physical or cognitive impairments.

Functional Independence Measure. The FIM is a clinician-rated assessment that is widely used within rehabilitation settings for the determination of functional dependence/independence. It is important to note that the FIM rates observed performance, not capacity; this limits the measure's usefulness in inpatient or other settings where the clinician has frequent observation of the patient. Each of the FIM's 18 items is rated on a 7-point Likert-like scale that ranges from total dependence to functional independence. The scale requires trained raters (with at least 80% accuracy), and certification is provided for a fee by the Uniform Data System for Medical Rehabilitation (UDS). The FIM features both a motor and a cognitive component. The items covered are listed in Table 55.3a–7.

The Functional Assessment Measure (FAM) was created to supplement the FIM and includes 12 items related to cognitive, behavioral, communication, and community functioning. These items are also listed in Table 55.3a–7. The FIM + FAM comprises a total of 30 items and is often used to evaluate change over the course of an inpatient stay. Both the FIM and the FAM were designed primarily for people with brain injury, but they are also widely used in other settings that provide treatment for older adults.

Table 55.3a–7.
Everyday Functioning Skills Assessed by the Functional Independence Measure and the Functional Assessment Measure

FIM	FAM
Eating	Swallowing
Grooming	Car transfer
Bathing	Community access
Dressing upper body	Reading
Dressing lower body	Writing
Toileting	Speech intelligibility
Bladder management	Emotional status
Bowel management	Adjustment to limitations
Bed, chair, wheelchair transfer	Employability
Toilet transfer	Orientation
Tub and shower transfer	Attention
Walking/wheelchair locomotion Stairs	Safety judgment
Comprehension	
Expression	
Social interaction	
Problem solving	
Memory	

Performance-Based Measures of Everyday Functioning

Performance-based measures of everyday functioning use role play and mock settings to simulate traditional everyday functioning tasks. These tasks are administered under consistent conditions and use standardized instructions. For instance, rather than ask a patient or a collateral informant about the patient's cooking skills and safety (which is limited by the insight, candor, and objectivity of the patient or the informant) or observe the patient at home and watch them prepare a meal (which may be too time- or labor-intensive), a performance-based measure will have the patient prepare a meal using a mock kitchen based in a laboratory or hospital. Performance-based measures assess capacity or what a person

“can do” and represent the enacted tense of the Glass model under standardized, optimal conditions rather than in the patient’s habitual environment. This distinction is important because in some disorders, what impairs performance is not a lack of capacity but rather a failure to translate functional capacity into self-initiated functional performance.

It should be noted that the distinction between clinician ratings and performance-based measures of functioning is fundamental. Performance-based measures typically use a mock setting and are scored similarly to a neuropsychological test, with little ambiguity in criteria. By contrast, clinician ratings occur in less-standardized settings (hospital or clinic), are generally geared toward more basic ADLs, and typically require a more experienced or highly trained rater to score appropriately.

A variety of performance-based measures have appeared over the past 30 years in discipline-specific journals (e.g., occupational therapy, clinical and educational psychology, psychiatry, neurology). The authors conducted a review of these measures. Table 55.3a–8, adapted from the authors’ review, shows the functional domains assessed by commonly used performance-based measures. The authors present measures that assess multiple domains as well as some that focus on a specific domain. Tables 55.3a–3 and 55.3.a–9 briefly describe these measures and provide information on scoring and approximate assessment times (more details in Moore et al., 2007). In addition to these tables, which primarily show assessments of traditional ADLs and IADLs, Table 55.3a–10 shows some common performance-based measures of physical functioning and simple motor skills. As there is no specific gold standard measure, a broad representation is presented in the tables.

Performance-based measures of everyday functioning, like all assessment tools, have strengths and weaknesses. The strengths are many. Foremost are the standardized methods of administration, which leave little ambiguity in the scoring. As a result, interexaminer reliability tends to be high. Additionally, these assessments focus on real-life skills in a safe setting (e.g., cooking tasks can be controlled) and are face valid. Furthermore, they do not rely on the patient’s insight or ability to answer questions on a self-report questionnaire which might be influenced by education or reading level, and they do not depend on the knowledge or objectivity of a collateral or proxy reporter. These instruments are good targets for intervention studies designed to improve everyday functioning and have been implemented in this role (e.g., the UCSD Performance-

based Skills Assessment, UPSA). The UPSA is a real-world outcome measure for the Measurement and Treatment Research to Improve Cognition in Schizophrenia (MATRICS) trial, which is designed to assess the effectiveness of antipsychotic medications in improving cognition. The consensus appears to be that performance-based measures have more strengths than weaknesses and offer benefits over other assessment approaches that make them useful for clinical treatment studies.

However, performance-based measures do have weaknesses. One is that the test environment is contrived (e.g., it is not the patient's own kitchen but a mock one). This decreases the patient's ability to follow behavioral scripts or schemas that allow them to successfully complete a task at home but not elsewhere. Performance-based assessments may achieve high reliability at the cost of validity. Perhaps the greatest weakness of performance-based measures of functional capacity, however, is that they measure capacity, not actual performance. For instance, a person may very well have the capacity to complete the task but may not have the initiative or supportive environment in order to complete the task on his or her own. Finally, most of the current performance-based measures are designed to only assess one given functional domain at a time, whereas in daily life, a person is often completing many functional tasks simultaneously.

While there are far more single- and/or multiple-domain tests that evaluate each separately, there have been some multitasking tests developed. For example, the Everyday Multitasking Test (MT) is a laboratory-based multitasking qualitative assessment in which individuals are required to complete four separate tasks within a 12-minute time limit. The four tasks include cooking a meal, advanced finances (e.g., paying bills), medication management (e.g., pill dispensing), and telephone communication. Completion of these unstructured tasks required the integration of multiple cognitive systems, which is reflective of everyday functioning environments.

Virtual Reality Performance-Based Measures of Everyday Functioning

While virtual reality (VR)-based assessment has been used to assess driving ability, there are several VR, performance-based everyday functioning assessments that have been developed recently that show promise for geriatric everyday functioning assessment. These VR tasks

also assess multitasking aspects of everyday functioning and may be particularly sensitive to executive dysfunction accompanying age-related neurodegenerative disorders involving frontal pathology (e.g., planning, task switching).

Table 55.3a–8. Domains Assessed by Several Performance-Based Batteries of Everyday Functioning

Instrument	Communication	Hygiene	Dress	Eating	Time	Safety	Finances	Cooking	Shop	Transportation	Medical Management	Other
Performance-based batteries												
Dementia (primarily Alzheimer disease, but some unspecified neurocognitive disorders)												
Activities of Daily Living Situational Test (AST) (Skurla, 1988)	X		X					X	X			
Direct Assessment of Functional Status (DAFS) (Loewenstein, 1989)	X	X		X	X		X		X	X		
Structured Assessment of Independent Living Skills (SAILS) (Mahurin, 1991)	X		X	X	X		X	X			X	Motor skills, expressive and receptive language, social
Functional Performance Measure (FPM) (Carswell, 1993)		X	X					X				
Cognitive Performance Test (CPT) (Burns, 1994)	X	X	X					X	X			
Refined ADL Assessment Scale (RADL) (Tappen, 1994)		X	X	X								
Direct Assessment of Functional Abilities (DAFA) (Karagiozis, 1998)							X	X	X	X		Awareness, reading, leisure
Texas Functional Living Scale (TFLS) (Cullum, 2001)	X		X		X		X					Memory

Table 55.3a–9.
Single Domain Performance-Based Batteries of Everyday Functioning

Test	Test Description	Site	Scoring	Admin Time (Minutes)	Other
Dementia (Primarily Alzheimer Disease—AD, some dementia NOS)					
Beck Dressing Performance Scale (BDPS) (Beck, 1988)	In most recent version, participant is rated on 42 discrete component steps of dressing for males and 45 steps for females (e.g., button shirt).	Home	Participants are scored on a scale from 0 to 7 with 7 indicating maximal assistance and 0 representing no assistance.	<30 minutes	
Financial Capacity Index (FCI) (Marson, 2000)	6 domains; 14 individual tasks of financial ability. Domains range from basic monetary skills to financial judgment.	Clinic	Cutoff scores place individuals into levels of capacity.	30–50 minutes	Modified version (FCI-8) assesses 8 domains and has 19 tasks.
Kitchen Task Assessment (KTA) (Baum, 1993)	Rate the participants' ability to cook pudding from provided directions. Six components are assessed. Components scored include performance of all steps, and judgment and safety.	Clinic	The level of support from the tester is scored from 0 to 3.	<30 minutes.	
Psychiatric Patients (Primarily schizophrenia, some mixed psychiatric groups)					
Medication Management Ability Assessment (MMAA) (Patterson, 2002)	Asks participant to walk through four fictitious medication regimens.	Clinic	Comprehensive manual available upon request.		
Individual medication points vary. Total score ranges from 0 to 25.	15 minutes.	Older Schizophrenia Patients			
Mixed (Psychiatric and Dementia)					
Time and Change Test (T&C) (Froehlich, 1998)	Tests participant's ability to tell time and make change.	Clinic	Screen for dementia or not based on cut scores.	2 minutes	
Older Healthy Individuals					
Drug Regimen Unassisted Grading Scale (DRUGS) (Edelberg, 1999)	Patient is asked to perform each of four medication-related tasks: identification, access, dosage, and timing. Participants used their own medications.	Clinic	Participant given a score of able (1) or unable (0) for each task for each medication.	>20 minutes	
Functional Ability to Take Medications (FATM) (Meyer, 1989)[a]	Patient is presented with six specific medication-related tasks (e.g., opening a pill bottle).	Clinic	Items are scored as either yes or no.	<10 minutes	Instrument was later slightly modified.

Note: Tests preceded by a < or a > indicate approximation of administration time based on the text provided. Readers are encouraged to examine the literature for additional studies pertinent to their clinical or research question that may apply their candidate measures.

[a]Abbreviation assigned by the author of the current chapter.

Modified from Moore DJ, Palmer BW, Patterson TL, Jeste DV. A review of performance-based measures of functional living skills. *J Psychiatr Res.* 2007;41(1–2):97–118. doi: 10.1016/j.jpsychires.2005.10.008.

The VR multiple errands test (VMET) was adapted from a non-VR version of the MET due to the need for a more feasible approach to assess multitasking and executive abilities in the context of everyday functioning. Several versions have been established, but in general, participants complete a set of diverse subtasks within a simulated shopping mall and/or office environment and include a planning component, tapping into the role of metacognition and metacognitive strategies in everyday task performance.

Table 55.3a–10.
Performance-Based Tests of Physical Functioning

Physical Performance Test (PPT)
Established Populations for Epidemiologic Studies of the Elderly (EPESE)
Timed Manual Performance Test (TMP)

Another measure is the Virtual Kitchen Challenge (VKC), a noninvasive VR meal preparation (breakfast and lunch) task that takes place in a virtual kitchen. Similar to the VMET, the VKC measures executive abilities in an everyday setting. Unlike the VMET test, tasks must be performed in a specific sequence, however, with little explicit rule constraints because the goal of this test was to explore whether and how often subjects participate in behavior that is clearly not goal-directed when there is no explicit instruction or "rules" directing against such behaviors.

Table 55.3a–11 provides a list and description of several recently developed VR assessments. Although many of these tests were not necessarily designed for older adult populations, they may prove useful in healthy and pathologic aging. The advantages of VR-based assessments are: (1) increased safety, (2) improved standardization and objectivity in terms of stimulus delivery, measurement/scoring, and error reduction, (3) ability to detect subtle deficits, and (4) portability which makes them ideal for clinical settings and has potential for remote delivery. Many of these tasks are new and are therefore still in the development and validation stages; however, they do show promise for geriatric assessment in future research and practice (Table 55.3a–11 lists the populations that have been used to date). It is important for these VR assessments that participants and patients are given a chance to familiarize themselves with the computerized interface, especially when they have no prior computer experience.

Table 55.3a–11. Virtual Reality (VR) Performance-Based Everyday Functioning Assessments

Test	Test Description	Scoring	Admin Time (Minutes)	Populations Used to Date	Other
Nonimmersive Virtual Coffee Task (NI-VCT; Allain et al., 2014)	14 steps; virtual environment simulates kitchen; patients must make a cup of coffee; requires multiple cognitive processes: serial ordering of several steps (open the drawer, etc.), object selection (coffee filter, etc.), and technical manipulations (coffee machine) to complete goal.	5 outcomes: Total completion time; percentage of task steps completed with or without error (range 0–100%); total number of errors (e.g., omissions, commissions).	15 minutes for instructions and training. No time limit, but in Allain et al., 2014 it took AD patients ~11 minutes and healthy older adult controls ~6 minutes.	AD patients and healthy older adult controls	Adapted from a subtask from the Naturalistic Action Test (NAT; Schwartz et al., 2003) and the Coffee Challenge (CC; Giovannetti et al., 2007) (both non-VR tasks)
Virtual Errands Test (VET; McGeorge et al., 2001); also called Virtual Multiple Errands Test (V-MET)	12 errands (in McGeorge version); diverse subtasks (e.g., collecting a book, meeting a colleague) within a simulated environment; includes a planning component, which taps into the role of metacognitive strategies in everyday tasks. McGeorge version more vocationally oriented and contains work-related errands, while other versions of the task include shopping-related errands.	Planning; total number of errands completed.	Unlimited planning time; 20 minutes for test.	Healthy adult controls; brain damage patients; Parkinson disease	Adapted from non-VR, version (Shallice & Burgess, 1991). There are several variations of the VET/VMET for different populations that differ in tasks/subtasks (e.g., Law et al., 2006; Cipresso et al., 2011)
Multitasking in the City Test (MCT; Jovanovski et al., 2012)	8 tasks; virtual environment has several stores (e.g., drug store, post office); specific task requirements/errands listed on screen, along with errands completed, amount of money in wallet, and clock displaying time; designed to be open-ended with few explicit rules (i.e., complete as many errands as possible in 15 minutes).	Planning; completion time; number of tasks completed; qualitative errors (i.e., task failures, task repetitions, inefficiencies).	Unlimited time for planning; 3 minutes for instructions and 15 minutes for test.	Stroke; TBI; Healthy young adult controls; not used in aging yet	
Virtual Reality Functional Capacity Assessment (VRFCAT; Ruse et al., 2014)	4 scenarios (i.e., navigating a kitchen, getting on a bus to go to a grocery store, finding/purchasing food in a grocery store, and returning home on a bus); 12 objectives; three factors identified in development: Reasoning and Problem Solving, Speed of Processing, and Working Memory.	Completion time for each objective; accuracy/errors for each objective.	Not specified; time limits for each task; for healthy controls range across 12 objectives was ~25–120 seconds, for schizophrenia was ~25–225 seconds	Healthy adult controls and schizophrenia (developed for schizophrenia and other CNS disorders; studies are underway)	
VRMMA (Virtual Reality Apartment Medication Management Assessment Kurtz et al., 2002)	3 types of pills must be "taken"; exploration phase then actual "test" phase. In "testing" phase, participant told several seconds into task a post-it note would appear telling them which medications to take and when to take them (e.g., "Remember to take: 2 yellow, 4 red, and 1 blue pill in 15 minutes" and to use all items in apartment that were explored during the practice phase; virtual apartment consists of a living room, bedroom, bathroom, and kitchen.)	Dependent measures include: quantitative errors; qualitative errors; time discrepancy; total distance traveled; clock checks; reminder note checks.	If an attempt to take medications not initiated by 18 minutes, notice appears saying "time has expired, please go take your medication now." If 23 minutes elapses and participant still has not taken medication, the program terminates.	Schizophrenia and healthy adult controls	Developed from non-VR task: Medication Management Abilities Assessment (MMAA; Patterson et al., 2002)

Direct Observation of Everyday Functioning

Some measures employ direct observation, which may be more valid than subjective reports. Direct observation has typically been used in inpatient settings where clinicians can easily record behaviors. Although many consider direct observation to be the "gold standard" of functional assessments, it is, in fact, more of a theoretical technique than a practical

tool. That is, the most accurate representation of functional ability would consist of observing someone in her natural environment as she conducts her daily tasks without knowing that she is being observed. In most cases, direct observation of this type is unethical and unrealistic. Even where the patient's consent has been obtained for direct observation, it is labor intensive and provides data only about the behaviors engaged during the observation period. Furthermore, a person who knows he is being observed will frequently alter his behavior, sometimes radically.

CLINICAL POPULATIONS AND EVERYDAY FUNCTIONING

The following text discusses selected domains of everyday functioning that are of concern among specific clinical populations of older adults or that have received substantial research (e.g., functional impairments in older people with schizophrenia). This list of clinical populations is in no way exhaustive, but it gives a sense of the ways in which functional impairment can differ from group to group.

Normal Aging

Cognitive declines associated with normal aging seldom reach a level sufficient to impact daily functioning. Among older people without dementia or some other condition known to affect cognition, the neuropsychological domains that show the greatest decline with aging are processing speed and psychomotor speed. Declines in these domains are unlikely to significantly influence basic ADLs such as grooming, bathing, or using a telephone. Normal declines in these domains may, however, have some effect on speeded IADLs such as driving. Driving relies heavily on intact processing and psychomotor speed, and as discussed above, driving is a domain that warrants particular attention from clinicians when assessing older adults.

Dementias and Neurologic Conditions

The cognitive profiles of individuals with dementia can be quite varied. AD, the most common of the dementias, often produces difficulties with memory (particularly with delayed recall) as well as language difficulties (e.g., anomia). Difficulties with memory can lead to problems with many IADLs, such as financial and medication management. Tasks such as

cooking and meal preparation are highly dependent on the order in which they are conducted, and a person with memory impairment may forget a critical step or unknowingly repeat a task.

This case presents an example of a thorough assessment of neuropsychological, mood, and daily functioning in a patient suspected of having AD.

DEMOGRAPHICS

Mrs. Smith is a 71-year-old, right-handed Caucasian woman.

EDUCATIONAL AND VOCATIONAL HISTORY

The patient completed 14 years of education. After completing 2 years of college, she accepted a position as a secretary in a law office and remained in that position until she retired at the age of 55.

BEHAVIORAL OBSERVATIONS

The patient was alert and oriented to the day of the week, year, and city but was incorrect by 2 days on the exact date. She knew the month, and she could name the president, governor, mayor, and the name of the building she was in. The patient was pleasant to work with. Her mood was positive, and her affect was congruent with her mood. She mentioned that her children were worried about her memory lately, particularly her daughter. She interacted with the examiner in an appropriate manner. She took a few breaks to stretch her legs. Her frustration tolerance was good. She showed very good attention and low distractibility. Gross visual acuity with glasses was intact, and her hearing was adequate. She was able to understand test instructions with minimal repetition. Overall, the patient seemed to put forth a good effort on all of the tests. The results are considered to be a valid estimate of her current cognitive and everyday functioning.

GENERAL COGNITIVE FUNCTIONING

Mattis DRS-2 out of a total possible score of 144:

Total raw score:	127	Scaled score: 6
Attention raw score:	36	Scaled score: 11
Initiation/perseveration raw score:	37	Scaled score: 11
Construction raw score:	6	Scaled score: 10
Conceptualization raw score:	32	Scaled score: 7
Memory raw score:	16	Scaled score: 2

VISUOSPATIAL FUNCTIONING

Performance on the Clock Drawing Test was normal, at the 50th percentile, consistent with her performance on the DRS construction score.

PSYCHOMOTOR SPEED

Trail Making Test Part A and Trail Making Test Part B were severely impaired, at the <1st percentile.

EVERYDAY FUNCTIONING ASSESSMENT

The patient was administered several measures of everyday functioning. Specifically, the patient was administered portions of the performance-based Independent Living Scale (ILS): Managing Money; the self-report Minimum Data Set (MDS) questionnaire that queries the frequency that one needs help on and the difficulty experienced when performing 20 IADLs; the Short Physical Performance Battery (SPPB); and an on-road driving assessment. On the ILS: Managing Money, her performance fell within the mildly impaired range when compared to matched peers. For example, the patient inaccurately calculated how much change she should get back if she purchased something for $1.19 and gave the clerk $5.00 (her answer was $4.79). When presented with mock check materials and specific directions for completing the check, she correctly filed out the check, except for writing the wrong date. She was able to calculate the balance in her checking account. On the self-report MDS, she reported that she only needs help “some of the time” with cooking and experienced no difficulty with any of the activities. On the SPPB, the patient scored 8 points total of 12 possible points, indicating relatively intact physical functioning: 3 out of 4 points on the balance tests (missed 1 point on holding the tandem stand for less than 10 seconds); 2 out of 4 points on the gait speed tests; and 3 out of 4 points on the chair stands. Finally, on the on-road drive, the patient’s discrete maneuvers were rated unsatisfactory within the majority of the eight domains evaluated but fully intact in the remaining domains.

CORROBORATING REPORT FROM MRS. SMITH’S DAUGHTER

The patient’s daughter stated that her mother had developed memory problems over the last 12 months. She stated that Mrs. Smith is able to remember to take her daily medications with no issues but has trouble remembering appointments and birthdays. Her daughter also reports that Mrs. Smith does require some assistance with managing finances and does not drive alone. Her daughter mentions that since Mrs. Smith has started being more diligent about using a pocket

calendar to keep track of events and appointments, her memory functioning is better.

MOOD ASSESSMENT

On the Center for Epidemiologic Studies Depression Scale (CES-D) (a self-report measure of depressive symptomatology), the patient endorsed two items, indicating that she was not experiencing significant clinical depressive symptoms.

SUMMARY AND CONCLUSIONS

Results of the current evaluation indicate that the patient's overall level of cognitive functioning was overall in the moderately impaired range for her age (DRS-2 Total score = 127); however, her memory and executive functioning were severely impaired, fitting the profile of amnestic Mild Cognitive Impairment (MCI) due to AD. The patient is overall independent in most IADLs. However, her memory impairments are having at least a mild effect on some domains, such as managing finances and keeping track of appointments, which is consistent with her daughter's reporting. The etiology of her cognitive deficits is unknown; however vascular disease does not appear to be a primary contributor, as she has no medical comorbidities, vascular or otherwise (e.g., no depressive symptomology). It was recommended that she receive assistance with her complex financial and medical decisions. She could continue to manage her own medication administration with some supervision and aid (e.g., weekly pill organizer). Her driving, while not impaired at this stage, should be closely monitored. She was advised not to drive alone and only drive in familiar areas that are proximally closer to her home. Finally, her family was cautioned that the observed difficulties may continue to progress, and plans should be made now for this possibility.

The use of memory aids such as calendars, electronic reminders, and checklists may help patients to circumvent their problems for a brief period; however, as dementia progresses, cognitive difficulties tend to worsen, and compensatory strategies may be less effective. Many people in the later stages of AD become completely dependent on all their ADLs. People in the early stages of AD can appear to have few daily functioning difficulties. They may be particularly capable of maintaining appropriate over-learned social interactions (e.g., introducing themselves to a new

person); however, if pressed for details about newly obtained information, they may have difficulty recalling.

Other neurodegenerative conditions can present interesting challenges for everyday functioning assessments. For example, people with Lewy body dementia can have profound impairments of visuospatial skills. They are likely to have great difficulty with higher-order tasks dependent on intact visuospatial functioning, such as driving, whereas they may have less difficulty with social skills. People with Parkinson disease may have a slightly different set of daily functioning difficulties. Parkinson disease causes particular difficulties with the initiation of motor movements and, more generally, with motor skills. Initiation problems may hinder a person from starting activities that they are cognitively capable of planning and executing. Difficulties with fine motor skills may prevent the accomplishment of basic tasks like opening medication bottles.

Psychiatric Conditions

Older people suffer from the same types of psychiatric conditions as younger people, although in some cases (e.g., depression), the incidence may increase in older adulthood. Accordingly, assessment instruments need to be designed to capture daily functioning difficulties in people with a serious mental illness. This group manifests particular deficits that may be important to evaluate. The following text reviews the difficulties with everyday functioning among these individuals, as well as some of the instruments used to assess those difficulties.

Depression. Depression, neuropsychological dysfunction, and difficulties with everyday functioning are all common in older age. Studies of older people show consistent evidence linking depression to neuropsychological dysfunction, specifically, impairments in executive function, which may relate to everyday functioning difficulties. Investigators have suggested a number of sociodemographic and clinical factors that are associated with worse cognitive performance in depressed patients, such as age, education, and symptom severity. A meta-analysis found that greater depressive symptom severity was related to poorer executive function, processing speed, and episodic memory. Given that neuropsychological dysfunction and difficulties with daily functioning can be more common among older adults, the presence of depression can exacerbate these difficulties.

Particularly among older individuals, the presence of depressive symptoms is associated with a decline in the performance of ADLs. Thirty percent to 60% of individuals who have been hospitalized for depression experience a drop in their ability to perform ADLs, including bathing, dressing, toileting, transferring, and eating. One study of 398 recently hospitalized older individuals found that nearly 40% of older patients experienced persistent depressive symptoms from hospitalization up to 3 months post discharge. This study also found that patients with mild and severe persistent depressive symptoms had a significantly higher risk of functional decline (measured by the Katz-6 ADL index score), falls, and mortality compared to patients with minimal symptoms. Patients with more depressive symptoms were distinguished from patients with minimal symptoms by factors such as more medical comorbidities, older age, and cognitive impairment. Other studies have confirmed that depressive symptoms are strongly associated with poor functional performance, and depression scores for older individuals were significantly higher for those who reported experiencing ADL decline. Among a community-based sample of older adults (aged 65 and older), neuropsychological impairment and depression appear to be two of the strongest predictors of ADL/IADL difficulties, along with age, pain difficulties, taking more than four medications, having a chronic condition, poor mental health and QoL, and BMI. Unintentional nonadherence to psychotropic medications has been shown to be associated with greater cognitive impairment. Among adults with a primary major depressive episode and severe depressive symptoms (mean Beck Depression Inventory = 34.3 [SD = 11.0]), cognitive impairment was strongly associated with impairment in IADLs (e.g., medication taking and finance handling), whereas more severe depressive symptomatology and older age were strongly associated with impairments in basic ADLs. However, patients' satisfaction in role functioning and relationships improved with age.

Schizophrenia. Daily functioning difficulties are common among people with schizophrenia. As a result, there are several performance-based instruments to capture everyday functioning difficulties common among older people with schizophrenia that have been developed. These instruments include the UPSA, including newer computerized versions; the Medication Management Adherence Assessment (MMAA); and the SSPA. Performance on these everyday functioning measures is strongly

correlated with global neuropsychological functioning. A recent study showed that among people with a schizophrenia diagnosis, working memory, sustained attention, and verbal fluency were predictors of functional capacity (UPSA-B scores), and negative symptoms were the strongest predictors of social skills performance (SSPA scores). In another study, cognitive performance in the neuropsychologically normal range was not associated with everyday functioning; however, cognitive impairment predicted functional impairments. Furthermore, negative symptoms, even lower levels, were correlated with worse social functioning. These results suggest that neuropsychological abilities and negative symptoms have differential effects on everyday functioning. These results suggest that neuropsychological abilities and social skills have differential effects on general everyday functioning skills. Consistently, neuropsychological impairment has been shown to be a stronger correlate of functional status than psychiatric symptoms among people with schizophrenia. Negative symptoms of schizophrenia (e.g., flat affect) tend to be correlated with neuropsychological impairment; however, positive symptoms are rarely associated with neuropsychological or daily functioning impairments.

Recent research indicates that scores on the UPSA are associated with "real-world" outcomes, thereby making the UPSA a potentially useful tool to aid in clinical decision making. For example, a recent study found that UPSA scores of 75 or above were predictive of patients' ability to reside independently (e.g., alone in a home or apartment). In this same study, the UPSA was significantly better at predicting residential independence than the Mattis Dementia Rating Scale (DRS), a commonly used instrument that assesses global cognitive functioning. In another study, higher scores on the UPSA were associated with greater involvement in community responsibilities, such as working for pay, engaging in volunteer work, and attending school, among Hispanic/Latino patients with psychosis. In contrast, the DRS was not significantly associated with greater engagement in community responsibilities. These two studies may suggest that performance-based assessments of daily functioning are more proximal to community functioning than global cognitive functioning.

Recently Hospitalized Older Individuals

Unfortunately, many older people never receive an assessment of their everyday functioning abilities until they are hospitalized. Because

information about how the person was functioning prior to hospitalization may be sparse, it is often difficult to determine how much change in daily functioning resulted from the hospital stay and related events. The hospitalization may result directly from a recent decline in functional abilities or from some unrelated cause (e.g., a need for hip replacement or coronary bypass surgery). Regardless of the reason, ADLs among older adult patients are more likely to deteriorate and less likely to improve after hospitalization. Specifically, it has been shown that 30% to 60% of older individuals who have had a recent hospital stay acquire at least one new dependency in daily functioning. A recent study showed that the variables most often associated with a decline in ADL among older patients who have been hospitalized are age, pain, medication use, and body mass index; and the factors highly associated with a decline in IADL are being separated or divorced, living with others (nonspouse), and self-rated memory. Few screening instruments have been developed to measure the risk of functional decline among older adult individuals who have been recently hospitalized; however, a recent review of the literature identified three useful screening instruments: Hospital Admission Risk Profile (HARP), Identification of Seniors at Risk (ISAR), and Care Complexity Prediction Instrument (COMPRI).

People Living With HIV

Neurocognitive impairment commonly occurs in HIV infection, particularly among older individuals living with HIV. Neurocognitive problems may stem from the disease itself, HIV medication side effects, comorbidities associated with HIV (e.g., stroke, diabetes) or a combination of factors. The severity of the HIV-associated neurocognitive disorders (HAND) varies from asymptomatic forms that do not interfere with daily functioning to more moderate and severe forms that interfere moderately or significantly with everyday functioning. Specifically, neurocognitive impairment in HIV has been associated with driving, medication management abilities, and other IADLs. Many of the daily functioning assessments used with older HIV-infected people, such as UPSA and Lawton & Brody ADL Scale, were originally developed in non–HIV-infected populations. While translating these assessments to the older HIV-positive population may be appropriate in terms of measuring functioning, the etiology of the everyday functioning impairment should be

considered in the context of the unique risk factors in this heterogeneous population.

DEMOGRAPHICS

Mr. Anderson is a 62-year-old, right-handed African American male.

EDUCATIONAL AND VOCATIONAL HISTORY

The patient completed 13 years of education and received his high school diploma. He denied having any problems learning to read or write and never skipped or repeated a grade. He worked as a cook in a restaurant for approximately 30 years.

BEHAVIORAL OBSERVATIONS

The patient was alert and oriented to the day of the week, date, year, and city. The patient was diagnosed with major depressive disorder in his early 20s and was diagnosed with HIV infection at age 50. He has been worried for some time that he may have some neurocognitive difficulties. He complains of slowed ability to process information, difficulty learning new strategies, and difficulty planning and initiating new activities. During the assessment, the patient was apathetic and appeared somewhat lethargic, but was pleasant and cooperative. Gross visual acuity and hearing were intact. Overall, the patient seemed to put forth very good effort on all of the tests. The results are considered to be a valid estimate of his current cognitive and everyday functioning.

GENERAL COGNITIVE FUNCTIONING

The patient was administered a comprehensive neuropsychological test battery. Using T-scores adjusted for age, education, sex, and ethnicity, Mr. Anderson was found to be impaired in the domains of learning and executive functioning. His performance was within normal limits on verbal functioning, speed of information processing, recall, motor, and attention/working memory. His global neuropsychological performance is mildly impaired (impairment ≥2 domains).

EVERYDAY FUNCTIONING ASSESSMENT

The patient was administered the UCSD Performance-based Skills Assessment (UPSA), which assesses the overall ability to manage everyday functional tasks, including the ability to plan and organize events, manage finances, communicate with others, arrange transportation needs, and conduct household chores. Overall, his performance fell within the moderately impaired range (overall score =

63). His UPSA score suggests some reduced capacity in maintaining his independent living situation.

CORROBORATING REPORT FROM MR. ANDERSON'S THERAPIST

The patient's therapist stated that the patient had experienced some mild difficulty performing day-to-day tasks, including managing his own medications and finances. Specifically, the therapist stated that on occasion, the patient has reported that he sometimes has difficulty organizing and managing his medications. The therapist has increasingly become concerned with the patient's neurocognitive and daily functioning difficulties. The therapist indicated that these neurocognitive and functional impairments have been stable over the past several years and do not appear to be worsening.

MOOD ASSESSMENT

The patient scored 11 on the Hamilton Depression scale, which is indicative of mild symptoms of depression. The patient denied suicidal ideation.

SUMMARY AND CONCLUSIONS

Results of the current evaluation indicate that the patient's overall level of cognitive functioning was mildly impaired as compared to other individuals of his demographic background. The patient also demonstrated moderate impairments on a measure of everyday functional abilities (UPSA). The patient's therapist corroborated many of the patient's daily functioning difficulties. These test results suggest mild to moderate impairments in cognitive and everyday functioning. The longitudinal course of these impairments has been stable. That is, cognitive and everyday functional abilities appear to have remained stable over the past several years, which is again consistent with published literature on this topic. Based on his current level of cognitive functioning and deficits in functional skills, the patient was recommended to seek additional assistance in instrumental activities in daily living activities. It was also recommended that the patient receive functional skills training classes, which may help improve his ability to perform essential everyday skills (e.g., manage finances, and communicate with others). Particularly important is his ability to self-administer his medications. Providers should consider additional training in managing medications as well as methods to reduce errors

in administering medications (e.g., blister packs, electronic reminders, pill organizers).

RECOMMENDATIONS FOR FUTURE INSTRUMENT DEVELOPMENT

Assessments of daily functioning continue to evolve. Below, the authors offer recommendations for future development.

Everyday functioning is multifaceted; however, most assessment instruments are designed to test a given domain in isolation. For instance, the MMAA assesses medication management abilities independent of other abilities. Medication management in “real life” occurs over a much longer time span and is intertwined with other daily tasks. The ideal assessment of daily functions would test multiple domains of functioning concurrently. Some multitasking tests of this nature have been developed, but additional assessments of this type are clearly warranted.

Another desirable component of any new assessment instrument is that they are adaptive. That is, instruments should have the flexibility to adjust to the level of mastery of a particular individual. If an item was too difficult, the individual could be tested with easier items or vice-versa. A great deal of research has been done on adaptive testing, particularly with computer-administered, standardized achievement tests. Hopefully, this technology can be applied to the assessment of functional capacity.

VR technology may offer a way of creating more realistic mock environments in which multiple aspects of functioning could be tested. Assessments could even be designed to recreate a patient’s unique habitual environment, and many assessments have already been developed and are currently being tested. Some argue that older adults are too resistant to digital technologies for such technologies to be useful to this population, but the degree of resistance may be exaggerated. Furthermore, performing VR tasks may not require high levels of technical knowledge. These techniques may be useful both for assessments and interventions. These technologies have already been implemented for the treatment of certain disorders (e.g., PTSD).

Very few functional-assessment instruments provide demographically adjusted normative data, with the most important variable being age. This constitutes a significant limitation as compared to other types of

assessment, such as neuropsychological tests, for which the assessor typically has an indication of where a given score falls on a continuum. Ideally, all functional assessments would have normative information. In the absence of normative data, an evaluator who is more experienced is likely to have a better sense of what a given score means in the context of other objectively gathered data. The authors understand that normative studies are not easily funded; however, the authors believe that future studies of this type should be a research priority.

In addition to demographically corrected normative data, there are significant advantages to the conorming of different assessment modalities together. If evidence could be obtained of how certain instruments work with one another, then better insight into a given patient's true difficulties would be available. For example, if a self-report, collateral report, and performance-based measure were concurrently administered to a large sample of older adults with varying diagnoses and ages, the results might help us to understand the distinct strengths and weaknesses of the various assessment modalities. It might be found that people who score below a given level of self- and collateral-reported functioning would derive no benefit from receiving a performance-based assessment. On the other hand, in people who report a relatively intact level of functioning, there might still be difficulties with performance-based assessments due to inaccuracies in self- or collateral reports. The combinations are many, but ideally, it would be helpful to know how the most widely used instruments worked together.

Finally, the discussion of norming and conorming is moot if the instruments in question have no validity for predicting actual functioning. Predictive validity is difficult to obtain without a widely recognized gold standard of assessment for everyday functioning abilities; however, the authors believe that using a multimodal assessment strategy allows for an accurate representation of daily functioning. Until reliable and valid instruments with strong predictive validity are established, there will be difficulty in establishing the true usefulness of everyday functioning assessments.

SUMMARY

Older adults are at significant risk for difficulties with everyday functioning. These difficulties can range from impairments in basic behaviors critical

for independent functioning, such as toileting, to optional daily tasks, such as driving. Several factors may influence daily functioning, and cognitive impairment appears to be a strong predictor of daily functioning difficulties. Numerous everyday functioning assessment methodologies are available and include clinical interviews, self- and collateral reports, clinician ratings, performance-based measures, and direct observation. Performance-based measures may offer significant advantages such as improved reliability and a better estimate of functional capacity as compared to other assessment approaches such as self-report. More research is clearly needed to develop quick, reliable, and valid assessments of everyday functioning for older adults; the field is currently burgeoning, and improved assessments will continue to be developed in the near future.

ACKNOWLEDGMENTS

The authors would like to thank Virginia Wadley, Ph.D., for contributing to one of the case presentations in this chapter, and Thomas L. Patterson, Ph.D., for contributing to a prior version of this chapter.

55.3b Psychiatric Problems in the Medically Ill Geriatric Patient

Anna Borisovskaya, M.D., Beth Ann Labardi, M.D., Matthew Alan Schreiber, M.D., Ph.D., and Marcella Pascualy, M.D.

Since the beginning of the 20th century, a dramatic increase in life expectancy has produced an aged population of unprecedented size and longevity. According to demographic forecasts, one out of five people will be over the age of 65 in the year 2060, up from one in seven in 2012. In the United States, a 65-year-old person will typically remain independent until they reach the age of 75 and will live an additional 6.5 years once they become dependent on others.

People over the age of 65 account for twice the average number of prescription drugs, one and a half times the number of physician contacts,

and three times the number of hospital-bed days. Overall, the aging population accounts for more than one-third of the total personal health expenditures in the United States. Among the top 5% of highest health care spenders who collectively make up one-half of total spending, adults over age 65 account for 40%.

Over half of the population that is 65 and older report having at least one chronic disability, and a third report having a chronic condition that is severe enough to limit their activities. For the psychiatrist, medical comorbidities and disabilities, which aggregate with age, are the most important factors distinguishing older patients from their younger counterparts.

Some of the most common disorders in the aged population include degenerative arthritis and cardiovascular disorders, mainly hypertension and heart disease. In addition, geriatric syndromes such as falls, vision and hearing loss, urinary incontinence, and impaired cognition disproportionately impact health care costs and quality of life. One recent study found that about 65% of adults over age 65 have two or more chronic diseases, and this increases to 82% in individuals over the age of 85.

Estimates of the prevalence of psychiatric disorders among the medically ill and disabled older adult vary widely across clinical settings, and reliable data on comorbidities is still sparse. For example, 30% of older adults in primary care have at least one active psychiatric diagnosis: 10% to 15% have clinically significant depressive syndromes such as major depression, dysthymia, or minor depression; 5% to 10% have dementia, and 2% to 5% have alcohol abuse or dependence or psychoses. The lowest prevalence rates for psychiatric symptoms and disorders are found among medically healthy persons living independently in the community, and prevalence increases with the severity of medical illnesses and extent of functional dependency (Fig. 55.3b–1). The relationship between functional health and psychiatric comorbidity has been most clearly established for depression, but emerging data suggest similar trends for anxiety disorders, sleep disorders, and psychoses. In addition to impairing day-to-day functioning and quality of life, depression in medically ill older adults has been associated with decreased self-care and adherence to treatment regimens for chronic medical conditions, worse medical outcomes, increased health care costs, and mortality from suicide and medical causes.

The profound changes in the demographics of chronic disease have resulted in an increased need for the psychiatric care of patients with comorbid medical and mental disorders. New models of practice, based on effective collaboration between psychiatrists and primary care providers or medical specialists, are required to address the needs of older patients. Clinical care of psychiatrically disturbed medical patients poses several special challenges for the psychiatrist. Clinical syndromes may vary in presentation from the classical disorders for which treatment guidelines are well established to situations where common disorders such as depression and anxiety are masked by medical comorbidities and functional disability in place of overt expression of emotional symptoms. Thus, one needs a working familiarity with the common medical and functional problems of the older adult and a full range of skills in psychotherapeutic and somatic treatment modalities. Despite these inherent challenges, most psychiatrically disturbed older persons can be substantially helped when approached within a systematic framework.

FIGURE 55.3b–1. Prevalence of depression in older adults.

APPROACH TO THE PATIENT

Mastery of a few central concepts helps integrate the range of clinical data essential in the successful evaluation and management of psychiatrically disturbed, medically ill geriatric patients (Table 55.3b–1). The adaptive reserve of all vital organs, including the brain, tends to decline with aging, even in the absence of manifesting disease. This loss of physiologic resilience is generally detectable in clinical settings only after a sudden or severe deterioration in the face of acute illness or psychosocial stress.

Age-related loss of adaptive reserve underlies the downward spiral and multiple organ failures often seen in sick older adults. It is responsible for the narrowed margin of safety observed for many drugs, changes in the presentation of disease, and increases in morbidity of medical and psychiatric disorders. For example, acute myocardial infarction in an octogenarian may present as painless delirium, while a mild chronic anxiety disorder may become fulminant panic in a patient with rectal bleeding who, ultimately, may not have a serious medical problem. Such complex patterns of causation are typical of psychiatric symptoms in the very old and in persons with multimorbidity—the most common chronic medical condition—used to define the presence of several comorbid medical conditions. Sometimes causal factors emerge clearly only after a successful intervention, or not at all.

Table 55.3b–1.
Key Concepts in Psychiatric Care of the Medically Ill Older Adult

Decreased organ reserve alters response to illness, treatment, and social stressors.
Comorbid medical illness affects presentation and treatment of psychopathology.
Nondrug treatments are preferable when effective.
Combining treatment modalities optimizes gains.
Comfort, function, and safety are the major goals of treatment.
Coordinated care is better care.
Family and caregivers are essential to patients' recovery and must be involved in the treatment.

A 78-year-old man with bipolar disorder since age 40 became manic while residing in a nursing home. His situation had been complicated by chronic alcoholism and mild dementia. He had no history of renal disease, and his serum creatinine was normal. After an initial period of manic grandiosity, when he was often seen near a local tavern, he soon deteriorated to crawling on his hands and knees, growling and barking like a dog, and striking out at all who approached him. His lithium level was 1.2 mEq/L with a maintenance dose of 750 mg/day. After a reduction in lithium dose to achieve a level of 0.6 mEq/L, the temporary addition of low-dose olanzapine, and close attention to adequate fluid intake and preventing access to alcohol, both the manic syndrome and the superimposed delirium cleared within 3 weeks without the need for psychiatric hospitalization.

Medical causes should be considered whenever an older adult patient develops a new psychiatric symptom or disorder. When psychotropic medications are used, clinicians are advised to carefully watch for the emergence of side effects, allow sufficient time for medications to reach effective plasma and receptor site concentrations, and seek optimal therapeutic outcomes. Particularly with newer-generation psychotropic medications, the differences between “geriatric” and “adult” doses are minimal; careful titration of medications from a low dose to a usual adult dose may be necessary to achieve the desired therapeutic benefit. Close collaboration with other clinicians and caregivers is essential for maximal safety and effectiveness at every stage of treatment. The greatest overall therapeutic gain, at the smallest cost in treatment-related adverse events, is usually achieved by combining psychotherapeutic, social, environmental, and somatic interventions. A rehabilitation model that specifies progress toward the attainment of specific goals in stepwise increments is a useful way to frame the ongoing process of care that is often most appropriate for chronically ill older adults.

An 83-year-old woman with long-standing diabetes and ischemic and hypertensive cardiovascular disease had become bedfast over several years in a nursing home. Two months before psychiatric consultation was requested, she developed a psychotic illness characterized by delusions of being beaten during the night, aggressive outbursts, and pervasive despondency, which led to disruptive nocturnal phone calls to her daughter and to the local fire station. Initial clinical assessment revealed moderately severe dementia in a personable but angry and frightened woman, eager for relief. Collateral history confirmed progressive cognitive deterioration over the course of her chronic medical illness, on a background of long-standing dysthymia. Trials of several antipsychotic and antidepressant medications had exacerbated her symptoms. A review of her medications showed that 4 of the 12 drugs she was taking on a regular basis were not essential for her medical management. A head computed tomography (CT) scan showed mild cerebral cortical atrophy, moderate periventricular white matter hyperintensities, and numerous lacunar infarcts. The onset of her psychosis was eventually associated with the initiation of aggressive treatment of arterial leg ulcers, including round-the-clock debridement dressings, oral antibiotics, and narcotic analgesics. Control of her diabetes had deteriorated, and her insulin dose had been increased. Nursing staff members had provided excellent physical care but were resentful of her racist attitudes and physical aggressiveness, which exacerbated her loneliness and paranoia. Her treatment plan was as follows: discontinuation of night-time debridements (allowing elimination of narcotics for pain), simplification of her drug regimen, preventing nocturnal hypoglycemia, installation of a night light in her room, problem-solving discussions with staff, weekly psychotherapy, and wheelchair walks, which represented her first opportunity to go outdoors for months. Her distressed phone calls ended soon after. Her mood, sleep, and interactions with staff improved gradually, and her delusions and racist remarks disappeared. Foci of psychotherapy were the discovery of traumas she experienced in Cossack Russia, psychoeducation about her delirium, and discussions of her desire to die rather than live in a deteriorated state. She developed a firm therapeutic alliance and regained the dignified and compassionate manner that characterized her response to adversity in the past.

PSYCHIATRIC SYNDROMES IN MEDICALLY ILL PATIENTS

General Principles

Systemic medical illness can mimic or cause almost any psychiatric syndrome, often through more than one pathophysiologic mechanism. They can also coexist with psychiatric illnesses that were present prior to the onset of such medical problems. The Diagnostic and Statistical Manual of Mental Disorders, fifth edition, text edition (DSM-5-TR) further simplified the classification of psychiatric disorders due to medical diseases, dividing them into cognitive disorders, psychotic disorders, depressive and bipolar disorders, anxiety disorders, obsessive-compulsive disorders, catatonic disorders, and personality changes. Changes from DSM-IV-TR include the addition of obsessive-compulsive and related disorders due to another medical condition, removal of amnestic disorder and sleep disorder due to a medical condition, and specifying depressive or bipolar illness due to another medical condition. Distinguishing a “medical” psychiatric syndrome from a primary psychiatric disorder is often difficult. For example, depressive symptoms in a hospitalized patient may be indicative of an adjustment disorder, demoralization, side effects of medications, delirium, withdrawal from substances, consequences of another medical illness, or major depressive disorder. At the same time, psychiatric illness may arise after serious medical illnesses such as sepsis, acute respiratory distress, myocardial infarction, and cerebrovascular accidents. Clues to the secondary nature of a psychiatric syndrome include partial expression, first onset in old age or a change in clinical features with recurrence of an earlier-onset disorder, lack of family history, a recent change in health or medical treatment, and concurrent cognitive processing deficits that point to impaired brain function.

Psychiatric disorders not caused directly by the effects of a medical illness interact with chronic medical conditions in complex ways. This is best understood for depression in the setting of chronic disease: Depression can amplify somatic symptoms, leading to excess functional impairment and overestimation of disease severity; it decreases motivation and brings about despair about the efficacy of treatment,

leading to poor treatment adherence, poor self-care, and finally, poor outcomes. In such cases, consideration should be given to the diagnosis introduced in DSM-5, Psychological Factors Affecting Other Medical Conditions, denoting psychological or behavioral factors that affect a medical condition adversely. Comorbid medical illness, in turn, can delay or prevent the recognition and treatment of psychiatric disorders that might be readily treated in primary care.

Medications as a Cause of Psychiatric Symptoms

Altered pharmacokinetics and polypharmacy place older adult patients at increased risk of developing adverse drug reactions. Many drugs that are used in the older adult tend to have a low therapeutic index increasing the likelihood of toxicity (e.g., anticoagulants, hypoglycemics, antineoplastics, diuretics). Most drugs, in sufficient doses, can affect central nervous system function in a vulnerable host. Drugs affecting the brain, either as their primary site of therapeutic action (e.g., all psychotropic drugs, narcotic analgesics, anti-Parkinson agents, and many antihypertensive agents) or as a secondary site not essential to their therapeutic effect (e.g., digitalis [Lanoxin], cimetidine [Tagamet], glucocorticoids, and nonsteroidal anti-inflammatory agents, such as aspirin and indomethacin), can cause psychiatric symptoms in older adult patients. As an example, corticosteroids used for the treatment of inflammatory states such as rheumatoid arthritis may lead to depression or irritability, while thyroid replacement and even antidepressants can cause anxiety. It's sobering to realize that adverse drug reactions are common and preventable in the older adult and that the very medications meant to cure the illness can, in fact, increase the burden of disease. Thorough knowledge of the side effects of any prescribed medication, careful monitoring for these side effects, and reduction in polypharmacy are paramount when any new medication appears on an older adult person's medication list.

Clues to a possible drug-induced psychiatric syndrome include the presence of associated systemic or neurologic signs and symptoms, such as recent loss of appetite, reduced sense of well-being, blurred vision, tremor, slurred speech, dizziness, gait instability, or somnolence. A patient's complaint of feeling "drugged," while occasionally indicative of a heightened focus on somatic symptoms, should raise suspicion of drug toxicity.

Identifying a drug as the primary cause of a change in mental state can be accomplished in several ways. Some drugs produce classical symptoms in overdose, such as nausea and distorted color vision in digitalis overdose or tinnitus and dizziness with aspirin. In other instances, a neuropsychiatric syndrome results from pathophysiologic mechanisms common to a number of drugs with very different primary indications but similar pharmacologic properties. An example is the central anticholinergic syndrome, characterized in its most extreme form by tachycardia, pupillary dilation, visual hallucinations, and delirium in patients receiving medications with known high affinity for muscarinic receptors, such as tricyclic antidepressants (TCAs), but also caused by pharmacodynamic interactions of a vulnerable brain with multiple drugs, each having weak but additive individual antimuscarinic actions.

Blood levels may not be helpful in determining whether a medication is causing a neuropsychiatric problem, except for the relatively few drugs readily measured in serum or plasma and for which therapeutic ranges are well established. However, medication toxicity may occur in older adults without elevated plasma levels, and improvement, when a suspect drug is decreased or discontinued is the most crucial test of its role in pathogenesis. A detailed history, a careful physical exam, and knowledge of drug–drug interactions are most conducive to making an accurate diagnosis of toxicity.

An 87-year-old woman came to a psychiatrist with mild depression associated with a recent cross-country move and hepatic cirrhosis of unknown etiology with mild renal insufficiency. Treatment was initiated with fluoxetine 20 mg/day and supportive psychotherapy. Over the ensuing 9 months, she was hospitalized several times with intractable vomiting for which no cause was found. When she again presented with the same picture and now ascites and severe demoralization, a fluoxetine level was obtained. The combined concentration of fluoxetine + norfluoxetine was within the expected range at 138 ng/mL (normal range of 100 to 930 ng/mL). Discontinuation of fluoxetine eliminated nausea, vomiting, and demoralization within a week.

Drug and Disease Interactions

Psychiatric symptoms arising from the interactive effects of medications and underlying disease may be severe enough to lead to psychiatric hospitalization. In a series of nearly 16,000 consecutive adult psychiatric admissions, about 1% was attributable to adverse drug reactions. Older adult patients were most often affected, particularly those with neurologic diseases or those receiving multiple medications. Nearly 30% of older adult persons develop delirium after hospitalization for acute medical illness. Particularly at risk are those with cognitive impairment at the time of admission, the very old (>80 years), patients with fractures or symptomatic infection, and those receiving neuroleptics or narcotics. People with dementia may be at higher risk of toxicity of some medications due to the combined risks of weight loss, increased permeability of the blood–brain barrier, and reduced acetylcholine in the brain, among other physiologic changes, which means paying even closer attention to prescribing medications in this group. Early detection of mental disorders due to drug–disease interactions depends on familiarity with the common medical illnesses of older people, their potential impact on brain function, the pharmacologic properties of drugs used in medical management and their special potential for interactive effects. Table 55.3b–2 shows examples of some drug–drug and drug–disease interactions that may be encountered in clinical practice.

Table 55.3b–2.
Examples of Drug–Drug/Drug–Disease Interactions in the Older Adult

Drug	Indication	Adverse Effect
Cimetidine	Gastroesophageal reflux	Delirium
		Elevated drug levels (e.g., TCAs, benzodiazepines, neuroleptics, propranolol, theophylline)
Metoclopramide	Gastroparesis	Parkinsonism, inappropriate prescription of levodopa
TCAs	Depression, anxiety, insomnia, chronic pain	Confusion
Constipation		
		Tachycardia, cardiac conduction defect, hypotension
		Altered effect of antihypertensive agents (↑ effect of diuretics, ↓ effect of α_2 agonists, e.g., clonidine)
SSRIs	Depression, anxiety, obsessive-compulsive symptoms	Apathy
		Insomnia
		Restlessness, agitation, extrapyramidal symptoms, akathisia
		Central bradycardia
		↑ Potential for diverse drug–drug interactions
		Destabilization of Coumadin dosing

		Gastrointestinal distress, diarrhea
NSAIDs	Arthritis	Cognitive impairment ↑ Serum lithium levels ↑ Blood pressure, ↓ hypertension control
Neuroleptics/atypical antipsychotics	Dementia with psychosis	Death ↑ Cognitive impairment Extrapyramidal symptoms Falls Aspiration pneumonia
Ginkgo biloba	Impaired memory, arterial insufficiency	↓ Clotting time Restlessness (high doses)
Glucocorticoids	Inflammation, COPD	Depression, mania, psychosis, cognitive impairment (especially at high doses), insomnia

COPD, chronic obstructive pulmonary disease; NSAIDs, nonsteroidal anti-inflammatory drugs; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

Differential Diagnosis

Differential diagnosis of psychiatric syndromes in the medically ill older patient begins with a mental status examination that incorporates a careful assessment of several cognitive dimensions, including attention and orientation (both impaired in delirium), memory and learning, and executive control function, the ability to understand, organize, and carry out goal-directed cognitive and motor sequences. Thorough collateral information and an evaluation of the patient's past and current medical conditions, emphasizing the disease of vital organs and painful conditions, are essential. Complete medication history and a focused physical examination are important, including, at a minimum, a review of vital signs and a screening neurologic examination to check for abnormal gait or movements, focal areas of weakness, or abnormal deep tendon reflexes. The judicious use of appropriate laboratory tests may clarify the

possibilities in complex situations (Table 55.3b–3). Finally, the gathered data can be synthesized into a list of possible differential diagnoses and probable causes. For example, in a patient with blood pressure in the low-normal range, pitting ankle edema, apathy, weakness, and depressed mood, who has been taking a high-potency diuretic for many years, an electrocardiogram (ECG) and echocardiogram may be needed to determine whether congestive heart failure (CHF) or the diuretic is the most salient contributor to the depressive syndrome, whether it is safe to try discontinuing the diuretic, and what special precautions are required in prescribing an antidepressant. In doubtful cases where the differential diagnosis includes a primary psychiatric disorder not caused by physical effects of illness, the electroencephalogram (EEG) may be helpful. The EEG in patients with psychiatric syndromes due to metabolic, toxic, or circulatory causes typically shows diffuse slowing, although it cannot implicate specific diseases or drugs, and the interpretation may be confounded when an underlying dementing illness is present. An increase in dominant frequency accompanying recovery lends weight to the formulation.

Table 55.3b–3.
Practical Evaluation of Psychiatrically Disturbed Medically Ill Older Patients

Establish rapport quickly.

Define the reason for the consultation or visit.

Learn and use a few rapid screening instruments:

- Cognition—e.g., Mini-Cog
- Depression—e.g., Patient Health Questionnaire-9 (PHQ-9)
- Neuropsychiatric symptoms—e.g., Neuropsychiatric Inventory (short version)
- Functional ability—e.g., Functional Activities Assessment

Expect more than one psychiatric diagnosis (e.g., delirium plus chronic depression).

Make a complete problem list:

- Medical
- Psychiatric
- Social
- Functional

Identify all drugs in current use:

- Prescription drugs
- Over-the-counter medications
- Vitamins, minerals, botanicals, and “natural” remedies
- Alcohol and tobacco
- Include those used infrequently
- Ask patients or caregivers to bring all medications from home in a paper bag for your inspection

Interview capable collateral sources:

- Family or other primary caregivers
- Primary physician
- Staff of residential facilities

For acute exacerbations of chronic problems, ask “why now?”

If problem unexplained, search for:

- Undiagnosed medical illness
- Drug effect or interaction
- Occult injury
- Undetected social problem (abandonment, abuse)

Conduct a screening physical examination: vital signs, gait, neurologic signs.

Obtain appropriate corroborating laboratory studies; consider broad-spectrum tests to screen for suspected disease, e.g., complete blood

count, blood glucose, serum electrolytes, blood urea nitrogen and creatinine, liver enzymes, thyroid-stimulating hormone and free thyroxine, vitamin B_{12} and folate, syphilis serology if indicated, urinalysis, electrocardiogram, chest radiograph, electroencephalography for delirium, erythrocyte sedimentation rate for occult systemic disorders, hip radiographs for a delirious patient who will not walk, neuroimaging (head computed tomography for screening, or magnetic resonance imaging when microvascular disease is a possibility; single photon emission computed tomography for more precise diagnosis).

When a drug is believed to cause or contribute to a psychiatric disorder, all drugs should be sorted into those with a high potential for causing psychiatric symptoms (such as anticholinergic and sedating drugs), those clearly required for the management of serious medical disease, and those that may be modified or stopped on a trial basis. Familiarity with drug side effects, drug–drug interactions, and the pathways for their elimination may assist in the detection of otherwise occult medication toxicity syndromes. Close adherence to the “rule of maximal simplification” of medication regimens can produce clinical improvement in up to half of all psychiatrically disturbed medically ill older persons.

A 73-year-old man with severe chronic obstructive lung disease (COPD) came for the treatment of anxiety with insomnia and severe daytime fatigue. He had been treated with fluoxetine for several years after initial psychiatric evaluation, to which clonazepam had been added by his pulmonologist in doses up to 2 mg/day without relief. Shortness of breath and activity-induced panic attacks were his most pervasive complaints. Physical examination and imaging disclosed hypertension (190/120), persistent tachycardia, and signs of emphysema but no indication of CHF. A walk with oximetry led to oxygen desaturation from 93% to 83% after 3 minutes. His medication list included two antihypertensive agents, only one of which he took since the other was a diuretic that prevented him from leaving home unless assured of constant proximity to a bathroom. He was also on three scheduled inhaled medications and albuterol when needed (PRN). It turned out that he was using his PRN albuterol at least 12 times daily, but his technique was ineffective in achieving drug deposition in smaller airways. Pulmonary function tests showed no improvement with bronchodilator therapy. Diagnoses of activity-dependent oxygen debt and albuterol toxicity were made, manifested by treatment-resistant anxiety and hypertension, tachycardia likely to endanger his heart if uncorrected, and severe exercise intolerance. Reduction in albuterol use to four times daily, the addition of a second antihypertensive drug without diuretic activity, and prescription of continuous oxygen therapy with judicious oral morphine significantly improved his shortness of breath and activity tolerance and reduced his blood pressure and tachycardia to safer levels.

Older adult patients who present with previously undiagnosed cognitive impairment warrant aggressive assessment. The most prevalent dementia syndrome among geriatric patients is Alzheimer disease, while dementia with Lewy bodies is a close second. Other common causes of cognitive impairment in older patients include vascular dementia, frontotemporal dementia, dementia due to Parkinson disease, Korsakoff syndrome, and potentially reversible cognitive impairment (if caused, e.g., by depression, drugs, B12 deficiency, and others) (see chapter on Dementias for additional discussion). A meta-analysis of rates of reversible dementia found that 9% of cases had a partially or completely reversible etiology

but that a total of only 0.6% of cases reversed with appropriate clinical management. These figures likely reflect general improvements in geriatric medical care.

Completing an evaluation of a patient with dementia often requires two or more visits, particularly for frail older adult patients, as well as a thorough collateral history gathering. Medical illness can interfere with the adequate diagnosis of dementia or unnecessarily delayed antidementia pharmacotherapy. Also often overlooked in the management of demented, medically ill patients is the opportunity to improve cognition by eliminating medications with mild but cumulative central nervous system effects that worsen both cognition and function.

Approach to Treatment: Overall Recommendations

When treating an older adult with medical comorbidities, some overarching principles are worth calling to mind. Where appropriate, involve family and other supports. Knowing the extent and reliability of a patient's social support system can aid in predicting what additional resources may be needed and how likely a given treatment is to be successful. Likewise, economic status can shape treatment and its delivery, especially in older adults managing multiple medical conditions, medications, Medicare copays, and hospital bills. The living environment should be safe and adequately accessible to needed medical resources and should be addressed directly in a multidisciplinary treatment plan if it is not. Do not neglect the patient's preferences in treatment, but continually assess for medical decision-making capacity.

Prescribing medications in the older adult poses a particular challenge for reasons such as polypharmacy, pharmacokinetic (altered volume of distribution, decreased renal and hepatic clearance) and pharmacodynamic (increased sensitivity to certain classes of drugs) changes that occur with aging, reduced functional reserve that limits compensatory homeostatic mechanisms, and underlying medical and neurologic diseases that impact drug metabolism and tolerance. These variables should be viewed as part of a constantly evolving process that will require continued attention to establish the most appropriate medication regimen for an older adult individual.

Polypharmacy is a significant concern in this population. A survey of community-dwelling older adults (aged 65 years and older) reported that 39.0% of the overall group surveyed used five or more medications and

that the average amount of prescription medication use in this population has doubled over the past three decades, with the most pronounced increases being in males over age 80. In addition, regular use of over-the-counter medications and herbal and dietary supplements are also on the rise in the older adult. An explicit-based guide such as the American Geriatrics Society Beers Criteria or the Screening Tool of Older People's Prescriptions (STOPP)/Screening Tool to Alert to Right Treatment (START) can be helpful in the clinician's efforts to evaluate medication regimens and reduce polypharmacy.

These are the general guidelines that we recommend when prescribing medications for an older adult patient:

- Always keep patients' goals of care, current health, and cognitive status in mind.
- Before adding a medication, carefully review the current regimen and attempt to simplify the dosing schedule, adjust, and discontinue any unnecessary medications.
- Aim to make only one medication change at a time so that the effects of changes can be determined and distinguished.
- Expect that some psychiatric medications will take longer to achieve a therapeutic effect in older, medically frail adults. Be patient and use a slow pace of titration.
- Focus on potential drug–drug interactions and keep the anticholinergic load to a minimum.
- Be equally concerned about overprescribing and underprescribing.
- Whenever possible, prescribe an affordable and streamlined regimen.
- Educate the patient and caregivers about side effects and expected improvements.
- Periodically review effectiveness, need for dose adjustment, or continued use. Ideally, use structured means of monitoring effectiveness. Standardized scales (patient self-report, caregiver report, or provider-administered) are invaluable feedback devices, and there are many available to the clinician spanning a range of disorders and symptoms.
- Be vigilant of treatment adherence.
- Do not neglect cognition, as it may be not only a primary target of treatment but a factor complicating the treatment of medical and psychiatric conditions.

PSYCHIATRIC SYMPTOMS ASSOCIATED WITH SPECIFIC MEDICAL DISORDERS

Vascular Disease

Vascular disease, once thought to be the principal cause of dementia and psychoses of later life, is again being increasingly recognized as a cause of late-onset psychopathology as well as a factor exacerbating pre-existing disorders such as recurrent major depression, bipolar disorder, and Alzheimer disease. Ischemic and hemorrhagic strokes cause a variety of disturbances of behavior and emotionality related both to the effects of the lesion on brain function and to psychological problems in adaptation to disability. Major or minor depressions are common, occurring in roughly one-third to a half of all patients following an acute cerebrovascular accident. The most recent review of available evidence shows a significant association between stroke severity and risk of poststroke depression, but not the stroke type or mechanism. Though lesion location has been extensively investigated as a risk factor for poststroke depression, the findings have been inconsistent. Left frontal or left basal ganglia lesions are convincingly correlated with depression within 2 months of a first clinical stroke, but it is still difficult to draw clear conclusions beyond this. The persistence of milder depressive syndromes after the acute phase has been associated with other factors, including functional impairment, cognitive impairment, and inadequate social support. Several studies have shown the presence and severity of depression to predict the severity of impairment in activities of daily living as well as mortality in the year(s) after a cerebrovascular accident. The link between mood and vascular health is also notable for its bidirectional relationship; depression is an independent risk factor for stroke.

The importance of cerebrovascular disease in geriatric psychiatry extends well beyond poststroke depression. The vascular depression hypothesis supposes that cerebrovascular disease may be etiologically related to geriatric depressive syndromes. The clinical presentation of this entity is characterized by cognitive deficits, psychomotor retardation, lack of insight, and disability disproportional to depression severity. Response to antidepressants is generalized as suboptimal in these cases. Though the most common neuropsychiatric outcomes of cerebrovascular disease are depression, anxiety, fatigue, and apathy, other forms of psychiatric or

behavioral morbidity may occur as well. Emotional lability, personality changes, psychosis, and mania are less common but may cause significant distress. There is often no clear relation to the location of the brain lesion, and management is especially challenging given the lack of an evidence base.

Cerebrovascular disease can also cause psychomotor slowing, impaired executive function, and significant functional dependency in patients who may or may not be clinically depressed. Common associated clinical features include executive dysfunction, encoding-based memory deficits, and, often, impaired gait and urinary control. Neuroimaging studies, especially those using magnetic resonance imaging, in affected patients typically demonstrate ischemic changes in subcortical and deep white matter and/or lacunar infarcts in the thalamus, the basal ganglia, and sometimes the upper brainstem. Interference with the function of frontal-subcortical circuits appears to be a common underlying anatomical feature of lesions that cause depression and executive dysfunction and can be seen as a partial disconnection syndrome. Many patients with subcortical vascular disease have minimal or no discernible mood change, showing instead only cognitive, motivational, and subtle neurologic signs. A diagnosis of vascular neurocognitive disorder may be appropriate in such cases, but minor depression may also be diagnosed when apathy and disengagement are functionally impairing. Vascular brain diseases can be caused by intrinsic disease of small and/or large vessels supplying the brain due to atherosclerotic narrowing, occlusive plaque emboli, medial (muscular) hypertrophy, or vascular amyloidosis, but cardiogenic causes must also be considered. Cognitive impairment resulting from the larger lesions of ischemic cortical strokes appears to be approximately as common as that resulting from lacunar strokes. This may be due to the lacunar infarct's role in unmasking impairment in preexisting diffuse cerebral small vessel disease. Among cardiogenic etiologies, several pathogenic mechanisms are recognized: hypertension, recurrent or severe hypotensive episodes, CHF, recurrent arrhythmias (especially atrial fibrillation), and especially coronary artery bypass grafting. Approximately 40% of heart failure patients will have cognitive impairment. A similar percentage of those who have had coronary artery bypass graft surgery for ischemic heart disease have cognitive impairment at 5 years postoperatively. Its causes are still the subject of active research, but emerging consensus favors variations in pre- and

postoperative control of vascular risk factors as one important determinant. Patients with modifiable but poorly controlled risk factors are more likely to have strokes and myocardial infarctions in the year following surgery. The heart–brain connection is further underscored by evidence that hemodynamic and serum cardiac markers (such as natriuretic peptides and troponin) are related to worse cognition and a higher risk of dementia. All physicians caring for such patients, including psychiatrists, need to be alert to the potential to improve long-term outcomes with aggressive management of vascular risk factors.

In fact, identifying and modifying risk factors for further vascular insults should be a key component in the psychiatric treatment plan of patients suspected of having vascular psychopathology. Relevant workup includes fasting lipids, homocysteine, vitamin B12, and folate levels; a careful history and ECG to identify cardiac arrhythmias or, if already recognized, coordination of care and education of other physicians about the possible cognitive consequences, monitoring serial blood pressure measurements to identify hypertension and hypotensive episodes. Once identified, appropriate therapeutic steps can be taken to reduce risks, such as the prescription of folate/vitamin B6/vitamin B12 combinations, antihypertensives, antithrombotic agents, or lipid-lowering drugs. Depression related either to an acute cerebrovascular accident or to significant cerebrovascular disease is responsive to pharmacologic treatment with antidepressants, but the best agent and duration of therapy are unclear. Suboptimal response or concurrent apathy may call for adjunctive therapies, particularly stimulants such as methylphenidate or amphetamines and psychosocial measures to provide time and activity structure. Selective serotonin reuptake inhibitors (SSRIs) are considered first-line because of the available evidence and safety profile. It should be noted, however, that there is an unresolved but active debate about possible higher mortality in patients treated with SSRIs, with some studies finding higher and others lower mortality rates in treated stroke survivors. Treatment of stroke survivors with antidepressants has been shown to significantly lower the incidence of poststroke depression and may enhance recovery independent of poststroke depression or their effect on mood. Poststroke response to antidepressant treatment results in improvements in activities of daily living and cognitive function and decreased disability. Brief psychosocial interventions focused on care management, psychoeducation, and family support can be beneficial.

When executive dysfunction or gait impairment is significant, extra caution is needed in choosing and titrating psychotropic medications. A broad treatment strategy is often needed for optimal results: securing structure and support to compensate for defective executive function; planned, supervised exercise to improve and maintain gait and balance; and management of frequently associated urinary incontinence. It is worth remembering that anticholinergic medications, frequently prescribed for incontinence due to overactive bladder, can impair alertness and general cognitive abilities and counteract the benefits of concurrent cholinesterase inhibitors. When the therapeutic benefit of anticholinergics used to treat urinary incontinence is questionable, they should be stopped.

Heart disease is now a well-recognized cause of depression and anxiety in patients with myocardial infarction or heart failure. Medical and psychological factors both play a part, and as with cerebrovascular disease, a bidirectional causational relationship exists. Depression is an independent risk factor for coronary heart disease and myocardial infarction, and untreated or inadequately treated major depression is associated with adverse outcomes in individuals with known coronary heart disease and those who have undergone coronary bypass grafting. Depression is thought to impact cardiovascular disease via impaired heart rate variability, systemic chronic inflammation, hypothalamic–pituitary–adrenal axis dysfunction, and endothelial dysfunction. Effective psychiatric treatment often requires both psychotherapeutic and pharmacologic management. The safety and efficacy of antidepressant drugs in patients with chronic heart disease have been evaluated in several studies, and there is evidence that antidepressants may increase all-cause mortality, likely via mechanisms associated with known adverse effects. SSRIs are usually the drugs of first choice. These drugs occasionally cause bradycardia by a central medullary mechanism but lack primary cardiotoxicity and are generally considered the safest and most effective for patients with heart disease. Patients who fail to respond to these agents and do not have serious cardiac conduction defects or severe chronic CHF can generally be safely treated with other newer antidepressants such as bupropion, mirtazapine, or serotonin-norepinephrine reuptake inhibitors (SNRIs) under close blood pressure monitoring. When selecting an antidepressant medication, it is important to remember that many cardiac patients take multiple medications, and potential drug–drug interactions should be minimized. While

electroconvulsive therapy (ECT) is an undisputed myocardial stressor and should generally be avoided in the acute postmyocardial infarction period, treatment can usually be given without major complications if anesthesia and treatment schedules are carefully individualized and managed.

A 72-year-old man had a history of recurrent major depression since early adulthood, as well as coronary heart disease. Depressive episodes were typically characterized by low mood, anergia, amotivation, and increased appetite and had a marked seasonal variation. With treatment with a selective serotonin reuptake inhibitor and seasonal phototherapy, he suffered no major episodes in a 3-year period of relative stability. In the month of January, he suffered a cardiac arrest and had a prolonged course of cardiopulmonary resuscitation complicated by difficult intubation in the field. During the hospitalization that followed, he was diagnosed with a diffuse anoxic brain injury, primarily affecting the subcortical watershed areas of the right hemisphere greater than the left. After his acute rehabilitation, he was left with residual left-sided weakness and new psychiatric complaints. He described his mood as “blah,” but not frankly depressed, could not find anything that interested him, and moved and spoke very slowly, even considering his physical limitations. He expressed worry about becoming like his father, who had Alzheimer disease because he could not follow complex instructions or adequately attend to challenging tasks. His wife took over the management of his medication as well as the bills, and his driving privileges were revoked. In addition, to close follow-up with his cardiologist and continued physical and occupational therapy, the man saw his psychiatrist, reporting that his previously effective antidepressant medication was no longer helping. In consultation with his cardiologist, low-dose methylphenidate was added to his medication regimen. At his psychiatry appointment 6 weeks later, his affect was notably brighter and more reactive, his speech and movements were less labored, and he had been able to enjoy dabbling in his old hobby of collecting military memorabilia.

Parkinson, Alzheimer, and Other Neurologic Diseases

Depression occurs with disproportionate frequency in Parkinson disease, affecting up to half of all patients at some point in the disease process. This depression is believed to be caused, in large part, by the neurodegenerative process itself; its presence is associated with evidence of damage to noradrenergic and serotonergic systems and is thought to identify a group of Parkinson patients with a more rapid course of the disease. Nevertheless, antidepressant drugs or other treatments can be effective. SSRIs have the most evidence supporting a benefit and are generally considered first line, given their relative safety and tolerability. TCAs have some evidence of efficacy but are less commonly used due to concerns about adverse effects in older patients and those with Parkinson disease specifically. SNRIs have been studied less, but from available evidence, they appear to be effective. Selegiline and safinamide, monoamine oxidase inhibitors, and anti-Parkinson agents, may be a useful addition to the treatment of depression in Parkinson patients. There have been several publications with positive outcomes in the treatment of depression in Parkinson disease with the use of dopamine agonists. However, concerns about methodology, clinical significance, and potential adverse effects outweigh the evidence, and routine use of these agents is not advised for the treatment of depressive symptoms. There is a paucity of data on the efficacy and tolerability of other standard antidepressant agents when used for Parkinson disease–induced depression. One systematic review suggests a good response to treatment with ECT but cautions about the propensity of adverse effects in this population, especially as the disease becomes more advanced. Importantly, cognitive behavioral therapy (CBT) has also proven effective.

Psychotic symptoms are common in Parkinson disease, with an estimated prevalence of around 60%, with visual hallucinations being the most common. Psychosis is more common as the disease progresses and is associated with comorbidities, including cognitive impairment, mood disorders, and sleep disorders. The first step in addressing psychotic symptoms is to rule out any concurrent processes that could cause worsened cognition or delirium (e.g., infections; anticholinergic medications). These syndromes may respond to lowering anti-Parkinson drug doses. If not, or if motor disability worsens to an unacceptable degree, atypical antipsychotic drugs with less impact on nigrostriatal dopaminergic pathways can be helpful. Pimavanserin [Nuplazid], a 5HTa inverse agonist approved by the Food and Drug Administration (FDA) to

treat Parkinson disease psychosis, has been found to be effective and well tolerated. It is unique in its status as an antipsychotic without dopamine-receptor–blocking properties, and given this different mechanism of action, the time to response is significantly longer—on the order of 4 to 6 weeks. Clozapine (Clozaril) and quetiapine (Seroquel) are the most extensively studied antipsychotics, and though clozapine is consistently efficacious, quetiapine is usually prescribed first because of the risk of agranulocytosis and the requirement for frequent blood monitoring with clozapine. Positive response to clozapine can occur at low doses and in timeframes as short as one week. Motor deterioration in a significant percentage of patients has been observed with olanzapine (Zyprexa), risperidone (Risperdal), ziprasidone (Geodon), and aripiprazole (Abilify). Cholinesterase inhibitors may also be beneficial in reducing hallucinations, though the data supporting this assertion is sparse.

Major neurocognitive disorder due to Parkinson disease is more commonly seen in those with more advanced disease and more advanced age. The affected cognitive domains include attention and visuospatial functions, with language functions being relatively preserved. Behavioral and neuropsychiatric symptoms, including those discussed above, are nearly always present. The currently available evidence supports the use of cholinesterase inhibitors in these patients, with a positive impact on global assessment, cognitive function, behavioral disturbance, and activities of daily living rating scales. The rivastigmine (Exelon) transdermal patch is often better tolerated than oral formulations, though exacerbation of tremor remains a concern. Response to memantine (Namenda) in this disorder has been disappointing.

In Alzheimer disease, depression affects up to one-third of patients, especially in milder stages, and may be the major presenting problem. Despite their widespread use, antidepressants lack clear evidence for this patient population. They are also associated with significant adverse effects, including falls, hyponatremia, cardiotoxicity, and increased bleeding risk. Trials of antidepressants may be best reserved for those with historical responses to antidepressants or those with moderate or severe depression who have not responded to behavioral interventions. As always, risks and benefits should be carefully weighed. Apathy is even more common than depression in major neurocognitive disorder due to Alzheimer disease, but similarly, antidepressants and other commonly used agents haven’t proven to be effective. Methylphenidate may be

beneficial, but the quality of current evidence is low. With the progression of dementia, classical presentations of depression become less frequent, while agitation, psychosis, and aggressive behavior with or without dysphoria become more common. Mixed behavioral syndromes are the rule in middle and later-stage dementia. Assaultive or threatening behavior demands thorough medical and socioenvironmental assessment to identify precipitating and aggravating factors, but pharmacologic interventions are often required. Second-generation antipsychotics are commonly used off-label in these cases, but their use has been controversial since black box labeling by the FDA. Recent reviews conclude that the use of these agents confers modest benefits for short-term treatment of aggression and psychosis as well as a small but significant benefit on caregiver burden. This is offset, however, by the substantial risk of serious adverse events, including 1.6 to 1.7 times increased mortality risk. Trials of valproate for these dementia-related behaviors have been disappointing. Existing evidence for the use of SSRIs for the treatment of agitation associated with Alzheimer disease is promising but limited. Further high-quality research is also needed on the use of cognitive enhancers for behavioral and psychological symptoms of dementia. Delirium induced by drugs or acute medical illness is a risk at all stages and in all types of dementias, as brain compensatory mechanisms are impaired.

A 75-year-old male Vietnam veteran with moderate major neurocognitive disorder due to Alzheimer disease was brought for psychiatric treatment because of increased episodes of tearfulness and speaking about the loss of life and other traumas witnessed in Vietnam. Upon interview, his family reported that this was a relatively new change for him and that he hadn't previously focused so much on these troubling memories. They also reported that the television in the home was often playing war movies or historical documentaries, as this was the patient's stated preference. The family was instructed to attempt to engage him in activities he used to enjoy or direct him toward different types of television programming. As a result of this, family and caregivers spent more time interacting with the man as well. His mood seemed to improve. A year later, the man returned with his caregiver and family, now with aggressive behaviors of grabbing and hitting as well as yelling out, especially around times of care provision. The patient was assessed for any physical cause of the discomfort, but none could be found. The caregiver received additional information on communicating with individuals with Alzheimer disease and providing distractions and rewards around these difficult times. The patient's behavior improved only minimally with these interventions, and a low dose of quetiapine was started. The behaviors improved, and the psychiatrist was able to gradually taper off the medication after 3 months.

Post-traumatic and postanoxic encephalopathies, hydrocephalus, central nervous system tumors and infections, multisystem atrophy, Shy–Drager syndrome, Huntington disease, demyelinating diseases such as multiple sclerosis, idiopathic inflammatory diseases such as systemic lupus erythematosus and temporal arteritis, and occupational neurodegenerations such as chronic organic solvent encephalopathies may all be associated with depressive, manic, delirious, and psychotic syndromes. Antidepressant trials are generally warranted for the treatment of depressive disorders associated with these diseases, though drug intolerance may be problematic and require the use of innovative and combination treatment strategies. The management of other psychiatric complications is less well established.

Chronic Respiratory, Metabolic, and Endocrine Disorders

Chronic obstructive respiratory disease (COPD) is the most prevalent of the chronic respiratory diseases in the second half of life. Cigarette smoking and, in the developing world, exposure to biomass fuels are significant risk factors. COPD is strongly associated with depression, anxiety, and, in advanced cases, a special form of panic disorder precipitated by exertion. Over 40% of patients with COPD suffer from depressive symptoms. Smoking is a shared risk factor in depression and COPD, and the rates of depression are even higher in COPD patients who are actively smoking. Untreated depression in COPD worsens overall outcomes with more COPD exacerbations per year, contributes to persistent smoking, and has been associated with increased risk of death, poorer social functioning, increased physical disability, poor adherence to treatment, and health care overutilization.

Psychological complications are common and include feelings of hopelessness and helplessness that contribute to the impaired treatment and rehabilitation adherence, anxiety-related dyspnea and secondary panic symptoms fostering further inactivity, fear of sudden death by asphyxiation, intense self-blame in patients whose illness is related to smoking and social isolation due to shame, low mood, and lack of motivation. For milder dysphoric states that do not meet the criteria for a depressive diagnosis, multidisciplinary rehabilitation and counseling approaches improve mood in many patients. In such cases, the efficacy of antidepressants in COPD has not been demonstrated either for alleviation of depression or improvement of dyspnea. However, available evidence suggests that, in patients with clinical depression and the absence of left ventricular disease or hypercapnia, antidepressant pharmacotherapy is beneficial for depression, anxiety, and somatic symptoms. A risk and benefit analysis regarding the use of antidepressants needs to be considered in each patient. Comprehensive nonpharmacologic interventions for anxious, depressed patients with COPD provide individualized education about the disease, its management, and adherence to recommended treatment, teach patients to modify their symptoms with appropriate techniques such as breathing retraining and offer supervised physical training. The use of behavioral activation, CBT, and collaborative care approaches should also be considered. Patients with pulmonary disabilities and those who require home oxygen therapy may benefit from self-help groups.

Deterioration in pulmonary or cardiopulmonary status in patients with COPD can lead to acute and chronic encephalopathies, sustained hypoxemia and hypercapnia, or to the central nervous system effects of drugs used in management (oral or inhaled bronchodilators, high-dose prednisone, cough or dyspnea suppressants, or benzodiazepines). Psychotic states may occur, usually related to the acute impairment of brain function by severe exacerbation of illness. Prior to the establishment of guidelines for oxygen therapy in COPD, neurocognitive impairment was thought to be quite widespread, but recent studies questioned the prevalence of cognitive disorders due to COPD prior to severe and end-stage disease. Patients with lung cancer may develop psychiatric complications similar to those occurring in COPD; in addition, paraneoplastic psychiatric syndromes with psychotic, cognitive, and/or affective symptoms have been reported.

Chronic renal and hepatic disease can lead to well-known delirium states due to their detrimental effects on nutrition, metabolism, clearance of toxic metabolites, and drug disposition. In addition to these transient alterations of mental function, the prevalence of other psychiatric disorders in these conditions approximates those for chronic disease in general. Pharmacologic treatment considerations include the effects of disease on half-life and plasma drug levels and adjusting prescribing accordingly.

In renal disease, depression is associated with clinical progression regardless of dialysis status and must be carefully distinguished from somatic symptoms of the underlying condition. These patients can benefit from assertive antidepressant treatment, taking into consideration drug metabolism concerns carefully. Although suicide risk in advanced renal disease appears to be less elevated than previously thought, both depression and renal disease can have significant effects on quality of life. Dialysis termination raises complex end-of-life issues where nephrologists, palliative care specialists, and psychiatrists can work closely together with patients. Hepatic disease, in general, increases the risk for both acute and chronic cognitive alterations; hepatitis C specifically is frequently comorbid with neuropsychiatric conditions. Fortunately, the advent of direct-acting antivirals has provided for curative treatment, likely greatly reducing both direct and indirect psychiatric morbidity from hepatitis C. These newer agents lead to much fewer psychiatric side effects than prior, less efficacious treatments such as

interferon, and evidence suggests patients with psychiatric comorbidities can safely be treated with these medications.

Diabetes is implicated in both depression and cognitive impairment. Depression rates are at least twice those of the general population and can be associated with poor glycemic control, lessened adherence to medications, and reduced self-care, all of which can, in turn, contribute to increased diabetic complications and elevated mortality rates. In short-term studies, treatment for depression improves both glucose management and quality of life. In older patients, type 2 diabetes is predominant and has been consistently associated with an elevated risk of dementia; recent guidelines for the treatment of diabetes in older adults recommend cognitive screening at baseline (without specific recommendations on the method) and regularly thereafter, especially for those at higher risk. The pathogenetic source of diabetic neurocognitive risk is not yet understood, but it has been suggested that both glucose control and insulin itself play a critical role in neuronal health. It remains unclear to what extent optimal glucose control can modify these risks, with longitudinal studies in this area an active area of exploration. Ongoing treatment of comorbid depression is very likely to improve long-term care of these patients, and as with other major chronic diseases in older patients, requires heightened vigilance for depression in the setting of somatic symptoms.

Hormonal changes have a complex and still unclear role in mood in older adults with multimorbidity. For example, even subtle thyroid abnormalities can play a role in mimicking or worsening psychiatric syndromes. Another area of interest and continuing investigation relates to changes in sex hormone levels which evolve substantially with age and can be deranged with illness. Testosterone repletion can be helpful in older men with depression, but only if hypogonadism (as reflected by low hormone levels) is present. Testosterone supplementation in men with normal hormone levels remains controversial and is likely to pose cardiovascular and prostate risks. Conversely, androgen deprivation therapy for prostate cancer poses a clear risk of depression. In women, the relationship between postmenopause sex hormones, cognition, and mood also appears to be highly complex, and hormone replacement likewise carries substantial risks versus uncertain benefits. For both older women and men, there is much to learn about the interrelationship of sex hormones and psychiatric conditions, both in health and disease.

Chronic Pain and Musculoskeletal Disorders

In older patients, the prevalence of chronic pain ranges between 36% and 80%, depending on the setting. Patients suffering from pain often restrict activity to prevent further deterioration and to avoid exacerbation of pain, which leads to deconditioning, isolation, and worsening disability. Over half of older adults with depressive disorders have chronic pain, with depression more likely to be present in patients with multisite pain and higher pain intensity and frequency. Older patients who have both chronic pain and depression are more likely to experience insomnia and suicidal ideation; they have a higher level of impairment and poorer quality of life. Hospitalized older patients with chronic pain, particularly from osteoarthritis, are more likely to exhibit severe frailty. Chronic pain is also a risk factor for premature death and accelerated cognitive decline, making it an important target for the prevention of these outcomes.

The causes of chronic pain in older adults include musculoskeletal disorders, neuropathies, and pain related to cancer, with musculoskeletal disorders being the predominant cause. These include fractures, osteoarthritis, rheumatoid arthritis, microcrystal disorders, myositis, vasculitis, and other arthropathies. Aging musculoskeletal tissues are less resilient due to the loss of ligament elasticity, redistribution of fat, osteoporosis, and subsequent decrease of bone strength. Sarcopenia, the loss of skeletal muscle mass, is a nearly universal aging phenomenon, contributing to disability and functional loss in older patients. The older adults are also at higher risk for infections that may affect the joints due to the comorbid predisposing disorders (peripheral vascular disease, diabetes mellitus), immunosuppression, and surgical interventions that are prevalent in this population. Falls are both a risk factor for incurring injuries that may result in chronic pain and a consequence of chronic pain. Insomnia is often comorbid with chronic lower back pain in older adults and may be a contributor to the severity of pain and associated disability.

Sixty percent to 70% of all joint diseases in the older adult is osteoarthritis, often comorbid with regional pain syndromes. A common complaint in ambulatory patients over the age of 75 is chronic low back pain, while knee osteoarthritis remains the most common cause of disability in older persons. Rheumatoid arthritis is to blame for 10% of all joint pain complaints, with patients who are taking biologic disease-modifying drugs being at the highest risk for depression, suicidal ideation,

and poor quality of life. The number of older adults with arthritis or joint symptoms is projected to be around 41.1 million by the year 2030.

Chronic pain is undertreated in older adults for several reasons, among them poor access to care, patients' concern about the meaning of pain and the cost of its diagnosis and treatment, and the patients' and providers' belief that pain is concomitant with aging, although there's evidence that a significant portion of older patients with chronic pain hope that physicians will pay more attention to their pain complaints. Physicians may fail to assess the patients' pain or believe in it when it is reported. There's also a persistent fear that prescribing opioid medications, often necessary for the control of pain when it doesn't respond to other agents, will result in addiction. A recent survey of hospitalized geriatric patients found a prevalence of pain at around 67.3%, but only 49% of these cases were treated; 75% of patients felt their pain medication was of low or no efficacy. Patients with cognitive impairment, particularly those with severe dementia and inability to communicate, are at risk for undertreatment of pain due to failure to identify pain and use appropriate tools for measuring pain.

Treatment of chronic pain in older adults is a complex undertaking, requiring a multidisciplinary approach. A comprehensive assessment should include a thorough history of pain, past medical history, history of substance abuse, physical and mental status examination, a thorough review of medications, and an examination of how pain affects the patient's quality of life and function. Self-report of pain is the gold standard for evaluation of pain in any patient, although this may be challenging in cognitively impaired, noncommunicative patients.

Pharmacologic treatment should be individualized for each patient; options for the treatment of pain exist, but each one has its pros and cons. It should be kept in mind that older adults are underrepresented in clinical trials testing interventions for chronic pain, and the impacts of comorbid medical conditions such as polypharmacy and frailty on the management of medications commonly used for pain are largely unknown. While opioids are an effective way to treat noncancer and possibly neuropathic pain, their duration of action in older adults is prolonged, and long-acting medications are particularly concerning. The consensus statement by the expert panel from the International Forum on Pain Medicine recommends that doses of opioids should be lower, and a longer time interval should be used between doses. Further, consideration of any concomitant

medications affecting respiratory function and pulmonary conditions should occur to avoid problems with hypoventilation and respiratory depression. The use of opioids in patients with a history of substance abuse should be carefully monitored. Further, it should be remembered that opioids may cause depression, the risk of which increases with the duration of exposure to opioids. Risk factors for opioid misuse, abuse, and the likelihood of overdose or opioid-induced respiratory depression should be considered in each individual case. The Risk Index for Overdose or Serious Opioid-induced Respiratory Depression (RIOSORD) has been validated in veteran and nonveteran users of prescription opioids and is one of the tools that may be used to evaluate the risk of adverse events with these medications.

TCAs, gabapentin, and pregabalin can manage neuropathic pain, but they are sedating. TCAs are also anticholinergic with risks of cognitive impairment, urinary retention, constipation, visual changes, and cardiac conduction disorders, among others. Some nonsteroidal anti-inflammatory drugs (NSAIDs) may cause gastrointestinal bleeding and discomfort.

Nonpharmacologic treatments should be utilized whenever possible: These include biofeedback, physical therapy, nutritional counseling, chiropractic, acupuncture, aquatic therapy, weight control, corticosteroid joint injections, and surgery if indicated. Psychoeducation, psychotherapy (CBT is proven effective in a variety of chronic pain disorders), and psychiatric medications such as antidepressants should be recommended if depression and/or anxiety symptoms are comorbid with pain. Due to increasing interest regarding the assessment and treatment of pain in older patients, recent years have seen publications of excellent guidelines. The authors recommend “Guidance on the management of pain in older people,” published in *Age Ageing.* 2013;42:i1–i57, by the British Geriatrics Society.

A high index of suspicion regarding the presence of untreated pain should be applied when working with patients with dementia. A change in their behavior, including aggression and agitation, could be related to pain. Other pain manifestations may include changes in facial expression, verbalizations, and body movements, as well as the onset of crying, irritability, and increased confusion. Using scales developed specifically for the evaluation of pain in patients with cognitive impairment will improve outcomes. An example of such a scale is the Pain Assessment in Advanced Dementia (PAINAD), applicable in long-term care and acute

geriatric care settings. Investigation of possible causes of pain should be undertaken with the assistance of collateral information, full medical history, and physical examination. Finally, a trial of an analgesic resulting in improvement in behavior may confirm the diagnosis of pain. For further guidance on addressing pain in patients with dementia, we recommend "The importance of pain management in older people with dementia," published in *Br Med Bull.* 2014;111(1):139–148, by Corbett et al.

An 81-year-old man with previously diagnosed dementia related to Alzheimer disease sustained a fall resulting in a right elbow fracture. After the orthopedic surgery, he had a difficult postoperative course complicated by severe confusion and a disrupted sleep–wake cycle. A geriatrician who examined the patient found a confused, thin, older adult man with a marked level of rigidity and cogwheeling in the left arm (the right arm could not be examined due to pain). He was disoriented, and his level of consciousness fluctuated markedly during the interview. He had difficulty focusing on the content of questions and was unable to explain why he was in the hospital. The patient's son reported that his father's memory and executive functioning have been declining for over 4 years, and the course of this disease was marked by visual hallucinations, usually of animals like cats, which were distressing for the patient and for his family. Rigidity and falls became a problem 2 years after the onset of cognitive impairment. After the surgery, the patient was described as markedly below his recent cognitive baseline. The geriatrician diagnosed the patient with delirium related to the recent surgery and the number of sedating medications on board, including morphine, fentanyl, zolpidem, and lorazepam. Discontinuation of the above medications and initiation of scheduled acetaminophen and tramadol for pain led to significant improvement in the patient's mental status and eventual discharge from the hospital to a rehabilitation facility. The geriatrician subsequently reexamined the patient and diagnosed him with dementia with Lewy bodies rather than Alzheimer disease, recommending avoidance of long-acting opioids and sedating medications, as well as initiation of rivastigmine patch to address cognitive impairment. The patient also worked with a physical therapist to improve balance and coordination, with the goal of fall prevention.

Neuropsychiatric Sequelae of COVID-19 Syndrome

Novel coronavirus SARS-CoV-2 emerged at the end of 2019 as a worldwide epidemic causing COVID-19. Though the primary manifestations of COVID-19 are respiratory, with the most common complaints including fever and cough, it can impact other organs, including the brain, through the direct neuroinvasion by coronavirus and through the dysregulated immune response resulting in excessive inflammation and cytokine network dysregulation. Additional mechanisms by which neuropsychiatric sequelae occur may be related to the side effects of drugs used to treat COVID-19, such as steroids, and coagulopathy related to increased prothrombin time. Neuropsychiatric symptoms of COVID-19 include headaches, myalgias, anosmia, ageusia, and asthenia, as well as more serious complications such as encephalopathy, encephalitis, meningitis, stroke, seizures, and neuropathies. Fatal outcomes related to the neuropsychiatric sequelae of COVID-19 have been documented, and in the COVID-19 survivors, the inflammatory process in the brain could trigger long-term mechanisms leading to neurodegenerative and neurologic disorders emerging down the line. Older adult people with medical comorbidities are more vulnerable to developing a fatal illness.

COVID-19 syndrome among hospitalized patients is associated with several psychological factors, including fear, loneliness, boredom, anger, and depression. Over the years 2020 and 2021, public health measures such as quarantine and isolation had their own mental health consequences, as people in the general population exhibit higher levels of stress, anxiety, and poor sleep quality. A month after the outbreak, a survey of people from Wuhan (where COVID-19 was first reported) and the surrounding cities in China showed that symptoms of post-traumatic stress disorder (PTSD) were present in 7% of the respondents. In a study of Indian adults (with India having been a pandemic hotspot), sleep difficulties, paranoia about having the COVID-19 infection, and distress were reported by 12.5%, 37.8%, and 36.4% respondents, with 80% of respondents expressing a need for mental health services. There have also been reports of vulnerable individuals engaging in suicidal behavior out of fear of COVID-19. Those with pre-existing mental health illnesses were more likely to experience anxiety, depression, distress, and insomnia. Additionally, patients with psychiatric disorders may be more vulnerable due to being on psychotropic medications with such side

effects as metabolic syndrome, comorbid medical problems, and smoking habits.

In the past, a significant percentage of patients infected with other types of coronavirus (e.g., SARS-CoV-1) have been diagnosed with PTSD, depression, pain disorder, panic disorder, and obsessive-compulsive disorder in the months postinfection, signaling that the burden of COVID-19 will likely emerge over the years following the pandemic. SARS-COV-2 infection has already been implicated in the onset of psychosis, mood disorders, PTSD, and suicide.

Attention must be given to monitoring older adult people with acute COVID-19 illness for neuropsychiatric symptoms, as delirium and depression may be underrecognized and undertreated. If psychiatric medications are continued or initiated for those patients who are receiving antiviral medications, drugs that do not act on the cytochrome P450 should be utilized preferentially.

Those with pre-existing psychiatric conditions and neurodegenerative disorders such as dementia may be at the highest risk for experiencing the neuropsychiatric complications of COVID-19. Individuals who are impacted by the COVID-19 pandemic in other ways, such as social isolation, are likely to experience less distress with support from their family and social networks. As older adult people living alone are particularly at risk for loneliness during quarantines, efforts to decrease their isolation should be actively undertaken. Given the risk of long-term neuropsychiatric sequelae of COVID-19 emerging over the years following the acute illness and the well-known risk factors for long-term cognitive and functional impairments following a critical illness, it is paramount to monitor the survivors' neuropsychiatric status throughout their life course, both for their benefit as well as to establish a framework for understanding the course of COVID-19 disease. Research about the impact of this pandemic on mental health, particularly in the older adult, is still lacking, an issue that must be addressed in the years to come.

Finally, adaptations for delivery systems for mental health care should be implemented to ensure continued access to care through the increased use of telehealth, creation of virtual mutual support meetings, provision of online resources, and creation of prevention programs for relatives of people who died from COVID-19 as had been done in some countries. Early experience with increased use of telehealth during the pandemic shows benefits with this model of care, such as reduced logistical barriers

to care and decreased no-show rates. In order to ensure availability of telemental health for all who need it for years to come, lifting reimbursement restrictions, lifting of the Ryan Haight Online Pharmacy Consumer Protection Act restriction on prescribing controlled substances via telemental health, suspension of restrictions on licensure requirements to practice telemental health across state lines are necessary, along with any other systematic changes that may be required.

COVID-19 has been a great challenge for the world to overcome, and it also presents a unique opportunity to redesign our health care system with an eye on quality and mitigation of health care disparities.

SPECIAL ISSUES IN THE CARE OF OLDER ADULT PATIENTS

Impaired Vision and Hearing

The importance of sensory impairments in patients who develop psychiatric disorders in later life justifies special attention to these issues during evaluation and treatment. Degenerative diseases of the eye and ear impair responsiveness to the interpersonal and social environment, increase feelings of vulnerability among older persons, and cause hallucinations in the affected sensory modality in some individuals. The most common vision problems in older adults include spatial contrast sensitivity, and scotopic dysfunction, which are important, respectively, for pattern recognition and adaptation to darkness, as well as slow visual processing. Visual hallucinations are common in later stages of Alzheimer disease as neuropsychiatric symptoms mount, in dementia with Lewy bodies, and in Parkinson disease, contributing to increased caregiver burden. Visual hallucinations in the absence of psychiatric disease (Charles Bonnet syndrome) occur in 10% to 50% of patients with low vision, a potentially distressing experience. In addition, deafness originating in childhood disease but exacerbated by presbycusis appears to be a risk factor for late-onset paranoid illness, and hearing and visual loss both contribute to the onset and persistence of depression.

Longitudinal population studies demonstrated that the presence of either visual or sensory impairment places the older adult at risk for cognitive decline, while those with both impairments may be at even higher risk for faster cognitive decline after the age of 50. In turn, those

suffering from comorbid sensory and cognitive impairment are vulnerable to increased risks of depression, death, lower autonomy, and hospitalization. They also contribute to higher health care spending.

Although the U.S. Preventive Services Task Force did not recommend routine screening for visual impairment in asymptomatic older adults, there may be a reason to perform routine screening in those who are frail and thus may be at even higher risk of being adversely affected by sensory impairments. Treatment of common causes of eye disease in the aging population, improvement in corrective lenses, cataract surgery, appropriate prescription of hearing aids or portable magnifiers, and attention to environmental lighting and sound may enhance the efficacy of specific interventions for psychiatric disorders in sensory-impaired patients. Research opportunities on how to improve the care of the aging population with sensory impairments abound, and contributions in this field may further assist clinicians with the care of persons with comorbid sensory and psychiatric disorders.

Falling

Falling and fall-related injuries occur in 30% of community-dwelling older adults and in more than 50% of those living in nursing homes each year. Increasingly, it is recognized that cognitively impaired older adults have an even higher prevalence of falls and associated morbidity. According to recent data from the Centers for Disease Control and Prevention, fall death rates among older adults increased about 30% from 2009 to 2018, with the fastest growing rate among adults aged 85 and older. Falls are the main contributor to injury, related disability, and premature death in older people. Complications of falling include hip fractures (25 per 1,000 women over age 85), other fractures, lingering painful soft tissue injuries, and head injuries with behavioral complications, which are widely feared by older persons as harbingers of death. In older patients with cancer, falls are also associated with an increased risk of chemotherapy toxicity and poorer survival. Risk factors for falling include conditions that cause postural instability, general muscular deconditioning, gait disorders, painful or deforming foot conditions, visual, auditory, vestibular, proprioceptive, and central neurologic impairments, decrease in cognition and speed of processing information, depressive symptoms, environmental hazards, inadequate ambulatory supports, urinary incontinence, and all classes of psychotropic medications. In hospitalized

patients, the presence of mental status deficits is one of the strongest risk factors for falls. Overall, the use of medications with sedative effects is the single most powerful predictor of falling in the older adult, all other things being equal. These include drugs used for the management of insomnia, anxiety, depression, and agitation (prescribed and over the counter), alcohol, and drugs used in the treatment of medical diseases that sedate by themselves or enhance the sedative effects of other drugs. The presence of multiple risk factors geometrically increases hazard.

Assessment of these risk factors and remediation whenever possible may prevent falls, with multifactorial interventions being more effective, given that falls often result from the interaction of multiple factors listed above. The goals of prevention include reduction of falls and associated risk for injury and maintaining the highest possible level of independence; just as important is education aimed at recognition of fall risks and their prevention for health care providers. Given the close relationship between gait, cognition, and falls, strategies that improve attention and executive function can help with deficits in gait control and fall prevention in older cognitively impaired adults. Falls are common in older patients with insomnia and sleep apnea, and treating sleep disorders with nonpharmacologic approaches may help improve attention, daytime vigilance, gait, and balance control, thereby preventing falls. Screening for falls and risk of falls is strongly recommended, given their potentially devastating consequences and the availability of useful interventions, such as exercise and physical therapy.

Psychiatric complications of falls include acute cognitive disturbance due to head injury and a common but rarely recognized phobic anxiety state (fear of further falls, which leads to limiting participation in activities of daily living, further deconditioning and curtailment of opportunities for social exchange, and sometimes permanent retirement to a wheelchair). Persistent fall phobias may become less common with aggressive rehabilitation after hip fracture and the dissemination of exercise programs for frail older adults.

Urinary Incontinence and Urinary Tract Infections

Urinary incontinence affects up to one-third of older adults living in the community and can cause significant suffering, decreased quality of life, and functional impairment, usually worsening as the problem becomes more severe. Notably, urgency urinary incontinence causes a higher

degree of disability than stress urinary incontinence. Routine screening for urinary incontinence is essential, as older patients are less likely to mention urinary incontinence to their physicians and suffer silently, limiting their trips away from home and their opportunities for social activities. Guidelines for screening for urinary incontinence have been published by several professional societies.

There are many causes of urinary incontinence, including urinary tract infections, altered mental status, restricted mobility, polypharmacy and specifically the use of diuretics, and chronic anatomical changes. A growing body of research has found associations between anxiety, depression, and all types of urinary incontinence in women; the use of antidepressants is independently associated with urinary incontinence as well.

Urinary tract infections are one of the most common infectious diseases in this age group and are associated with multi-infarct dementia in older women. Conversely, patients with dementia are at higher risk for urinary tract infections. Patients with acute or untreated chronic urinary symptoms should be referred to their primary care physician, gynecologist, or urologist for a thorough workup.

Frailty

Frailty is a clinical syndrome comprised of several physical symptoms, including weight loss, exhaustion, sedentary behavior, slow gait, and muscle strength. Those who fulfill 3 of these 5 criteria are considered to have physical frailty. Those who have 1 to 2 of these criteria are considered to have prephysical frailty. Other symptoms of frailty include weakness, inactivity, balance and gait abnormalities, and decreased food intake. However, frailty is also a multidimensional syndrome that encompasses physical, social, and cognitive dimensions. It is thought of as an age-related state of vulnerability related to reduced reserve and capacity of the organism to withstand stress and maintain homeostasis, a syndrome characterized by the decline of multiple physiologic systems. Many medical problems can lead to frailty, including chronic infections and inflammatory conditions, cancer, CHF, and thyroid abnormalities. Some common psychiatric problems may also manifest as frailty, among them depression, psychosis, grief, and dementia. Frailty is associated with, and predictive of, physical disability, falls, hospitalizations, malnutrition, and increased mortality. The prevalence of this syndrome in the older adult is

between 14% and 24%, depending on the definition of frailty, and is generally higher among women and blacks.

Recent data indicate that cognitive function is significantly poorer in patients who are frail; moreover, a higher level of physical frailty is associated with a faster rate of global cognitive decline. Impaired cognition and frailty may be independent syndromes, but they often overlap and share common risk factors such as hormonal changes, nutrition, cardiovascular risks, mental health and, most importantly, increasing age. The systemic changes related to chronic inflammatory conditions, poor nutrition, and declining function of endocrine and immune systems affect neurons in the hippocampi and microglia, placing the brain at risk for cognitive impairment, delirium, and dementia. A recent systematic review and meta-analysis found that frailty was a significant predictor of Alzheimer disease, vascular dementia, and all dementia among community-dwelling older people. The interconnectedness between cognitive and physical aspects of decline related to frailty led to the consideration of a concept of cognitive frailty, which consists of the following criteria: (1) presence of physical frailty and cognitive impairment, (2) exclusion of concurrent Alzheimer disease dementia or other forms of dementia. This definition is still being refined, and further research is needed to develop successful preventive strategies for this syndrome.

An association of significance also exists between depression and frailty. A recent study of men older than 75 years of age found that those with current symptoms of major depressive disorder had a fourfold increase in mortality, mostly due to comorbidity with frailty. Another cross-sectional study of older adult men found that those with frailty were much more likely to also suffer from anxiety and depression. Among hospitalized patients, frailty is often comorbid with delirium, conferring a poorer prognosis and decreased survival than either condition alone.

The best approach to the treatment of frailty and associated mental health conditions starts with a comprehensive geriatric assessment, whether conducted during an acute admission or on an outpatient basis. Encouraging studies of using exercise to improve endurance and increase strength and balance in frail patients have been conducted, but there is little known at this time on the potential value of nutritional changes or pharmacologic agents. Interventions of most benefit are likely to be multidisciplinary and multidimensional, addressing the whole person

rather than a single disease or organ system at a time and paying attention to the mental health problems of an aging, frail patient.

Overreliance on Drugs for Managing Mental Disorders

Judiciously prescribed medications are likely to remain the mainstay of treatment for older, medically ill patients. However, potentially inappropriate medication (PIM) use is more likely in older patients leading to increased adverse drug reactions and decreased efficacy. In a comprehensive survey of PIM medication lists in the literature, psychoactive medications were strikingly commonly cited, especially TCAs and benzodiazepines; antihistamines, which are often used as sleep aids and for anxiety even in medically ill late-life adults, were also commonly cited as inappropriate in older patients. The only medications almost universally represented across all surveyed PIM lists were diazepam, chlordiazepoxide, and amitriptyline (along with the nonpsychotropic indomethacin).

Considering the risks that can be present for older patients treated with medications, whether overtly cited as PIM or with polypharmacy more generally, psychiatrists and other physicians tend to underutilize psychotherapeutic and behavioral interventions in the care of sick or frail older patients. Care for psychiatric illness can be greatly enhanced by a psychotherapeutic orientation. While access to formal office-based individual psychotherapy is often a limited resource, there is accumulating evidence that brief therapeutic interventions, which can be delivered in the primary care setting where chronically medically ill patients are most often cared for, can provide considerable benefit and are easier to access for these patients. As mental health care becomes more available in an integrated care setting, psychotherapeutic interventions may prove highly efficacious and cost-effective as a complement to, and at times an alternative to, long-term medication use. Even more encouraging from a public health perspective, emerging evidence indicates that older patients can benefit from the delivery of psychological care via telehealth modalities. This has the potential to help greatly improve access to mental health care for older patients who commonly face social, financial, and medical barriers to travel for in-person care.

In turn, increased use of nonpharmacologic treatments could potentially be of benefit in reducing the risks of adverse effects from medication overuse and polypharmacy. Brief structured psychotherapies can be

delivered individually, with key family members, or in groups in both specialty mental health and primary care settings. More broadly, the psychiatrist's use of psychotherapeutic techniques from diverse orientations can include the capacity to develop emotional connections with patients and empathic integration of the needs of the patients, their families, and professional caregivers into a comprehensive and workable treatment plan. In this way, elements of psychotherapy can make substantial contributions both to medical management and to patients' comfort and capacity to persevere in the face of demoralization from a serious and ongoing illness.

A HEALTH SYSTEMS APPROACH TO THE CARE OF THE MEDICALLY ILL GERIATRIC PATIENT

Older adults are less likely than younger patients to seek and receive specialty mental health services and, when referred by their primary care providers, are less likely than younger patients to follow through on such referrals. Older adults, their family members, and their physicians often attribute enduring but treatable psychiatric symptoms to "normal aging," stressful life events, grief, social isolation, losses, financial difficulties, care-taking responsibilities, dementia, or medical illness, resulting in hopelessness and therapeutic nihilism in patients and providers. Older adults may also fear stigmatization associated with mental disorders or psychiatric treatments. As a result, the majority of this subset of the population receives care for mental and emotional problems exclusively in the general medical sector, and many who could benefit from the treatment of psychiatric disorders do not receive it. It is worth noting that Caucasian men over the age of 85 are at the highest risk for suicide in the United States, primarily due to their use of firearms during suicide attempts, and that many older adults visit primary care providers in the weeks leading up to the suicide attempt. Primary care visits should be an opportunity to intervene; however, there is evidence that depression in older adults is often unrecognized in this setting, which is particularly problematic for men and members of ethnic minority groups. Recent data indicate that the accuracy of diagnosis of depression in primary care usually improves with repeated visits, and it is recommended that those patients suspected to have depression should be reassessed rather than have one-off visits; the use of rating scales can also aid the diagnosis.

Even if depression is diagnosed, only a minority of patients receive successful treatment despite robust evidence for the efficacy of treatments such as antidepressant medications and psychotherapy in old age. In recent years, the rate of antidepressant prescribing in primary care has increased substantially, but many depressed older adults are started on an antidepressant with little follow-up. As a result, many stop taking medication prematurely, stay on inadequate doses for too long or do not change medication or receive psychotherapy if an initial trial of an antidepressant fails.

Despite most practice guidelines recommending that primary care providers should play a central role in the detection of cognitive impairment and dementia, there is a concerning lack of diagnosis of dementia in this setting, with rates of underdiagnosis ranging between 50% and 80%. Thus, patients with declining cognitive ability, usually in great need of treatment and advice on planning for the future, are not able to take advantage of the interventions available to them. The lack of diagnosis is partly due to a lack of recommendations for systematic screening of all at-risk patients and partly due to a lack of comfort on the part of primary care physicians when it comes to mental health in geriatric patients since their training does not emphasize geriatrics or mental health. Further, when dementia is diagnosed, the diagnosis is often undisclosed to patients and their caregivers, and treatment is not offered —largely due to providers' lack of confidence and comfort with the pharmacologic options available.

Older adults may have difficulty accessing specialty mental health care, especially when it is provided only in off-site specialty clinics. This problem is only compounded by the dearth of geriatric psychiatrists: by the year 2030, there will be only one such specialist per 20,195 older Americans. Some improvements in access have been made in recent years, such as the Medicare Improvement for Patients and Providers Act of 2008, reducing the copayment for outpatient mental health services to 20%, down from 50%, but barriers in private insurance plans regarding psychiatric medications and mental health services such as psychotherapy still exist.

Efforts to improve the care of common mental disorders in primary care have included training of primary care providers, development of treatment guidelines for depression or dementia, and the incorporation of routine screening into primary care practice as recommended for

depression by the National Preventive Services Task Force. Attention must be paid to medical education—encouraging physicians to specialize in geriatric medicine and psychiatry, making an effort to promote geriatric education in medical schools and residencies, and even changing the structure of medical textbooks that are often organized in chapters covering a single-disease entity, rather than teaching management of patients with multimorbidity. Clinical guidelines should be redesigned to address multimorbidity. All these measures are necessary, but they should be accompanied by promoting effective models of care.

The present overarching organization of primary care is designed for short visits meant to take care of one problem at a time—and geriatric patients with mental health problems such as depression or dementia, especially those with several comorbid medical conditions or frailty, fall so far outside of such a simplistic paradigm that there is no schema in which to tackle their complex presentations. Collaborative models of care have been demonstrated to substantially improve clinical outcomes. In these approaches, mental health specialists collaborate with primary care providers to manage individuals with comorbid medical and mental disorders within the primary care setting. Such interventions have included systematic case finding using simple screening instruments such as the Patient Health Questionnaire-9 (PHQ-9), patient and family education and activation, clinician education and support, systematic assessment and treatment matching, proactive outcomes tracking, and integration of primary care and specialty mental health services. These models may use a geriatric psychiatry care manager with special expertise in the recognition and treatment of common mental disorders or a mental health specialist such as a psychologist or psychiatrist working with a primary care clinic to provide consultation and treatment on site. On-site services can reduce barriers to access and communication between primary and specialty providers, maintain the comfort of patients accustomed to receiving their care in a single setting, and result in better care for both medical and psychiatric problems. In a similar fashion, geriatric psychiatrists have also developed successful models for integrated care provided on-site in nursing homes. Psychiatrists and other mental health specialists working in these general medical settings can also help refer patients to further specialty mental health care as needed or link them to helpful community services. Innovative programs built to provide psychosocial skills, integrated illness self-management,

collaborative care, and behavioral health homes are becoming the current evidence-based approaches to providing the best care for older adults with serious mental illness (Bartels).

This kind of collaborative care may be especially important for older adults with multimorbidity, the prevalence of which is increasing in adults aged 45 and over, with nearly 70% of Medicare beneficiaries having two or more chronic conditions such as diabetes, arthritis, and heart disease, and corresponding increases in health care costs. Depression is more likely to be present in people with multimorbidity, compounding the negative consequences of chronic physical conditions and lending importance to the need for addressing both medical and mental disorders. Multimorbidity requires a comprehensive treatment approach that addresses all problems present in an older adult patient seamlessly, accounting for interactions between treatments and conditions and the patient's own preferences. The National Quality Forum, in its publication of the Multiple Chronic Conditions Measurement Framework, proposed focusing on patient-centered quality measures such as optimizing function, ascertaining patient-important outcomes, and avoiding inappropriate care. There is evidence that organizational interventions, just as patient-oriented interventions, hold promise in addressing multimorbidity.

Centers for Medicare and Medicaid Services and private health insurance plans should redesign payment from focusing on specific diseases and procedures to value-based quality services promising relief for individuals with multiple medical and mental health problems. In this regard, accountable care organizations (ACOs) and patient-centered medical homes (PCMHs) hold promise. Through their emphasis on high-quality primary care, ACOs and PCMHs may help transform the failing health care system.

The PCMH is a model of health care delivery of a "medical home" where a primary care provider will design and coordinate comprehensive, evidence-based, cost-effective care for the patient. All aspects of care, including end-of-life care and mental health care, are coordinated and provided through the PCMH. An essential component of the success of the PCMH is a trusting relationship between the primary care provider and the patient. While this is a new and emerging model of health care, emerging data encourages optimism—we can expect that the PCMH will increase patient satisfaction and decrease health care costs. Following

the paradigm of providing quality coordinated care, the last few years have seen the emergence of the ACO, defined by the Centers for Medicare and Medicaid Services as “an organization of health care providers that agrees to be accountable for the quality, cost, and overall care of Medicare beneficiaries enrolled in the traditional fee-for-service program who are assigned to it.” Similar to the PCMH, the ACO has a strong basis in primary care. The ACO is also driven by intertwining the quality and cost of care and by magnifying outcome improvements. As new PCMHs and ACOs continue to emerge, and already existing organizations continue to improve, it should be remembered that providing care for a whole patient, geriatric or not, means attending to their psychosocial concerns, including mental health, substance abuse, living and family situation, and caregivers if applicable (for patients with physical and mental disabilities, dementia, etc.). Financial incentives that reward addressing behavioral health care on par with medical problems, and reward for improved outcomes rather than fee-for-service approaches, must be implemented.

Finally, to provide the best possible care for patients with psychiatric and medical comorbidities during their hospital stay, collaborative interdisciplinary care is necessary and is best accomplished by the creation of an inpatient psychiatric consultation–liaison service. Such hospital-based service can provide effective early management of affective and cognitive disorders, help with detection and management of delirium, perform risk assessments, provide advocacy, and address psychosocial and ethical issues.

55.3c Sleep Disorders in Older Adults

Jana R. Cooke, M.D., and Sonia Ancoli-Israel, Ph.D.

Up to half of older adults report chronic difficulties with their sleep. A number of changes occur in sleep architecture and sleep patterns with normal aging. However, problems with sleep are not an inevitable part of aging and are associated with significant morbidity. Sleep disturbances in older adults are generally related to specific sleep disorders, comorbid conditions, or both.

SLEEP AND AGING

Older adults report several subjective sleep complaints, including difficulty falling asleep, waking up often during the night, waking up too early in the morning, and needing to nap during the daytime or evening. Studies using polysomnography (PSG) to objectively measure sleep have confirmed that older people spend more time in bed, have more awakenings at night (decreased sleep efficiency), and take longer to fall asleep compared with their younger counterparts. The proportion of time spent in the lighter stages of sleep (stages 1 and 2) is greater, and the amount of slow-wave (stage 3) and rapid eye movement (REM) sleep is decreased in older adults compared to young adults. Almost all of these changes in sleep architecture, however, occur between early and middle adulthood. A meta-analysis that included 65 studies and 3,577 subjects ranging from 5 to 102 years in age suggested that sleep efficiency (the percentage of time in bed spent sleeping) alone continues to decrease after the age of 60 years, whereas the other sleep parameters remain relatively stable. Older adults are, on average, sleepier than their younger counterparts during the daytime when tested objectively, suggesting that they are less likely to obtain an adequate amount of restorative sleep at night.

CONSEQUENCES OF POOR SLEEP IN OLDER ADULTS

Insufficient sleep is associated with significant morbidity and increased mortality. Patients with difficulty sleeping report decreased physical health status, mental well-being, and quality of life compared to those without sleep difficulties. In older adults, subjectively and objectively assessed sleep problems are associated with an increased risk of falls, along with ambulation, balance, and visual difficulties—even after controlling for medication use. Chronic sleep difficulties at any age can lead to deficits in attention, response times, short-term memory, and performance level. In older adults, subjective reports of too little sleep (less than 4.5 hours per night), objectively measured falling to sleep difficulty, and fragmented sleep have all been associated with poor cognition. Accordingly, poor sleep is also associated with an increased risk for long-term care placement. Both reported sleep difficulties and objectively measured sleep disturbances are associated with increased mortality. In a longitudinal study of 185 healthy older adults, lower sleep efficiency (less than 80%) increased the risk of all-cause mortality almost twofold. In another large prospective study, women over the age of 69 who reported sleeping 9 to 10 hours in a 24-hour period (including napping) were almost 60% more likely to die from cardiovascular or other noncancer causes compared to women who slept between 7 and 8 hours.

SLEEP–WAKE DISORDERS IN OLDER ADULTS

Contributors to sleep disturbances in older adults can include comorbid medical or psychiatric illnesses, medications, circadian rhythm disturbances, psychosocial changes, and/or certain specific sleep–wake disorders.

Comorbid Medical and Psychiatric Illnesses

Complaints of sleep difficulties are strongly correlated with complaints about health and depression. In the 2003 National Sleep Foundation survey of adults aged 65 years and older, those with more medical conditions reported significantly more sleep complaints. Approximately 67% of older adults have multiple comorbidities, including cardiovascular disease, pulmonary disease, cancer, diabetes, and arthritis, and as the number of medical conditions increases, the likelihood of having sleep difficulties increases. The physical discomfort and emotional distress from chronic medical diseases contribute to an increased number of nighttime

awakenings and daytime sleepiness which subsequently can have a negative impact on these medical illnesses. Many chronic medical conditions are also associated with an increased prevalence of sleep disorders, including insomnia, sleep apnea, and restless legs syndrome (RLS).

Depression and anxiety both commonly occur in older adults, and both mental health conditions coexist with insomnia. Older adults are more likely to experience major life stressors such as the death of a spouse, medical illness/injury, functional decline, and lack of social contact, all of which can increase their risk for developing depression and anxiety. In a large cross-sectional survey, insomnia was present in 65% of respondents with major depression, 61% of those with panic disorder, and 44% of those with generalized anxiety disorder. Longitudinal studies have also found that insomnia may increase the risk of depression in older adults.

Table 55.3c–1.
Four Cardinal Sleep Rules

1. Do not spend too much time in bed
2. Keep a consistent waketime
3. Get out of bed if you can't sleep
4. Don't get into bed unless you are sleepy

Medications

Medications used to treat chronic medical and psychiatric conditions can contribute to or even cause sleep disruptions. Nearly 9 of 10 older adults chronically take prescription medications, with more than one-third of them taking more than five medications daily. Medications known to disturb sleep include beta blockers, bronchodilators, corticosteroids, decongestants, antidepressants, and diuretics. Clinicians should advise patients to take sedating medications prior to bedtime and stimulating medications and diuretics earlier in the day to avoid further sleep disruptions.

INSOMNIA DISORDER

Insomnia is one of the most common medical and sleep complaints, and it is frequently comorbid with most medical and psychiatric disorders. The diagnosis requires three main features: persistent sleep difficulty, adequate sleep opportunity, and associated daytime impairment. For insomnia to be considered chronic, the symptoms must occur at least three times per week for at least 3 months. Patients may complain of difficulty falling and/or staying asleep or early morning wakening. All other etiologies (e.g., primary sleep disorder, comorbid medical or psychiatric conditions, medications) must be ruled out before making this diagnosis.

Treatment of Insomnia

Cognitive behavioral therapy for insomnia (CBT-I) and pharmacotherapy are the main treatment options for chronic insomnia. A mounting body of research has found that in older adults, the risk of sleep medication side effects (including impaired balance, dizziness, grogginess, and confusion) and the potential risk of long-term effects on cognition is significant. In contrast, CBT-I is safe, the effects are long lasting, and it is endorsed as a first-line treatment for chronic insomnia by multiple societies and guideline panels.

Table 55.3c–2.
Sleep Hygiene

1. Restrict naps to 30 minutes in the late morning or early afternoon
2. Exercise regularly
3. Spend time outside each day
4. Eat a light snack (i.e., milk, bread) before bed
5. Avoid caffeine, tobacco, and alcohol after lunch
6. Limit liquids in the evening
7. Keep the bedroom dark and cool
8. Avoid electronics, especially blue light, 2 hours prior to bedtime

Behavioral Treatments. CBT-I has been shown to have excellent short- and long-term effectiveness in both younger and older adults. This multicomponent approach addresses common thoughts and maladaptive behaviors that interfere with sleep. A typical program consists of 6 to 10 weekly sessions administered by a specially trained clinician. Behavioral components include establishing a strict bedtime/wake time, reduction in

time in bed, and sleep hygiene. Cognitive restructuring involves changing unrealistic beliefs or irrational fears about sleep and/or the loss of sleep. Finally, patients are educated about sleep behaviors that promote sleep and those practices that may be interfering with their sleep (Tables 55.3c–1 and 55.3c–2).

The use of CBT-I has been limited by a lack of trained clinicians and the requirement of 6 to 10 sessions for therapy. An abbreviated form of CBT-I called brief behavioral therapy for insomnia (BBTI) was created to overcome these impediments. A course of BBTI consists of four sessions, three of which last 30 minutes or less, some by phone, and can be administered by nurses within the primary care setting. BBTI is exclusively focused on behavior with the core components of stimulus control and sleep restriction. Several randomized trials have shown BBTI to be effective in older adults.

Pharmacologic Treatments. In some cases, it may be appropriate to prescribe medications to treat insomnia (Table 55.3c–3). Outcome studies have demonstrated that CBT-I, in combination with medication, is superior for the treatment of insomnia when compared to medication alone. With this approach, sleep aids provide short-term relief for insomnia, while CBT-I (or BBTI) provides longer-lasting benefits.

In 2019, The American Geriatrics Society Beers Criteria for potentially inappropriate medication use in older adults issued strong recommendations for the avoidance of most medications used for sleep, including benzodiazepines, antidepressants, nonbenzodiazepines/benzodiazepine receptor agonists, and first-generation antihistamines.

Table 55.3c–3.
U.S. Food and Drug Administration–Approved Non-benzodiazepines for Insomnia

Agent	Indication	Required Time in Bed (hours)	[a]Medication Appears in Beers Criteria Recommendations
Eszopiclone (Lunesta)	Sleep initiation/maintenance	8+	Yes
Zaleplon (Sonata)	Sleep initiation	4	Yes
Zolpidem (Ambien)	Sleep initiation	7–8	Yes
Zolpidem MR (Ambien CR)	Sleep initiation/maintenance	7–8	Yes
Zolpidem SL (Edluar)	Sleep initiation	7–8	Yes
Zolpidem oral spray (Zolpimist)	Sleep initiation	7–8	Yes
Zolpidem SL (Intermezzo)	Sleep initiation	4	Yes
Ramelteon (Rozerem)[b]	Sleep initiation	—	No
Doxepin (Silenor)	Sleep maintenance	—	Yes
Suvorexant (Belsomra)	Sleep initiation/maintenance	7	No
Lemborexant (Dayvigo)	Sleep initiation/maintenance	7	No

[a]See text for specific Beer's Criteria cautions regarding potentially inappropriate use of sleep medications in older adults.
[b]Not DEA controlled.

The selective short-acting nonbenzodiazepines (type 1 gamma-aminobutyric acid [GABA] benzodiazepine receptor agonists), including eszopiclone, zaleplon, and zolpidem, have been shown to be effective in the short-term management of insomnia in older adults. Despite an overall improved side-effect profile, safety concerns remain, including increased risk for falls, delirium, and complex sleep-related behaviors. The 2019 Beers Criteria strongly recommends avoidance of this class of medications in older adults.

Although in the past, benzodiazepines were commonly prescribed for insomnia in older adults, there are significant risks associated with this class of medications, including an increased risk of falls, cognitive impairment, and driving accidents. In 2019, the Beers Criteria also strongly recommended the avoidance of benzodiazepine use in older adults.

A small number of industry-sponsored studies suggest that low doses of the tricyclic antidepressant (TCA) doxepin (≤6 mg/day) may be effective and safe for the promotion of sleep maintenance in older adults. The 2019 Beers Criteria strongly recommended avoiding doses >6 mg/day in older adults due to concerns about its significant anticholinergic and sedating properties and its tendency to induce orthostatic hypotension. A strong recommendation to avoid the use of doxepin at any dose in older adults who are at risk for delirium or who have neurocognitive disorders was also included.

Ramelteon, a melatonin receptor, appears to be safe in older adults, although its effectiveness is limited. Orexin receptor antagonists (suvorexant, lemborexant) are the newest class of FDA-approved sleep medications. These are approved for use in older adults with insomnia, and suvorexant, in particular, is approved for use in patients with Alzheimer disease (AD). But because both meds are relatively new, the experience with them is limited.

A variety of other classes of medications, including antihistamines, antidepressants, antipsychotics, and anticonvulsants, are prescribed for insomnia. As per the 2005 NIH State of the Science Conference on the Manifestations and Management of Chronic Insomnia in Adults, there is no systematic evidence to support this practice, and the risks largely outweigh the benefits in older adults.

CIRCADIAN RHYTHM SLEEP–WAKE DISORDERS

In humans, the sleep–wake cycle is controlled by an endogenous clock operating over an approximate 24-hour period called the circadian rhythm. This rhythm is synchronized by external time cues ("zeitgebers"), such as the light–dark cycle, which serves as the major external time signal in humans. Circadian rhythm sleep–wake disorders (CRSDs) may develop when dyssynchrony between the endogenous clock and external environmental zeitgebers occurs.

FIGURE 55.3c–1. Standard phase of sleep versus advanced phase of sleep.

Several factors associated with aging can contribute to the development of CRSDs. The circadian pacemaker, located in the suprachiasmatic nucleus, degenerates with age, which may result in weaker rhythms. The nocturnal secretion of endogenous melatonin, which plays an important role in the sleep–wake cycle, gradually decreases with age, resulting in disrupted circadian rhythms. In addition, environmental cues needed to synchronize the circadian rhythm of the sleep–wake cycle may be absent or weak in older patients. For example, one study showed that daily bright light exposure averaged about 60 minutes for healthy older adults, 30 minutes for patients with AD living at home, and 0 minutes for nursing home patients. Studies of sleep in institutionalized patients have found that this low level of light exposure is associated with sleep fragmentation and CRSDs. Gradual decreases in the amplitude of the circadian rhythm are also associated with aging and may lead to an increase in the frequency of nighttime awakenings and the severity of daytime sleepiness.

The most common CRSD experienced by older adults is advanced sleep phase syndrome (ASPS), which is characterized by sleep and wake times that are several hours earlier than societal norms. Individuals with ASPS will typically get sleepy in the early evening, timed with the drop in body temperature, and wake in the early morning (Fig. 55.3c–1). Although sleep itself may be normal, delays in sleep onset due to obligations or societal customs may result in insufficient sleep time (as these individuals experience an early-morning awakening regardless of what time they go to bed) and sleepiness during the day. The prevalence of ASPS is about 1% in middle-aged and older adults and increases with age. Men and women are equally affected. Careful and detailed sleep history and sleep diary are required to make this diagnosis. Activity monitoring with wrist actigraphy, if available, can be helpful as well.

Treatment of Advanced Sleep Phase Syndrome

For older adults with ASPS, treatment can be simply to adopt an earlier bedtime which coincides with the onset of sleepiness, to provide for enough sleep. For many patients, however, this may not be desirable due to interference with lifestyle. Treatment of CRSDs focuses on strengthening and synchronizing the sleep–wake cycle. Bright light is the strongest cue for circadian entrainment and is, therefore, the most common and the most effective treatment for circadian rhythm shifts. For older patients with ASPS, including those who reside in nursing homes, evening light exposure has been shown to strengthen the sleep–wake cycle and delay circadian rhythms. Patients with ASPS should be advised to avoid bright light during the morning and should be educated on sleep hygiene practices, including adherence to a strict sleep schedule. Early-evening artificial bright light via a bright light box has also been shown to improve sleep continuity in both healthy and institutionalized older patients.

There is no evidence to support morning melatonin therapy to delay the sleep phase in ASPS, especially given its sedating properties.

OBSTRUCTIVE SLEEP APNEA–HYPOPNEA

Obstructive sleep apnea (OSA)–hypopnea syndrome describes a spectrum of intermittent respiratory events occurring during sleep, ranging from primary snoring to increased respiratory effort without an increase in

airflow, which results in arousal from sleep (flow-limitation events, typically called upper airway resistance), to substantial decreases in airflow (hypopneas), to complete cessation of airflow (apneas), or some combination of these events.

The prevalence of OSA increases or stabilizes with age, per most longitudinal and cross-sectional studies. In a large series of randomly selected community-dwelling older adults 65 to 95 years of age, researchers reported that 81% of the study subjects had an apnea–hypopnea index (AHI) of 5 or greater, with prevalence rates of 62% for an AHI of 10 or greater, 44% for an AHI of 20 or greater, and 24% for an AHI of 40 or greater. In a longitudinal study, the prevalence only changed with associated changes in body mass index. The Sleep Heart Health Study, which reported prevalence rates of OSA by 10-year age groups, found increasing rates of OSA with increasing age for those subjects with an AHI of 15 or greater.

Institutionalized older adult patients appear to have even higher rates of OSA than those older adult patients who live independently. Patients with dementias involving degeneration in brainstem areas responsible for regulating respiration and other autonomic functions relevant to sleep maintenance may have a higher risk of developing OSA. Institutionalized older adult patients with more severe dementia have been reported to have more severe OSA than those older patients with milder or no dementia. This study also reported that patients with more severe OSA had lower cognition scores during testing, suggesting that more severe OSA was associated with more severe dementia.

Risk factors for OSA in older adults are similar to those found in the younger population, including increasing age, gender, and obesity. Other conditions that increase the risk of developing OSA include the use of sedating medications, alcohol consumption, family history/genetic factors, menopausal status, race, smoking, and craniofacial morphology.

Snoring and excessive daytime sleepiness (EDS) are the predominant symptoms of OSA in older adults. Less common presentations include insomnia, particularly sleep maintenance complaints, nocturnal confusion, nocturia, and daytime cognitive impairment, such as difficulty with concentration and short-term memory loss. Unintentional dozing is a common manifestation of untreated OSA in older patients. As with younger adults, excessive sleepiness can lead to social, occupational,

and cognitive difficulties, which is of particular relevance in patients with underlying cognitive impairment at baseline.

The presence of OSA is associated with significant morbidity, including cardiovascular disease, depression, and cognitive dysfunction. The presence of untreated OSA has been linked to an increased risk of developing dementia and mild cognitive impairment. Older patients with severe OSA (defined as an AHI of 30 or greater) have consistently been found to have impairments in attention, concentration, memory consolidation, immediate and delayed recall, executive tasks, planning and sequential thinking, visuomotor skills, and manual dexterity. Even older adults with milder OSA may experience similar deficits. In a substudy of the Study of Osteopathic Fractures, those older women (mean age 82) without dementia with OSA (AHI of 15 or greater) were found to have an increased risk of developing cognitive impairment. In middle-aged and older adults, research across a variety of studies suggests that OSA is associated with an increase in AD biomarkers (amyloid-beta and tau) as measured in cerebrospinal fluid, by positron emission tomography and in blood serum.

OSA is an independent risk factor for the development of systemic hypertension; it is one of the only known causes of hypertension. The exact relationship between OSA and other cardiovascular diseases (including myocardial infarction, pulmonary hypertension, stroke, arrhythmias, and congestive heart failure) in older adults remains unclear, although results from a few recent studies have provided some insight. The Sleep Heart Health Study found a positive association between the severity of OSA and the risk of developing cardiovascular disease, including coronary artery disease, congestive heart failure, and stroke. OSA is highly prevalent in patients who have suffered an ischemic stroke. The American Heart Association and American Stroke Association now recommend screening patients who have experienced an ischemic stroke or transient ischemic attack for sleep apnea. One recent study found an OSA prevalence of nearly 62% in patients with a stroke/transient ischemic attack history.

As with younger adults, clinicians should use a stepwise approach in evaluating older adult patients with suspected OSA. A complete sleep history focused on symptoms of OSA, including EDS, unintentional napping, snoring, trouble with maintaining sleep, and symptoms of other sleep disorders (e.g., RLS, insomnia), should be obtained, preferably in

the presence of a bed partner or caregiver. The patient's medical history should be reviewed, with attention paid to comorbid medical conditions, medications, the use of alcohol and/or tobacco products, and evidence of cognitive impairment. If these are suggestive of OSA, an overnight sleep recording should be obtained for diagnostic purposes. Both unattended ("home") and attended (in the laboratory) sleep studies can be employed to make the diagnosis of OSA.

Treatment of Obstructive Sleep Apnea–Hypopnea Syndrome

Continuous positive airway pressure (CPAP) is the gold standard and most effective treatment of OSA and has been shown to improve cognition functioning, cardiovascular disease outcomes, and EDS in older adults. CPAP compliance can be an issue for any patient with OSA, regardless of age. Older adults may need additional education and assistance with mask fit and comfort features of CPAP initially. Studies support the idea that patients with mild and moderate AD can also be compliant with CPAP treatment, as the only factor associated with poor compliance was the presence of depression—not age, the severity of dementia, or the severity of OSA. There is also preliminary evidence to suggest that CPAP treatment may normalize AD biomarkers.

Alternative treatments include the use of an oral appliance, upper airway surgery, and a hypoglossal nerve stimulator ("pacemaker"), which is surgically implanted in the chest wall. Clinicians should counsel all patients on weight loss, smoking cessation, and abstinence from the consumption of alcohol. Sedating medications, especially those known to result in respiratory depression, including benzodiazepines, muscle relaxers, and opioids, should be avoided in older adults with OSA.

Most experts agree that the treatment of OSA in older adults should be guided by the patient's symptoms and the severity of the OSA. If an older adult has comorbid conditions such as hypertension, depression, cognitive dysfunction, or cardiovascular disease or if the OSA is severe, treatment should be considered. Age alone should not be a determining factor in treatment decisions.

RESTLESS LEGS SYNDROME/PERIODIC LIMB MOVEMENTS IN SLEEP

RLS is a common sleep-related movement disorder characterized by an urge to move the legs or leg dysesthesia ("a creepy crawling" or "restless" sensation) that occurs while the person is in a relaxed awake, typically inactive state, particularly in the evening, and is transiently relieved by movement. During sleep, many patients with RLS have characteristic limb movements, called periodic limb movements in sleep (PLMS), which may or may not be associated with sleep disruption. When the PLMS results in sleep disturbance, the diagnosis is periodic limb movement disorder (PLMD), which can result in EDS.

The pathophysiology of RLS remains incompletely understood, although both central and peripheral nervous system abnormalities have been identified. Iron stores and alterations in dopaminergic systems have both been implicated in RLS.

Epidemiologic studies reveal the prevalence of RLS in older adults ranges from 9% to 20% and increases with age. Studies have also found that RLS occurs twice as often in older women than in older men. Comorbid conditions associated with RLS include iron deficiency, end-stage renal disease, neuropathy, fibromyalgia, diabetes, Parkinson disease, and multiple sclerosis.

Like RLS, the prevalence of PLMS increases with age, with a reported prevalence of up to 45% in community-dwelling adults older than the age of 65 years. It is equally prevalent in older men and women. Despite its high prevalence in older adults, the severity of PLMS does not appear to progress with age.

The diagnosis of RLS is a clinical one, based on history alone—PSG has no role in the diagnosis. Table 55.3c–4 lists the four essential questions that clinicians should ask. In order to make the diagnosis of RLS, the answer to all four questions needs to be "yes." Questionnaires such as the Cambridge-Hopkins diagnostic questionnaire for RLS (CH-RLSq) and the RLS Diagnostic Index (RLS-DI) can also be helpful. Other conditions that may be mistaken for RLS, such as peripheral neuropathy, myalgia, leg cramps, positional discomfort, arthritis, pruritus, and vascular insufficiency, need to be ruled out, although many of these can coexist with RLS. In patients with significant cognitive impairment, signs of discomfort in the legs, such as rubbing the legs, which are present or worse during inactivity and which are lessened by activity, may be observed.

Table 55.3c–4.
Four Essential Questions for Restless Legs Syndrome Diagnosis[a]

1. Do you experience the urge to move your legs (or other parts of your body), typically accompanied or caused by an uncomfortable and/or unpleasant sensation in the affected body part?
2. Does the urge to move or the uncomfortable sensation begin and/or worsen during periods of rest or inactivity?
3. Is the urge to move or uncomfortable sensation partially or totally relieved by movement?
4. Is the urge to move or the uncomfortable sensation worse in the evening or at night compared to the daytime, or does it only occur in the evening or at night?

[a]All four questions should be answered in the affirmative for the diagnosis of restless legs syndrome (RLS).

In contrast, the diagnosis of PLMS requires PSG and is seen in more than 80% of patients with RLS who undergo PSG. PLMS is defined as periodic episodes of repetitive limb movements during sleep, typically separated by 20 to 40 seconds. PLMD is diagnosed when the clinical history of EDS with subjective sleep complaints is combined with PSG showing PLMS, excluding other sleep disorders.

Treatment of Restless Legs Syndrome and Periodic Limb Movement Disorder

Medications that suppress the leg movements and/or the related arousals are the currently recommended treatments for both RLS and PLMD. Nonergot dopamine agonists (ropinirole, pramipexole, and rotigotine transdermal) and alpha-2-delta calcium channel ligands (gabapentin enacarbil, pregabalin, and gabapentin) are both considered first-line treatment for RLS. Augmentation is a common complication of long-term dopaminergic therapy and is characterized by worsening RLS symptoms (earlier onset of symptoms, the spread of symptoms to the arms and torso) with increasing doses of the medication. If augmentation occurs, reducing the dose, splitting the dose into daytime/nighttime, and/or discontinuation of the medication is recommended.

In addition, supplemental iron is recommended in patients with RLS whose serum ferritin level is ≤75 mcg/L. A number of medications can

exacerbate RLS, including antidepressants, neuroleptic agents, and sedating antihistamines (including those found in the nonprescription sleep aids and allergy relief medications), and should be discontinued if possible. Sleep deprivation, either from insufficient sleep time and/or due to comorbid sleep disorders, can also aggravate RLS and should be reviewed and further evaluated if indicated.

RAPID EYE MOVEMENT SLEEP BEHAVIOR DISORDER

REM sleep behavior disorder (RBD) is a parasomnia characterized by dream-enacting behavior with a reported prevalence of 2% in adults over 60 years of age and 6% in those over 70 years of age. It is more commonly diagnosed in men (9:1 male-to-female ratio), although this may represent a referral bias. The development of RBD is a harbinger of alpha-synuclein neurodegeneration. After a prolonged interval (average 10 years), most older patients with RBD will show signs and symptoms of Parkinson disease or another related disorder such as multisystem atrophy or dementia with Lewy bodies. In addition to synucleinopathies, RBD occurs in nonsynucleinopathic dementias/neurogenerative diseases, with some brainstem lesions, and with certain medications (antidepressants).

RBD is characterized by elaborate, complex, and purposeful motor activities and vocalization associated with dreams (“acting-out dreams”) due to the loss of REM sleep atonia. Patients may punch, kick, yell, or jump/run out of bed, and these actions correlate with dream imagery. The episodes typically occur during the second half of the sleep period, when REM sleep predominates. Sleep behaviors can place the patient and/or bed partner at risk for injuries, which have been reported to occur in 32% to 64% of cases.

The diagnosis of RBD requires a sleep history, in the presence of the bed partner if possible, and an overnight polysomnogram with video recording to confirm the relationship between REM sleep and complex motor behaviors. Even in the absence of abnormal behavior during the PSG recording, REM sleep atonia is characteristically present.

Treatment of Rapid Eye Movement Sleep Behavior Disorder

The primary goal of RBD treatment is to create a safe sleeping environment. Heavy or sharp items should be removed from the bed's vicinity, and doors/windows should be locked. Measures to avoid being injured by falling out of bed can be used (i.e., bedrails, a low-profile bed, or a mattress on the floor).

Melatonin is the preferred first-line therapy for patients with RBD. By an unclear mechanism, melatonin in high doses (6 to 18 mg) augments REM sleep atonia and improves RBD symptoms. Melatonin is generally well tolerated. Low-dose clonazepam (0.5 to 1 mg) is also an effective treatment for RBD, although its side effects may limit its utility, especially in older adults with neurodegenerative disorders. Maintaining good sleep hygiene and educating the patient and their bed partner are also important aspects of RBD treatment.

SLEEP IN NEUROCOGNITIVE DISORDERS

Recent studies support a possible connection between sleep disturbances, especially OSA, fragmented sleep, abnormal duration of sleep, and the development of cognitive impairment, suggesting that the sleep–wake cycle may play an important role in cognitive aging. Patients with neurocognitive disorders, both those living independently and those institutionalized, experience disrupted sleep which may be due, in part, to neurodegeneration in areas of the brain responsible for sleep regulation. It has been reported that 19% to 44% of community-dwelling patients with dementia complain of sleep disturbances, and the prevalence is estimated to be even higher in patients with dementia who are institutionalized. Disrupted sleep commonly results in napping, both intentional and unintentional, and can be manifested as abnormal nocturnal behaviors, including wandering and confusion, which are significant contributors to caregiver stress and may result in the need for patient institutionalization.

Patients with neurocognitive disorders can have primary sleep disorders such as OSA, PLMS, RLS, or RBD or may have disturbed sleep related to pain, medications, circadian rhythm changes, or depression. Therefore, disturbed sleep related to a neurocognitive disorder itself should be a diagnosis of exclusion.

As with all older adults, treatment of specific sleep disorders in older patients with neurocognitive disorders should be targeted for that specific sleep disorder. Patients with OSA should be treated with CPAP if

appropriate, whereas patients with circadian rhythm disturbances should be treated with bright-light therapy. Given the high risk-to-benefit ratio of most medications in this patient population, nonpharmacologic interventions such as regular physical activity and restricting time in bed are preferred. Medications, including sedative–hypnotics, antihistamines, and antipsychotics, all have significant side effects, including residual daytime sleepiness (the so-called “hangover effect”) and motor and/or cognitive functioning impairment. Further, the efficacy and safety of sleep medications have not been adequately studied in patients with neurocognitive disorders; there is little evidence to support their use.

SLEEP IN NURSING HOMES

Institutionalized older adults experience more fragmented and disturbed sleep than those living in the community. Nursing home patients have poorer sleep quality, more fragmentation of sleep, more advanced sleep–wake cycles, and more daytime sleepiness and are prescribed sedative–hypnotics more frequently than older adults living in the community or in assisted living facilities. During any 1 hour of a 24-hour day, institutionalized patients with major neurocognitive disorders may not spend a single hour completely awake or completely asleep.

Excessive nighttime noise and inadequate ambient light exposure both contribute to sleep disruption in nursing home patients. In a study of institutionalized patients, most were found to be exposed to less than 10 minutes of bright light per day. In contrast, patients with more light exposure had fewer sleep disruptions. In addition, nursing home patients may spend large portions of their day in bed, and inactivity is known to disrupt circadian rhythms.

Institutionalized patients should have a careful sleep evaluation, including an assessment for the presence of primary sleep and circadian rhythm disorders. A thorough review of medications should be performed, and medical and psychiatric history should be taken. Reduction in nighttime light and noise increases in daytime light exposure and improvements in sleep hygiene should be implemented. The use of sleep medications should, in general, be avoided.

CONCLUSION

For many older adults, aging is associated with significant changes in sleep with a variety of potential contributors, including medications, comorbid conditions, circadian rhythm disruption, and specific sleep–wake disorders. As with younger adults, a thorough sleep history should be taken, and often an overnight sleep recording should be performed. Treatment should address the primary sleep problem and can result in significant improvement in both quality of life and daytime functioning.

55.3d Anxiety Disorders in Older Adults

Helmet T. Karim, Ph.D., and Carmen Andreescu, M.D.

In DSM-5, the chapter on anxiety disorders has been revised to include separation anxiety disorder and selective mutism—but given the lack of research in late life, we will not review these, although symptoms suggesting separation anxiety are frequently encountered in Alzheimer disease (AD) and related dementias. No longer included are obsessive-compulsive disorder (OCD) or post-traumatic stress disorder (PTSD), and acute stress disorder (which have separate chapters in DSM-5). The term "anxiety disorders" used in this chapter nonetheless is used to refer to all the DSM-5 diagnoses within anxiety-, trauma-, and stressor-related and obsessive-compulsive and related disorders. When we refer to these disorders in aggregate (i.e., when there are no specific distinctions between them that we are highlighting), we will use the term "anxiety disorders" otherwise, we will specify the distinctions.

There has been increasing evidence that anxiety in late life has greater clinical consequences and is more prevalent than previously thought. Although much less is still known about late-life anxiety than about other common late-life psychiatric conditions such as depression or dementia, current studies show that in community samples, anxiety is more common than depression in older adults. In addition, anxiety disorders in later life can greatly impact quality of life, increase disability levels, and impact recovery from illness as well as having reciprocal associations with several disorders including cardiovascular disease and dementia. When compared to the body of research of anxiety in younger adults or children, limited data suggest that older adults present with the same anxiety disorders as do younger adults, although several additional anxiety syndromes may be particularly relevant to older adults. Many anxiety disorders are thought to "carry over" from adulthood to late life, though there are some studies that show some anxiety disorders may appear de novo in late life. Virtually all epidemiologic research is consistent in finding that the prevalence of anxiety, trauma- and stress-related, and obsessive-compulsive and related disorders is lower among older adults than among younger adults, particularly with respect to panic disorder and social anxiety disorder (social phobia). Rates vary considerably by study, however, leading to contradictory conclusions: either anxiety, trauma- and

stress-related, and obsessive-compulsive and related disorders in older adults are extremely rare or they constitute the most common class of geriatric psychiatric conditions, with substantially higher prevalence rates than mood disorders.

Diagnostic issues are complicated by medical illness and medications, which can cause or contribute to anxiety-like symptoms. Clinicians may also attribute symptoms to realistic, age-appropriate health problems, worries, or fears, but severe worry or anxiety can, at times, be dismissed as part of the normal aging process, which may hinder detection. Furthermore, in some disorders, like dementia, anxiety may present as agitation, which complicates diagnosis and treatment.

Although some of these factors may lead investigators to believe that anxiety disorders are uncommon in older adults, it is more likely that anxiety is underdiagnosed in the presence of medical conditions or depression. Clinicians may conclude that anxiety or avoidance is an inevitable or adaptive response to aging and, therefore, not pathologic. In many cases, this conclusion may be inaccurate. Differences in the presentation of certain anxiety disorders in older adults may also muddy the diagnostic waters. Older adults may also express anxiety in ways that are different from younger adults—in particular, assessing avoidance or worry may be difficult as older adults may regard symptoms associated with avoidance or worry as signs of weakness. Older adults may also experience more impairment with even subthreshold levels of anxiety. Finally, there is insufficient research on differences in presentation or etiology between late-onset anxiety disorders and disorders originating earlier in life that have persisted until or recurred in old age. Additional research on these topics is necessary to clarify the many unresolved issues surrounding anxiety in older adults.

DEFINITION, HISTORY, AND COMPARATIVE NOSOLOGY

The definition, history, and comparative nosology of anxiety, trauma- and stressor-related, and obsessive-compulsive and related disorder diagnoses, as defined by the various versions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) and the *International Statistical Classification of Diseases and Related Health Problems* (ICD). To date, no geriatric-specific anxiety disorders have been included in the

diagnostic nomenclature. In general, the DSM excludes anxiety disorders that are "due to the direct physiological effects of a general medical condition."

EPIDEMIOLOGY

Prevalence

The prevalence of anxiety disorders in older adults is controversial. Investigations have found rates ranging from 0.7% to 19% in community samples and 1% to 28% in medical settings. A recent review of epidemiologic studies in Europe found a range of 4% to 14%. The prevalence of clinically relevant symptoms is much higher, ranging from 15% to 52% in community samples and 15% to 56% in clinical samples. By comparison, another recent review found prevalence rates of major depression ranging from 0.9% to 9% among community-dwelling older adults. Thus, it appears likely that, as in younger adults, anxiety disorders as a class are more common than major depression in older adults—though many of these estimates for anxiety include PTSD and OCD.

Table 55.3d–1.
Prevalence Estimates of Anxiety Disorders in Older Adults

Generalized anxiety disorder	0.7–9%
Specific phobia	3–5%
Social anxiety disorder (social phobia)	0.2–2%
Panic disorder	0.1–1%
Agoraphobia	0.4%
Obsessive-compulsive disorder	0.1–2%
Hoarding disorder	14%
Post-traumatic stress disorder	8.7%

It is generally accepted now that prevalence of anxiety disorders likely decreases among older adults, and sex differences, with women reporting higher rates than men, appear to attenuate among the oldest old. The exception, however, is generalized anxiety disorder (GAD) which maintains similar prevalence rates in younger and older adults. One study

found that women were twice as likely to present with GAD or agoraphobia as men, independent of age, but did not find such an association with other anxiety disorders in community-dwelling older adults. There appears to be a lower comorbidity of anxiety disorders and alcohol abuse among older adults than among younger adults, although this may be influenced by relatively low rates of substance use disorders among older adults. Of note, the rates of prescription drug misuse have increased among older adults including opioid and benzodiazepine abuse. Most studies conclude that GAD and phobias are the most common anxiety disorders among older adults, with panic disorder and social anxiety disorder (social phobia) much less common than in younger age groups. Estimated prevalence rates for specific anxiety disorders are listed in Table 55.3d–1.

Incidence

Incidence studies of late-life anxiety are relatively rare, so most data on the age of onset come from retrospective reporting. The incidence of agoraphobia in women may increase in late life, whereas specific phobia, OCD in men, and panic disorder are typically continuations from earlier life or the result of another psychiatric or medical illness. While it is thought that most anxiety disorders are chronic and usually occur earlier in life, GAD and agoraphobia may have onset later in life. In one study, 75% of all anxiety disorders have an onset before age 21 and 95% before age 51. However, approximately half of GAD cases arise for the first time in later life after age 50. Those with an earlier onset GAD (compared to later onset) tend to have a more severe course and pathologic worry, while later onset is often characterized by more medical comorbidity and disability. One study found that agoraphobia in late life was frequently triggered by physical illness or trauma.

Prevalence Within Special Groups

Anxiety disorders are common in diseases of older adults. Rates as high as 30% have been reported in patients with cardiac conditions such as coronary heart disease and atrial fibrillation. In chronic obstructive pulmonary disease patients, prevalence rates of panic disorder range from 8% to 32%, with GAD rates ranging from 10% to 16%. Approximately 40% of patients with Parkinson disease report anxiety symptoms. Vestibular diseases have a similar comorbidity with anxiety disorders

(37% to 42%). In irritable bowel syndrome, 20% of patients have comorbid anxiety. GAD may occur in 15% to 21% of patients with neurologic conditions such as stroke and AD. GAD is thought to have reciprocal relationships with coronary heart disease and dementia, which may worsen overall outcomes, especially if they are left undiagnosed and untreated.

Although rates of anxiety disorders in special populations are typically higher, this is not the case for studies in nursing home patients, among whom the reported rate is approximately 5%. A review of prevalence data on anxiety disorders among caregivers for individuals with dementia found rates ranging from 4% to 16%. In a review and meta-analysis of studies involving widows, prevalence rates were 12% for PTSD, 10% for panic disorder, and 31% for GAD. By comparison, the prevalence of major depression was 22%.

Some data suggest that anxiety may be more common in older individuals from minority groups, although a recent study of older Black individuals found 6.6% reporting an anxiety disorder (vs. 2.4% for major depression), consistent with other research. The distribution of disorders, however, was different from what has been reported in other samples. For example, the most common anxiety disorders in this sample were PTSD (2.9%) and social anxiety disorder (social phobia) (2.1%). Another study examining race and sex differences found highest rates of GAD among older Black women and the lowest rates of GAD among older Black men. One study found that while PTSD prevalence did not differ between Black and White individuals, older White individuals who had experienced nonphysical trauma were more likely to report hyperarousal than older Black individuals. The oldest old and those in the South were less likely to report anxiety disorders. Almost one-fourth (24%) of older Puerto Rican primary care patients met criteria for an anxiety disorder, primarily specific phobia (12%), GAD (11%), or panic attacks (11%). Hispanic individuals often express distress via somatic rather than cognitive complaints, which may explain some of this discrepancy. Across all ethnic groups, phobias appear to be associated with lower income.

Although older veterans report rates of PTSD that are substantially lower than the rates found in younger veterans (e.g., 6% vs. 19% in one study), rates of PTSD are high among aging former prisoners of war (POWs) (e.g., 20%). The prevalence of PTSD appears to be highest among Holocaust survivors (e.g., 45%).

Comorbidity With Mood Disorders

As is the case with younger adults, comorbidity of anxiety and mood disorders is very common. Data from the Epidemiologic Catchment Area survey and two Dutch studies found that 21% to 37% of community-dwelling patients with an anxiety disorder (as defined by DSM-IV) experienced comorbid depression. Although these rates suggest that the disorders frequently overlap, it appears that most DSM-IV anxiety disorders in older adults are unaccompanied by a mood disorder. One study found that 74% of older adults with anxiety did not have a mood disorder, while depression without comorbid anxiety is much less common in late life. Some epidemiologic evidence in younger adults suggests that anxiety disorders precede mood disorders and may partially explain this prevalence. Some research indicates that this comorbidity may increase in certain conditions or populations (e.g., higher comorbidity in residential care facilities). Among nursing home patients, 42% of those with a DSM-IV anxiety disorder experienced comorbid major depression.

ETIOLOGY AND RISK FACTORS

Although much less research has been conducted on anxiety disorders than on depression in older adults, it appears that risk factors are similar for both conditions. Female sex, cognitive impairment, chronic health conditions, poor self-rated health, recent adverse life events, poverty, history of mental illness in parents, lower education, being a caregiver, social isolation, bereavement, adverse events in childhood, and functional limitations are among the most important factors increasing vulnerability. Many of these risk factors are shared in younger and older adults. Psychological risk factors for both anxiety disorders and depression include personality traits (i.e., neuroticism), dysfunctional coping, and other forms of psychopathology. Marital status (unmarried) appears to be associated with depression but not anxiety, being childless, having lower income, and experiencing traumatic events are more typically associated with anxiety than with depression. Older age appears to be somewhat protective for anxiety disorders. However, one may have to keep in mind that anxiety in old age may be often atypical and several symptoms do not fall under the current DSM categories. Also, of interest, one study that examined depression and anxiety disorders simultaneously found that although risk factors were similar for both classes of conditions, odds

ratios associated with virtually all risks were higher for anxiety disorders than for depression.

In nursing home patients, anxiety disorders appear to be related to younger age, lower levels of social support, better cognitive performance, depression, and history of stroke. Comorbid anxiety and depressive disorders are associated with the presence of pain, loneliness, and perceived lack of adequate care.

With respect to specific anxiety disorders, female sex, marital status (divorced or widowed), and comorbid psychiatric illness (specifically major depression and social anxiety disorder [social phobia]) are risk factors for agoraphobia in older adults. Late-onset agoraphobia is often associated with medical illness or traumatic events such as victimization or falls. Panic disorder is more strongly associated with disability than with health problems. Phobic disorders are associated with lower income and early parental loss. Risk factors for PTSD include female sex, neuroticism, low self-efficacy, and childhood trauma, and there are some reports of new-onset or worsening PTSD symptoms with cognitive decline. There is some evidence that re-experiencing symptoms in PTSD declines with age. In a cross-sectional study, only 10% of individuals over age 65 reported re-experiencing symptoms compared to 21.5% in those aged 18 to 24 years.

DIAGNOSIS AND CLINICAL FEATURES

While many clinical features of anxiety in younger adults can be encountered in older adults, older adults also experience atypical anxiety syndromes (see next section).

Similar to what has been reported in younger samples, severe and difficult to control worry, sleep disturbance, fatigue, and muscle tension appear to be the cardinal features of late-life GAD. There are some differences, for instance in the nature of worries (e.g., more health related in late life). It is also widely accepted that it is more difficult to assess anxiety symptoms in late life as they often manifest as somatic symptoms and comorbid with medical conditions.

Older adults with panic disorder report fewer and less severe panic symptoms, lower levels of arousal, and less depression than younger individuals. Late-onset panic disorder appears to be associated with lower levels of cognitive and somatic distress during panic attacks. OCD may differ somewhat between older and younger patients, with older persons

reporting more contamination and religious obsessions but fewer rituals involving symmetry or counting. Older individuals reported lower severity of obsessions overall (compared to younger individuals). There is strong evidence that compulsive hoarding increases with age and even more so in dementia.

Older adults appear to develop PTSD and other anxiety syndromes after exposure to traumatic events less frequently than younger adults. Older PTSD patients report more social dysfunction than younger patients, and in older adults, the external locus of control appears to be associated with more avoidance, social dysfunction, and depression. Older PTSD patients may present more somatic than psychological symptoms and may report less severe PTSD symptomatology.

Anxiety Syndromes of Particular Relevance to Older Adults

Agoraphobia, fear of falling, hoarding, and complicated grief merit special mention because they may be anxiety syndromes with particular relevance to older adults. Each of these disorders has a higher prevalence in older adults compared to younger adults.

Agoraphobia. As shown in Table 55.3d–1, prevalence rates of agoraphobia vary widely in older adults, suggesting a lack of diagnostic consensus. Distinguishing between adaptive and excessive avoidance is challenging, and patients typically believe that their behavior is reasonable, given age-associated medical conditions and physical limitations. Because panic disorder is rare in older adults, agoraphobia without history of panic disorder (DSM-IV) is the most common symptom presentation. In DSM-5, where panic disorder and agoraphobia have been diagnostically uncoupled, the diagnosis of agoraphobia would apply.

In one study of older adults that used conservative criteria that defined agoraphobia as avoidance due to a panic attack rather than panic-like symptoms, the prevalence of comorbid panic disorder was still much lower (8%) than the prevalence of major depression (25%) or social phobia (20%). This suggests that older adults may limit their activity (i.e., develop agoraphobia) more often than do younger adults in response to panic attacks that do not meet criteria for panic disorder. Only 11% of late-onset patients with agoraphobia had histories of panic attacks in another investigation with looser criteria for agoraphobia; instead, they developed

their fear in response to medical illness, physical injury, or traumatic events.

Across the lifespan, clinical features of agoraphobia are fairly consistent; however, age may impact the type of situation feared. The most common situations feared in older adults include being in line, being in shops, and being in open spaces. Older individuals may fear or avoid these situations due to thoughts that help may not be available in the event of embarrassing symptoms (e.g., fear of falling, fear of incontinence).

Fear of Falling. Although under DSM-5 diagnostic criteria fear of falling can only be classified as a specific phobia, other type, if the patient perceives it to be excessive or unreasonable, it is a common and disabling anxiety syndrome in older adults. As many as 25% of community-dwelling older adults report fear of falling. Although individuals with a past fall are more likely to develop fear of falling than those without such history, most individuals reporting fear do not have a history of falls. Typical screening tools are often not well suited for identifying fear of falling so it is commonly underdiagnosed and left untreated.

Fear of falling has potentially serious consequences, including, paradoxically, increased risk of falls. Approximately half of those with fear of falling restrict their activities due to fear, and the risk of falling is highest among those who do, even among those who have never experienced a fall. Fear of falling may lead to maladaptive changes in gait parameters, further increasing the risk of future falls, and may interfere with rehabilitation following a fall. For example, in one investigation of patients recovering from hip fracture surgery, fear of falling predicted poor functional recovery, although pain and depression did not. Older patients are often more likely to receive an opioid or benzodiazepine prescription and are subsequently more likely to experience side effects including cognitive impairment, dizziness, impaired balance, and higher likelihood of falls.

As is true with other anxiety syndromes, fear of falling is frequently, although not always, comorbid with other anxiety disorders and depression. In one sample of individuals with high fear of falling and a recent fall, 36% had depression and 19% had an anxiety disorder, most commonly agoraphobia without panic, and anxiety was a strong predictor of fear of falling even after controlling for factors such as dizziness, visual

impairment, number of medications, and depressive disorders and symptoms.

Hoarding. Once considered a subtype of OCD, hoarding disorder is now considered a separable syndrome and is a new diagnostic category in DSM-5. Nationally representative epidemiologic studies of hoarding disorder with DSM-5 criteria are not available, but smaller epidemiologic surveys estimate a 1.5% to 6% prevalence of hoarding behaviors (not necessarily at the level of a hoarding disorder diagnosis) in the general population. Hoarding symptoms may be nearly three times more prevalent in older adults compared with younger adults. Older adults may also show more severe hoarding symptoms than do middle-aged adults and is even more prevalent in patients with dementia.

Older adults who are hoarders are typically female, never married, and living alone. Hoarding is typically a chronic condition with an early onset and progressive course. For those with a late onset of symptoms, hoarding likely begins secondary to a disease process occurring in later life, such as dementia. Pest infestations, fire hazards, and falling are risk factors for older adults with hoarding behaviors. People with hoarding disorders often have poor physical health and a greater number of comorbid medical conditions compared to those without hoarding disorders and several factors may explain these associations including impulsivity, executive dysfunction, and emotion regulation though there is limited research.

Coronavirus Pandemic and Anxiety in Late Life. During the coronavirus disease (COVID) pandemic, older adults experienced greater adverse health effects (e.g., more complications, higher mortality), difficulties adapting to a new status quo (e.g., telemedicine, telecommunication), and greater isolation and potentially more frequent grief. There was some concern that older adults may subsequently experience greater mental health conditions, especially anxiety including agoraphobia. However, compared to younger adults, several studies demonstrated lower rates of anxiety: in August 2020, the Center for Disease Control reported lower rates of anxiety (6.2%) in older adults (>65 years) compared to younger adults (18 to 24 years, 49.1%) or midlife (45 to 64 years, 16.1%). A study from Spain replicated these findings, showing lower rates of anxiety, depression, and PTSD. However, this may be due to differences in coping, emotion regulation, and expressed

anxiety, as one study showed that in a study of 7,127 older adults, 12.3% reported worsened anxiety after lockdown. Apprehension regarding COVID was also much higher compared to anticipatory apprehension related to other disorders, like influenza, prompting the term coronaphobia which may be driven by uncertainty regarding the future and the virus, significant changes in daily life due to the virus, low optimism (especially early on), poor health-related outcomes, and misinformation on social media, news sources, and other online sources. Finally, COVID survivors at times experience additional symptoms for months during the convalescent period (long COVID syndrome), including fatigue and pain, but also depression and anxiety. Thus, one study found that 3 months after recovery, 6.5% of COVID survivors experienced anxiety compared to 1.6% in a comparison group who did not have COVID. Further impact associated with social changes during the pandemic as well as with long COVID syndrome in older adults will require additional research.

PATHOLOGY AND LABORATORY EXAMINATION

Most research on the biology of late-life anxiety has focused on PTSD and, more recently, GAD. Studies in PTSD, GAD, and other late-life anxiety disorders have examined cognitive performance, hypothalamic–pituitary–adrenal (HPA) axis function, and other markers of autonomic arousal, neuroimaging, and genetics. These are summarized in Figure 55.3d–1.

Post-Traumatic Stress Disorder

With respect to neuropsychological functioning, older persons with PTSD display poorer explicit memory, visuospatial functioning, attention, inhibitory control, information processing speed, and working memory than those with trauma exposure but no PTSD and those without trauma exposure. Among those with PTSD, improvement in recall may be associated with improvement in PTSD symptoms. It is hypothesized that lack of cognitive resources to manage trauma may result in engagement of more maladaptive strategies for coping with symptoms.

Other research shows evidence of HPA axis dysregulation associated with late-life PTSD. Individuals with PTSD show flatter circadian salivary cortisol patterns and lower urinary cortisol excretion than do those without PTSD, and better explicit memory performance is associated with lower

salivary cortisol levels. Urinary cortisol excretion and glucocorticoid receptor–mediated responsiveness appear to be associated with age of first trauma exposure, and cortisol level may be associated with severity of childhood trauma. Moreover, cortisol administration may enhance working memory performance in older veterans with PTSD. Glucocorticoid receptor, plasma adrenocorticotropic hormone (ACTH), and cortisol suppression in response to dexamethasone administration are greater in older PTSD patients. Older PTSD patients may have higher levels of dehydroepiandrosterone (DHEA) and DHEA sulfate ester (DHEAS) and a lower cortisol/DHEA ratio. The cortisol/DHEA ratio appears to be predicted by the severity of childhood trauma and current PTSD symptoms, and both variables are predicted by symptom improvement and coping. A recent meta-analysis, however, revealed mixed findings on the association between PTSD and diurnal cortisol where some of these studies suggested that cortisol levels correlated more with trauma exposure in general rather than PTSD.

Previous studies have also identified associations between PTSD and proinflammatory factors, neurotrophic factors, and neurotransmitters. Much of this evidence is not widely studied in late-life PTSD, but given that anxiety disorders are thought to be lifetime disorders, they may still be relevant in late life. Childhood maltreatment and exposure to trauma are associated with higher levels of interleukin-6 (IL-6), IL-1β, and tumor necrosis factor-α (TNF-α), and exposure to trauma is additionally associated with higher C-reactive protein (CRP). As reviewed throughout, these can promote several downstream effects, including those related to dementia promoting amyloid and tau accumulation as well as worsening vascular risk factors. In addition, midlife individuals with PTSD have lowered peripheral brain-derived neurotrophic factor (BDNF) levels, and while its relationship with brain function is unclear, it is known that BDNF gene expression in the hippocampus, amygdala, and prefrontal cortex is necessary for the formation of emotional memories, including those related to fear extinction. In midlife, individuals with PTSD may have altered peripheral serotonin and norepinephrine levels, but these findings are mixed. There are very limited studies that investigate these mechanisms in late life, but these are urgently needed to better understand PTSD in older adults, given the cohorts of aging war veterans.

FIGURE 55.3d–1. Factors associated with late-life PTSD and GAD. This figure summarizes findings on genetics, inflammation, cortisol, BDNF, estradiol, amyloid, structural gray matter volume, diffusion-weighted imaging, and fMRI. Shared findings are in *black*, while GAD only is in *blue*, and PTSD only is in *red*. (See eBook for color image.)

In terms of brain structure, although one investigation found no differences in hippocampal volumes in Holocaust survivors relative to controls, among those with PTSD, smaller left hippocampal volumes were found in those who had no prior history of trauma before the index trauma. These findings suggest that smaller hippocampal volume may be a risk factor for the development of PTSD. In midlife, there is evidence that PTSD is associated with lower volumes in the hippocampus, amygdala, anterior cingulate, corpus callosum, pons, and cerebellum, as well as total cerebral volume. There is some limited evidence that fractional anisotropy, indicating diffusivity of water in the white matter tracts, is lower in the corpus callosum in adults with PTSD compared to those without. Very few studies have investigated the association between PTSD and white matter hyperintensities, a marker of cerebral small vessel damage, and none have found a significant association between these factors unlike in many other psychiatric disorders in late life including bipolar disorder and major depression. Finally, machine learning algorithms using normative data to estimate an individual's brain age found accelerated brain aging in PTSD compared to those without PTSD.

There is even more limited research on brain activity (using functional MRI or other such methods) in late-life PTSD. In midlife, these can be classified into three categories: (1) symptom provocation where participants are shown stimuli related to their trauma, (2) activation tasks where participants are shown negative imagery that is unrelated to their trauma, and (3) affective priming tasks where participants are shown some affective priming stimulus then shown a neutral stimulus where a decision is made (to test priming effects of negative stimuli). In symptom provocation paradigms, participants are read scripts of the traumatic events described in their own words or presented stimuli (images, words, sounds, etc.) related to it and these studies have largely identified mixed findings—amygdala, ventromedial prefrontal cortex (vmPFC), insula, and dorsal anterior cingulate cortex (dACC) hyper- and hypoactivation, but some have also identified hippocampal hypoactivation related to these paradigms. Studies using trauma-unrelated tasks, where participants are shown fearful faces or negative imagery have been more consistent in identifying that in participants with PTSD, compared to those without, there was hypoactivation of the vmPFC, rostral ACC, and dorsal ACC as well as hyperactivation of the amygdala. Using affective priming tasks, researchers have found that individuals with PTSD have hyperactive amygdala compared to trauma-exposed participants and non–trauma-exposed participants, but other regions have not been consistently identified (hyperactive insula, rostral ACC, vmPFC, and hippocampus).

There are three prevailing models related to PTSD brain activity. The functional neurocircuitry model posits that a hyperactive amygdala contributes to heightened processing of threatening stimuli and is combined with a hypoactive PFC (vmPFC, ACC, medial PFC) that contributes to persistent fear of trauma and nontrauma stimuli, which is all further combined with a hypoactive hippocampus that prevents adaptive fear learning and extinction. The triple network model posits a hypoactive executive control and default mode network and a hyperactive salience network resulting in impoverished cognitive function combined with deficits in self-referential processing (e.g., heightened rumination) and worsened processing between those networks (salience network). The dissociative subtype model posits that individuals with PTSD and chronic dissociation have hyperactivity in the midline prefrontal, dACC, and limbic regions that underlies states of detachment and depersonalization from their emotional experiences. These models have been developed on

midlife PTSD and they do not take into account the age-related effect of white matter deterioration and cortical thinning. More data is needed to integrate these models as it relates to late-life PTSD.

Generalized Anxiety Disorder

In recent years, there has been an increased interest in the neural mechanisms of late-life GAD. There are now several studies that explore cortisol, inflammation, neurotrophic factors, hormones, and brain structure and function.

In late life, GAD is associated with elevated levels of cortisol when compared with non-GAD participants. In addition, elevated levels of worry are also associated with levels of cortisol regardless of the categorical diagnosis. Response to treatment with escitalopram in individuals with late-life GAD was associated with lowered levels of cortisol that correlated with lowered levels of worry. In another late-life GAD study, response to cognitive behavioral therapy in addition to escitalopram or escitalopram monotherapy alone was associated with lowered levels of cortisol.

Both animal and human studies have shown that anxiety is associated with an increase in cell-mediated immune activity and inflammation. In a large study, participants with varying anxiety disorders in late life (including GAD, panic disorder, and social phobia) had greater levels of proinflammatory cytokines compared to those without anxiety after adjusting for other factors including depression. Other studies have found that late-life GAD is associated with greater levels of CRP, TNF-α, homocysteine, fibrinogen, and IL-6). There are several behavioral factors that may explain some of these differences including diet, lifestyle, and substance use in addition to autonomic differences like heart rate, blood pressure, vasoconstriction, and platelet aggregation. These factors may also help explain differences in risk for cardiovascular and cerebrovascular diseases. Inflammation has been shown to be involved in hippocampal neurogenesis, reduced BDNF expression (which has also been shown in late-life GAD), and potentiation of both glutamate neurotoxicity and amyloid formation.

Estradiol may be another important factor involved in the increased incidence of GAD later in life. Studies have shown that during menopausal transition, hormone levels mediated increased levels of anxiety. Panic attacks worsen during menopause and, in one study, women randomized to oral estrogens showed improved depression and anxiety over 4 years.

Studies have shown that estradiol modulates fear learning and extinction, as well as the activity in both the amygdala and vmPFC. Of note, one prospective study in postmenopausal women showed no association between hormone therapy and anxiety.

Several imaging studies have identified neuroanatomical correlates of late-life GAD using MRI. These studies have largely found that individuals with GAD, compared to those without, had lower volumes in the dorsolateral prefrontal cortex (dlPFC), orbitofrontal cortex, inferior frontal gyrus, supplemental motor area, dorsal ACC, hippocampus, middle and superior temporal gyrus, rostral and pregenual ACC, amygdala, and putamen. In addition, worry severity has been independently associated with lower limbic, medial temporal cortex, and prefrontal regions of the brain, regardless of diagnosis. In another study, GAD was associated with reduced cortical thickness in the entire prefrontal cortex. In addition, one study found that greater pretreatment left dorsal ACC volumes was associated with greater improvement of worry in participants with late-life GAD treated with citalopram. There are some conflicting findings that show greater orbitofrontal cortex, ACC, amygdala, and dorsomedial PFC volumes in late-life GAD compared to older adults without GAD. More recently, one study identified that individuals with higher worry and rumination in late life had more advanced brain age, a marker of accelerated aging. The authors put forth a model where repetitive negative thoughts (worry and rumination) may be neurotoxic to the gray matter, though longitudinal studies will be needed to confirm the causal nature of this association.

Individuals with late-life GAD had lower fractional anisotropy in the uncinate fasciculus and middle cingulum. Another study found that greater worry severity was associated with lower mean diffusivity in the prefrontal cortex. Both studies indicate some deterioration of white matter in tracts salient for emotion regulation in mood and anxiety disorders. One study, however, failed to identify any differences between older adults with and without GAD using diffusion imaging.

Unlike mood disorders, studies on white matter hyperintensities have failed to identify any direct association with late-life GAD (similar to late-life PTSD). One study did find that greater activation of the limbic cortex during emotion reactivity did indirectly tie white matter hyperintensities to late-life worry; they found that greater white matter hyperintensities were significantly correlated with lower vmPFC and higher amygdala activation

during emotion reactivity, which were associated with greater worry severity. Thus, white matter hyperintensities may modify neural activity, which in turn may affect late-life symptoms of anxiety.

In fMRI studies, authors have utilized both emotion reactivity and emotional Stroop tasks. During an emotional Stroop task, one study identified lower activation in the orbitofrontal cortex, dlPFC, and superior frontal gyrus in late-life GAD participants. During emotion reactivity, one study was able to show that greater worry was associated with lower activity in the medial PFC and precuneus/posterior cingulate, while greater global anxiety was associated with greater activity in the visual cortex, parahippocampus, hippocampus, precuneus, and posterior cingulate. These studies show dysregulated limbic systems and attenuated prefrontal systems that fail to regulate worry.

Using arterial spin labeling, some studies have identified alterations in cerebral blood flow using worry-specific scripts. One study found that older nonanxious participants had greater blood flow during worry induction in the insula, amygdala, and temporal– occipital cortex, while older anxious participants did not show increased blood flow in the amygdala and insula. Using a similar paradigm in another study, they additionally found that worry induction activated the visual cortex, thalamus, caudate, and medial frontal cortex, and participants with GAD had greater blood flow in the visual and parietal cortex and middle and superior frontal gyri. They also found that the thalamus increased in activation with subsequent worry induction during the paradigm. The authors identify three major hubs of worry: emotion generation (dACC, SMA, visual cortex), a subcortical process that maintains worry (amygdala, insula, hippocampus, caudate/thalamus), and regions related to emotion regulation (supplemental motor area, vmPFC, and dACC).

Another feature is altered connectivity during resting state and worry induction. One study showed hyperconnectivity in the default mode network in participants with GAD compared to those without GAD. During reappraisal of worry, nonanxious individuals showed greater mPFC to the insula and dlPFC connectivity, while those with GAD had greater paraventricular–amygdala connectivity. After treatment with citalopram, individuals with GAD had normalized connectivity patterns similar to participants without GAD. A more recent analysis also showed an inverse U-shaped association between worry and limbic–PFC connectivity, where this connectivity is maximized with moderate levels of worry.

In conclusion, these studies indicate a complex neural network supporting the GAD psychopathology, with some specific structural changes driven by older age.

Other Anxiety Disorders

Older adult female social anxiety disorder (social phobia) patients in one sample showed greater hemodynamic responses, cardiac vagal attenuation, and sympathetic vasomotor activation than those without social anxiety disorder (social phobia) in response to a public speaking challenge. Older adults with specific phobias show greater and longer-lasting cortisol response to stress than nonanxious older adults. Older adults with depression and comorbid anxiety disorders show greater memory declines over time than those with depression alone.

Genetic Factors

Anxiety disorders have been found to have a 30% to 60% heritability in twin studies. In genome-wide studies and meta-analyses, there are several studies that have focused on genetic factors associated with anxiety disorders, but there is fairly limited research on individual diagnoses. These studies have found shared genetic risk factors with neuroticism, depression, and antidepressant treatment response. BDNF receptor gene, NTRK2, has been identified as a potential genetic marker of anxiety, which has also been implicated in autism, suicide, AD, insomnia, coronary artery disease, and alcohol dependence. NTRK2 and BDNF are thought to regulate short- and long-term potentiation of brain synapses. In one meta-analysis, the transmembrane protein 106B (TMEM106B) was associated with anxiety disorders—a single-nucleotide polymorphism (SNP) within the region coding for the calmodulin-lysine N-methyltransferase (CAMKMT) was associated with anxiety, which acts in the formation of trimethyllysine in calmodulin, the gene encodes the protein methyltransferase is involved in calcium-dependent signaling.

In a case-control design, GAD was associated with the short allele of the 5-HTTLPR, which codes for the serotonin transporter and has been widely implicated in several psychiatric disorders, including depression. Comorbid depression and GAD have been associated with the minor G allele of the functional 5-hydroxytryptamine receptor 1A (5-HT1A), conferring diminished serotonergic signaling. Case-control studies have also identified genes associated with monoamine oxidase A (MAOA,

involved in the deamination of neurotransmitters including dopamine, norepinephrine, and serotonin), neuropeptide S receptor (NPSR1, which is involved in arousal and has anxiolytic effects), catechol-O-methyltransferase (COMT, which degrade neurotransmitters like dopamine, norepinephrine, and serotonin), and corticotropin-releasing hormone receptor 1 (CRHR1, which binds corticotropin-releasing hormone—involved in stress). There is also some evidence that anxiety is associated with shorter telomere lengths, indicating accelerated processes of aging.

All these studies were done on midlife anxiety; thus, it is less clear how they extrapolate to anxiety in late life.

DIFFERENTIAL DIAGNOSIS

The most common differential diagnoses are medical conditions and depression. In primary care or specialty medical settings, somatic symptoms of anxiety may be difficult to distinguish from those of cardiovascular, endocrine, gastrointestinal, metabolic, neurologic, or pulmonary disorders or from the effects of medications, including antihypertensives, β-agonists, corticosteroids, digitalis, nonsteroidal anti-inflammatory drugs (NSAIDs), and thyroid medication. A workup to identify medical conditions that may be contributing to anxiety in older adults should comprise a complete medical history and physical examination, and laboratory tests, including complete blood count, thyroid function, levels of electrolytes, vitamin B_{12}, and folate. It should be noted, however, that anxiety can coexist with medical conditions and may lead to excess disability and, potentially, exacerbation of the medical condition itself. Treatment of anxiety as a co-occurring disorder may be appropriate, particularly when the medical condition is stable.

Several symptoms of major depression and GAD overlap (e.g., irritability, decreased concentration, sleep changes, and fatigue), and rates of comorbid anxiety disorders are as high as 40% to 50% in samples of depressed older adults presenting to mental health clinics. Abuse of opioids and benzodiazepines—often comorbid with anxiety disorders—is becoming increasingly more common in older adults. Cognitive disorders may also complicate diagnosis, especially in patients with dementia, where irritability, anger, and agitation are more common.

Other differentials include bipolar disorder in hypomanic phases, especially for patients with irritable mood, insomnia, difficulties concentrating, and racing thoughts. The differential is made more difficult by the relatively high rates of comorbidity (lifetime prevalence of any anxiety disorder in bipolar disorder is 43% to 45%). Among the modalities available to differentiate clinically are a past history consistent with bipolar disorder, alternations between the hypomanic clinical presentation and depression, and the distinct quality of thought process. Thus, racing thoughts in hypomania/mania follow a tangential/flight of ideas process, while racing thoughts in anxiety are usually perseverative on specific negative themes. Rarely, patients with delusional disorders may be initially misdiagnosed as GAD, given their intense preoccupations and "worries" related to selective themes.

Specific training about anxiety disorders for geriatric mental health providers can boost recognition rates, especially in depressed older adults. Table 55.3d–2 summarizes differences in the typical presentation of depression and anxiety in older adults. Because anxiety typically develops before depression and follows a chronic rather than episodic course, questions about symptoms such as worry, feeling tense or nervous, or finding it difficult to relax at times when the individual was not depressed may clarify whether a depressive episode is superimposed on a pre-existing anxiety disorder. Neurocognitive screening tools may also help to identify underlying cognitive impairment.

COURSE AND PROGNOSIS

The course of anxiety disorders in older adults is typically chronic, with frequent relapse and uncommon remission. Prognosis is often poor; recent investigations have found higher mortality risk associated with generalized anxiety and PTSD symptoms, and panic attacks, even after controlling for medical factors and depression. This is worsened as some patients are reluctant to take medications for long intervals of time, thus making relapse common. Patients may turn to alternative treatments with low success.

With respect to specific anxiety disorders, GAD may be characterized by periods of remission and relapse occurring over decades but with longer symptomatic periods in older than in younger adults. One influential view holds that late-life GAD and depression exist on a continuum, with

GAD representing the mildest form of the disorder and comorbid GAD and depression representing the most severe syndrome. Providing more support for the hypothesis that GAD and depression exist on a continuum, one epidemiologic study found that only 12% of individuals with GAD at baseline continued to have GAD without major depression at a 3-year follow-up. Almost half (48%) had remitted, and 40% went on to develop major depression, either with or without comorbid GAD. Ten-year follow-up data from the same study indicated that excess mortality was associated with depression in men but not in women; GAD, either with or without comorbid depression, was not associated with mortality. A 40-year follow-up of individuals retrospectively diagnosed with GAD found evidence that the disorder may convert to a somatoform disorder over the lifespan. There is mounting evidence that GAD may be associated with greater cognitive decline and greater conversion to AD from mild cognitive impairment, which we discuss later in this chapter.

Table 55.3d–2.
Characteristics of Depression and Anxiety in Older Adults

Typical Presentation	Depression	Anxiety
Somatic symptoms	Vegetative (e.g., poor appetite, fatigue)	Autonomic (e.g., palpitations, dizziness, gastrointestinal distress)
Activity level	Typically psychomotor retardation	Agitation or subjective feeling of restlessness
Enjoyment of life	Diminished	Not diminished, but patient may claim that they have no time to enjoy life
Sleep disturbance	Early-morning awakening	Difficulty falling or staying asleep
Thought content	Rumination about past losses or failures, suicidal ideation	Worry about current or future threats or dangers
Behavior	Decreased activity	May exhibit excessive activity (e.g., cleaning, taking on too many projects or responsibilities)
Family relationships	May be isolated or disconnected from family	May be overinvolved or intrusive with family
Social networks	Diminished	Often not diminished, may hide symptoms from network
Onset	May have early or late onset	More typically early onset
Course	Episodic	Chronic
Attribution	Patient may believe that symptoms are part of normal aging	Patient may believe that symptoms are part of their personality or a

	or a natural response to life events	natural response to life events

A 50-year follow-up study of OCD patients found remission rates of approximately 60%. By contrast, a 50-year follow-up of panic disorder patients found only 6% of patients not meeting the criteria for any psychiatric disorder at the final assessment point. In this study, the prevalence of panic disorder with and without agoraphobia began to decline after approximately age 40 years, whereas the incidence of somatoform disorders and agoraphobia without panic rose steadily from age 20 through 60 years and then leveled off. Although PTSD symptoms are most prominent immediately after the trauma, they can persist for decades, and some evidence suggests that they may emerge for the first time or increase in later life, especially in the context of cognitive decline. Late-life PTSD is associated with an increased risk of major cardiovascular events and all-cause mortality, as well as all-cause dementia, including AD, vascular dementia, dementia with Lewy bodies, and frontotemporal lobe dementia. PTSD has also been associated with an increased risk of suicide. Late-life PTSD is often underrecognized and undertreated.

Consequences

Consequences of anxiety disorders include activity limitations, higher numbers of general practitioner and home health visits, loneliness, poor life satisfaction, poor perceived health, worse cognitive function, and perceived lack of help. Older GAD patients report poorer role functioning, social functioning, and energy levels than individuals with other chronic conditions such as heart disease and diabetes. Anxiety, especially GAD and its cardinal symptom, severe worry, has been associated with worse cognitive decline compared to those without GAD or low worry. In one 3-year longitudinal study, people with Mild Cognitive Impairment (MCI) and worry had a fivefold increased risk of AD compared to those with just MCI. In general, anxiety increases the risk of developing major depressive disorder as well, including in older adults. Older adults with PTSD, even in the absence of depression, experience more days spent in bed and days with limited activity and lower levels of life satisfaction than those without PTSD after controlling for factors including age, chronic diseases, functional limitations, social network size, and cognitive functioning. They

also make more visits to mental health providers and have higher rates of benzodiazepine use. The 2013 State of Health report in the United States listed anxiety as one of the four diseases with the largest number of years lived with disability.

In nursing home patients, anxiety disorders and depression are associated with lower levels of well-being, although not necessarily with higher levels of disability. Patients with depression, either alone or combined with anxiety, report lower levels of well-being than patients with pure anxiety. Individuals with anxiety and/or depression receive less assistance with activities of daily living, make more visits to medical specialists, and take more medications, especially antidepressants. The use of antidepressants is typically more common in patients with combined anxiety and depression relative to others. Patients with anxiety make more visits to medical specialists than those without anxiety or depression.

Anxiety and Dementia

While late-life depression is well-known to play a major role in incident cognitive decline, incident dementia, and conversion from MCI to AD, there is increasing interest in anxiety as a prodromal factor associated with dementia. Over the last decade, several studies have shown that both GAD and PTSD are associated with dementia. Anxiety is the most common neuropsychiatric symptom (NPS) in dementia.

In a meta-analysis, the authors reported that anxious participants showed a decline in executive function over time but not in memory when compared to those without anxiety. The authors also verified that anxiety was associated with incident cognitive impairment and dementia. PTSD has also been associated with incident dementia (including AD, vascular dementia, frontotemporal lobe dementia, and Parkinson disease). One study showed that AD and vascular dementia increased the risk for delayed emergence, re-emergence, and worsening of PTSD symptoms.

The direction of the relationship between anxiety and dementia remains a matter of debate, given the paucity of longitudinal studies using adequate anxiety measures and following up participants for a long enough time to detect subtle cognitive changes. The “anxiety as prodrome” hypothesis posits that anxiety symptoms are triggered by the awareness of worsening cognitive functioning. These tend to decrease as neurodegenerative processes advance as a consequence of more

advanced cognitive dysfunction. The “anxiety as a risk factor” hypothesis posits that chronic anxiety and worry convert the immediate psychological and physiologic responses to daily stressors into prolonged physiologic activation of the regulatory systems, which produces moderate but chronic levels of activation of the cardiovascular, HPA, and immune systems. Thus, anxiety is correlated with higher levels of stress, cortisol, BDNF, proinflammatory factors, and heart rate/blood pressure. In a large study, anxiety was associated with higher levels of proinflammatory cytokines adjusting for depression, lifestyle factors, and demographic factors. Several studies have shown that inflammation is associated with worse cognitive performance and cognitive decline, including dementia. Anxiety is also correlated with higher levels of cortisol, and there is evidence that glucocorticoid overstimulation in the medial temporal lobe is associated with hippocampal atrophy and cognitive dysfunction. There are several studies that show anxiety is independently associated with lower levels of BDNF, which is associated with lower levels of synaptic plasticity important in learning, memory, and neuronal repair. Greater anxiety has also been correlated with greater deposition of amyloid and tau, an association that may be mediated by inflammation and increased cortisol. In animal models, administration of cortisol was associated with increased depositions of amyloid and tau. In a longitudinal study, participants with anxiety and significant amyloid depositions had a more rapid cognitive decline. In another study, APOE ε4 allele carriers who had significant amyloid depositions in the brain were more likely to have more severe anxiety, especially among women. Finally, anxiety is associated with greater cardiovascular disease, cerebrovascular disease, and vascular dementia—this may be driven by increased, blood pressure, vasoconstriction, and platelet aggregation commonly associated with anxiety.

Anxiety as a Risk Factor for Other Medical Conditions

Anxiety may also serve as a risk factor for common medical conditions of later life. Studies have reported an increased risk of vascular problems, respiratory disease, chronic pain, gastrointestinal conditions, and cancer associated with PTSD.

Substantial evidence links anxiety to heart disease and stroke. GAD is independently associated with a higher risk of overall mortality, stroke, cardiovascular mortality, heart failure, and coronary heart disease

independent of other risk factors, including depression. Symptoms of phobic anxiety may predict the onset of ventricular arrhythmias in patients with coronary artery disease. GAD, panic attacks, and PTSD symptoms lead to an elevated risk of coronary heart disease, even in the absence of major depression. PTSD symptoms are also associated prospectively with nonfatal myocardial infarction. The reported lifetime prevalence of anxiety disorders is considerably higher than the current prevalence of coronary heart disease, suggesting that anxiety might represent a risk factor rather than a consequence of heart disease.

TREATMENT

Anxiety disorders in older adults are frequently undetected and untreated (e.g., one study found that only 36% of patients with late-life GAD received any treatment). Older adults are significantly less likely than younger adults to receive treatment for anxiety and even less likely to seek treatment. When treatment takes place, it usually involves benzodiazepines or other anxiolytic medications rather than antidepressants or psychotherapy. Treatment response rates tend to be worse in older adults compared to younger adults. Several factors may be associated with worse response (e.g., worse cognitive function), but there are also changes in pharmacokinetics (reduced glomerular filtration and hepatic metabolization), which may also increase both side effects and effectiveness. Longitudinal studies have shown recurrence and chronicity rates up to 39% to 52% after 3 to 6 years. For late-life GAD, persistent worry is a significant component of relapse. Older adults tend to prefer psychotherapeutic approaches, though meta-analyses have shown that they are less effective than pharmacotherapies.

Pharmacotherapy

Research on the treatment of anxiety in older adults is limited. Selective serotonin reuptake inhibitors (SSRIs) and serotonin–norepinephrine reuptake inhibitors (SNRIs) are the first-line treatment for late-life anxiety disorders with similar side-effect profiles in younger adults and are relatively well tolerated. Recent evidence suggests that SSRI pharmacotherapy is superior to psychotherapy as an acute treatment for geriatric anxiety. Data from controlled trials support the use of escitalopram (Lexapro), duloxetine (Cymbalta), pregabalin (Lyrica),

venlafaxine XR (Effexor), citalopram (Celexa), and sertraline (Zoloft) for late-life GAD. In a randomized trial, pregabalin was associated with a 2-point greater reduction in overall anxiety, a difference statistically significant although clinically trivial. In general, there are specific potential risks that should be monitored in older adults, including the risk of falls, gastrointestinal bleed, bone loss, hyponatremia, and monitoring of blood pressure in SNRIs (especially venlafaxine). Another study also found that Buspirone was effective and well tolerated in late-life GAD. The antipsychotic Quetiapine has demonstrated efficacy and tolerability both as a monotherapy and as adjunctive therapy to SSRIs, but one study reported multiple side effects, including drowsiness, dry mouth, dizziness, headache, and nausea. Mirtazapine is a popular choice for its effects on sleep and appetite, but the evidence of its efficacy is limited and inconsistent. Tricyclic antidepressants or monoamine oxidase inhibitors (MAOI) may be efficacious; however, they should be considered only for treatment-resistant patients due to their side-effect profiles and safety concerns.

Data are even more sparse with respect to the treatment of other anxiety disorders, but evidence from controlled trials and open-label studies suggests the efficacy of sertraline, citalopram, and escitalopram, as well as of imipramine (Tofranil) and alprazolam (Xanax), for panic disorder in older adults. The SSRIs citalopram, escitalopram, and sertraline may be particularly effective treatments for anxiety in older adults based on their low propensity for drug interactions and short half-lives. Fluvoxamine (Luvox) has demonstrated efficacy in an open-label trial, including older patients with GAD, panic disorder, or OCD.

For PTSD, only one small open-label pharmacotherapy study has been conducted in adults with a mean age greater than 60 years, and studies with mean ages of 50 years or older have veteran samples comprised almost exclusively of men. Randomized, controlled trials in this age group support the use of sertraline and mirtazapine, and an open-label trial supports the efficacy of citalopram. Prazosin may improve sleep quality and PTSD-related nightmares; its impact on other PTSD symptoms is less clear.

Benzodiazepines are often the only mental health treatment received by older adults with anxiety disorders, and they are prescribed more frequently to older adults than to younger adults. Although benzodiazepines are effective in reducing anxiety and may be useful as

an adjunctive, as-needed, or short-term treatment strategy, long-term daily use is associated with falls, fractures, addiction/misuse, and cognitive decline in older adults. Among benzodiazepines, lorazepam has a relatively short half-life and no active metabolites and is, therefore, preferable to alprazolam or clonazepam, which are more likely to accumulate and achieve toxic levels in older adults. Benzodiazepine taper should be very gradual in older adults, even after a short duration of use.

Overall, in anxiety disorders, the focus of research on pharmacotherapy has shifted from serotonin and norepinephrine pathways to other neurotransmitters such as glutamate, GABA, and neuropeptides. Ketamine, riluzole, oxytocin, neuropeptide Y, psilocybin, and others have been studied for GAD or PTSD. None have been tested in older populations.

Comorbid Anxiety and Depressive Disorders. Older adults with depression and comorbid anxiety disorders or significant anxiety symptoms typically demonstrate a delayed acute treatment response and increased risk of relapse of depression. Older adults with depression and concurrent anxiety symptoms require 50% more time to respond to antidepressants and are more likely to discontinue treatment. Anxiety symptoms often persist after treatment and remission of depression, increasing the risk for depressive relapse. They may also report more suicidal ideation. In one study of older primary care patients, suicidal ideation increased by 8% in the presence of anxiety disorders (compared to no anxiety disorders) and by 18% in the presence of comorbid depression and anxiety. For these reasons, it is especially important to treat older adults with depression and coexisting anxiety to complete remission. Open-label trials support the potential utility of escitalopram for comorbid depression and GAD in older adults. Both anxiety and depression are associated independently with worse cognitive function, which is associated with treatment resistance in anxiety and depression.

Augmentation and Maintenance Treatment. No randomized trials have tested augmentation strategies with anxious older adults who fail to respond to first-line treatment. A group of older adults with anxiety disorders (mostly GAD) who did not respond to an initial trial of an antidepressant or benzodiazepine responded to adjunctive risperidone (average dose 1.2 mg per day).

Although data suggest the continued efficacy of citalopram for GAD after 24 weeks of treatment, with an additional 20% of patients responding in the second 12 weeks, no research has examined maintenance therapies for late-life anxiety. Given the chronic course of anxiety disorders and their association with relapse of depression, studies on this topic should be a high priority.

Clinical Management. Because SSRIs may initially exacerbate symptoms of anxiety, older adults should be started on a low dose (Table 55.3d–3). In clinical practice, however, older adults with anxiety or depression are frequently maintained on minimum or even subtherapeutic doses, with corresponding limited benefits. If the patient is tolerating the medication, the dose should be increased at least to the minimum target dose within 4 weeks. If the patient has not made a full response (e.g., achieved at least a 50% decrease in symptoms) within another 4 to 6 weeks, the dose should be gradually increased, with continued increases up to the maximum until a response is achieved or the patient is no longer able to tolerate the medication.

Table 55.3d–3.
Usual Starting, Minimum Target, and Maximum Dose of Commonly Used Antidepressant Older Adults With Anxiety Disorders

Medication	Starting Dose (Total mg/day)[a]	Minimum Target Dose (Total mg/day)	Maximum Dose (Total mg/day)[b]
Citalopram	10	20	20[c]
Escitalopram	5	10	20
Sertraline	12.5–25	50	200
Fluvoxamine	25	100	300
Venlafaxine XR	37.5	75	225
Mirtazapine	7.5	15	45
Duloxetine	20–40	60	120
Pregabalin[d]	75–150	300	600
Buspirone[d]	15	30	60
Quetiapine[d]	25–50	50	300

[a]Older anxious patients should be started on the lowest available dose and titrate slowly (increments q5–7 days) to avoid side effects. Use of liquid form is recommended, when available, to start at very low doses.

[b]Higher doses are sometimes used on a case-by-case basis; lower doses are often used in the oldest old.

[c]The U.S. FDA revised recommendations for citalopram: maximum recommended dose is 20 mg/day for patients older than 60 years of age.

[d]Divided BID/TID.

Older adults with anxiety are frequently more resistant to the idea of pharmacotherapy and more sensitive to side effects than younger adults with anxiety or older adults with depression, sometimes attributing to the drug symptoms that preceded the initiation of a medication trial. Therefore, the specific agent may be less important than good clinical management, including information about the safety and nonaddictive potential of the medication, reassurance about the transient and noncatastrophic nature of side effects, availability of the physician at any

time in the event of bothersome symptoms, and frequent visits initially (ideally weekly for the first month and biweekly thereafter until a response is achieved). Patients may need continued reassurance at every dose change and, in the event of emergent side effects, should be encouraged to stay the course for at least 1 or 2 weeks. Clinicians may need to think creatively to facilitate this process, for example, by suggesting that patients split the dose between morning and evening administration or take over-the-counter medications temporarily to counteract side effects.

Psychotherapy

Some evidence suggests that SSRI medications may be more effective than psychotherapy as an acute treatment for late-life anxiety disorders. Research, mostly with older GAD patients, provides support for the effectiveness of cognitive behavioral therapy (CBT) relative to a waiting list and active control conditions such as supportive therapy and attention placebo. One study has demonstrated the superiority of CBT to supportive psychotherapy in a well-characterized sample of older adults with anxiety disorders (52% with panic disorder), and all participants in this investigation were taking medications but had failed to respond prior to receiving psychotherapy. Response to CBT for GAD in older adults may be compromised by memory impairment, executive dysfunction, or failure to complete at-home practice. A recent study has demonstrated that the sequence of antidepressant medication augmented with CBT in older adults with GAD leads to worry reduction in the short term. This study also found that both maintenance medication and CBT could prevent relapse compared with a placebo, providing two strategies for improving outcomes in GAD in older adults.

For older individuals who refuse to take medications or for whom they are contraindicated, relaxation training may be the most effective component of a behavioral treatment for GAD or distressing anxiety symptoms that do not meet the criteria for a specific anxiety disorder. Recommending a good relaxation tape with breathing or meditation exercises, progressive muscle relaxation, or imagery may be helpful; if, after a few weeks of practice, the patient does not report sufficient gains, it may be worthwhile to reopen a discussion about medications. One study showed that for older patients, relaxation therapy might be the most efficacious aspect of CBT. While older adults can learn and effectively use reappraisal, this may be more challenging in a population with diminishing

cognitive abilities. Mindfulness-based stress reduction has also been shown to reduce anxiety symptoms in older adults, even showing preliminary efficacy in individuals with cognitive dysfunction. Finally, acceptance and commitment therapy has shown improvement in worry severity in late-life GAD.

For anxiety disorders other than GAD, some evidence supports the use of CBT for panic disorder in older adults, although results from a study that included a substantial proportion of older panic disorder patients suggest the superiority of sertraline over CBT. There are no published data beyond case reports documenting the behavioral treatment of specific phobias or OCD, all of which use exposure-based protocols, and no data on the treatment of older adults with agoraphobia without panic disorder or social anxiety disorder (social phobia). Case reports of PTSD treatment in older adults have described gains associated with psychodynamic and supportive approaches, CBT, eye movement desensitization and reprocessing life review, and exposure therapy. A pilot study of prolonged exposure therapy in older veterans with PTSD showed a significant decrease in their symptoms of PTSD.

Recommendations specific to late-life anxiety include (1) ensuring that sufficient time is devoted to learning skills such as relaxation training; (2) practicing skills multiple times in a session to ensure that the rationale and procedures are well understood prior to assigning at-home practice; (3) ensuring that anxiety levels become sufficiently high during exposure exercises, which may be facilitated by, for example, having patients hyperventilate briefly before engaging in imaginal exposure; (4) not avoiding difficult or painful issues or worries if appropriate (e.g., imaginal exposure to issues surrounding an ill spouse's death); (5) de-emphasizing more abstract cognitive restructuring techniques in favor of simpler strategies (e.g., coping statements); and (6) between-session reminder phone calls and weekly review of concepts. There is also some evidence that incorporating religious or spiritual themes may also help, especially in older Black individuals.

Mrs. H was a 69-year-old married White woman with a college degree. She reported that she was “always a worrier” but believed that she was acting in the best interests of her family by looking out for their well-being. She indicated that her worrying had caused problems within her family; for example, her daughter was annoyed with Mrs. H for sending her classified ads and articles about employment resources to encourage her to find a new job. She further stated that her concern about her children led her to telephone them daily, and she had once contacted the police when her call was not returned by the next day.

In addition to worrying about her children, she indicated that she was concerned about her husband’s health, finances, and her health, particularly her recent diagnosis of gastroesophageal reflux disease. Although she believed that her worry was normal under the circumstances and she was resistant to the idea of taking medication, she indicated that sleep disturbance, fatigue, and difficulty concentrating were making it difficult for her to accomplish daily tasks.

Mrs. H was started on 50 mg per day of sertraline but called the psychiatrist’s office after 3 days to report that she had discontinued the drug after experiencing an upset stomach and a burning sensation in her throat. She agreed with the doctor’s recommendation for her to restart the medication at a reduced dose of 25 mg per day and to take chewable calcium tablets as often as needed. He called her back 2 days later to inquire about the success of this strategy. Although Mrs. H reported that the symptoms continued, she agreed to continue the medication for another week until her next scheduled appointment. At that point, she was unwilling to consider raising the dose but agreed to stay the course for another 2 weeks, at which point she reported that the side effects were “unpleasant but manageable” and reluctantly agreed to try 50 mg per day. Over the next 3 months, her dose was gradually increased to 200 mg per day, with diminishing side effects. Mrs. H reported that although she continued to worry about her family, the thoughts were less distressing, and she was sleeping better and had more energy.

Mrs. P was an 82-year-old Black woman whose daughter brought her to the clinic out of concern that she was depressed. Although Mrs. P lived independently and had been sleeping and eating well, she had refused to leave her home unaccompanied since experiencing a noninjurious fall 3 months before the appointment. She denied feeling sad and reported that she enjoyed watching television, listening to music on the radio, and having family and friends from her church visit her in her home. She stated that although she used to take walks for exercise and do her grocery shopping at the corner market, she now experienced considerable anxiety about not having help available should she fall outside of her home. Her family was trying to decide whether she should come to live with one of her children. Because of her strong preference to continue living on her own, she agreed to come to the clinic for an evaluation.

After consulting with her physician, who reported that she did not have orthostasis or other medical conditions increasing her risk of falling, the psychiatrist decided first to have Mrs. P evaluated by a physical therapist, who tested her gait and taught her to use a cane. Although Mrs. P reported that she was using the cane to feel more secure within her home, she continued to avoid unaccompanied trips outside of her home. She was then referred to a psychologist for behavioral treatment.

Mrs. P and the psychologist collaboratively developed a hierarchy of situations involving exposure to trips outside of the home that varied in duration, distance, and availability of family members for support. Her family was enlisted to help with the treatment by initially being available by telephone while she was engaged in an exposure. As treatment progressed, she was “weaned” from making calls to family members immediately before, during, and after her walks. At this point, which took six sessions over an 8-week period, Mrs. P reported that she was able to leave her home alone, taking her cell phone but not using it routinely during every excursion. Treatment was deemed successful and terminated.

Transcranial Magnetic Stimulation

Transcranial magnetic stimulation (TMS) is a safe, effective, noninvasive, and nonconvulsive treatment alternative that has been approved for the

treatment of treatment-resistant depression as well as OCD. Currently, TMS is only FDA-approved for treatment-resistant depression and OCD. For OCD, only high-frequency deep repetitive transcranial magnetic stimulation (dTMS) over the dorsomedial prefrontal and anterior cingulate cortices (dmPFC-ACC) with an H7 coil using the BrainsWay system has been approved. Several studies have shown that this approach can help reduce obsessional ideation. Research aiming to develop other targets, including in the dlPFC, supplemental motor area, and orbitofrontal cortex, is under way.

Studies have shown that in patients with comorbid depression and generalized anxiety, TMS can help improve symptoms of depression and anxiety. However, TMS is not approved for GAD. In a meta-analysis of four studies, it was found that there is consistent evidence that low-frequency stimulation over the right dlPFC reduces anxiety symptoms. There is mounting evidence for the use of TMS in PTSD. In a meta-analysis of nine studies, it was found that high-frequency TMS of the right dlPFC resulted in improvement of PTSD and, in some studies, comorbid depression. There is more limited evidence for the efficacy of TMS in panic disorder and specific phobia. In one randomized, double-blind study, low-frequency TMS over the right dlPFC in patients with panic disorder and depression was associated with a greater response to panic disorder, depression, and social adjustment compared to sham TMS. There is even more limited evidence for a specific phobia, with most studies only looking at changes in biomarkers after a single session of TMS, which is not sufficient to look at treatment efficacy.

In general, TMS is well tolerated and is a promising new approach showing efficacy for GAD, PTSD, and OCD and it may be a well-tolerated option for older anxious individuals. Currently, there are no studies regarding TMS's efficacy and tolerability in late-life anxiety.

FUTURE DIRECTIONS

Anxiety disorders are more common than usually recognized in older adults. In the mental health clinic setting, they are typically seen as a co-occurring diagnosis with depression, although this has changed as public awareness about anxiety and its treatment has grown. Coexisting anxiety and depression typically represent a more severe disorder than depression alone. Because onset is often early in life, older adults with

anxiety disorders have usually experienced a chronic course. Distress and impairment associated with these disorders can be substantial. Data on biologic factors involved in late-life anxiety implicate HPA axis dysregulation and genetic, cognitive, neuroanatomical influences are under investigation. There is also some preliminary evidence regarding altered brain activity and connectivity. SSRI medications appear to represent the first-line acute treatment for geriatric anxiety. Very few maintenance studies have been performed, and more research is needed. Psychotherapy has shown some efficacy in older adults for GAD and panic disorder with promising pilot studies in PTSD and has not been adequately investigated for phobias, including agoraphobia. A focus on anxiety disorders across the life span is needed; one practical step toward this is including older participants in clinical trials within multiple settings, including community and residential facilities.

55.3e Geriatric Mood Disorders

Talya Shahal, M.D., Jennie Davidow, M.D., Jennifer R. Gatchel, M.D., Ph.D., and Brent P. Forester, M.D., M.Sc.

Geriatric mood disorders cause suffering, increase the medical burden, worsen the outcomes of many medical conditions, and contribute to disability. Depression increases the risk of obesity, frailty, diabetes, cognitive impairment, and mortality. Investigators at the World Health Organization concluded that depression produces a greater decrement in health than angina, arthritis, asthma, and diabetes. This finding holds across countries and demographic characteristics. The complexity of geriatric mood disorders and comorbid medical illnesses requires coordination of care among health professionals and continuity of care. Moreover, the behavioral disability of persistent geriatric mood disorders often requires expensive support systems. Outpatient costs of depressed older adults were found to be about 50% higher compared to nondepressed older adults, even after adjustment for medical comorbidities.

Despite the availability of relatively efficacious treatments, geriatric depression continues to be underdiagnosed. The failure to recognize geriatric depression stems from the clinical complexity of the syndrome, symptom overlap with medical comorbidities, social bias, and barriers in the settings in which most depressed older adults are treated. Depression in older individuals does not have pathognomonic symptoms or signs. Older adults are more likely to describe somatic symptoms as their primary concern, such as those related to sleep, fatigue, decreased appetite and body weight, gastrointestinal distress, pain, hypochondriasis, and exhibit psychomotor slowing or agitation, as well as cognitive symptoms such as deficits in memory, concentration, processing speed, and executive functioning. Many of the symptoms of depression (e.g., loss

of interest, lack of energy, loss of appetite, and sleep problems) can be caused by medical illnesses. Moreover, depressed patients often have several chronic medical illnesses, which makes it difficult to determine whether a symptom is caused by depression, a medical illness, or both. Depressive disorders and medical illnesses frequently co-occur, share symptoms, and often have a bidirectional risk relationship–a depressive disorder is associated with poor health, and many medical illnesses are associated with an increased risk for a depressive disorder. In addition, depressed older adults often experience anhedonia (depression without sadness) or irritability rather than a depressed mood, which can be difficult to ascertain during a brief examination.

Although the prevalence of major depressive disorder (MDD) among older adults is lower compared to younger adults, older adults have higher incidence rates of other depressive disorders (i.e., minor, subsyndromal, or subthreshold depression, dysthymia, or adjustment disorder with depressed mood). Subthreshold depression syndromes are associated with a greater odds of lifetime psychiatric disorders and of developing a MDD or an anxiety disorder in subsequent years. In addition, subthreshold depression syndromes also cause significant impairment and decreased quality of life, such as increased disability, morbidity, and mortality. This underscores the importance of detecting and aggressively treating subclinical depressive syndromes in older adults. Depression in older adults is associated with a worse trajectory compared to younger adults, likely moderated by depression severity, number of previous episodes, and medical comorbidity. Additional risk factors for a poor depression outcome are older age, severe depression at baseline, comorbid dysthymia, and younger age of onset. Older adults who experience social isolation are at greater risk for increased morbidity, diminished immune function, depression, and cognitive decline. Loneliness specifically has been linked closely to depressed mood, decreased well-being, and higher mortality.

Ageism among patients and health professionals may lead to diagnostic complacency based on the view that older individuals who lose their physical prowess and social status have valid reasons to be depressed. Two-thirds of depressed older adults are treated in busy primary care offices. Such settings are geared to acute care of medical problems creating barriers to effective diagnosis and referral to mental health treatment. In addition, many older adults are reluctant to receive mental

health treatment, which may be related to high levels of perceived public stigma toward mental illness as well as negative attitudes toward mental health treatment. Furthermore, racial and ethnic minority older adults often experience a greater burden of unmet mental health needs related to patient, provider, and health care system barriers. Shortages in the geriatric and geriatric psychiatry physician workforce exacerbate access to mental health treatment.

Incorrectly attributing physical symptoms to depression may lead to premature discontinuation of standard medical assessment and failure to identify a medical cause for physical complaints. Although late-life depression is underdiagnosed, many nondepressed older patients receive antidepressants. Inappropriate use of antidepressant medication may increase the cost of care and lead to adverse side effects or drug interactions. To address these issues, the collaborative care model seeks to improve the quality of assessment and treatment of depression in primary care settings. In this model, the behavioral health team, consisting of a behavioral health support specialist and supervising psychiatrist, deploys standardized assessment and measurement-based care within a primary care setting. Nearly two decades of research have demonstrated that the implementation of a collaborative care model in primary care practices across various healthcare systems leads to substantial clinical improvement of depression and anxiety in older adults and an overall reduction in healthcare costs.

The past decade has witnessed an acceleration of the understanding of the neurobiology of late-life mood disorders. Future studies designed using the NIMH Research Domain Criteria (RDoC) guidelines will hopefully identify critical neurobiologic targets paving the way for novel pharmacotherapy, and psychotherapy treatment approaches for late-life mood disorders.

EPIDEMIOLOGY

The National Comorbidity Survey Replication discovered that the overall prevalence of major depression among persons aged 65 years or older was estimated to be 1.5% in women and 0.2% in men, with an overall prevalence of 1%, approximately one-fourth of that in younger adults. Recent data identified MDD in 1% to 5% of community-dwelling older adults and 6.5% to 9% of the patients treated within primary care clinics.

However, when combining symptoms of major or minor depression with reported treatment for depression, the cumulative depression prevalence in later life is noted to be as high as 11.19%, with similar rates for men (10.19%) and women (11.44%). Further, in this population study of late-life depression, Caucasians and Hispanics had nearly three times the prevalence of depression found in African Americans.

Between 15% and 36% of community-dwelling older adults endorse subthreshold, though clinically significant, depressive symptoms. Subthreshold depression is lower in community settings versus primary care settings and highest in long-term care settings. Approximately 8% to 10% of older adults with subthreshold depression develop major depression per year.

The prevalence of major depression has been increasing in recent birth cohorts compared to cohorts born in the early part of the 20th century. Depression appears to have an increasingly earlier onset in cohorts born in recent years, and there is a narrowing in the differential risk for depression between genders.

Depression frequently occurs in medical populations. For patients treated in primary care settings, depression was identified in 17% to 37% of patients. Approximately 30% of these patients had major depression, and the remainder had a variety of depressive syndromes that could benefit from medical attention. Major depression occurs in roughly 25% of older home care patients, 11% of medically hospitalized patients, and up to 48% of individuals in long-term care settings.

As the world population ages, prevalence rates for older adults with bipolar disorder (BD) are also rising, now estimated to account for 25% of all bipolar patients. While the estimated lifetime prevalence of BD in the U.S. population for individuals aged 60 years and older is 1% to 2%, rates in specific clinical populations vary from 3% of nursing home residents up to 7% of psychiatric outpatients, 10% of psychiatric inpatients, and 17% of individuals presenting for psychiatric treatment in ER settings. Further, approximately 70% to 95% represent cases with onset prior to age 50 years that have persisted into later life. Approximately 69% of late-life bipolar patients are women.

In summary, mood disorders occur in the older geriatric population at a rate lower than that of younger adults. However, significantly higher rates of mood disorders occur in medically ill, disabled, or institutionalized older adults. With the aging of birth cohorts who appear to be at particular risk

for depression, an unprecedented number of older adults are expected to require psychiatric attention.

SUBTYPES OF LATE-LIFE DEPRESSION

Depression in Medically Ill Patients

Geriatric depression typically occurs in the context of medical disorders. Sometimes these conditions predispose or trigger depression. For example, subclinical hypothyroidism increases the risk for depression more than fourfold, while nearly a third of patients develop depression within a year after myocardial infarction. The prevalence of depression is also higher among patients with hypertension. Overall medical severity and disability appear to be important risk factors for depression. For these reasons, geriatric depression is viewed as a heterogeneous entity.

Older adults with chronic disease have a 50% greater risk for depression than older, medically healthy adults. The prevalence rate of depression among patients with chronic disease is up to 50%. Depression frequently occurs due to comorbid medical conditions such as thyroid disease, diabetes, cardiac disease, and other chronic medical conditions and can predict cardiovascular disease and all-cause mortality independently of a wide range of potential confounders. Depression increases the risk of coronary disease by 60% to 80% while also increasing the risk of cancer and a shortened survival time, regardless of cancer etiology. Individuals with malnutrition, metabolic syndrome, and posthip fracture surgery are all at elevated risk of depression. Depression not only is a contributor to hypertension but also may affect the outcomes and prognosis of hypertension and the efficacy of drugs. Data from a large health maintenance organization population suggest that the health care cost of depressed medical patients is twice that of nondepressed patients with similar levels of medical morbidity, though only a small proportion of the increased costs are spent on specialty mental health care.

Depression impairs social function more than heart and lung disease, arthritis, hypertension, and diabetes and leads to greater impairment in physical function than arthritis, hypertension, and diabetes. This effect seems to be mediated through decreasing adherence to treatment, as well as through biologic mechanisms such as changes in sympathetic–parasympathetic balance, changes in serotonin-mediated thrombogenesis, and changes in the immune system.

Depression is underdiagnosed and undertreated in primary care settings. Approximately 11% of depressed high utilizers of primary care services receive adequate antidepressant treatment, whereas 34% receive inadequate treatment and 55% receive no treatment. The pattern of inadequate treatment of depression also extends to long-term care settings, where 23% of nursing home residents diagnosed with depression receive no treatment.

Depression in Patients With Cancer

Among patients with cancer, depressive symptoms are associated with decreased quality of life, significant deterioration in physical activities, relationship difficulties, and greater pain. For older adults, the combined impact of aging and cancer can be devastating, and older adults with cancer have some of the highest rates of completed suicide. Depression among patients with cancer has a negative impact on treatment engagement and adherence. Nevertheless, older adults are far less likely to be accurately diagnosed or treated for depression compared to other age groups, resulting in decreased quality of life, poor treatment adherence, increased length of hospital stay and health service utilization, and in severe cases, suicide. Despite its importance, the area of mental health for older adults with cancer is underdeveloped. Almost half of all cancer patients who have serious depressive symptoms are not treated for these symptoms. This is partially explained by the overlap of depressive symptoms and cancer, cancer treatment-related symptoms, time and resource limitations, and inappropriate normalization of depressive symptoms among people with cancer. A recent study found that a history of depression treatment prior to a cancer diagnosis is significantly associated with the presence of elevated depressive symptoms among older adults with cancer, highlighting the importance of a detailed psychiatric history when evaluating the risk for current depressive syndromes. As there are no empirically validated guidelines that combine best practices for depression management in both oncology and geriatrics, clinicians should work closely with older patients and care partners in order to identify and treat impairing symptoms and to make referrals to psychosocial services when necessary.

Depression in Patients With Dementia

In DSM-5, cognitive disorders are described on a spectrum: mild and major neurocognitive disorders (MaNCD) and their etiologic subtypes. Despite a recent change in nomenclature, the term dementia continues to be used frequently in clinical settings and is retained here for consistency. In patients with mild neurocognitive disorder, depression prevalence is above 30%. The depression prevalence among patients with Alzheimer disease (AD) varies from 5% to 48% based on patient sampling, dementia severity, and diagnostic criteria used. Examination of the interval between the occurrence of depression and the development of dementia suggests that depression may represent an early symptom, risk factor, or prodrome of dementia. A meta-analysis concluded that a history of depression doubles the risk of developing dementia in late life. Depression occurs in approximately 25% of patients with cerebrovascular disease and in up to 50% of those with Parkinson disease. The similarity of depressive manifestations with symptoms and signs of neurocognitive disorders, for example, loss of interest, decreased energy, agitation or psychomotor retardation, poor concentration, and apathy, often poses diagnostic problems. Sad mood and psychic rather than vegetative features have been found useful in distinguishing depressed patients with dementia from patients with dementia alone.

Several studies suggest that AD pathology, amyloid beta (Aβ) or tau, may be associated with late-life depression. Among cognitively normal community-dwelling older individuals without major depression, Aβ burden (measured by positron emission tomography [PET] imaging) was associated with worsening anxious-depressive symptoms over a 1- to 5-year follow-up. Regional tau burden (measured by PET imaging) was also cross-sectionally associated with subclinical depressive symptoms independent of brain amyloid in this community-dwelling sample. Patients with amnestic mild neurocognitive disorder and a history of major depression had higher Aβ deposition, mainly in the frontal cortex, compared to patients with amnestic mild neurocognitive disorder without a history of major depression. Individuals with AD who have a history of depression had a greater amyloid plaque burden in the hippocampus than those without depression. Moreover, one study found evidence that citalopram can decrease Aβ plaques in the brains of mouse models of AD mice and stop the growth or slow the production of pre-existing plaques in AD mouse models and in humans. A recent pilot study found that amyloid status predicted poor antidepressant response among cognitively intact

older adults, suggesting that alternative treatment approaches may be needed for amyloid-positive depressed older adults. However, further investigation, including prospective controlled trials, is needed to understand the relationship between antidepressant medication and AD pathology.

Finally, depression increases the risk of conversion of mild neurocognitive disorder to AD, and long-term treatment with antidepressants delays the conversion of mild neurocognitive disorder to Alzheimer dementia.

Despite these findings supporting depression as a risk factor or prodrome of dementia, there have been contrasting findings among studies. Indeed, a recent study comparing cortical amyloid deposition (measured by PET imaging) in older adults with major depression versus nondepressed cognitively normal older adults found that those with major depression had less Aβ deposition than nondepressed individuals. Aβ deposition was not associated with depression history characteristics in this sample, but it was associated with worse memory performance. These variable findings may, in part, reflect the heterogeneity of late-life depression, encompassing both early-onset MDD and late-life onset depressive symptoms that occur as part of the prodrome of dementia syndrome. Future work disentangling differential neurobiology underlying these presentations is critical to clarify prognosis and treatment and ultimately to reduce dementia risk.

Depression With Reversible Dementia

Some depressed older adults develop a dementia syndrome that improves or largely subsides after the remission of depression. This syndrome has been termed *pseudodementia*, *dementia syndrome of depression*, or *depression with reversible dementia*, and it has attracted considerable clinical interest. Abnormal executive function, processing speed, memory consolidation, and working memory may persist after the remission of mood symptoms in many patients with geriatric depression. Older adults with both depression and diabetes were found to be particularly vulnerable to cognitive deficits.

Depressed older adults who remain with some cognitive impairment even after improvement of depression usually have early-stage dementia whose cognitive manifestations are exaggerated when the depressive syndrome is superimposed. Although some disagreement exists, it

appears that even those individuals with nearly complete cognitive recovery develop high rates of irreversible dementia (about 20% per year) on follow-up. Many of these patients may remain nondemented for 1 to 2 years before the development of irreversible dementia. About 40% of older adults with depression and mild cognitive impairment progressed to AD within 27 months. A presence of active depression within the last 2 years compared to those with a more remote history of depression was found to be a marker of even greater risk, possibly reflecting a more aggressive progression of underlying Alzheimer pathology. The heterogeneity of the course of depression with reversible dementia suggests that patients suffering from this syndrome can be ordered along a continuum. At the one end of the continuum lie cases in which the cognitive disturbance results predominantly from the depressive syndrome itself. On the other end are cases in which the neurocognitive impairment originates from a progressive subclinical neurodegenerative disorder with some contribution by the depressive syndrome. Therefore, the identification of cognitive dysfunction in older adults with depression constitutes an indication for a thorough diagnostic workup and frequent follow-up aimed at the identification of treatable neurocognitive disorders.

Psychotic Depression

Psychotic depression occurs in 20% to 45% of hospitalized depressed older adults and in 3.6% of depressed older adults living in the community. Patients with psychotic depression more commonly present with delusions, whereas hallucinations are less frequent. The usual themes of depressive delusions are guilt, hypochondriasis, nihilism, persecution, and sometimes jealousy. Depressive delusions can be distinguished from the delusions of patients with dementia in that the latter are less systematized and less congruent to affective disturbance. Patients with psychotic depression have more severe depressive symptomatology and a poorer prognosis compared to patients with nonpsychotic depression. In addition, symptoms of malnutrition, dehydration, and cognitive deficits are often present.

Late-Life Bipolar Disorder

Although community prevalence rates of BD are lower in older adult populations than in younger adult ones, recurrent episodes of mania and hypomania persist into later life and affect 5% to 10% of psychiatric

patients. Late-onset mania often occurs in patients who have had recurrent depression episodes since early life. Late-life BD occurs in the context of cognitive impairment, high medical burden, disability, and limited psychosocial support. These factors influence the course of late-life BD. Importantly, decrements in physical health-related quality of life in this population are not an inevitable consequence of aging, and adequate attention to medical comorbidity at any age may have a tangible impact.

Cognitive impairment occurs in 40% to 60% of symptomatic bipolar older adults and may persist after improvement of mood symptoms. Deficits in attention, executive functions, and memory have been noted. Older adults with BD manic episodes may have more severe executive function deficits than older adults with unipolar depression. These impairments may reflect, in part, processes involved in the pathophysiology of mood disorders, including dysfunction of corticostriatal circuits and other limbic pathways. Cognitive impairment may be a prodrome of dementia and may also be associated with poor outcomes in late-life mania. Evidence regarding the connection between late-life BD and the progression of cognitive dysfunction has been inconsistent. While epidemiologic and cross-sectional studies have shown that BD increases the risk for dementia later in life, a recent review and meta-analysis examining longitudinal cognitive performance among patients with late-life BD did not identify any evidence of accelerated deterioration in cognitive functioning.

Older adults with BD have higher stroke risk factors than both aged controls and unipolar older adults. Late-onset mania is especially associated with vascular burden and high mortality due to cerebrovascular disease. Neuroimaging studies have revealed a high frequency of signal hyperintensities and silent strokes in older bipolar patients. Structural abnormalities are most prominent in BD with late age at the onset of the first episode. Cardiac pathology, renal impairment, and thyroid dysfunction are also common in aged bipolar patients. While evidence supporting an association between cerebrovascular disease and late-onset BD is reasonably strong, the mechanisms underlying this relationship are less clear. The presence of cardiovascular risk factors, which increase stroke risk, is also more common among patients with late-life BD. However, it remains unclear whether ischemic brain disease is a cause and/or consequence of late-life BD. Regardless, these findings highlight the

importance of cardiovascular care as part of routine clinical management in older adult BD.

BD leads to behavioral disability that worsens the symptom course in BD. Disability in older adults can lead to institutionalization and influence morbidity and mortality. Geriatric bipolar patients report low perceived social support compared to same-age controls. Bipolar patients with a history of frequent or lengthy episodes of illness lack social support. The effect of social support on treatment outcomes of BD in older adults requires further investigation.

Depression and Disability

According to the World Health Organization, unipolar depression alone is responsible for more than 1 in 10 years lived with disability worldwide. The morbidity and mortality associated with major depression render it the number one cause of disability worldwide and exerts an extraordinary economic burden on society in terms of lost productivity. Depression is among the 10 diseases that increase disability-adjusted life years (DALYs) the most. DALY is a measure of years of life lost to premature death and years lived with a disability. In a 12-year follow-up study, individuals with major depression at baseline were four times more likely to report incident disability after controlling for medical illness and sociodemographic factors. Whereas depression increases the risk of disability, the opposite is also true. Increases in disability over time predict the emergence of depressive symptoms. Impairment in instrumental activities of daily living is related to depressive symptomatology and particularly to anxiety, helplessness, hopelessness, and worthlessness. Disability is associated with executive dysfunction and with late-onset depression.

Bereavement

Depressive symptoms or syndromes often follow a significant loss. Older adults may be at heightened risk for negative bereavement outcomes, including depression due to changes in social, financial, and practical support, isolation and loneliness, needing to simultaneously cope with pre-existing chronic illness, reduced mobility, and cognitive decline. The prevalence of bereavement-related psychological disorders varies, with approximately 9% to 25% of bereaved older adults developing prolonged grief disorder, 15% experiencing depressive symptoms, and 9% to 16% developing bereavement-related PTSD. Approximately 7% of bereaved

older adults will develop continued distress and impairment lasting for years after the death, termed “persistent complex bereavement disorder” in DSM-5.

SUICIDE RISK

Older adults are at significant risk of death by suicide relative to younger adults. White men older than 85 years have the highest rates of suicide deaths, almost four times the rate in the general population (i.e., 47.17 per 100,000 vs. 14.21 per 100,000). Older adults have high suicide rates worldwide, with more than 7,000 yearly deaths by suicide of people aged 60 and older in the United States alone. Suicide ranks ninth among causes of death in the United States, ahead of sepsis, liver disease, and hypertension. Among older Americans who reported suicidal ideation in the past year, 12.7% reported at least one suicide attempt in the past year. Among older adults who died by suicide, lifetime suicide attempts prevalence was higher among people ages 65 to 74 years compared to ages 75 to 84 years. In this population that was studied, the prevalence of psychiatric disorders, legal and financial stressors, and relationship problems decreased with age. In contrast, physical conditions and bereavement increased with age. The severity of depression, psychotic depression, alcoholism, recent bereavement, abuse of sedatives, physical illnesses, and recent development of disability is the most important risk factors in depressed older adults. Accumulation of chronic medical conditions, social isolation, psychiatric and neurocognitive disorders (which might contribute to cognitive disinhibition and altered decision making), as well as physical and psychological pain, may also contribute to the increased risk in this population. Aging reduces suicide attempts but increases their lethality. Elder frailty might also contribute to suicide lethality. It is estimated that within the United States, there are 25 attempts for every suicide death. Among older adults, there are only four attempts for every suicide death, making nonlethal suicide attempts less common. Therefore, it is critically important to identify suicidal ideation and risk early in this age group before it escalates into an attempt. Suicide victims are demographically different from individuals who attempt suicide. About 60% of those who commit suicide are men, while 75% of those who attempt suicide are women. More than 70% of suicide victims in the United States use firearms compared to only 10% in Italy. Additional

leading suicide methods in the United States include drug overdose and self-inflicted lacerations. In late life, suicide attempts are often more carefully planned and are preceded by fewer warnings of suicidal intent.

Indeed, unlike the high frequency of suicide attempts in late life, reports of suicidal ideation decrease in older adults. Despite its lower frequency, suicidal ideation is a risk factor for suicide in older adults. The severity of depression is the strongest predictor of the course of suicidal ideation. In older adults with major depression, suicidal ideation is most common in those with previous serious suicide attempts, high severity of depression, and poor social support.

Depression is the most common psychiatric diagnosis in older adult suicide victims, unlike younger adults in whom substance abuse alone or with comorbid mood disorders and psychosis are the most frequent diagnoses. Major depression is identified in 80% of suicide victims older than 74 years of age. Many older adult suicide victims are widowed, and fewer are single, separated, or divorced, compared with younger adults. Depressive symptoms, medical status, disability (pain and functional impairment), perceived health status, cognitive difficulties, social disconnectedness, and perceived burdensomeness and hopelessness, as well as access to deadly means, were identified as risk factors for suicidal ideation and death in older adults. Insomnia, one of the most common symptoms of depression at any age and particularly in late life, is an independent risk factor for suicidal ideation in adults and suicidal death in older adults. It is unclear whether the treatment of insomnia can mitigate this risk. Studies suggest that although older adults may exhibit less avoidance of death-related topics and greater overall acceptance of death, it is problematic when older adults express a desire for their life to end, even without active thoughts of ending one's own life. They should not be viewed as normative, as even passive suicidal ideation is associated with an increased risk for suicidal behavior.

Suicide among patients with dementia is 8 times more common than in the general older adult population. Suicide occurs mostly in the early stages of dementia and is related to disinhibition, impaired problem-solving, and poor decision-making associated with cognitive decline.

Suicide is also a leading cause of death in patients with bipolar illness. By one estimate, 25% to 50% of all patients with BD will attempt suicide at least once in their life, and 8% to 19% will die of suicide. Risk factors for suicide in BD include younger age of illness onset, history of past suicide

behavior, family history of suicide acts, comorbid borderline personality disorder, substance use disorders, and hopelessness.

The clinical characteristics of depressed older adult suicide victims suggest that identification of depression and appropriate care can reduce the incidence of suicide. The majority of older adult suicide victims see their physicians within a few months of their death, and over a third, within a week of their suicide. Among depressed older adults seen in primary care in the 12 months prior to a suicide attempt, less than 5% received appropriate depression treatment prior to the attempt. Therefore, a reliable assessment of suicide risk is critical since protective measures may avert suicide. There is no evidence that questions about suicide can increase the likelihood of suicidal behavior. Brief interventions such as safety planning in addition to aggressive treatment of depression may prevent suicide, as suicidal ideation is closely associated with depressive symptomatology in older adults. Worsening depression and suicidal ideation may indicate the need for psychiatric hospitalization and/or ECT.

BIOLOGIC DYSFUNCTION

The Late-Onset Hypothesis

An early hypothesis of late-life depression postulated that major depression with the onset of the first episode in late life includes a large subgroup of patients in whom neurologic brain abnormalities contribute to the development of a depressive syndrome. Clinical findings supported the “late-onset hypothesis.” Relative to older adults with early-onset major depression, individuals with late-onset major depression have a less frequent family history of mood disorders, a higher prevalence of dementing disorders, and a higher rate of dementia development on follow-up, although some disagreement exists. Most older adults with major depression and initially reversible dementia have late-onset depression. Despite the improvement of cognitive functions with the remission of a depressive syndrome, many of these patients develop irreversible dementia during long-term follow-up. The “late-onset depression” hypothesis pointed out the importance of aging and disease-related brain changes in late-life depression. Additional research has highlighted mild behavioral impairment, a constellation of affective and behavioral symptoms with onset later in life, as a prodrome for dementia syndromes.

The Depression-Executive Dysfunction Hypothesis

This hypothesis postulates that a “depression-executive dysfunction (DED)” syndrome exists with a clinical presentation resembling medial-frontal lobe syndrome. Clinical studies documented that the DED syndrome is common and characterized by psychomotor retardation, reduced interest in activities, apathy, impaired insight, suspiciousness, and severe behavioral disability, but less pronounced depressive ideation and vegetative signs.

Recent clinical studies found that DED is common, with approximately 30% of depressed older adults who have abnormal performance in tests of verbal fluency, response inhibition, novel problem solving, cognitive flexibility, working memory, and/or ideomotor planning. Patients with depression and executive dysfunction have a poor, slow, and unstable response to antidepressants as well as early relapse and recurrence. Similarly, depressed older adults who reported executive functioning complaints at baseline had a slower response to escitalopram treatment than those without executive functioning complaints.

A recent systematic review identified a triad of depressive symptoms, executive dysfunction, and impaired gait speed in up to 17% of older adults with depression. This may represent a distinct entity with shared etiology and has significant implications on fall risk, daily activities, quality of life, and overall morbidity and mortality. This triad is associated with vascular risk factors and white matter hyperintensities (WMH), suggesting that frontal-subcortical dysfunction might be the underlying cause.

The DED hypothesis assumes that executive dysfunction is the clinical expression of frontolimbic dysfunctions predisposing to late-life depression. The limbic system evaluates reward-related stimuli and organizes stress responses, and higher neocortical structures exert control over these processes. Insula metabolism may be a treatment-specific biomarker in major depression. Specifically, insula hypometabolism was associated with remission in response to cognitive-behavioral therapy and poor response to escitalopram, while insula hypermetabolism was associated with remission to escitalopram and poor response to cognitive-behavioral therapy in a mixed-age sample. Reduced bilateral activation of the dorsal-anterior cingulate and the hippocampus was demonstrated in severely depressed, nondemented older adults performing a word-activation task. Low resting functional connectivity within the cognitive control network and high-resting

functional connectivity within the default mode network distinguished depressed from normal older adult subjects. Low resting functional connectivity within the cognitive control network predicted a low remission rate and persistence of depressive symptoms and signs, apathy, and dysexecutive behavior after treatment with escitalopram. In contrast, resting functional connectivity within the default mode network was correlated with pessimism but did not predict treatment response.

Patients with DED syndrome often present with apathy. Resting functional connectivity studies of apathy in late–late-life depression showed that apathy is characterized by abnormalities in the cognitive control network as well as in reward and salience networks.

Depression frequently develops in disorders of subcortical structures, including vascular dementia, Parkinson disease, Huntington disease, supranuclear palsy, basal ganglia calcification, and stroke of the caudate head. WMH are common in geriatric depression and are often located in subcortical structures and their frontal projections, compromising connections between limbic and dorsal cortical structures. WMH may interfere with limbic–dorsal balance and lead to chronic depressive syndromes. Subcortical WMHs have been associated with both executive dysfunction and nonremission of late-life depression.

Complementing these findings, diffusion tensor imaging studies documented that reduced white matter integrity in distributed cerebral networks that connect the prefrontal cortex with subcortical and posterior cortical regions (dorsal and rostral anterior cingulate cortex [ACC], dorsolateral-prefrontal cortex [DLPFC], hippocampus, posterior cingulate, insula, neostriatum, and the midbrain as well as select temporal and parietal regions) are associated with executive dysfunction and poor response of late-life major depression to a serotonin reuptake inhibitor. Similarly, lower activation in the DLPFC and other brain regions during an in-scanner performance of the Wisconsin Card Sorting Test of executive function predicted a less favorable response to cognitive behavioral therapy in depressed older adults. Depressed, older, short serotonin transporter 5-HTTLPR allele carriers had both a lower remission rate than long allele homozygotes and more microstructural white matter abnormalities in frontolimbic areas. These abnormalities may be caused by inflammatory responses, vascular disease, prominent aging-related changes, degenerative brain disease, or an accumulation of those and other factors.

The Inflammation Hypothesis

The inflammation hypothesis postulates that aging-related immune processes promote changes in the emotional and cognitive neural networks predisposing to geriatric depression and/or triggering metabolic brain changes mediating the depressive syndrome in late life. The hypothesis is supported by emerging findings suggesting that: (1) aging leads to a proinflammatory state; (2) immune responses of the CNS can influence the function of some of the emotional and cognitive networks pertinent to geriatric depression; (3) elevation of peripheral cytokines and acute phase proteins (mainly IL-6, Tumor Necrosis Factor (TNF), and C-reactive protein) is associated with depressive symptoms in older adults; (4) some antidepressants reduce the expression of several inflammation markers in the periphery; (5) blocking peripheral cytokines from disrupting the blood–brain barrier (BBB) exhibited antidepressant actions, and (6) pretreatment of cytokine plasma levels may influence the response to antidepressants. Dysregulation of both the innate and adaptive immune systems occurs in depressed patients and hinders favorable prognosis, including antidepressant responses.

Aging promotes a chronic state of neuroinflammation, and animal and human studies suggest that this proinflammatory state may compromise neural systems related to depression. In aged rodents, the cerebral cortex produces more inflammatory cytokines than the cortex of adult animals. In older animals, the inflammatory cytokine IL-6 has higher concentrations in the hippocampus, cerebral cortex, and cerebellum than in the same regions of younger animals. In normal human adults, enhanced activity of the subgenual anterior cingulate cortex and reduced functional connectivity (FC) of the subgenual anterior cingulate with the amygdala, medial-prefrontal cortex, and nucleus accumbens during emotional face processing was modulated by a peripheral inflammatory response (IL-6). Cytokines induce indoleamine 2,3-dioxygenase, an enzyme that reduces serotonin production. They also dysregulate the glutamate system, promote excitotoxicity and decrease the production of neurotrophic factors, neuroplasticity, and neurogenesis. Inflammatory responses to immune challenge influence the function of emotional networks. A single nucleotide polymorphism (SNP) encoding IL-1b has been associated with both reduced activity of the anterior cingulate and the amygdala in response to emotional probes and with poor response of major depression to an antidepressant. Patients treated with the cytokine

interferon-α (IFN-α) have greater activation of the dorsal-anterior cingulate than controls. Administration of IFN-α also increased glutamate in the basal ganglia of nondepressed subjects with hepatitis C (mean age 45). Changes in glutamate concentrations were, in turn, associated with anhedonia and psychomotor slowing. Cytokines contribute to oxidative stress, which damages glial cells in the prefrontal cortex and the amygdala. Inflammation may cause resistance to glucocorticoids in immunocytes and their cellular targets.

Peripheral inflammatory markers are elevated in late-life depression, and their levels are associated with the severity of depression and with cognitive symptoms of depression. A recent meta-analysis of 82 studies showed that peripheral levels of IL-6, TNF-α, IL-10, soluble IL-2 receptor, C–C chemokine ligand 2, IL-13, IL-18, IL-12, IL-1 receptor antagonist, and soluble TNF receptor 2 were elevated and interferon-gamma levels were lower in individuals with major depression compared to controls. Several of these inflammatory markers (TNF-α, IL-6, and IL-1b) were found to correlate with the severity of depressive and cognitive symptoms. Increased inflammatory markers have been associated with atypical symptoms of depression and with suicidal behavior in MDD. In brain autopsies of suicide victims, increased cytokine concentrations have been found in the orbitofrontal cortex and the dorsolateral prefrontal cortex. Higher levels of IL-6 predicted the chronicity of depression, as well as higher severity of depression at follow-up. Elevated IL-6 levels have also been associated with increased suicide risk, with the highest levels of IL-6 correlating with the most violent suicide attempts.

Proinflammatory changes occur in various medical illnesses and health risk factors predisposing to late-life depression. Increased circulating inflammatory cytokines have been found in cardiovascular disease. High body mass index and smoking have been associated with increased inflammatory markers in major depression. Chronic stress, a precipitant of depression, increases circulating IL-1β and IL-6 as well as cognitive impairment in older adults. Childhood trauma has been shown to cause long-lasting effects on peripheral inflammation later in life and is associated with an increased risk of depression. Although peripheral cytokines do not cross the blood–brain barrier, they send signals via molecular, cellular, and neural routes, which ultimately enhance brain inflammation. Aging may exacerbate the effects of stress in the brain,

leading to behavioral and cognitive changes similar to those of depressive syndromes.

A large community-based prospective cohort study spanning over 20 years monitored high-sensitivity C-reactive protein (CRP) among individuals from middle-to late-life. Those with repeated or chronic elevations in systemic inflammation had greater symptoms of depression than older adults. These associations occurred independently of medical comorbidity and did not differ based on late-life cognitive status or *APOE* ε4 genotype.

The role of inflammation in depression treatment response has been studied. Tricyclic antidepressants (TCAs) may reduce some proinflammatory cytokines, increase anti-inflammatory cytokines, and reduce polysaccharide-induced “sickness behavior” in animals. Pretreatment cytokine plasma levels may influence the response to antidepressants in humans. SSRI-resistant patients had higher TNF-α plasma levels, while euthymic patients with a history of depression had TNF-α levels similar to those of normal controls. A higher level of TNF-α was shown to predict failure of depression to respond to escitalopram. The largest study to date reported that patients with baseline low C-reactive protein (CRP <1 mg/L) levels had greater improvement in depression when treated with escitalopram than with nortriptyline. In contrast, patients with higher CRP levels had greater improvement when treated with nortriptyline than with escitalopram. In treatment-resistant major depression, baseline concentrations of high-sensitivity CRP (>5 mg/L), TNF, and TNF-soluble receptors were associated with a favorable response to the TNF antagonist infliximab.

In addition to influencing treatment response, neuroinflammation has also been speculated to underlie the relationship between depression and neurodegenerative diseases. The exaggerated release of proinflammatory cytokines may lead to neuronal damage. Such damage can interfere with anti-inflammatory and immunosuppressant regulation, leading to cognitive impairment, neurodegeneration, and decreased neurogenesis in different brain areas, including the hippocampus. Reduced hippocampal volume is one of the early brain changes associated with dementia.

The Vascular Depression Hypothesis

This hypothesis postulates that cerebrovascular disease predisposes, precipitates, or perpetuates some late-life depressive syndromes. The

hypothesis was based on the high comorbidity of depression and vascular risk factors; the high incidence of depression poststroke; the high prevalence of WMHs in late-onset depression; the high frequency of cognitive impairment in depressed patients with vascular risk factors; and the similarity of cognitive abnormalities of depression to those associated with WMH. Recent studies show greater WMH severity in specific white matter fiber tracts in late-life depression, including the cingulum bundle, uncinate fasciculus, and superior longitudinal fasciculus. Fiber tract structural connectivity is positively correlated with resting state functional connectivity of connected regions.

A syndrome of “subcortical ischemic depression” has been proposed based on WMH literature. This syndrome is defined by the combination of depression and MRI evidence of subcortical ischemic changes. Age, lassitude, and a history of hypertension were positively associated with the diagnosis of subcortical ischemic vascular depression, whereas a family history of mental illness and loss of libido were negatively associated with this diagnosis.

MRI stigmata of cerebral small vessel disease (i.e., WMHs, lacunes, microbleeds, perivascular spaces, and cerebral atrophy) are associated with depression and stroke. Studies found that a history of depression increases the risk of vascular disease and stroke and may promote inflammation or epigenetic changes of genes related to vascular integrity, suggesting that depression has a bidirectional relationship with vascular disease.

Patients with vascular depression often present with psychomotor retardation, anhedonia, lack of insight into their illness and disability, and are less likely to report feelings of guilt. WMHs are associated with executive dysfunction and reduced activation of brain regions related to executive and psychomotor functions. Executive dysfunction was associated with bilateral WMH in the inferior frontal white matter, temporal-occipital periventricular white matter, and the anterior limb of the internal capsule, as well as scattered clusters in the prefrontal white matter. WMHs were correlated with impairments in goal maintenance during a continuous performance task but also with reduced activity in DLPFC and reduced connectivity of the DLPFC with task-relevant brain regions, including the middle frontal gyrus and supramarginal gyrus.

WMH and microstructural brain abnormalities predict a poor response of late-life depression to antidepressants. Increases in WMH volume over

2- and 4-year intervals are associated with nonremission or relapse. Microstructural white matter abnormalities in multiple frontolimbic brain areas, including the rostral- and dorsal-anterior cingulate, DLPFC, genu, hippocampus, posterior cingulate, left superior corona radiata, and right inferior longitudinal fasciculus are associated with nonremission.

The disconnection of structures regulating mood and cognition may be one of the mechanisms by which cerebrovascular disease promotes late-life depression. Another mechanism may be vascular dysregulation leading to reduced cerebral blood flow (CBF). Mild CBF reduction may impair cognitive and affective processes, while greater CBF reduction in the context of autoregulatory deficits may cause ischemic injury.

Vascular diseases impair vascular regulation. Vascular changes, including increased intima-media thickness, increased arterial stiffness, and endothelial dysfunction, are pronounced in late-life depression, and endothelial function may be most impaired in nonresponders to antidepressants. In late-life depression, perfusion deficits are more severe, particularly in the medial- and lateral-prefrontal cortices and subcortical and temporal structures.

Arguably, at least three interconnected processes may lead to “vascular depression,” that is, disconnection of networks responsible for the regulation of mood and cognition, reduced regional CBF, and inflammatory responses related to vascular disease. As an example, inflammation leads to vascular remodeling, accelerates vascular damage, and may contribute to perfusion deficits. In turn, regional perfusion deficits adversely affect gray matter function and contribute to the development of WMHs that disrupt regional structural and functional connectivity.

Genetic Studies

It is well established that the risk for MDD is partially mediated by genetic factors. A meta-analysis quantified the increased risk of MDD as an odds ratio (OR) of 2.84 (95% CI = 2.31–3.49) for first-degree relatives of individuals with MDD. A large twin study in a Swedish population estimated the heritability of MDD to be approximately 37%, which is consistent with estimates made in previous studies. In more recent years, technologic advances have enabled researchers to move beyond family-based heritability studies of MDD to identify disease-associated susceptibility loci using genome-wide association studies (GWAS). What has become clear from these studies is that MDD is a polygenic disorder,

with multiple loci being identified, but each with a small effect. A recent genome-wide meta-analysis of MDD analyzed data from 807,553 individuals of all ages had identified 102 independent variants, 269 genes, and 15 gene-sets associated with depression. In an independent replication sample of 1,306,354 individuals, 87 of the 102 associated variants remained significant following multiple testing corrections. This meta-analysis identified significant genetic correlations among the general population for depression with neuroticism (which was bidirectional), anorexia nervosa, attention-deficit hyperactivity disorder (ADHD), schizophrenia, and BD. Interestingly, previously identified depression-associated genes were not identified in this study. These genes include those associated with the serotonergic system, such as SLC6A4, GNB3, HTR2A, and TPH2. This is unexpected, as the serotonergic system forms the basis of most antidepressant treatments but could indicate a functional separation between genetic pathways of depressive disease and pathways of antidepressant treatment.

In many cases, it is possible to identify associations between particular genes and characteristics (endophenotypes) that may predispose an individual toward the development of depression. One such endophenotype is hippocampal volume loss. In a cohort of 138 older adults aged 60 and above, genetic variants at three *AGTR1* SNPs (a gene encoding the angiotensin-II type 1 receptor of the renin-angiotensin system [RAS]) were independently associated with accelerated hippocampal volume loss in the right hemisphere over a 4-year follow-up period. In addition, the *AGTR1* risk alleles predicted worse episodic memory performance and interacted with the *APOE4* allele to accelerate right hippocampal volume loss. These initial findings suggest that targeting molecules in the RAS may have the benefit in late-life depression. Future work will involve investigating the effects of genetic variation on other relevant endophenotypes of mood disorders in older adults.

Genetic studies using SNP heritability approaches have provided evidence suggesting that some loci may contribute to both unipolar major depression and BD, particularly those involving calcium channel signaling. GWAS in BD has identified several risk-conferring variants, including markers within the *CACNA1C* gene (encoding the α subunit of the L-type voltage-dependent calcium [Ca^{2+}] channel CaV1.2) and the *ANK3* gene (encoding ankyrin G, a cytoskeletal protein involved in scaffolding in the

axon initial segment and in nodes of Ranvier), which may be mechanistically linked through providing signaling integrity in GABAergic neurons. Initial findings have shown that variants in these genes may functionally impact neuronal circuitry involved in affective processing in individuals with BD carrying the risk variants. An additional study analyzing four independent genome-wide data sets along with data contributed to the Psychiatric Genomics Consortium Bipolar Group identified the *CACNA1C* gene as well as pathways involved in hormonal regulation, second messenger systems, glutamate systems, and neuronal development, as contributing to the genetic predisposition and underlying neurobiology of BD.

In addition to work studying candidate loci, recent evidence also suggests that epigenetic mechanisms, processes affecting gene expression and translation that do not involve changes in the DNA sequence, could play a role in depression neurobiology and risk. Through one model, epigenetic mechanisms could mediate the lasting increases in depression risk following exposure to an adverse life event, such as childhood trauma, which is strongly associated with depression in adulthood. An additional model suggests that underlying genetic and environmental factors, and interactions between the two, drive aberrant epigenetic mechanisms targeting stress response pathways, neuronal plasticity, and other behaviorally relevant pathways that have been implicated in MDD.

A Model of Late-Life Depression

Accumulation, and perhaps a synergy of noxious factors, is consistent with the clinical reality of geriatric populations in whom a variety of processes contribute to brain dysfunction, leading to depression and to cognitive impairment. Etiologic factors, directly or by causing brain abnormalities increasing vulnerability to depression, promote metabolic changes mediating the expression of the depressive syndrome. Etiologic factors include cerebrovascular lesions, perfusion-related abnormalities, and inflammatory and repair responses. Abnormalities in frontolimbic and frontostriatal functional architecture resulting from these processes may serve as vulnerability factors for depression. Heredity, epigenetic factors, and psychological vulnerability represent additional predisposing factors. Biologic responses to stress may promote processes serving as etiologic or vulnerability factors of late-life depression.

A working model of late-life depression postulates that depressive syndrome represents the clinical expression of dysfunction in reward, salience, and cognitive control networks. The degree of dysfunction may determine the intensity of symptoms related to mood, cognition, and/or motoric behavior and account for the heterogeneous clinical presentations of late-life depressive syndrome. Abnormalities in the frontolimbic system are involved in functional abnormalities, chronicity, and relapse of depressive symptoms. Genetic factors, aging, and disease-related processes (e.g., inflammation, vascular disease, neurodegenerative disease pathology accumulation [e.g., Aβ and tau]) may cause dysfunction in reward, salience, and cognitive control networks. Many of these factors, as well as psychological factors, start in mid-life and continue into late-life. These stressors might lead to depression directly, through inflammatory responses and structural brain changes, or indirectly through neglect of health. This model seeks to consolidate hypotheses surrounding etiologic, predisposing, and stress-related factors and mechanisms mediating the behavioral expressions of late-life depression and the course of illness. Although the hypotheses are described separately, some of their mechanisms overlap, and additional mechanisms may be at play.

Brain Structure Studies

Neuroradiologic studies suggest frontostriatal and limbic impairment in depression. WMHs prevalent in geriatric depression are mainly located in subcortical structures and the medial-orbitofrontal cortex. An increase in the volume of WMHs over a 2-year period predicted lower rates of sustained late-life MDD remission during the same period, and worsening of white matter grade in older adults over a 5-year period has been associated with cognitive decline.

Histopathologic and neuroimaging studies of individuals with mood disorders have provided evidence of microscopic and macroscopic changes in several brain regions. Low volumes of the subgenual anterior cingulate, the head of the caudate nucleus, the putamen, and the hippocampus have been noted in mixed-age depressed patients. Reduced hippocampal volume has also been found in depressed older adults. Small left hippocampal volume in geriatric depression was associated with the later development of dementia. Reduction in orbitofrontal cortex volume has been reported in depressed older adults

compared to normal controls. Abnormalities in neurons of the DLPFC have been observed in unipolar and BD. Moreover, a reduction in glia of the subgenual prelimbic anterior cingulate gyrus has been reported in unipolar-depressed patients. Finally, amygdala volume findings in depressed patients have been mixed.

Brain Function Studies

Increased metabolism has been noted in limbic regions, including the amygdala, the rostral-anterior cingulate, and the posterior orbital cortex as well as anterior (right and left superior frontal gyri) and posterior (precuneus, inferior parietal lobule) cortical regions. In contrast, dorsal neocortical areas, such as the lateral and DLPFC, and the dorsal-anterior cingulate, as well as the caudate, have reduced blood flow during depression. Reduced bilateral activation of the dorsal-anterior cingulate and the hippocampus was demonstrated in severely depressed, nondemented older adults performing a word-activation task.

The limbic system evaluates reward-related stimuli and organizes stress responses. Reciprocal pathways link limbic structures with striatal and neocortical sites. It has been proposed that abnormalities in the reciprocal relationship between ventral limbic and dorsal cortical neural systems are critical physiologic disturbances in depression. White matter abnormalities compromising connections between limbic and dorsal cortical structures may interfere with limbic–dorsal balance and lead to chronic depressive syndromes.

A recent study provided evidence for insula metabolism as a treatment-specific biomarker in MDD. In this positron emission-based study, insula hypometabolism (relative to whole-brain levels) was associated with remission in response to cognitive-behavioral therapy and poor response to escitalopram, while insula hypermetabolism was associated with remission to escitalopram and poor response to cognitive-behavioral therapy in a mixed-age sample. This finding will require replication in an independent prospective sample and also in an older-aged sample but offers promise for the use of brain-based biomarkers in guiding treatment selection in MDD. Other studies found that treatment with SSRI or total sleep deprivation (TSD) resulted in decreased metabolism in anterior cortical and limbic regions and increased posterior cortical metabolism in geriatric depression. The metabolic changes after SSRI treatment were associated with improvement in depressive symptoms. In behavioral and

imaging studies of the brain as people age, patterns of resilience to negative emotional experiences and reactivity to positive emotional experiences were noted. Older adults exhibit less reactivity to negative stimuli and greater memory for positive information. However, older adults who have damage to areas of the prefrontal cortex related to emotion regulation are more likely to experience negative outcomes such as depression.

COURSE AND OUTCOME

Geriatric Depression

Knowledge of risk factors and periods of high risk for particular adverse outcomes enables the clinician to use appropriate diagnostic methods and offer preventive treatments with favorable risk-benefit ratios. Despite advances in antidepressant therapies, longitudinal studies of 1 to 6 years duration suggest that 7% to 30% of geriatric patients have chronic major depression. If partially remitted subjects are considered chronic, the rate of chronicity reaches 40%. Chronicity of depression may be predicted by a history of a long current episode or long previous episodes, coexisting medical illness, high severity of depression, nonmelancholic presentation, and delusions.

Naturalistic treatment studies of geriatric populations observed a 13% to 19% rate of relapse/recurrence at 1 year, while a 15% relapse rate is observed in patients receiving controlled antidepressant treatment. This percentage is lower than the relapse/recurrence rate (34%) reported in younger adults. However, if the follow-up of older adults with depression is extended from 3 to 6 years, the recurrence rate increases to 38%. A 20-year follow-up study of mixed-age patients with depression showed that 95% of patients had a recurrence. Patients with only minor or subsyndromal depression have an increased risk (approximately fivefold) of major depression compared with unaffected individuals after 1 year. Depression outcomes are also predicted by initial medical burden, self-rated health, and social support- both objective and perceived.

Relapse/recurrence appears to have different predictors than a recovery of depression. The likelihood of relapse/recurrence may be high in patients with a history of frequent episodes, late age of illness onset, history of dysthymia, intercurrent medical illness, greater functional

impairment, and higher baseline depression, and those in whom there is a perceived external locus of control.

Geriatric Bipolar Disorder

In geriatric BD, relapse and hospital readmission after manic episodes are common as episodes become more frequent, and the interval between episodes becomes shorter with age. In comparison to younger patients with BD, there is evidence to suggest that geriatric BD patients have less severe manic episodes, are more likely to relapse into depression after a manic episode, are less likely to experience psychotic symptoms, are more likely to experience rapid cycling between episodes, and are less likely to attempt suicide.

EVALUATION AND TREATMENT OF GERIATRIC DEPRESSION AND BIPOLAR DISORDER

Overview of Geriatric Depression Evaluation and Treatment

The objectives of geriatric depression treatment include:

1. Remission of depression
2. Reduction in the risk of relapse and recurrence
3. Improvement of cognitive and functional status
4. Development of skills or provision of support needed for coping with handicaps and psychosocial adversity.

Clinicians should expect an improvement in both disability and excess medical morbidity with adequate treatment.

Geriatric depression can be effectively treated with psychotherapy, pharmacotherapy, or combination treatment. Appropriate behavioral rehabilitation techniques should be combined with antidepressant treatment in order to enable older adults to regain function as depressive syndrome subsides.

Long-term outcomes of depressed older adults can be improved by

1. Identifying and treating comorbid psychiatric and medical conditions
2. Minimizing medication side effects
3. Striving for full remission of acute symptoms

4. Providing psychoeducation for patients, families, and health care professionals about the illness and the importance of adhering to treatment recommendations, both acutely and after symptom remission.

The evaluation of geriatric depression should include assessment of psychopathology, medical and neurologic status, pharmacotherapy, functional impairment, and psychosocial factors, as well as suicidal risk. For instance, neurocognitive disorders, anxiety, sleep disorders, use of drugs that may cause depression (e.g., steroids), and benzodiazepine and alcohol abuse often contribute to late-life depression and worsen its course. Therefore, attention to these problems should be part of the assessment of depressed older adults. A further complexity of assessment includes the risk of missing a bipolar depression diagnosis. As such, a diagnosis would alter clinical management and contraindicate the use of antidepressant monotherapy. Rating scales, including the Hamilton Depression Rating Scale, the Cornell Scale for Depression in Dementia, the Geriatric Depression Scale, and the Mini-Mental State Examination or Montreal Cognitive Assessment (MOCA), can be useful in assessment.

Adults with comorbid medical illnesses, including both chronic/deteriorating processes and acute/debilitating events, are preferentially affected by late-life depression. Further, a number of other medical conditions, such as viral infections, endocrinopathies (e.g., thyroid and parathyroid abnormalities), vitamin B_{12} deficiency, and malignancies (e.g., lymphoma and pancreatic cancer), are often associated with depression. Vitamin D deficiency has also been linked to late-life depression. Medical conditions likely to respond promptly to treatment (e.g., amphetamine withdrawal) should be treated first, and antidepressants should only be used if depression persists. For many other medical conditions, however, depression may not remit until an antidepressant agent is used. For example, depression in a hypothyroid older adult patient rarely responds to thyroid supplementation alone. Similarly, an antidepressant trial often is ineffective before hypothyroidism is corrected. Thyroid supplementation and an antidepressant drug, however, offer the highest probability of antidepressant response.

Some drugs can contribute to or cause late-life depression, such as steroids, antiparkinsonian drugs, benzodiazepines, and β-blockers. If the

depression occurs in a patient receiving methyldopa (Aldomet), cimetidine (Tagamet), clonidine (Catapres), hydralazine, propranolol (Inderal), or reserpine, switching to another medication is recommended. If the depression occurs in a patient treated with digitalis, estrogens, tamoxifen (Soltamox), vinblastine, or vincristine, the medication should be continued, and depression should be treated with antidepressants. There is no agreement on the best strategy for depression that occurs in patients treated with benzodiazepines, corticosteroids, progesterone, propoxyphene (Darvon), or psychostimulants. As interferon-α treatment frequently is associated with depression, increased frequency of psychiatric follow-up and starting or increasing antidepressant treatment prophylactically should be considered before initiating such treatment in patients with a history of depression.

The evaluation of geriatric depression should also include assessments of the psychosocial situation and functional capacity of a patient, as functional difficulties can lead to physical limitations and social isolation, which can further worsen the course of depression. As a more extreme example, poststroke patients experience a “psychosocial storm” characterized by individual strain (e.g., difficulties with ADLs, demanding rehabilitation for the patient) as well as family/caregiver strain (e.g., alteration of usual family roles in accommodating the increased need of the poststroke family member) that increase feelings of helplessness, hopelessness, and depression in both the patient and the family/caregiver. Indeed, depressive symptoms seem to be increased in caregivers of patients with chronic illness, which is particularly pronounced in caregivers of patients with dementia. Other psychosocial factors to consider include race and ethnicity, as there is evidence for disparities in antidepressant medication prescriptions and symptom severity between different racial and ethnic groups. Further, evaluation of adverse childhood experiences (e.g., physical, sexual, and emotional abuse) should be a part of the assessment, as the negative effects of repeated adverse childhood experiences do not diminish in later life and are associated with depression in older adults.

Psychotherapy for Geriatric Depression

For the treatment of major depression in later life, current practice guidelines recommend a combination of pharmacotherapy and psychotherapy, with psychotherapy alone often sufficing as a first-line

treatment for minor depression in later life. Psychotherapy may play an essential role in the care of bereaved depressed older adults or in patients who have significant life crises, lack social support, develop disabilities, or lack coping skills to deal with their life situations. Psychotherapy may be helpful in supporting older adults to cope with their symptoms and adhere to treatment before antidepressant drugs take effect, and it should be considered in patients who cannot tolerate biologic treatments. Telepsychiatry may offer an efficacious option for psychotherapy delivery for homebound older adults. One study showed that an integrated telehealth service for older adults with depression was better than treatment as usual. Telepsychiatry was widely adapted during the COVID-19 pandemic to help meet the mental health needs of the geriatric population at a time when in-person visits posed significant exposure and health risks. A study of behavioral activation delivered via telepsychiatry found that it was effective at increasing social interaction, satisfaction with social support, and reducing disability.

A number of psychotherapeutic modalities, including interpersonal therapy, cognitive-behavioral therapy, and problem-solving therapy (PST), have been found effective in depressed older adults without significant cognitive impairment or medical burden. For patients with executive dysfunction, a number of psychotherapies have been found effective, including a modification of PST where the therapist is more directive, the focus is on less complex problems to facilitate learning, and the program is more structured. PST has been shown to be more effective than supportive therapy in reducing depression and disability in older adults with depression and executive dysfunction. Additionally, problem-adaptation therapy (PATH) was developed for older individuals with major depression and intermediate cognitive impairment and disability; this modality combines PST, environmental adaptation tools, and caregiver involvement to target the behavioral limitations inherent in depression and disability.

Extending the focus on the environment, ecosystem-focused therapy (EFT) has been developed to support patients through the “psychosocial storm” of an acute medical illness where depression is often a major contributor to disability and a hindrance to recovery. EFT has been developed as a treatment for poststroke depression. A meta-analysis showed that antidepressants are only weakly efficacious in poststroke depression and the efficacy of conventional psychotherapies is

questionable. The aim of EFT is to help the patient develop new perspectives and skills to confront the significant changes to their ecosystem brought on by these acute changes. A preliminary study showed that EFT is more efficacious than education in stroke and depression.

According to a meta-analysis of psychotherapy studies in a wide range of late-life depressive syndromes, psychotherapy, and pharmacotherapy have comparable efficacy. Although psychotherapy has proven to be an effective treatment in this population, it is often an underutilized resource. One idea behind the underutilization is that the complexity of available psychotherapies makes their implementation difficult in a general community setting.

To streamline both the delivery and language of psychotherapy interventions, it has been proposed that neurobiologic constructs be used to identify biologically meaningful behavioral targets that can serve as the basis for simplified and effective treatments. This view of treatment is supported by the RDoC project and has been successfully applied to the treatment of late-life depression with the development of “Engage,” a psychotherapy using simple-to-learn strategies that target accepted neurobiologic domains of late-life depression. Initial studies suggest that ENGAGE can be taught to community-based therapists, is noninferior to PST, and engages its behavioral targets.

Pharmacotherapy for Geriatric Depression

Overview. Older adults benefit from the same psychopharmacologic agents as younger patients. Benzodiazepines should generally be avoided. Residual anxiety should be treated with an increase of the dosage of the antidepressant to maximum levels rather than prescribing a benzodiazepine. Residual insomnia in depressed older adults can be treated with alternate agents such as trazodone (Desyrel). Orexin antagonists, including suvorexant and lemborexant, may also be considered for short-term treatment of insomnia in the geriatric population. Data shows suvorexant is well tolerated in the geriatric population with adverse events ratings comparable to placebo, with mild adverse effects including daytime sedation and sleepiness. Nonbenzodiazepine medications, including zolpidem (Ambien) or zaleplon (Sonata), have improved safety profiles compared to benzodiazepines. However, they

also have side effects in this population, including cognitive impairment, serious injury, and fractures.

Clinical practice guidelines recommend that SSRIs and other second-generation antidepressants (e.g., serotonin-norepinephrine reuptake inhibitors [SNRIs], bupropion, mirtazapine) are the first-line treatment for late-life depression. Late-life depression responds more slowly to antidepressants than the depression of younger adults. Executive dysfunction, slow cognitive processing speed, WMH, microstructural white matter abnormalities, and small hippocampal volumes each predict a slower and less complete response to antidepressant treatment. Older adult patients who respond to antidepressant treatment usually require 8 to 12 weeks to achieve full remission. The minimal length of an antidepressant trial should be 3 to 4 weeks at an adequate dose before a switch to another antidepressant or an augmentation agent is used. Patients who show no signs of improvement by the fourth week, however, will not likely respond to further treatment with the same agent.

Selective Serotonin Reuptake Inhibitors. Studies of older adult outpatients have shown that SSRIs are equally effective as tertiary amine tricyclics in the acute treatment of late-life depression. Recent findings suggest that SSRIs may delay the onset of AD in individuals with a previous history of depression, another reason to consider their use in this population. The dosages of SSRIs should be increased gradually. The starting daily dosages are 10 to 20 mg for fluoxetine, paroxetine, and citalopram, 5 to 10 mg for escitalopram and vortioxetine, and 25 to 50 mg for sertraline. For some patients, daily dosages of 20 mg of fluoxetine, paroxetine, and citalopram, 10 mg of escitalopram, and 100 mg of sertraline are sufficient, although higher dosages may be required. The most frequent side effects of SSRIs are insomnia, akathisia, nausea, anorexia, and pseudoparkinsonism. Inappropriate secretion of antidiuretic hormone (SIADH) leading to hyponatremia is much more common in older adults than in younger adults. Further, SSRIs may lead to an increased risk of bleeding, fragility fractures, poor mobility, and stroke.

Drug interactions should be considered in older adult patients receiving SSRIs. Fluoxetine and paroxetine inhibit the cytochrome P450 2D6 liver cytochrome isoenzyme. This pathway is essential for the hydroxylation of nortriptyline and desipramine and the metabolism of antipsychotics and type 1A antiarrhythmic drugs (encainide, flecainide), β-blockers, and

verapamil, whose plasma levels may be raised when fluoxetine or paroxetine is administered. The metabolite of fluoxetine, norfluoxetine, is an inhibitor of the 3A4 isoenzyme. The 3A4 isoenzyme is responsible for the metabolism of alprazolam (Xanax), carbamazepine (Tegretol), quinidine, erythromycin, and astemizole and may lead to an increase in the plasma level of these agents. Sertraline, citalopram, and escitalopram have a weak inhibitory action of the 2D6 isoenzyme and do not inhibit the 3A4. Fluvoxamine (Luvox) inhibits the P450 3A4 and the 1A2 cytochrome isoenzymes but does not significantly inhibit the 2D6 isoenzyme. Drugs metabolized by the 3A4 should be avoided in patients receiving fluvoxamine. Similarly, theophylline should be cautiously prescribed in fluvoxamine-treated patients since fluvoxamine may produce a threefold decrease in theophylline clearance by inhibiting the 1A2 isoenzyme.

Vortioxetine is a newer SSRI that is a serotonin 1A receptor agonist and a serotonin 3 receptor antagonist. It is also an antagonist of the serotonin 1D and 7 receptors and a partial agonist of the serotonin 1B receptors, although with somewhat lower affinity. Vortioxetine has been found to be effective in late-life depression. It may improve cognitive domains, including memory and executive dysfunction in the context of depression, The general starting dose is 10 mg daily, and a range of 5 to 20 mg daily is efficacious. Vortioxetine neither inhibits nor induces liver enzymes. It is metabolized by the 2D6 isoenzyme, and its dosage should be adjusted when coadministered with 2D6 inhibitors or inducers.

Vilazodone was approved by the FDA for the treatment of MDD in 2011 and is both an SRI and a partial agonist at the 5-HT1A receptor. Data on vilazodone in the geriatric population is limited, though vilazodone performed comparably to paroxetine in late-life depression in one study. Vilazodone is metabolized by CYP450 3 A4 and is highly protein bound, so it should be used with caution in combination with other drugs that are highly protein bound, such as digoxin or warfarin. The starting dose is 10 mg/day and is then titrated to a therapeutic dose of 20 to 40 mg/day. Adverse effects include diarrhea, nausea, and headaches.

Serotonin-Norepinephrine Reuptake Inhibitors. Venlafaxine XR (extended-release) leads to high remission rates (asymptomatic states) and has been found effective in hospitalized depressed patients as well as in drug-resistant depression and depressed patients with chronic pain. For this reason, venlafaxine should be considered in severe depression and in

depression unresponsive to other agents. Older adult patients appear to require dosages comparable to those of younger adults. Daily dosages of 112.5 to 225.0 mg are adequate for the majority of older adults. Nausea, a rather frequent side effect of venlafaxine, can be minimized by a slow increase in the daily dosage. Blood pressure should be monitored, especially in patients receiving dosages above 225 mg daily, since venlafaxine can increase blood pressure. Venlafaxine has limited drug–drug interactions and may be selected in older adults who require treatment with drugs interacting with other antidepressants. Venlafaxine has a short elimination half-life, but the extended-release preparation can be administered in a single dose. Nonetheless, abrupt discontinuation of venlafaxine XR may cause a withdrawal syndrome.

Duloxetine, an SNRI with relatively balanced serotonergic and noradrenergic action, has demonstrated efficacy in late-life depression as well as the treatment of comorbid pain. Following a week of 30 mg/day, the dose can usually be increased to 60 mg/day after a week of treatment if tolerated, with additional time on that does not associated with an increased chance of remission. For patients who remit on a dose of 60 mg, remission will typically occur by week 12 of treatment; additional time at that dose is not associated with an increased chance of remission.

Levomilnacipran is an SNRI with higher selectivity for norepinephrine reuptake inhibition than other SNRIs and has proven effective for major depression, although studies specific to late-life depression are ongoing. There is some evidence to suggest that individuals older than 60 years of age may have a greater antidepressant response to this medication than younger individuals. There is also evidence, however, suggesting that levomilnacipran may be less well tolerated in older adults with depression. Levomilnacipran has also been shown to inhibit the beta-site amyloid precursor protein cleaving enzyme-1. An investigation is currently underway to determine whether it may prevent beta-amyloid plaque formation. Levomilnacipran is largely metabolized by cytochrome P450 3A4. The medication is intended for once-daily dosing with a starting dose of 20 mg daily. The target dose range is 40 to 120 mg daily.

Tricyclic Antidepressants. The secondary amines, nortriptyline, and desipramine are the most frequently used TCAs in geriatric depression. They have lower anticholinergic and sedative effects than the tertiary amines amitriptyline, doxepin, and imipramine. Nortriptyline appears to

have a lower potential for orthostatic hypotension than other TCAs. The plasma levels of antidepressants required for the treatment of depressed older adult patients are similar to those needed by young adults (nortriptyline plasma levels of 60 to 150 ng/mL and desipramine above 115 ng/mL). Older adult patients often develop therapeutic blood levels of nortriptyline or desipramine while on low daily dosages (nortriptyline 1.0 to 1.2 mg/kg of body weight and desipramine 1.5 to 2.0 mg/kg). Older patients are more likely than younger patients to develop delirium, constipation, urinary retention, dry mouth, and orthostatic hypotension from these medications. For this reason, the dosages of antidepressants should be increased at a slower pace than in younger adults. Older adults on nortriptyline more often develop higher plasma levels of the nortriptyline metabolite 10-hydroxy-nortriptyline than do young adults, even when the plasma levels of the parent compound are similar. High 10-hydroxy-nortriptyline levels may contribute to cardiac conduction defects in older adults.

Orthostatic blood pressure, the electrocardiogram (ECG), and urination should be monitored frequently in older adults receiving nortriptyline or desipramine. Pretreatment systolic orthostatic hypotension has been found to correlate with antidepressant response to nortriptyline in some older adults. Therefore, nortriptyline, rather than desipramine, should be considered in such patients, and orthostatic blood pressure and subjective symptoms of orthostasis should be monitored carefully. TCAs have anticholinergic properties. For this reason, these drugs should be avoided in patients with prostatic hypertrophy or patients with narrow-angle glaucoma. Nortriptyline and desipramine have properties similar to those of type 1A antiarrhythmic drugs (quinidine-like drugs). When administered to patients with right or left bundle branch block, tricyclics may cause a second-degree block in approximately 10% of cases. For this reason, an ECG should always precede the use of tricyclics in older adults. A multicenter study (CAST-II) demonstrated that type 1A antiarrhythmics increase cardiac mortality in postmyocardial infarction patients. Although TCAs were not used in this study, the type 1A antiarrhythmic properties of TCAs suggest cautious use in depressed patients with ischemic heart disease.

Monoamine Oxidase (MAO) Inhibitors. The MAO inhibitors have been studied in depressed patients who are in their late 60s to early 70s.

However, limited information exists on the use of these agents in the old-old. MAO inhibitors are effective in patients with major depression as well as depressed patients with panic attacks. Low dosages of MAO inhibitors (e.g., phenelzine 30 to 45 mg daily or tranylcypromine 20 to 30 mg daily) should be used in older adults. Orthostatic hypotension is the most frequent important side effect of MAO inhibitors. This side effect is of concern in older adults because it may lead to falls and fractures, especially of the hip or the humerus. Other side effects include weight gain, insomnia, lack of energy, and daytime somnolence in phenelzine-treated patients and nervousness, insomnia, and excessive perspiration in tranylcypromine-treated patients. Peripheral neuropathy occurs in a small percentage of patients on MAO inhibitors and often responds to pyridoxine. Sympathomimetic amines, monoamine precursors, TCAs, SSRIs, venlafaxine, concomitant administration of two MAO inhibitors, and tyramine-rich food may cause a hypertensive crisis and should be avoided in patients on MAO inhibitors. The selegiline patch does not require diet restrictions at the lowest 6-mg dose and may be safer during diet violation than other MAOIs at higher doses. The advantage of transdermal administration is that intestinal monoamine oxidase is not inactivated to the same degree as oral administration, reducing the risk of a hypertensive crisis triggered by ingested monoamines.

Other Antidepressants. Bupropion, noradrenaline, and dopamine reuptake inhibitors have proven efficacy in younger adults as well as older adults with major depression based on a number of limited trials of the IR, SR, and XL formulations. Bupropion does not cause cognitive impairment or sedation, is safe in overdose, and lacks significant cardiotoxicity; it should be considered in older adult cardiac patients. Bupropion has few drug interactions, but it should not be prescribed in patients receiving MAO inhibitors. Bupropion may exacerbate pre-existing hypertension, and regular monitoring of blood pressure is required. Seizures have been reported in 0.4% of patients treated with bupropion, but the risk of seizures can be minimized by the use of sustained-release preparations, slow introduction of bupropion (100 mg daily), and restriction of the total daily dosage to 450 mg. Most older adults require a total daily dose of 300 mg.

Mirtazapine has been increasingly used in frail, depressed nursing home patients with anorexia. Mirtazapine antagonizes the α-2 presynaptic

inhibitory receptor as well as the 5-HT2 and the 5-HT3 serotonin receptors. Mirtazapine is an antagonist of histaminergic receptors and has a mild antagonist effect on the α-1 adrenergic and muscarinic receptors. These effects account for the sedative, hypotensive, and anticholinergic side effects of mirtazapine. Mirtazapine is not an inhibitor of the P450 cytochrome. Side effects include somnolence, dizziness, increased appetite, weight gain, and hyponatremia. A mild increase in cholesterol and triglycerides has been observed in 15% and 6% of patients, respectively. The starting dosage of mirtazapine is 7.5 to 15 mg and should be administered at bedtime to reduce daytime sedation. Daily dosages from 30 to 45 mg are sufficient for the treatment of late-life depression.

Psychostimulants may be helpful as augmentation agents in the treatment of late-life depression. Dextroamphetamine and methylphenidate appear to improve apathy and anergy in medical patients or cognitively impaired patients. Dextroamphetamine or methylphenidate at dosages of 5 to 10 mg in the morning and at noon is sufficient. Psychostimulants have a rapid onset of action, minimal side effects, limited potential for tolerance, and low risk for addiction. In patients with Parkinson disease, pramipexole, a dopamine receptor D2/D3 agonist, has been shown to improve depressive symptoms, including in treatment-resistant depression.

Complementary and Alternative Medicines. There are a number of natural supplements with some evidence of efficacy in geriatric populations. For instance, omega-3 fatty acids, St. John's wort, and *S*-adenosyl-*L*-methionine (SAMe) have shown some benefit for depression in a limited number of small studies in older adults. St. John's wort must be used with caution in geriatric populations due to drug–drug interactions through the induction of cytochrome P450 3A4. In addition, there has been limited study of nonpharmacologic alternative therapies in older adults. Tai Chi, and mind-body exercise practice, have been found beneficial in augmenting escitalopram in late-life depression in a randomized control trial. Bright light treatment is another noninvasive treatment with some evidence of efficacy in geriatric depression. Evidence also suggests that exercise confers a modest benefit in late-life depression compared with usual care or nonactive control interventions. Adherence to the Mediterranean diet and tea drinking was also associated

with having a beneficial effect on depressive symptoms in older adults in one study. Future study of these alternative approaches and their optimal delivery in older adults is needed.

Somatic Treatments

Electroconvulsive Therapy (ECT). ECT should be considered in both geriatric depression and mania because of its efficacy, rapid onset of action, and safety. In 2018, the FDA approved ECT for the treatment of severe major depressive episodes associated with MDD or BD in patients aged 13 years and older with treatment-resistant symptoms or who require a rapid response to treatment due to the severity of their psychiatric or medical condition. ECT may therefore be chosen in patients with severe mood syndromes unable to tolerate the long waiting imposed by the gradual introduction of antidepressants or mood stabilizers and the slow onset of drug action in older adults. In addition, ECT can be effective in treating neuropsychiatric comorbidities such as catatonia and parkinsonism, often present in depressed older adults.

ECT treatment characteristics must be chosen with an eye to maximizing treatment efficacy while minimizing cognitive side effects. An example of one such consideration is that ECT administration as often as three times weekly appears beneficial in producing a more rapid recovery than ECT given twice or once a week, yet less frequent ECT is associated with less cognitive impairment in the time period shortly after ECT. No differences in cognition have been found. However, 1 month after ECT completion between groups that had ECT thrice or twice weekly. ECT treatment variables to consider are electrode placement (right unilateral vs. bilateral), treatment frequency, stimulus intensity (energy), duration, pulse width, and pulse frequency. The effects of these choices are described elsewhere in this book. High-dose, ultra-brief, right unilateral ECT treatment has become a common choice due to reports of comparable efficacy and reduced cognitive side effects compared with bilateral ECT.

The mortality rate for all ages following a single ECT treatment is approximately 1 per 80,000 treatments, corresponding to 1 per 10,000 ECT-treated patients. This rate may be higher in older adults with severe medical conditions, but it appears to be lower than that for some medication treatments (TCAs), and there is some evidence that it may be compensated for by decreases in mortality following hospitalization

(compared with depressed patients receiving other forms of treatment or no treatment at all). The majority of deaths (67%) related to ECT are due to cardiac complications and occur immediately after ECT or within a few hours of treatment. Compared to younger adults, older adults and patients with pre-existing cardiac disease are more prone to cardiovascular events occurring in the context of ECT, including ischemic syndromes, arrhythmias, decompensation of heart failure, and severe transient rise in blood pressure. With adequate medical evaluation, however, monitoring during and after ECT, and appropriate intervention, most cardiovascular events related to ECT have a benign outcome.

Geriatric patients require a longer time to recover their memory than younger adults, especially after bilateral ECT. Moreover, geriatric patients sometimes develop prolonged confusion after ECT. The increase in falls with ECT has been reported as up to 15% in older adults. Controlled studies, however, are needed in order to examine whether and to what extent ECT-related confusion is responsible for these falls. The practice of favoring ECT over antidepressants in medically ill depressed patients may have led to inflated reports of ECT-related morbidity. Anecdotal literature suggests that ECT was used uneventfully in patients over 100 years old and in older adults with aortic aneurysm, cardiac pacemaker, history of myocardial infarction or stroke, transient ischemic attacks, severe hypertension, arrhythmias, or need for anticoagulants.

Other Therapies

Vagal nerve stimulation (VNS) is an FDA-approved treatment for chronic and recurrent depression. Through an implanted generator, electrical signals are delivered to the left cervical vagus nerve, where it is postulated that stimulation of the afferent fibers leads to modulation of mood-related networks (e.g., amygdala and locus coeruleus). Although studies of efficacy in geriatric depression are lacking, VNS does not carry an increased risk of surgical complications and does not necessarily increase the risk for cardiac abnormalities in this population.

Transcranial magnetic stimulation (TMS) is also FDA-approved for the treatment of depression. In this noninvasive procedure, an electromagnetic field is generated that depolarizes neurons leading to modulation of cortical activity. This procedure is well tolerated with minimal cognitive side effects and has been shown to lead to a higher remission rate than sham TMS in studies. One study of repetitive transcranial

magnetic stimulation (rTMS) in older adults with unipolar and bipolar depression found that it led to significant improvements in depression and anxiety from baseline to post-treatment in all age groups, with those aged 60 years and older showing statistically greater improvement than younger participants. Another preliminary study with TMS showed a significant reduction of depressive symptoms in poststroke depression, and rTMS has been found efficacious in vascular depression.

Treatment of Bereavement

For many bereaved older adults, symptoms of bereavement will resolve on their own over time. For this reason, prophylactic treatment is not recommended for the entire bereaved older adult population. Self-help groups, counseling, group therapy, and individual psychotherapy can be considered for individuals with an intense reaction to loss or a history of depression. A recent systematic review of treatment options for grieving older adults reported that viable treatment approaches are those incorporating behavioral activation and guidance on coping with issues related to secondary changes brought on by loss. Overall, grief interventions typically had small effects on grief-related symptoms in older adults.

Bereaved persons with depressive symptomatology that do not meet the criteria for major depression may benefit from brief focused psychotherapy. Interpersonal therapy lends itself well to this purpose since it addresses issues related to loss, depression, and change of roles.

Although antidepressant drugs can be effective in bereaved older adults with depressive symptoms, clear guidelines are not available. If major depression develops during the bereavement period, antidepressant treatment should be considered.

Complicated grief—a persistent complex bereavement disorder characterized by prolonged acute grief, feeling that life has no meaning, avoidance behaviors, and dysregulated emotions—has been identified in DSM-5 as a condition in need of further study. Complicated grief treatment (CGT) has been developed as a 16-week treatment with components of prolonged exposure, interpersonal therapy (IPT), and motivational interviewing and has been found to be more efficacious in symptom improvement than IPT in older adults. It appears that antidepressants may enhance the response to CGT but that antidepressants alone may be ineffective.

Treatment of Psychotic Depression

For the treatment of psychotic depression, the recommended treatment includes combinations of antidepressants (SSRIs or venlafaxine XR) and atypical neuroleptics (except clozapine), although there are limited clinical trials for older adults. In one multicenter 12-week double-blind, randomized controlled trial (STOP-PD) and a follow-up study (STOP-PD II), combination pharmacotherapy with olanzapine and sertraline was associated with higher remission rates during the trial period compared to olanzapine plus placebo in patients. ECT treatment is another option, especially if combination drug treatment fails or is poorly tolerated.

Treatment of Depression in Dementia

In older adults with major depression and mild-to-moderate dementia, the historical treatment of choice was a combination of an antidepressant with psychosocial intervention, although there are limited data to support the use of antidepressant medication. Indeed, in a large, well-powered study, not only were antidepressants (i.e., sertraline and mirtazapine) found ineffective in depressed demented patients but they also were associated with more adverse effects than placebo. A review article in 2017 found that evidence does not support the use of pharmacologic treatment of depression in patients with dementia. Further, a more recent meta-analysis in 2021 found that nonpharmacologic interventions were more efficacious than drug interventions in reducing depressive symptoms in older adults with depression symptoms and comorbid dementia without an MDD diagnosis. These findings suggest that psychosocial interventions such as PATH and caregiver-focused treatment may be better first-line treatment options for this population.

Treatment-Resistant Depression

Change in antidepressant strategy should take into consideration that depressed older patients take a longer time to respond to antidepressants than younger adults. If a patient has had little or no response to an adequate antidepressant trial, switching to a different antidepressant rather than using an augmenting agent is an appropriate first step. If a patient has had little or no response to an initial SSRI, the patient may be switched to an SNRI or bupropion (SR or XL). If a patient has had little or no response to venlafaxine, the patient may be switched to an SSRI. If the

patient has had little or no response to a TCA or bupropion, switching to an SSRI or SNRI is appropriate. Although studies on older adults are lacking, research on younger patients suggests that switching from one SSRI to another is an effective strategy.

Augmentation therapies are recommended in depressed older adults with partial response to the initial antidepressant, although there is limited agreement on the choice of augmentation therapies. Bupropion, lithium, or nortriptyline may be added if the initial antidepressant is an SSRI. If the initial antidepressant is a TCA, lithium or an SSRI may be added. If the patient was on bupropion, an SSRI or lithium may be added. An additional augmentation strategy in older adults is the combination of an SSRI or SNRI plus mirtazapine. In a study of middle-aged adults (mean age in mid-40s), mirtazapine (30 mg) plus fluoxetine (20 mg), venlafaxine (225 mg), or bupropion (150 mg) achieved greater remission rates (46% to 58%) after 6 weeks than fluoxetine monotherapy (25%). Among those who responded, double-blind discontinuation of one agent led to relapse in 40% of the cases.

The addition of methylphenidate may be helpful to accelerate treatment response to an SSRI antidepressant and may improve mood and well-being and lead to a higher remission rate compared to either drug alone.

Treatment with an atypical neuroleptic, alone or in combination with other medications, is sometimes effective for treatment-resistant depression. The augmentation of antidepressants with aripiprazole has been found to be effective in older adults. In one large RCT, aripiprazole augmentation (dose range 2 to 15 mg daily, target dose 10 mg daily) led to a higher remission rate compared to placebo, with remission rates sustained at a 12-week follow-up. Adverse effects reported included increased dream activity, weight gain, tremor, and extrapyramidal symptoms, including akathisia and parkinsonism. Quetiapine XR has been found effective as an augmenting agent for depression in younger adults, with more limited data available for its efficacy in older adults. In one placebo-controlled RCT of quetiapine in older patients with MDD, quetiapine monotherapy was associated with higher remission rates of depression than placebo and was well tolerated, with adverse events including dizziness, headache, and somnolence.

Brexpiprazole is a novel antipsychotic that is structurally similar to aripiprazole and is a partial agonist of D2 and 5-HT1A receptors and a strong antagonist of 5HT2A and norepinephrine alpha1B and alpha 2 C

receptors. Brexipiprazole is metabolized by cytochrome P450 CYP3A4 and CYP2D6, so the dose should be reduced when prescribed with inhibitors of these enzymes. A lower starting dosage is recommended in older adults (0.5 mg/day) with a maximum of 3 mg/day. While efficacious in studies on younger adults with depression, its efficacy has not been studied specifically in older adults. It should be noted that the use of antipsychotic agents (both atypical and typical) in older individuals with dementia has been associated with a greater risk of mortality and increased risk of cerebrovascular events. It is unclear if this risk extends to older adult patients with mood disorders who do not have dementia. When medication treatment fails, ECT may offer the best chance for response and remission.

Subcutaneous ketamine, an intervention for depression of emerging interest in the general adult population, was well tolerated (at doses of 0.1 to 0.5 mg/kg) and found to lead to remission of symptoms in a recent randomized control trial (n = 16) for treatment-resistant depression in older adults. Repeated treatments (up to five treatments administered at intervals of 1 week or greater apart) resulted in a higher likelihood of remission or a longer time to relapse.

In contrast, in one study, esketamine (the S-enantiomer of ketamine racemate, which has shown efficacy in younger adults with treatment-resistant depression) in combination with an antidepressant did not differ significantly from antidepressant plus placebo nasal spray when studied in older adults with treatment-resistant depression. The adverse event profile was similar to that seen in esketamine studies of younger patients. Future work is needed to evaluate rapidly-acting antidepressants in older adult populations.

Continuation and Maintenance Treatment

The intent of continuation treatment (6 months) is to prevent relapse of the acute episode, while maintenance treatment is offered after the first 6 months of remission in order to prevent a new depressive episode. Continuation and maintenance treatment should use the same dosages of antidepressants as those of acute treatment. Continuation treatment should be offered to all patients with late-life depression. Patients at high risk for recurrence should have maintenance treatment. The strongest predictor of recurrence is a history of three or more lifetime episodes of depression. For such patients, experts recommend treatment for 3 years

or longer. Disagreement exists concerning the optimal maintenance treatment duration in older adults with fewer episodes. Other predictors of depression recurrence are high severity of the initial episode and persisting anxiety, and in mixed-age populations, late age of illness onset is a strong predictor of recurrence. In patients with psychotic depression who achieve remission following treatment with an antidepressant and an antipsychotic, continuation of the antipsychotic drug is recommended, typically for 6 months, but some experts recommend shorter or longer treatment. For depressed patients who failed antidepressants but responded to ECT, antidepressants (other than those to which the patient previously failed to respond) plus a mood stabilizer should be used for continuation/maintenance treatment. Continuation/maintenance ECT is another option, with the PRIDE study showing that four additional treatments after remission was beneficial in sustaining mood improvement for most patients.

Adherence. Approximately 70% of patients fail to take 25% to 50% of their medications. Older patients and their families may often have difficulty accepting the diagnosis of depression and understanding the need for long-term treatment. Further, cognitive impairment, physical disability, and financial hardship faced by many older adults may present a challenge to treatment adherence. Concurrent medical illnesses may interfere with an antidepressant response or the attainment of adequate dosages. Alcohol and other substance use disorders may undercut pharmacotherapy. Difficulties accessing health care may hinder the ability of older adults, especially functionally dependent older adults, to obtain adequate treatment.

Care Delivery

Several interventions have been developed to improve the treatment of geriatric depression in the primary care setting. The Improving Mood-Promoting Access to Collaborative Treatment (IMPACT) study focused on older adults and offered access for up to 12 months to a depression care manager who was supervised by a psychiatrist and an expert primary care physician. The depression care manager offers education, care management, and support of antidepressant management by the primary care physician or PST (brief structured psychotherapy). Depressed primary care older adult patients receiving the IMPACT intervention were

more likely to receive antidepressants or psychotherapy than usual care patients. They had lower depressive symptomatology and higher overall function, response and remission rates, quality of life, and satisfaction with treatment. These benefits were sustained 12 months after the end of the intervention. A recent systematic review showed that the collaborative care model for depressive disorders among older adults is feasible and beneficial in diverse settings.

Positive outcomes have also been reported by the Prevention of Suicide in Primary Care Elderly: Collaborative Trial (PROSPECT). The lynchpin of the PROSPECT intervention was the use of care managers, who were trained social workers, nurses, and psychologists who worked alongside primary care physicians. They followed the patients and monitored their psychiatric symptoms and signs, treatment adherence, and side effects, and provided appropriately timed and targeted recommendations to physicians according to an algorithm. Patients treated in practices offering the PROSPECT intervention had a higher likelihood of receiving antidepressant treatment, a greater decline in the rate of suicidal ideation, and a more favorable course of depression over a period of 24 months. The beneficial effects of the PROSPECT intervention were most pronounced in primary care patients with major depression rather than minor depression.

The concept of an integrated care model has been extended to depressed patients with chronic medical illnesses. The personalized adherence intervention for depression and COPD (PID-C) is an integrated approach implemented by care managers to improve adherence to treatment for both COPD and depression with a focus on helping patients to overcome barriers to treatment and offering interventions that support patients in using treatment prescribed by their own physicians. PID-C reduced depressive symptoms and dyspnea-related disability more than usual care.

Clinical case management has been shown to reduce the severity of depression and improve disability in low-income, disabled older adults suffering from major depression.

Overview of Geriatric Bipolar Disorder Evaluation and Treatment

The goals of geriatric BD include symptom amelioration (i.e., resolution of mania, remission of depression, and maintenance of euthymia) as well as improvements in functional status and prevention of recurrences. The

evaluation of geriatric BD should include a comprehensive assessment exploring comorbidity (psychiatric, medical, and neurologic), functional status, and psychosocial factors. Further, substance use disorders are common in geriatric BD patients and should be routinely assessed and treatment offered in the evaluation period. Medications should be evaluated as well, given that medications such as corticosteroids and dopaminergic agents such as stimulants and antiparkinsonian drugs can precipitate mania.

Older adults with BD often have limited, slow, or fragile treatment responses. Guidelines for dosage and duration of treatment with antimanic agents cannot be extrapolated directly from younger adult studies because aging, comorbid neurologic diseases, high medical burden, and poor social support may directly or indirectly, through poor adherence, interfere with the treatment response of late-life BD and increase vulnerability to side effects.

Pharmacotherapy for Geriatric Bipolar Disorder

Lithium is the best-investigated drug in geriatric mania. Data shows that in older adults with bipolar depression or treatment-resistant MDD, lithium users experienced less depressive symptomatology, lower clinical severity, and less frequent psychiatric admissions compared to those not prescribed lithium. Lithium may be less effective in mania with comorbid neurologic and medical disorders than in uncomplicated mania. Age-associated decline in renal clearance in older adults leads to high lithium plasma levels even when low dosages are used. Lithium should be introduced slowly, starting with daily dosages of 150 mg. About one-half of the dosage required for young adults is sufficient for older adults. The half-life of lithium is about 24 to 36 hours in patients who are in their 70s. Therefore, steady-state pharmacokinetics is anticipated 5 or more days after the stabilization of the daily dosage. In some older adults, lithium plasma levels of 0.3 to 0.6 mEq/L were found to be effective. Controlled studies, however, are needed to establish the efficacy of low lithium plasma levels in older adults. The onset of action of lithium is slow and may require several days or weeks.

The side effects of lithium can be pronounced in geriatric patients. Older adult patients often develop a fine tremor or myoclonus at lithium plasma levels considered nontoxic in young adults. Lithium can produce parkinsonian symptoms or worsen pre-existing Parkinson disease.

Delirium can develop at plasma levels below the therapeutic range. Neuroleptics increase the risk of delirium in older adult patients on lithium. Lithium may worsen cognitive function, especially in individuals with dementia, though some research suggests that long-term lithium treatment might have neuroprotective effects. Longer lithium exposure has been associated with greater white matter integrity in older adults with bipolar depression. Lithium inhibits glycogen synthase kinase 3, a key enzyme in the metabolism of amyloid precursor protein and in the phosphorylation of tau protein, which may reduce the risk of AD. A case-control study of older adults with BD reported that patients treated continuously with lithium had a significantly lower prevalence rate of dementia than patients who did not receive continuous lithium treatment. Sinoatrial block may be caused by lithium in predisposed patients; digitalis and β-blockers increase the risk for sinoatrial block. Salt depletion, thiazide diuretics, and nonsteroidal anti-inflammatory drugs (NSAIDs) may raise the lithium plasma levels and result in toxicity. Chronic kidney disease appears to be common in older adults treated with lithium.

The antiepileptics sodium divalproex, carbamazepine, and lamotrigine are effective for preventative treatment in BD. Anticonvulsants are effective in both lithium responders and lithium nonresponders. The GERI-BD trial demonstrated that lithium and divalproex were found to be equally well tolerated and efficacious, with lithium associated with a greater reduction in manic symptoms over 9 weeks. However, anticonvulsants may be more effective than lithium in patients with rapidly cycling mania or dysphoric mania. Although there is limited research on anticonvulsants in older adult populations with BD, anticonvulsants should be considered, especially in patients at high risk for lithium toxicity or history of poor response to lithium. Drowsiness and sedation are frequent dose-dependent side effects of valproate and carbamazepine. Many patients are habituated to sedation. Therefore, the slow introduction of valproate or carbamazepine may reduce this problem. In older adults, the principal side effects of valproate are gastrointestinal distress and ataxia. Frequent side effects of carbamazepine are ataxia and confusion. Carbamazepine can also cause hyponatremia. Approximately 0.4% of patients receiving valproate and 2.0% of patients receiving carbamazepine develop leukopenia with a white blood cell count below 4,000/mm^3. Valproate may cause thrombocytopenia in older patients much more frequently than in younger adults. Carbamazepine-treated patients have a reduction in their

white blood cell count during the first 2 weeks. For this reason, periodic monitoring of the white count is indicated, especially during the early phases of treatment with anticonvulsants.

Lamotrigine is generally well tolerated and does not cause weight gain, sedation, sexual side effects, or cognitive impairment. There is some preliminary evidence to suggest that lamotrigine might be associated with improved cognitive status in adults with bipolar depression. It helps mainly for depression, which for bipolar patients is often a greater concern than mania or hypomania. A mild rash is common, and the risk of serious but not life-threatening rash is approximately 1 in 250. The risk of Stevens–Johnson syndrome is approximately 1 in 1,000, or perhaps lower, with cautious uptitration as recommended to reduce the rash risk. Lamotrigine should be stopped immediately if a rash develops. Simultaneous treatment with valproate can more than double lamotrigine's half-life, so such patients should start at no more than 25 mg every other day with dose increases no more than once every 2 weeks in the first weeks. Effective doses are usually 100 to 200 mg/day. Thus, a drawback of lamotrigine is that it can take weeks to reach a therapeutic dose.

Agitated manic older adult patients may be treated with low dosages of lorazepam. Lorazepam is favored over other benzodiazepines because it undergoes only phase II metabolism (glucuronidation), a process minimally affected by aging. Effective alternatives to lorazepam are atypical and high-potency neuroleptics in oral (e.g., risperidone 1 to 2 mg, olanzapine 5 to 10 mg daily) or injectable (e.g., haloperidol 0.5 to 5 mg daily) form. These drugs should be used early in the treatment of acute mania and should be withdrawn when the agitation is controlled, and therapeutic plasma levels of a mood stabilizer are established.

In addition to agitated mania, antipsychotic agents may also be useful in the treatment of mania as well as bipolar depression. For instance, there is evidence that atypical antipsychotics, including olanzapine, risperidone, and quetiapine, may be effective in the treatment of geriatric mania, while quetiapine and lurasidone may have some efficacy in bipolar depression. Lurasidone has been associated with sustained improvement in depression symptoms in older adults with bipolar depression, with common adverse effects including headache, nasopharyngitis, and insomnia. Adjunctive lurasidone therapy (used in combination with lithium or valproate) led to higher rates of tremor and akathisia than monotherapy

and did not differ from placebo when used as adjunctive therapy in one study.

Paliperidone and cariprazine have also been found effective in the treatment of acute mania for the general adult population alone or in combination with a mood stabilizer, though data on these agents is limited in the geriatric population.

Asenapine has been studied in a small number of open-label trials with manic patients aged 60 years and older, with results showing efficacy in reducing manic and hypomanic symptoms. Side effects of asenapine observed in these trials included QTc prolongation, restlessness, gastrointestinal discomfort, and extrapyramidal symptoms. Clearance of asenapine appears to decline with age, though the safety profile does not seem to differ significantly between older and younger patients.

Aripiprazole may be efficacious in treating symptoms of mania when used in conjunction with a mood stabilizer for older adults who do not respond well to other first-line treatments, though current data specific to older adults with this medication are limited. An open-label trial of aripiprazole adjunctive to traditional mood stabilizers in 20 older adults found significant improvement in mania symptoms over 12 weeks. The increased risk of weight gain, hyperlipidemia, and diabetes associated with at least some atypical neuroleptics raises the risk of cardiovascular disease.

Antidepressant use in BD is controversial due to concern about antidepressant-induced mania or mixed states, although studies of such complications are limited in older populations.

Other Treatments for Geriatric Bipolar Disorder

ECT is efficacious in late-life bipolar depression. In fact, a recent mixed-age observational study found that higher age was associated with a better prognosis for response to ECT in patients with BD. Limited data support the efficacy of ECT in the treatment of mania in older adults. TMS has been shown to be a treatment option for geriatric bipolar depression, with one study showing that rTMS leads to greater improvement in unipolar and bipolar depression and anxiety symptom scores in patients older than 60 and appeared to be well-tolerated. Cognitive-behavioral therapy, family-focused therapy, and interpersonal social rhythm therapy have been shown to be effective as adjuncts to medications in shortening the time to remission from a depressive episode. Psychosocial

interventions targeting adherence to treatment, such as customized adherence enhancement (CAE) therapy, have been found effective in geriatric BD in improving treatment adherence, reducing mood-related symptoms and signs and global psychopathology, and improving functioning.

The Helping Older People Experience Success (HOPES) program is a 2-year program for older adults with severe mental illness that aims to improve self-efficacy, increase community engagement, and decrease reliance on healthcare services by offering weekly social skills training, health care management by a nurse, and bimonthly community outings to practice skills. The HOPES intervention was shown in an RCT to improve patient outcomes at the conclusion of the 2-year program and at 3-year follow-up.

An enhanced clinical intervention (ECI) intensive, including educational modules and illness management components (such as the development of crisis plans; and psychoeducation about symptoms and side effects), was shown to help older adults with BD improve global functioning and quality of life.

A 12-week group intervention called “Medication Adherence Skills Training of Middle-Aged and Elderly Adults with Bipolar Disorder” (MAST-BD) comprised of four modules—educational, motivational, medication management, and symptom management—was developed to target medication nonadherence. This intervention was shown to improve adherence, as well as depressive symptoms and quality of life.

FUTURE DIRECTIONS

Although medical and neurologic comorbidity of geriatric mood disorders may complicate care, they have served as a window to mechanisms contributing to geriatric mood disorders. The clinical association of depressive symptoms with impairment in specific cognitive functions has been a central stimulus to research on geriatric depression. Studies of the integrity of white matter in distinct brain regions have begun to identify abnormalities leading to disconnection states contributing to late-life depression and executive dysfunction. Advances in neuroimaging and electrophysiology make possible the identification of structural, functional, and processing abnormalities predisposing depressed older adults to poor response to antidepressants or to mood stabilizers. Genetics research

identified some polymorphisms that increase the risk of resistance to some antidepressants. Neuroimaging studies are underway to identify the mechanisms by which genetic factors increase resistance to antidepressants and also to investigate endophenotypes of geriatric mood disorders and biomarkers that may predict response to specific interventions.

With the recently advanced hypotheses of geriatric depression, there is the promise to guide novel treatment development. For example, studies of the “DED syndrome” demonstrated that executive dysfunction and structural and functional abnormalities of the cognitive control system are associated with poor response to antidepressant drugs. However, appropriately modified PST reduced both depression and disability more than supportive therapy in depressed, nondemented patients with major depression and executive dysfunction. PATH was developed in order to address the clinical needs of depressed older adults with cognitive impairment up to moderate dementia. A neuroplasticity-based computerized cognitive remediation-geriatric depression treatment (nCCR-GD) was developed to target executive dysfunction in late-life depression. The underlying assumption was that remediation of these deficits may improve the functional brain networks shared by executive dysfunction and depression. Two studies have now shown that this software improves both depressive symptoms and executive function in late-life major depression. Because it is standardized and self-administered, nCCR is not subject to therapists’ skill drift and may be helpful in minimizing barriers to access to care due to its low cost and administration in a patient’s home. Future work may investigate whether nCCR alone or in combination with TMS or pharmacotherapy may ameliorate specific cognitive dysfunction and improve outcomes in geriatric depression and BD.

While the inflammation hypothesis of late-life depression has generated interest in the role of anti-inflammatory agents in the treatment of late-life depression, many questions remain. The position of inflammation in the chain of biologic events leading to late-life depression needs to be clarified. Assuming that the brain’s inflammatory responses have regional specificity, it is unclear whether the localization of these responses influences the clinical profile of late-life depression and its course. In addition, the role of peripheral inflammatory indices in determining the choice of antidepressants needs to be further understood. A review of

meta-analyses suggests that in the subgroup of individuals with MDD and evidence of increased inflammatory biomarkers, NSAIDs, omega-3 fatty acids, and cytokine antagonists may have antidepressant properties.

Minocycline, a microglia inhibitor, has been shown to exert an antidepressant effect in a meta-analysis of clinical trials, though it was noted that studies had a small sample size and only a small number were RCTs. A larger RCT of minocycline and celecoxib as adjunctive treatments for bipolar depression did not show an effect compared to a placebo. Etanercept, an agent that reduces TNF-α–mediated cellular response, reduced symptoms of depression in a placebo-controlled study of patients with psoriasis. The cyclooxygenase-2 inhibitor celecoxib has been found to augment the efficacy of reboxetine and fluoxetine in patients with MDD. In treatment-resistant major depression, baseline high concentrations of high-sensitivity CRP predicted a favorable response to the TNF antagonist, infliximab. Adequately powered randomized controlled trials need to clarify which anti-inflammatory agents have antidepressant action and for whom.

In addition, future work is needed to ascertain whether antihypertensive, antihypercholesterolemic, and antiplatelet agents and diabetes control can improve the outcomes of vascular depression. Longitudinal assessment of depressive symptomatology during antiplatelet secondary prevention trials can evaluate the efficacy of these agents in improving the course of vascular depression. Modulators of the RAS improve cerebral perfusion and may improve cognition. Angiotensin receptor blocker (ARB) use has been associated with improvement in depression, anxiety, and quality of life in one study. Direct studies are needed to clarify the role of ARBs in the treatment of vascular depression. Few studies suggest that calcium channel blockers may reduce depressive symptoms, and in an early study of vascular depression treated with a variety of antidepressants, the addition of nimodipine improved depressive symptoms more than the addition of an inactive comparator. Finally, anti-inflammatory agents may have a role in vascular depression, but studies are lacking.

Advances in biology and psychotherapeutic interventions, along with clinical and psychosocial studies of the comorbidity and social complexity of geriatric mood disorders, are generating knowledge on which to build comprehensive models of care. For programs such as PID-C to become part of the mainstay of clinical treatment of late-life depression, their efficacy, implementation potential, and fiscal feasibility need to be

demonstrated. The IMPACT and PROSPECT interventions are concrete examples of treatment models that address the clinical complexity of geriatric depression and the barriers imposed by the primary care setting. Reimbursement constraints remain a barrier to the implementation of such programs. Studies are underway that build on the principles of these models and focus on existing services supported by the available reimbursement system. Such studies offer focused training to clinicians and interventions at the organizational level to increase functional collaborative relationships between primary care practices and already funded independent mental health clinics. Further research is needed to find efficient interventions and to weigh costs versus benefits in various older adult populations with distinct needs.

55.3f Alzheimer Disease and Other Neurocognitive Disorders

Gary W. Small, M.D., and Stephen T. Chen, M.D.

In part because of medical technologic advances, people in industrialized societies are living longer, and the number of older persons is growing rapidly. Because age is a major risk factor for developing Alzheimer disease and other neurocognitive disorders (NCDs), the number of persons suffering from these illnesses has increased along with the aging of our society in recent years. With the exception of rare genetic mutations, the cause of Alzheimer disease is not known. Scientists are actively searching for disease-modifying treatments and possible cures, and improved knowledge of potential risk and protective factors and biomarkers may contribute to preventive strategies. Along with such approaches, accurate early diagnosis, symptomatic treatments, and environmental interventions are essential to minimize the suffering of patients and family members and to optimize the quality of life for patients.

HISTORY

In 1906, the German psychiatrist and neurologist Alois Alzheimer first described a middle-aged patient who had suffered from a progressive dementia that affected language, memory, and behavior. After the patient's death at age 55 years, Alzheimer applied new staining techniques to the patient's brain tissue and demonstrated the presence of what is now termed neurofibrillary tangles and neuritic plaques in the neocortex and other brain regions. For years, Alzheimer disease was considered presenile dementia because it was not known that plaques and tangles were present in most older adults with dementia. However, in the late 1960s, when the degree of dementia was shown to correlate with the number of neuritic plaques in neocortical association areas in cases of senile dementia, late-onset Alzheimer disease was finally recognized.

Over the last several decades, the recognition that cognitive decline may be pathologic rather than normal in aging has helped to drive scientific advances but has also served to stigmatize the condition. Many older people have been reluctant to seek help for memory symptoms because of

fear that they may be suffering from Alzheimer disease. Thus, symptomatic treatments are often begun after patients are already suffering from moderate degrees of dementia. However, if treatments that delay the onset of Alzheimer disease can be developed, there may be less emphasis on the treatment of the disease state and greater attention to prevention and deceleration strategies, reducing the stigma and increasing access to care.

COMPARATIVE NOSOLOGY

A definitive diagnosis of Alzheimer disease can be made only by histopathologic examination of brain tissue, generally postmortem. Therefore, most cases are diagnosed based on clinical information and, in some settings, additional diagnostic studies.

Current diagnostic criteria for dementia and Alzheimer disease are provided by two important references (Table 55.3f–1). In the fifth edition of the *Diagnostic and Statistical Manual* (DSM-5) published in 2013, the syndrome of dementia from the revised fourth edition (DSM-IV-TR) is subsumed under the new category "Major Neurocognitive Disorders." A major NCD requires a significant decline in at least one cognitive domain and daily functioning based on subjective concern and clinical assessment. DSM-5 provides additional diagnostic criteria for specific NCD subtypes, which include vascular, frontotemporal, traumatic brain injury, and Lewy bodies.

In 2011, a work group formed by the National Institute on Aging and the Alzheimer Association (NIA-AA) published diagnostic guidelines for "probable" and "possible" Alzheimer disease. Criteria for both are similar to those for a major NCD but require cognitive impairment based on history and objective cognitive assessment and a minimum of two cognitive or behavioral domains affected. Probable Alzheimer disease further specifies that cognitive impairment is insidious in onset, progressive, and prominent in memory, language, visuospatial, or executive functioning. Possible Alzheimer disease should be considered when the course is atypical or cannot be reliably documented, and there is evidence of other etiologies, for example, cerebrovascular disease or Lewy body dementia.

Both DSM-5 and the NIA-AA group recognize milder levels of cognitive impairment or a predementia stage of Alzheimer disease. In DSM-5, "Mild Neurocognitive Disorders," which feature "modest" cognitive decline and no functional impairment, was added as a new diagnostic category to encourage earlier diagnosis and intervention, which may more effectively

modify the course of illness than that in the later stages. The NIA-AA guidelines refer to the predementia stage as “mild cognitive impairment (MCI).” Core clinical criteria for MCI include concern for cognitive changes, impairment in one or more cognitive domains, preferably measured by serial objective testing, preserved independence in daily activities, and no evidence of dementia and other etiologies of cognitive impairment. Not all patients with MCI progress to dementia, though somewhere between 6 and 25% convert to dementia each year. While either mild NCD or MCI can be diagnosed with only clinical data, the DSM-5 and the NIA-AA guidelines both refer to research biomarkers for Alzheimer disease that may aid diagnosis, particularly in the earlier stages of the disease. Such biomarkers include structural neuroimaging with magnetic resonance imaging (MRI), molecular neuroimaging with positron emission tomography (PET), cerebrospinal fluid (CSF) analysis, and genetic testing. Biomarker research and its potential impact on the nosology of Alzheimer disease are discussed below.

Table 55.3f–1.
Comparison of Diagnostic Criteria for Mild and Major Neurocognitive Disorders in Fifth Edition of the Diagnostic and Statistical Manual (DSM-5), Mild Cognitive Impairment, and National Institute on Aging-Alzheimer’s Association Criteria for Probable Alzheimer Disease Dementia

	Mild Neurocognitive Disorder	Mild Cognitive Impairment	Major Neurocognitive Disorder	Probable Alzheimer Disease Dementia
Core Criteria	Modest cognitive decline based on concern of the individual, informant, or clinician, or on clinical assessment	Concern for cognitive decline reported by patient, informant, or clinician, and objective evidence of cognitive impairment	Decline in one or more cognitive domains: complex attention, memory/learning, language, perceptual-motor, executive functioning, social cognition	Insidious onset of cognitive decline evident on history and exam in a minimum of 2 cognitive domains: learning/memory, language, visuospatial, executive functioning, personality/behavior
Functional Criteria	Cognitive deficits do not interfere with capacity for independence in everyday activities	Preservation of independence in functional abilities	Cognitive deficits interfere with independence in everyday activities	Inability to function at work or usual activities at previous level
Exclusion Criteria	Core criteria do not occur exclusively during delirium or other mental disorders	No dementia	Core criteria do not occur exclusively during delirium or are better accounted for by another mental disorder	Not explained by delirium or major psychiatric disorder, and no core/prominent features of other dementias, active neurologic or medical condition, or medication that can cause cognitive impairment

EPIDEMIOLOGY

NCDs are the most common psychiatric disorders in older persons and a growing public health problem in the United States. According to data compiled by the Alzheimer's Association in 2021, Alzheimer disease accounts for 60% to 80% of dementia cases and afflicts 6.2 million people in the United States or more than 1 in 9 people over the age of 65. As the baby boom generation (born between 1946 and 1964) ages, this number is expected to more than double by 2050 to 12.7 million (Fig. 55.3f–1). Alzheimer disease is the fifth leading cause of death as well as the leading cause of disability and poor health among older adults. Individuals with Alzheimer disease can live a relatively long time, on average 4 to 8 years after diagnosis, and require significant caregiving for much of this time. Alzheimer disease and other NCDs cost society over $355 billion in direct health care and long-term care costs and $257 billion in unpaid caregiving annually. These costs do not account for the additional health and financial burdens of dementia caregivers, who suffer more stress, depression, chronic health conditions, and loss of employment than other caregivers and adults. Direct costs are projected to exceed $1.1 trillion in 2050 if current trajectories hold. Recent research is focusing on novel treatments that effectively delay the onset of disease. Treatment that delays onset by 1 to 5 years is projected to reduce direct health costs by 14% to 39%.

FIGURE 55.3f–1. Projected number of people aged 65 and older (Total and by Age) in the U.S. population with dementia due to Alzheimer disease, 2020 to 2060. (Data from Rajan KB, Weuve J, Barnes LL, McAninch EA, Wilson RS, Evans DA. Population estimate of people with clinical AD and mild cognitive impairment in the United States [2020–2060]. *Alzheimers Dementia*. 2021;17:1966–1975.)

ETIOLOGY

The search for possible causes for Alzheimer disease has seen significant advances but remains inconclusive. Scientists are approaching this search from various angles, which include genetics, neurochemistry, neuropathology, and neuroimaging studies. Hopefully, this search will eventually lead to treatments that may delay or even halt the disease process.

Alzheimer disease was first characterized and remains pathogenetically defined by its histopathologic features, neuritic plaques (extracellular deposits of amyloidogenic proteins), and neurofibrillary tangles (abnormal intracellular cytoskeletal filaments). Reduction in neuron number and synapses and an accumulation of plaques and tangles occur in the frontal, temporal, and parietal lobes; that finding is consistent with the involvement of association and limbic brain structures.

Extensive study of the formation of plaques and tangles and other neurobiologic changes associated with neurodegeneration have led to two prevailing hypotheses to explain the mechanisms that lead to Alzheimer

disease: the cholinergic and the amyloid cascade hypotheses. The cholinergic hypothesis posits that a dysfunctional cholinergic system causes the symptoms of Alzheimer disease. Clinical evidence suggests that anticholinergic medications impair cognitive function in older adults, and biochemical and neuropathologic evidence confirm a presynaptic cholinergic deficit in brains with Alzheimer disease. The amyloid hypothesis states that Alzheimer disease is caused by the excess accumulation and deposition of β-amyloid to form neuritic plaques. Additionally, the accumulation of β-amyloid is believed to result in neuronal dystrophy and neurofibrillary tangles and induce cholinergic dysfunction, oxidative stress, inflammation, and vascular damage.

Discoveries in the area of genetics and molecular biology have been critical to our understanding of the etiology of Alzheimer disease and have shown relationships between genes and pathogenesis. The high frequency of Down syndrome (trisomy 21) patients who invariably develop Alzheimer disease neuropathology and dementia by their 40s led to finding significant linkage to chromosome 21 in some early-onset families. Excitement escalated when the gene coding for the amyloid precursor protein (APP) found in senile plaques was localized to the same chromosome 21 regions. APP mutations, however, are relatively rare. Most early-onset pedigrees not segregating APP mutations show mutations of a chromosome 14 gene (presenilin 1). Another form of early-onset Alzheimer disease is represented by families of Volga German origin, in whom chromosome 1 mutations (presenilin 2) have been identified.

Studies of the common late-onset disease (symptoms beginning after age 60 years) showed evidence for linkage or association or both for a chromosome 19 region. Apolipoprotein E (APOE) was a candidate Alzheimer disease susceptibility gene partly because APOE and CSF bound to immobilized β-amyloid peptide and antisera to APOE stain senile plaques and neurofibrillary tangles. In addition, APOE localized to the same region of chromosome 19 identified in linkage studies.

APOE has three allelic variants (2, 3, and 4). Everyone inherits one allele from each parent so that five common genotypes are possible (2/3, 3/3, 2/4, 3/4, and 4/4). The sixth genotype (2/2) is rare. In the general population, approximately 3% of persons have the 4/4 genotype, 20% have the 3/4 genotype, and most people have the 3/3 genotype. The APOE-4 allele increases risk and decreases age at dementia onset in a dose-related fashion. That is, Alzheimer disease risk is lowest for the 3/3 genotype, higher for the 3/4 genotype, and highest for the 4/4 genotype.

By contrast, the APOE-2 allele has a protective effect, so Alzheimer disease risk is lower for people with the 2/3 genotype than for those with the 3/3 genotype. Susceptibility to Alzheimer disease from APOE affects many races and has been confirmed worldwide.

More recent research has focused on inflammatory pathways and mediators that contribute to the neurodegenerative process. Pathologic β-amyloid can activate phagocytic microglia and astrocytes to secrete cytokines, chemokines, and other proinflammatory molecules, such as prostaglandins and free radicals, which can have deleterious effects on the brain. Several inflammatory processes are over-represented in brains with Alzheimer disease. Microglia are highly activated and surround β-amyloid plaques. Interleukin-1 overexpression promotes the synthesis and processing of APP and, thus, amyloid production and plaque deposition. It also induces the activity and mRNA expression of acetylcholinesterase, which reduces cholinergic activity. Chemokines and their receptors are upregulated and may contribute to plaque-associated inflammation and neurodegeneration. Complement activation fragments, reactive astrocytes, and activated microglia are all highly colocalized with plaques containing aggregated β-amyloid. Chronic inflammation is a well-known contributor to vascular disease and may be the common pathway to the prevalent coexistence of vascular and Alzheimer disease pathology. Another common link may be APOE-4, a risk factor for developing not only late-onset Alzheimer disease but also atherosclerosis. These relationships suggest that neurovascular damage is a primary occurrence and that subsequent injuries, including Aβ deposition, amplify and/or exacerbate vascular damage that then leads to neurodegeneration and, eventually, cognitive decline.

Our current database suggests that Alzheimer disease may be a heterogeneous condition and therefore has multiple causative factors. Investigations comparing familial (one or more affected first-degree relatives of a proband or large autosomal dominant kindreds) and sporadic Alzheimer disease patients, as well as patients with early-onset (60 years or younger) and late-onset dementia, have demonstrated clinical and biologic differences among them. Other studies suggest differences in disease expression between men and women, cerebral glucose metabolism, neuroendocrine function, and a possible interaction among age at onset, sex, and family history of dementia. Case-control studies have identified prior head trauma and depression as risk factors for Alzheimer disease, and higher educational achievement, larger brain size,

and cardiovascular conditioning as protective factors. In some cases, the entire cause may lie in a single genetic defect, while in others, a mixture of genetic and environmental factors may play a role. The likelihood of multiple causative factors suggests that there are multiple approaches for developing effective prevention and treatment strategies.

CLINICAL EVALUATION

NCDs in late life usually begin with milder forms of cognitive decline and progress gradually. Early on, pathologic cognitive decline may be difficult to distinguish from normal aging, in which there is commonly an awareness of mild memory changes but with minimal objective cognitive deficits. However, as neurodegeneration progresses, MCI, often an intermediate state between normal aging and NCD, develops and places patients at increased risk for developing an NCD. Patients with primarily memory deficits may have the amnestic subtype of MCI, which is more likely than other MCI subtypes to progress to dementia due to Alzheimer disease.

The clinical hallmark of Alzheimer disease is memory impairment. Short-term memory is affected initially. Patients experience difficulty in learning new information, as shown by their inability to recall three objects after 5 minutes or even after just two distractions. Long-term memory may be affected, and patients may not recall important past personal information. Other cognitive areas may be impaired, including abstract thinking, judgment, personality, and language.

In a typical case of Alzheimer disease, the onset is so insidious that family members have difficulty recognizing when the impairment began. Diagnosis is often missed or delayed because of the insidious onset and gradual progression of symptoms, but also due to lack of attention to cognitive issues during medical screenings. Prevalence studies of community samples have documented high proportions of undiagnosed cases. A complete history of the patient's cognitive and everyday functioning from someone who knows the patient well and physical, neurologic, and mental status examinations are essential in the clinical evaluation. The history should include screening questions for behavioral changes, including apathy, paranoia, agitation, insomnia, anxiety, and depression. On examination, the patient may show *apraxia* (inability to carry out motor commands, even though comprehension and motor function are intact), *agnosia* (inability to recognize objects, despite intact sensory function), or difficulties in visuospatial skills (inability to copy two-

dimensional and three-dimensional figures or to assemble blocks). Brief standardized mental status tests (e.g., the Mini-Mental State Examination, Montreal Cognitive Assessment) are useful screening tools, and more extensive neuropsychologic batteries provide details on the nature and degree of cognitive deficits.

IMAGING AND LABORATORY EXAMINATION

Structural neuroimaging, preferably MRI, is appropriate to detect potentially treatable lesions that may affect cognitive functioning. MRI can also detect atrophy suggestive of a neurodegenerative process, though, in clinical practice, radiologists interpret structural scanning results based on visual readings, which may be insensitive in detecting subtle atrophy.

Clinical laboratory studies, including complete blood count, comprehensive metabolic panel, urinalysis, thyroid hormone levels, and vitamin B12 levels, should be ordered to detect potentially treatable medical conditions that may cause cognitive impairment.

Biomarkers

Recent advances in biomarker research have moved the field away from defining Alzheimer disease as a clinical syndrome toward defining it by its postmortem neuropathology or in vivo biomarkers. In 2018 the NIA-AA created a “research framework” that defines Alzheimer disease by the presence of certain imaging and CSF biomarkers based on studies that have shown that these biomarkers are valid proxies for the neuropathology of Alzheimer disease. The framework recognizes three groups of biomarkers: those that measure β-amyloid plaques, fibrillar tau, and neurodegeneration or neuronal injury. The authors’ intent in shifting from a syndromal to a biologic construct was primarily for research purposes, to “enable a more precise approach to interventional trials where specific pathways can be targeted in the disease process and in the appropriate people.”

The earliest currently used imaging biomarker is brain atrophy, which likely reflects loss and shrinkage of the neuropil. Atrophy in the entorhinal cortex and hippocampus is associated with an increased risk for progressive memory decline and the development of Alzheimer disease. MRI, in conjunction with image analysis programs, can detect relatively small volumes of brain atrophy. These analyses have shown that medial

temporal or hippocampal atrophy measures can distinguish patients with a clinical diagnosis of Alzheimer disease from controls. PET scans measuring regional glucose metabolism after injection of fluorodeoxyglucose (FDG) also can detect brain atrophy and differentiate patients with Alzheimer disease from cognitively intact individuals and those with MCI and other NCDs. Patients with Alzheimer disease show hypometabolism in the posterior cingulate, parietal, temporal, and frontal regions, and these patterns can be observed in patients with MCI as well (Fig. 55.3f–2). Combining genetic risk assessment with PET is a potential strategy for the early detection of Alzheimer disease. Imaging studies using FDG-PET have shown brain metabolic deficits in nondemented middle-aged and older persons with the APOE-4 allele. In clinical practice, FDG-PET scans have been approved for reimbursement by the U.S. Centers for Medicare and Medicaid Services to assist with the differential diagnosis of Alzheimer disease and frontotemporal dementia, making this technique more accessible to patients and their physicians.

Several small-molecule probes for use with PET imaging have been found to provide in vivo measures of amyloid plaques and tau tangles. PET studies using Pittsburgh Compound-B (PIB), a derivative of thioflavin-T amyloid dye, show significantly greater cortical retention in patients with Alzheimer disease compared with controls (Fig. 55.3f–3). PET scans using FDDNP, which can measure both amyloid plaques and tau tangles, have been shown to differentiate patients with Alzheimer disease from those with MCI and cognitively intact controls and can predict future cognitive decline (see Fig. 55.3f–2). FDDNP-PET scans also can be displayed as three-dimensional cortical surface projections, which show signal patterns remarkably similar to those expected from autopsy studies demonstrating regional brain accumulation patterns of plaques and tangles (Fig. 55.3f–4). PET studies have shown that elevated binding of the tau ligand flortaucipir to medial temporal lobe structures and the neocortex is associated with clinical impairment across the normal aging to dementia spectrum and the presence of postmortem tau pathology. Newer PET ligands are being developed to, more specifically, image amyloid plaques or tau tangles.

CSF examination is another tool for the early detection of Alzheimer disease pathology. CSF levels of proteins associated with plaques and tangles, such as elevated phosphorylated tau and ratio comparisons of different β-amyloid peptides, have been shown to distinguish patients with Alzheimer disease from normal controls and other types of dementia, as well as correlate with imaging biomarkers and disease progression. While

CSF study is not used extensively in clinical settings, this technique may ultimately be more accessible and affordable than imaging. Scientists are investigating other potential fluid biomarkers that would circumvent the potential risks of lumbar puncture. A promising blood biomarker using 30 serum proteins showed 88% sensitivity and 82% specificity for Alzheimer disease.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of Alzheimer disease can be a challenge. Other neurocognitive, psychiatric, neurologic, and medical disorders can present similarly to Alzheimer disease. Except for measures of regional cerebral glucose metabolism using PET scanning, most biomarkers are still available only for research purposes, and the clinician is left with conventional methods of evaluation: the patient's history, mental status and physical examination, structural imaging, and laboratory tests. The history provides important information, and informants familiar with the patient's cognitive function should be sought for corroboration. Even with the most thorough evaluation, diagnostic errors occur. When patients are followed for an autopsy for neuropathologic confirmation, the accuracy of prior clinical diagnosis can be as low as 60%.

FIGURE 55.3f–2. Representative examples of brain positron emission tomographic (PET) images from a control subject **(left)**, a patient with mild cognitive impairment (MCI) **(center)**, and a patient with Alzheimer disease **(right)**, including the use of the agents FDDNP **(top)**, FDG **(middle)**, and MPPF **(bottom)**. For each imaging method, the patient with MCI shows intermediate values between those of the control and the patient with Alzheimer disease. Absolute scales are comparable within subjects with a specific probe, and lighter colors indicate higher values. In the patient with Alzheimer disease, the arrows point to frontal, parietal, and posterior cingulate **(upper)**, frontal and temporal-parietal **(middle)**, and medial temporal **(lower)** regions. (Adapted with permission from Kepe V, Barrio JR, Huang SC, et al. Serotonin 1A receptors in the living brain of Alzheimer's disease patients. *Proc Natl Acad Sci USA*. 2006;103(3):702–707.)

Major vascular NCD is estimated to account for 10% to 20% of major NCDs in late life. Clinically, the disorder is characterized by a sudden onset of illness and stepwise decline in cognitive function rather than the insidious onset and gradually progressive course of Alzheimer disease. The frequent coexistence of vascular disease and Alzheimer pathology (estimated to occur in about one-third of all major NCDs) impairs diagnostic accuracy.

FIGURE 55.3f–3. Pittsburgh Compound-B (PIB)-standardized uptake images showing higher PIB retention in a 79-year-old patient with Alzheimer disease than in a 67-year-old healthy control. (Reproduced with permission from Klunk WE, Engler H, Nordberg A, et al. Imaging brain amyloid in Alzheimer's disease with Pittsburgh Compound-B. *Ann Neurol*. 2004;55(3):306–319. doi: 10.1002/ana.20009.)

Even though Alzheimer disease and vascular disease account for most cases of major NCDs, other conditions must be considered and sometimes can be differentiated from Alzheimer disease by their clinical presentation. For example, frontotemporal lobar degeneration is characterized by marked personality and behavioral changes, executive dysfunction, and relative preservation of other cognitive domains. By contrast, patients with Lewy body disease may evidence visual hallucinations, delusions, fluctuating mental status, REM sleep behavior disorder, and sensitivity to antipsychotic medications.

Substances, including prescribed medications, may cause memory loss and cognitive dysfunction. For older patients, medications deserve special emphasis as a cause of cognitive impairment because of widespread polypharmacy and age-related changes in body function and pharmacokinetics. The American Geriatrics Society updates its Beers criteria for potentially inappropriate medication use in older adults every 3 years. These criteria include many medications that can cause cognitive impairment (JAGS). An older person's brain can be extremely sensitive to changes in its environment, and almost any physical illness can impair brain function and produce a dementia-like syndrome. Numerous potentially treatable physical and mental conditions and offending medications must be considered whenever the diagnosis of dementia is entertained (see Table 55.3f–1).

The clinical presentation of late-life depression may mimic that of an NCD. The earlier term "depressive pseudodementia" is no longer considered useful because the cognitive impairment associated with depression is real. The reported frequency of mistaking depressed patients for patients with an NCD ranges from 5% to 15%. Psychomotor retardation, impaired concentration, and apathy characteristic of the depressed patient may be mistaken for symptoms of an NCD, especially when these symptoms are accompanied by memory loss. In the dementia syndrome of depression, however, the complaints of memory tend to exceed the actual memory impairment observed on neuropsychologic testing. The fact that NCDs and depression often coexist further clouds the diagnostic picture. About 30% of patients with a progressive NCD also suffer from some form of depression.

FIGURE 55.3f–4. Three-dimensional cortical surface projection images of FDDNP-positron emission tomography (PET) scans from a control subject and a patient with Alzheimer disease showing lateral **(upper)** and medial **(lower)** brain surfaces. Brighter colors indicate higher levels of plaques and tangles. (Reprinted from Small GW, Bookheimer SY, Thompson PM, et al. Current and future uses of neuroimaging for cognitively impaired patients. *Lancet Neurol*. 2008;7(2):161–172. doi: 10.1016/S1474-4422(08)70019-X.)

Depression is a risk factor and a prodrome of dementia, and shared neurobiologic mechanisms may influence both conditions. Although depression occurring in the course of dementia may reflect a psychologic reaction to cognitive losses, PET scanning of patients with late-life depression shows increased signals indicating higher levels of amyloid plaques and tau tangles in patterns that overlap with those observed in Alzheimer dementia (Fig. 55.3f–5).

Many people, as they age, complain of forgetfulness and worry about its meaning. Age-associated memory impairment, as defined by a workgroup convened by the National Institute of Mental Health (NIMH) in 1987, applies to healthy persons 50 years and older who have subjective complaints of memory loss and mild deficiencies in memory performance compared to young adults. About 40% of persons in their 50s and up to

85% of those aged 80 years and older suffer from age-associated memory impairment. Data suggest that the condition is stable over intervals of up to 4 years and thus is presumed to reflect normal aging and does not usually progress to dementia. Although it may take them longer to remember, most older adults continue to recall information they have learned well and important events from the past. Because age-associated memory impairment is so common, it is also referred to as normal aging.

FIGURE 55.3f–5. Statistical parametric mapping of results of fluorodeoxyglucose (FDG)-PET scanning shows a 5% decline in metabolic activity in the left dorsolateral prefrontal cortex after a 2-week healthy lifestyle program, including memory training, physical conditioning, and healthy diet, whereas no such decline was observed in the control group. The darker areas highlight the location of all cortical voxels showing significantly greater decline ($P < .01$) in the intervention group compared with the control group. The left image is a left lateral viewpoint; the right image viewpoint is from the top of the brain. The arrows point to the voxels of peak significance ($Z = 3.82$, $P < .001$). (Reprinted from Small GW, Silverman DH, Siddarth P, et al. Effects of a 14-day healthy longevity lifestyle program on cognition and brain function. *Am J Geriatr Psychiatry*. 2006;14(6):538–545. doi: 10.1097/01.JGP.0000219279.72210.ca.)

COURSE AND PROGNOSIS

Alzheimer disease is a progressive disease that eventually leads to death, not directly from its impact on cognition, but usually from intercurrent illnesses. The rate of progression varies, and it is difficult to estimate how rapid a decline a patient may have. Some patients become extremely impaired within 1 year; others experience plateaus for several years. The majority experience behavioral disturbances such as agitation and psychosis at some point during the illness. Other causes of NCDs,

including frontotemporal lobar degeneration, vascular disease, and Lewy body disease, are gradually progressive as well.

TREATMENT

The first step in treating NCDs is attempting to identify any underlying illnesses that may be causing cognitive impairment and other symptoms of the syndrome. Occasionally, dementia can be effectively resolved when the underlying cause (e.g., drug toxicity, hypothyroidism) is treated. If none is found or if the symptoms persist after appropriate specific treatment, then symptomatic treatments are indicated.

Psychopharmacotherapy

Several pharmacologic treatments are available for Alzheimer disease (Tables 55.3f–2 and 55.3f–3). Many of these approaches diminish symptoms and increase the quality of life, but none has proven to be a disease-modifying treatment or a treatment that has an enduring effect on the clinical progression of Alzheimer disease by interfering with the pathophysiologic processes that lead to cell death. Most pharmacologic agents now available or in development target, a specific symptom (e.g., agitation or memory loss) and are derived from the known neurobiology of the disease (e.g., a specific neurotransmitter deficit) or hypothesized antidementia approaches (e.g., antiamyloid, antitau, anti-inflammation, or antioxidation).

Table 55.3f–2.
Substances and Potentially Reversible Conditions That Might Cause Neurocognitive Impairment Resembling Alzheimer Disease

Substances
Anticholinergic agents
Antihypertensives
Antipsychotics
Corticosteroids
Digitalis
Opiates
Nonsteroidal anti-inflammatory agents
Phenytoin
Polypharmacy
Benzodiazepines
Psychiatric Disorders
Anxiety
Depression
Mania
Delusional (paranoid) disorders
Metabolic and Endocrine Disorders
Addison disease
Cushing syndrome
Hepatic failure
Hypercarbia (chronic obstructive pulmonary disease)
Hypernatremia
Hyperparathyroidism
Hypo/hyperthyroidism
Hypoglycemia
Hyponatremia
Renal failure
Volume depletion
Miscellaneous Conditions
Fecal impaction
Hospitalization
Impaired hearing or vision

One approach to improving memory function, based on the cholinergic hypothesis of Alzheimer disease, has been to enhance cholinergic activity in the brain. The U.S. Food and Drug Administration (FDA) has approved

four cholinesterase inhibitors (ChEIs)—tacrine (Cognex), donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne)—and one *N*-methyl D-aspartate–receptor antagonist memantine (Namenda) for the treatment of Alzheimer disease. These drugs have proven benefits for memory, other aspects of cognition, behavioral disturbances, overall functioning, and even caregiver burden. Tacrine caused high rates of hepatotoxicity and was discontinued in 2013.

ChEIs were originally indicated only for mildly to moderately ill patients with Alzheimer disease, but their efficacy has since been demonstrated in severe Alzheimer disease, Lewy body disease, and dementia associated with Parkinson disease. Memantine is indicated for moderately to severely ill patients with Alzheimer disease. Data from clinical trials have demonstrated that combining a ChEI with memantine provides a beneficial response compared to either medication alone.

Table 55.3f–3.
Medications Used or Under Investigation for the Treatment of Alzheimer Disease

Cholinesterase Inhibitors
Tacrine[a]
Donepezil[a]
Rivastigmine[a]
Galantamine[a]
Sustained-release physostigmine
Eptastigmine
Cholinergic Agonists
Xanomeline
Milameline
Antioxidants
Vitamin E (α-tocopherol)
Hormones
Conjugated estrogens
***N*-Methyl D-aspartate Antagonist**
Memantine[a]
Other Potential Cognitive Enhancers
Acetyl-L-carnitine
Curcumin
Ginkgo biloba
Nonsteroidal anti-inflammatory drugs
Omega-3 fatty acids

[a]Approved by the U.S. Food and Drug Administration.

Clinical research also points to the importance of early detection and treatment with ChEIs. In randomized, placebo-controlled inpatients with Alzheimer disease, these medications result in less cognitive decline compared with a placebo after 6 months of treatment. During the following 6-month open-label treatment periods, the patients who were originally treated with a placebo were given active drug, and at 1 year, better cognitive performance was observed in patients who began drug treatment from the beginning of the trial compared with those who had been placebo-delayed for 6 months.

Studies using ChEIs in patients with MCI have been inconclusive. For example, a randomized, placebo-controlled trial in patients with MCI showed that donepezil delayed progression to Alzheimer disease compared with placebo after 1 year of treatment; however, no difference between the drug and placebo was found after 3 years of treatment.

Studies have examined a variety of other agents that may improve cognitive functioning, including estrogen, nonsteroidal anti-inflammatory agents, and antioxidant supplements. Unfortunately, any clinical benefit from these various treatments has been inconclusive. The widespread use of over-the-counter preparations should be evaluated routinely, as some do carry risks. For example, while vitamin E (α-tocopherol) at 2,000 IU daily lowered rates of functional decline in patients with moderately severe Alzheimer disease in one study, meta-analyses have found an increased risk of myocardial infarction in older patients taking daily vitamin E supplementation, particularly doses greater than 400 IU.

Research on treatments that are superior to current therapeutics (the last one approved by the FDA in 2003) has focused on disease-modifying therapies. As of 2020, nearly a hundred potentially disease-modifying treatments were under investigation, representing 80% of all agents under investigation for Alzheimer disease. Seventeen agents were in Phase 3 clinical trials. Mechanisms of action target a variety of pathways, including amyloid (monoclonal antibodies, vaccines, antiaggregation), tau (antiaggregation), inflammation (protease inhibitor, omega-3 fatty acid), metabolic (insulin sensitizer), vascular (antihypertensives, statin), synaptic plasticity (synaptic vesicle protein and glutamate modulators), and neurogenesis. Developing these treatments is quite challenging, as these studies require more participants, biomarkers, longer trials, and greater cost compared with symptomatic treatments.

Psychiatric medications may be helpful for treating behavioral disturbances associated with dementia, such as depression, agitation, psychosis, and anxiety, although the FDA has approved none for such use. (Table 55.3f–4) Patients who have dementia with concurrent depression may benefit from antidepressant medications, though data are limited. A 2018 Cochrane review of 10 randomized placebo-controlled trials of different antidepressants with a total of 1,592 participants with dementia and depression suggested questionable benefit. The authors found high-quality evidence of little or no difference in depression symptom rating scales between antidepressants and placebo. There was high-quality evidence of no effect of antidepressants on activities of daily living and

moderate-quality evidence of no effect on cognition. There was moderate quality evidence of higher remission rates in the antidepressant group than in the placebo group. The data for antidepressants are even more limited for treating agitation. One randomized controlled trial of 186 participants with Alzheimer disease and agitation showed that citalopram reduced agitation significantly more than placebo. A smaller study of patients with Alzheimer disease on donepezil showed that sertraline reduced overall behavioral disturbances more than placebo.

Table 55.3f–4.
Medications Used or Under Investigation for the Treatment of Behaviors Associated With Alzheimer Disease and Other Neurocognitive Disorders

Antipsychotics
Aripiprazole
Haloperidol
Olanzapine
Quetiapine
Risperidone
Brexpiprazole
Anticonvulsants/Mood Stabilizers
Carbamazepine
Divalproex sodium
Gabapentin
Lithium
Antidepressants
Citalopram
Escitalopram
Paroxetine
Sertraline
Trazodone
Anxiolytics
Buspirone
Clonazepam
Lorazepam
Antiparkinsonian Drugs
Selegiline
α-Adrenergic Receptor Antagonists
Propranolol
Pindolol
Prazosin
Others
Dextromethorphan/Quinidine
Dronabinol
Methylphenidate
Pimavanserin

Antipsychotic drugs may be effective in treating psychotic symptoms and agitation. Multiple controlled trials and meta-analyses of controlled trials of

antipsychotic treatment in dementia indicate that antipsychotics have a significantly greater effect than placebo, but the effect sizes are mostly less than 20%. As there is no evidence that one agent is superior to others, the side-effect profile is a primary consideration when choosing a specific agent.

First-generation or “conventional” antipsychotics may be generally categorized as “high-potency” or “low-potency” antipsychotics, according to how potently they occupy dopamine-2 receptors. High-potency agents such as haloperidol are more likely to cause parkinsonian symptoms, whereas such low-potency drugs as chlorpromazine cause sedation, postural hypotension, and anticholinergic effects. Less frequently, tardive dyskinesia and neuroleptic malignant syndrome may develop with either. Clozapine, while considered an “atypical” antipsychotic, can have similar side effects as low-potency antipsychotics and requires routine blood-count monitoring because of the risk of agranulocytosis. Because of the lower associated risk for neuromotor side effects, second-generation atypical antipsychotic drugs, such as quetiapine, risperidone, olanzapine, and aripiprazole, have received greater attention in recent years. However, these atypical agents are associated with other adverse effects, including metabolic syndrome, vascular events, and cardiac arrhythmias, which warrant vigilant monitoring. Overall, conventional and atypical antipsychotic medications have been associated with increased mortality rates in older adult patients with dementia, which prompted the FDA to issue black box warnings for all antipsychotics. Investigators have more recently challenged the basis for these warnings, with data showing no significant differences in mortality in this population between antipsychotics and placebo. Pimavanserin, which has FDA approval for treating psychosis in Parkinson disease without dementia, has shown potential efficacy and an acceptable tolerability profile in treating psychosis in Alzheimer disease and other dementias.

Benzodiazepines and anticonvulsants have been used and studied for the treatment of agitation. However, there is little evidence for their use in patients with dementia, and they have undesirable adverse effects, such as sedation, confusion, memory impairment, dysarthria, and ataxia. Moreover, chronic benzodiazepine use has been associated with an increased risk for Alzheimer disease.

Dementia Care Management

While disease-modifying treatments remain elusive, patients with Alzheimer disease and other progressive dementias require a holistic approach to care, given the many ways these diseases affect their lives. In 2015, the American Academy of Neurology (AAN) and the American Psychiatric Association (APA) formed a Dementia Measurement Set Update Work Group to review and update previous guidelines on dementia care. The Work Group designed a comprehensive dementia management strategy that includes measures for disclosure of dementia diagnosis, education and support of caregivers, functional status assessment, screening and management of behavioral and psychiatric symptoms, safety concern screening and follow-up, driving screening, advance care planning and palliative care counseling, pain assessment, and pharmacologic treatment. Descriptions of these interventions are in Table 55.3f–5. Some of the desired outcomes from this strategy include: increased patient and caregiver engagement in disease education, better treatment planning and advanced decision making, improved quality of care and caregiver burden, maintenance or improvement of cognitive, physical, and functional levels, decreased complications and behavioral and psychiatric symptoms, improved safety awareness and risk management, and recognition of and adherence to end of life wishes.

Attention to the Environment. Attending to patients' environments is essential to their well-being and can mitigate the need for pharmacotherapy for behavioral disturbances. Patients with cognitive losses are sensitive to their surroundings and do their best with optimal stimulation. Understimulation may cause withdrawal; overstimulation may cause confusion and agitation. Familiar and consistent surroundings and caregivers will maximize the patient's cognitive functions and minimize behavioral disturbances. If moves cannot be avoided, placing familiar objects (e.g., photographs and furniture) in the new environment helps create a more recognizable, comfortable, and homelike atmosphere. Daily routines—regularly scheduled awakening, bedtime, meals, and physical exercise—increase a patient's sense of security. Memory and orientation can be facilitated by prominent displays of clocks and calendars, daylight exposure, a night light, checklists, and diaries. Medication schedules should be simplified as much as possible. Newspapers, radio, and television, appropriate to the patient's cognitive level, can be useful in maintaining a patient's contact with and awareness of the outside world. Daily simple yet meaningful tasks that the patient can complete provide a

valuable sense of usefulness and accomplishment for the patient. Specific therapies such as music and activity therapies have also been shown to improve behavior.

Family Intervention. Addressing the needs of the patient with Alzheimer disease would not be complete without addressing the needs of the patient's care network. While the identified patient is the one suffering from the disease and in need of treatment, often the spouse or adult child initiates contact with the physician and has their own reasons for evaluation and treatment. Considerable skill and sensitivity are necessary to maintain an alliance with family members while respecting the patient's autonomy, dignity, and privacy. Psychotherapeutic intervention with family members is a critical aspect of treatment. Caregiver and family stress can result in suboptimal care for the patient, as they themselves might experience frustration, anxiety, fatigue, anger, resentment, guilt, and even depression. Interpersonal conflicts among the family members may arise and require resolution to help the patient. Children and siblings might become anxious about their own risk of developing Alzheimer disease. Education and counseling about the nature of the patient's illness help relatives to cope with their feelings. Relatives may need reassurance that their emotional reactions are common and that talking about them can bring relief. Many relatives also need help in grieving the loss of the person they once knew. The Alzheimer's Association, a national organization of family members and stakeholders with local chapters throughout the United States has been at the forefront of providing educational and emotional support for family members. Sometimes, a family member's needs may exceed this level of support and require individual attention in the form of treatment for anxiety or depression or a full physical and neuropsychologic evaluation, which may either allay anxiety about having the disease or occasionally uncover early signs of cognitive impairment, which may lead to more anxiety, but also the opportunity for early intervention.

Table 55.3f–5.
2015 Dementia Management Measurement Set Update

Measure Title	Measure Description
Disclosure of dementia diagnosis[a]	Percentage of patients with a diagnosis of a qualifying dementing disorder or disease whose diagnosis has been disclosed to them and, if available, their primary caregiver
Education and support of caregivers for patients with dementia	Percentage of patients with dementia whose caregivers were provided with education on dementia disease management and health behavior changes and were referred to additional resources for support in the last 12 months
Functional status assessment for patients with dementia	Percentage of patients with dementia for whom an assessment of functional status was performed at least once in the last 12 months
Screening and management of behavioral and psychiatric symptoms associated with dementia (BPSD)	Percentage of patients with dementia for whom there was a documented screening for behavioral and psychiatric symptoms, including depression, and for whom, if screening positive, there was also documentation of recommendations for management in the last 12 months
Safety concern screening and follow-up for patients with dementia	Percentage of patients with dementia or their caregivers for whom there was a documented safety screening in 2 domains of risk, dangerousness to self or others and environmental risks, and for whom, if screening positive, there was documentation they were provided with recommendations for their mitigation, which may include referral to other resources, in the last 12 months
Driving screening and follow-up for patients with	Percentage of patients with dementia for whom there was a documented screening

dementia	for driving risks and for whom, if screening positive, there was also documentation they were informed of alternatives to driving in the last 12 months
Advance care planning and palliative care counseling for patients with dementia	Percentage of patients with dementia who have an advance care plan or surrogate decision maker documented in the medical record or documentation in the medical record that an advance care plan was discussed but the patient did not wish or was not able to name a surrogate decision maker or provide an advance care plan and percentage of patients with dementia or their surrogate decision maker who received comprehensive counseling regarding ongoing palliation and symptom management and end-of-life decisions within 2 years of initial diagnosis or assumption of care
Pain assessment and follow-up for patients with dementia[a]	Percentage of patients with dementia who underwent documented screening for pain symptoms at every visit and if screening positive also had a documentation of a follow-up plan
Pharmacologic treatment of dementia[a]	Percentage of patients with dementia or their caregivers with whom available guideline-appropriate pharmacologic treatment options and nonpharmacological behavior and lifestyle modifications were discussed at least once in the last 12-month period

[a]New measure added in 2015.

Prevention Strategies. The MacArthur Foundation's studies on aging have shown that early lifestyle choices, more than genes, determine our health and vitality as we age. Epidemiologic, survey, and animal data suggest that these lifestyle choices can specifically impact brain health. Reducing modifiable cardiovascular risk factors, depression, low education, and physical inactivity by just 10% to 25% could potentially prevent millions of cases of Alzheimer disease worldwide. Some of these same risk factors have been shown to be associated with subjective memory impairment, a possible precursor to MCI and Alzheimer disease, in cognitively intact persons of all ages. These same individuals reported better memory if they engaged in healthy lifestyle habits such as regular exercise, a nutritious diet, and not smoking. One controlled study demonstrated that participating in a healthy lifestyle program combining mental and physical exercise, stress reduction, and a healthy diet for just 2 weeks was associated with significant positive effects on cognitive performance and brain metabolism (see Fig. 55.3f–5). Subsequent primary prevention studies have similarly focused on multidomain prevention strategies, incorporating a combination of nutritional education, physical activity, and vascular care, and found mixed results, either no benefit or potential improvement or maintenance of cognition, particularly among individuals with increased risk for dementia. Results from three large multidomain dementia prevention trials suggest that targeting preventive interventions to at-risk people is an effective strategy. Modifying one's lifestyle to incorporate some of these healthy behaviors comes with minimal risk and offers other proven health benefits. Until more effective pharmacotherapies are available, prevention strategies through healthy lifestyle choices may be the safest and most beneficial way to reduce one's risk for developing Alzheimer disease and other NCDs.

SUMMARY

Alzheimer disease and other NCDs continue to challenge clinicians and researchers to find effective ways to reduce the suffering of patients afflicted with these disorders. We have learned a great deal about their neurobiology and how to diagnose these illnesses. Scientists are working rigorously to discover evidence for disease-modifying treatments. Until such a discovery is made, clinicians can still have a meaningful impact on the lives of patients and their families through a combination of treatment modalities, including the use of available symptomatic medications,

preventive medical care, a healthy lifestyle strategy, education, and comprehensive dementia care.

55.3g Delirium

Jayson Varughese, M.D., M.S., and Susan W. Lehmann, M.D., M.S.

Delirium is an acute cognitive disorder of attention and awareness which disproportionately affects geriatric patients. Reports indicate that delirium is present in one-third of hospitalized older patients and occurs in 15% of

older patients presenting to emergency departments. The incidence of delirium is high among individuals with dementia, especially Alzheimer disease. Delirium is usually an indicator of severe underlying medical illness or metabolic derangement. However, it may also occur in vulnerable individuals with relatively minor medical provocations, such as constipation or mild dehydration.

Delirium is frequently unrecognized, yet the costs of not detecting delirium are significant. Delirium is associated with poor outcomes, both in the hospital and after discharge. Patients who are delirious are more likely to have longer lengths of hospitalization. Older patients with delirium are at increased risk for nursing home placement and are at increased risk for prolonged cognitive impairment and dementia. Delirium is associated with high rates of morbidity as well as an increased risk of mortality. Indeed, it has been estimated that the U.S. healthcare costs which are attributable to delirium range from 40 to 150 billion dollars annually. Studies indicate that delirium may be preventable in up to 30% to 40% of cases, and so assessment for delirium has become a significant focus for patient safety management in acute care hospitals.

DEFINITION

Delirium is a multifactorial syndrome whose hallmark features are that of disturbance in attention, awareness, and cognition. The symptoms develop acutely, usually over hours or days, in the setting of serious medical illness or in the postoperative period. Symptoms include impaired ability to focus or sustain attention as well as disorientation to the environment. Delusions or perceptual disturbances such as hallucinations (usually visual) are common, as are incoherent and disorganized speech. Patients usually have disrupted sleep–wake cycles and may be lethargic and drowsy or agitated and hyperalert. A key feature of delirium is that these disturbances tend to fluctuate in severity during the day.

The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition, text revision (DSM-5-TR), classifies delirium as a neurocognitive disorder. Historically, other terms used to describe delirium include “acute brain failure,” “acute confusional state,” “organic brain syndrome,” or “encephalopathy.” However, there is some consensus advocating the use of two terms: delirium and acute encephalopathy. Acute encephalopathy is not a syndrome; rather, it is defined as a rapidly developing pathologic process and could be the underlying disorder causing delirium.

HISTORY

The syndrome of delirium has been described in medical writing for over 2,000 years. It was recognized as early as the fifth-century BC, when Hippocrates recorded a detailed description of the clinical features of delirium, noted that the syndrome was linked to physical disease, and suggested that it carried a poor prognosis. In the first century AD, the Roman Celsus distinguished delirium from major mood disorders and hysteria. In the second century, Galen also noted that the brain could be disturbed *secondarily* in diseases such as pneumonia. In antiquity and in medieval times, delirium was recognized, usually in the context of febrile illness, and was called by a variety of different names.

In his classic textbook, *General Psychopathology,* first published in 1913, the German psychiatrist Karl Jaspers reported his observations of delirious patients as follows:

> Delirium is characterized by the patient turning away from external reality . . . He is dominated by an anxiety which is often extreme and a drive for aimless activity . . . When left alone the patient is always on the verge of sleep which, however, is never fully achieved.

In 1935, Harold Wolff and Desmond Curran published a study of 106 patients with delirium hospitalized in the United States and the United Kingdom, with careful cataloging of psychobiologic functions and case reports for 20 of the patients. These authors made several observations of note—for example, that patients recede into vagueness and hallucinations when external stimulation ceases and that summoning relatives to the bedside of the delirious patient does much to restore function. Most important, however, was that they established for this cohort of patients that symptomatology was independent of etiology in delirium.

In the 1940s, John Romano and George Engel performed a series of EEG studies on delirious patients and demonstrated that the degree of EEG slowing was correlated with the severity of the disturbance in consciousness. These authors hypothesized that delirium represented a state of “cerebral insufficiency.”

Zbigniew J. Lipowski wrote extensively about delirium and emphasized both the prevalence and seriousness of delirium as a public health problem. His work ushered in the contemporary era of research about delirium, and his book, *Delirium: Acute Confusional States,* published in 1990, is considered a classic in the field. Sharon Inouye and her

colleagues in geriatric medicine have carried out a series of investigations regarding the prevention of delirium, which led to the development of a successful preventive multistep approach to delirium prevention and management. This work has highlighted the importance of recognizing delirium as an indicator of the quality of care.

COMPARATIVE NOSOLOGY

The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition, text revision (DSM-5-TR) defines delirium as a neurocognitive disorder whose key features are disturbances of attention and awareness, which develop acutely and which fluctuate over time. Typically, these changes in attention and awareness ebb and flow throughout the day such that the patient may appear lucid and talkative at one point in time and then a few hours later might appear lethargic and confused. In addition, there are impairments in other aspects of cognitive functioning, such as orientation to time and place, memory, expressive and/or receptive language, and visuospatial abilities. Abnormal perceptions, especially visual and tactile hallucinations, are common. There must be evidence from the patient's history and physical examination or laboratory investigations to indicate that these disturbances are due to an underlying medical illness or due to substance intoxication or withdrawal.

The DSM-5-TR criteria include specifications about whether the delirium is acute (i.e., lasting a few hours or a few days) or if it is persistent (i.e., lasting weeks or months). In addition, the DSM-5-TR recognizes three psychomotor subtypes of delirium: hyperactive, hypoactive, and mixed levels of activity.

For delirium, due to another medical condition, the DSM-5-TR requires that there be evidence from the history, physical examination, or laboratory findings that the delirium is due to a specific underlying medical condition. In clinical settings, it is unusual for there to be one single, identifiable cause that is clearly the etiology of the delirious state, and, more commonly, delirium is attributable to multiple causes. DSM-5-TR also specifies substance intoxication delirium and substance withdrawal delirium, which should be used when the symptoms of disturbed attention, awareness, and impaired cognition are most significant from a clinical standpoint and require clinical attention.

In the *International Classification of Diseases*, 10th revision (ICD-10), delirium due to medications or substances is specified separately by the

causative medication or substance.

EPIDEMIOLOGY

Incidence and prevalence rates for delirium vary widely, depending on the clinical setting and patient characteristics. Prevalence in the community is approximately 0.4% of adults and 1.1% of people aged 55 and older. Among patients over age 70 admitted to a hospital, about one-third have delirium. Of these individuals, about half are delirious at the time of admission, and the rest develop delirium during their hospitalization. The onset of the presenting symptoms of delirium is frequently a reason that a patient is brought to an emergency department for evaluation. Overall, the incidence of delirium during hospitalization ranges from 6% to 56%, with higher rates being more commonly seen among patients with dementia. Incidence rates of delirium also vary across hospital services. Incidence rates of delirium are highest in intensive care units, postoperative clinical units, and palliative care settings. Prevalence rates of delirium have been reported to range from 23% in hospitalized older adults in inpatient settings to 35% in palliative care settings and up to 70% in mechanically ventilated patients. Among residents in nursing homes who are aged 75 and older, the prevalence of delirium is as high as 60%. Among patients with terminal illnesses, up to 80% of individuals become delirious around the time of death. The wide range of prevalence rates across settings reflects the interaction between the individual's risk factors and clinical settings.

Risk factors for delirium are listed in Table 55.3g–1. These include pre-existing characteristics which predispose an individual to delirium as well as factors that precipitate an episode of delirium. Predisposing risk factors include pre-existing cognitive impairment, advanced age, frailty, previous history of delirium, severe medical illness, alcohol or sedative dependence, hearing or vision impairment, and poor nutritional status. Precipitating factors include bed rest or immobilization, medications (especially opioids, anticholinergic medications, and benzodiazepines), physical restraints, sleep deprivation, and low hematocrit. Awareness of risk factors for delirium, especially those which are modifiable, is critical for delirium prevention efforts.

Table 55.3g–1.
Risk Factors for Delirium

Pre-existing cognitive impairment (dementia, executive dysfunction)
Previous history of delirium
Multiple medical problems
Multiple medications (especially opioids, anticholinergics, and benzodiazepines)
Advanced age
Structural brain disease (e.g., stroke or traumatic brain injury)
Alcohol or sedative dependence
Chronic liver disease
Severe medical illness
Terminal illness
Chronic psychiatric illness
Undernutrition (low albumin and prealbumin)
Compromised cerebral circulation
Deafness or hearing impairment
Blindness or visual impairment
Sleep deprivation
Immobilization
Frailty
Stress, including psychosocial stress

ETIOLOGY

While delirium can be caused by a single etiologic factor, most commonly, the etiology is multifactorial. Predisposing risk factors, as described above, confer vulnerability to delirium. The development of delirium depends upon the complex interplay of predisposing and precipitating factors. Aging and neurodegenerative conditions can affect key processes, including brain connectivity, neuroinflammation, glial cell alterations, and vascular changes. These factors may underlie an increased vulnerability to delirium due to a relatively minor condition, such as a urinary tract infection. At the same time, delirium often develops as a consequence of serious medical and/or metabolic derangement and, therefore, is considered a medical emergency. Recognition of the multifactorial etiology of delirium is essential

to clinical management because a multidimensional approach to both prevention and treatment is needed.

Table 55.3g–2 presents a list of etiologies for delirium frequently seen in older patient populations. Among hospitalized older adults, the most important causes are infections and medications. Infections can include urinary tract infections, pneumonia, and sepsis. Many medications have been implicated as being deliriogenic in vulnerable populations, and their use should be avoided if possible. In particular, opioids, anticholinergic medications, and benzodiazepines are frequent causes of delirium in older patients. Anticholinergic medications include atropine, diphenhydramine, benztropine, and oxybutynin (Ditropan), as well as medications with strong anticholinergic side effects such as imipramine, ranitidine (Zantac), dipyridamole (Persantine), warfarin (Coumadin), isosorbide, theophylline (Theo-Dur), nifedipine (Adalat, Procardia), and prednisolone (Prelone). Among opioid medications, meperidine appears to be most likely to induce delirium, and hydromorphone is the least likely to cause delirium. Among the benzodiazepines, the most lipophilic drugs with the longest elimination half-lives are most likely to cause delirium, including chlordiazepoxide (Librium), flurazepam (Dalmane), and diazepam (Valium).

Table 55.3g–2.
Etiologies of Delirium in Older Adult Patients

Systemic Illnesses
Infections: Pneumonia, urinary tract infection, sepsis, influenza
Metabolic derangements: Dehydration, hypoxia, hypoglycemia, hyperammonemia, uremia, hyponatremia, thiamine deficiency, hyperthyroidism
Cardiovascular conditions: Arrhythmia, congestive heart failure, myocardial infarction, severe hypertension
Medications
Anticholinergics
Benzodiazepines, other sedative hypnotics (e.g., barbiturates)
Opioids
Antiarrhythmics
Certain antibiotics (e.g., fluoroquinolones, clarithromycin)
Digoxin
Interferons
Withdrawal States
Alcohol
Benzodiazepines, other sedative hypnotics
Primary Brain Diseases
Stroke or transient ischemic attack
Trauma: Brain injury, subdural hematoma
Infection/inflammation: Abscess, meningitis, encephalitis, vasculitis
Aneurysm
Epilepsy: Nonconvulsive status epilepticus, postictal states
Surgery or Trauma
Hip fracture repair
Open heart surgery (e.g., coronary artery bypass grafting)

A 79-year-old woman with metastatic ovarian cancer was admitted to the hospital with acute onset of vomiting, inability to stand, and delirium. She had been treated with warfarin for a hypercoagulable state. On admission workup, she was found to have a cerebellar hemorrhage with evidence of increased intracranial pressure. Anticoagulation was reversed, the hemorrhaging stopped, and intracranial pressure was normalized. Digoxin was started for newly diagnosed atrial fibrillation. She returned to her baseline level of cognitive function, which was completely normal. She was transferred to a rehabilitation facility to improve her ability to ambulate, which was still affected by the cerebellar hemorrhage. Soon after her admission to the rehabilitation unit, she was reported to be disoriented. She began to accuse the staff of waking her up at 3 AM. Labs were ordered to determine the cause of her mental status change. Her digoxin level was elevated at 2.4 ng/mL (normal range 0.5 to 2.0 ng/mL). Her dose of digoxin was reduced, and her symptoms of delirium resolved over several days without other intervention.

The definitive pathophysiology and etiology of delirium remain unclear, but evidence indicates that several sets of biologic factors appear to be involved. Major mechanisms leading to delirium include systemic inflammation (involving increased inflammatory cytokines like IL-1, IL-1β, and TNF), hypoxia, impaired blood flow, impaired tissue perfusion, and impaired metabolism. Pre-existing brain pathology and ongoing inflammation can damage vascular endothelium and the blood–brain barrier (BBB). The precise causal relationship between inflammation and delirium is not clearly understood. It is thought that inflammation affects the BBB to increase the permeability of inflammatory mediators into the brain, which affects neuronal cells (e.g., microglial cells, astrocytes) that produce both neuronal cell dysfunction and death. In addition, there is in vitro evidence suggesting that these neuronal cells can be primed by neurodegeneration to show an exaggerated inflammatory response which suggests a causal link with dementia syndromes. Vascular supply of glucose and oxygen can also lead to impaired function of brain structures. It is thought that delirium represents a reversible syndrome of neuronal dysregulation caused by disruption of oxidative metabolism. Certain brain structures, such as the cerebral cortex and hippocampus, are relatively

more sensitive to this disruption than other parts of the brain. At the cellular level, disruption of oxidative metabolism results in an inability to maintain ionic gradients. In addition, there is abnormal synthesis, release, and metabolism of neurotransmitters and an inability to dispose of neurotoxins.

Given the altered arousal states present in different subtypes of delirium, it is widely assumed that the reticular activating system (RAS) pathway, which regulates alertness, is affected. There are neocortical and limbic inputs to this system that control attention. Many neurotransmitters have been implicated in affecting this pathway, as well as other brain areas, that can precipitate delirium, including acetylcholine, dopamine, histamine, norepinephrine, and GABA (gamma-aminobutyric acid). Cholinergic deficiency and dopamine excess have both been implicated in delirium. There is evidence suggesting that increased anticholinergic burden increases delirium risk, which is correlated with adverse cognitive effects of anticholinergic medications. Cholinergic, dopaminergic, and serotonergic neurons are especially sensitive to oxidative stress. In hypoxia, not only are derangements of these systems found, but there is also an increase in the release of glutamate. It has been hypothesized that the presence of dopamine is required for at least some glutamate-mediated neuronal injury in hypoxia. Increased dopaminergic neurotransmission is also believed to underlie the perceptual disturbances often seen in delirium, and antidopaminergic antipsychotic drugs can effectively treat these disturbances. Neurotransmitter disturbances of histamine and norepinephrine may also be involved in delirium pathogenesis. Histamine activates neuronal connections in the prefrontal cortex, limbic system, and basal ganglia that influence arousal and wakefulness. First-generation antihistamines (H1 and H2 receptor antagonists) have sedative effects that can lead to delirium. Regarding norepinephrine, both excess norepinephrine and diminished norepinephrine activity can impair frontal cortical function. During stress, the amygdala activates locus coeruleus firing triggering high noradrenergic activity that impairs attention. During inflammatory events such as trauma and sepsis, sympathetic nervous system activation results in high noradrenergic activity, which is associated with postoperative delirium in older adult patients. Increased noradrenergic drive is also present during alcohol withdrawal, which accounts for withdrawal symptoms like high blood pressure, tremor, and agitation. Delirium tremens is associated with GABA hypoactivity and hyperactivity of glutamate and norepinephrine. GABA hyperactivity is implicated in hepatic encephalopathy. Sedative hypnotics like benzodiazepines can produce

cognitive impairment by enhancing GABA tone in corticothalamic networks, which has also been implicated in delirium pathogenesis.

DIAGNOSIS AND CLINICAL FEATURES

Delirium is a clinical diagnosis based on history, physical examination, and mental status examination. However, the first step is a suspicion of the disorder based on clinical observation. Because the features of delirium are quite variable and, by definition, tend to fluctuate over time, it is often overlooked or unrecognized by clinicians. Patients with delirium may seem so drowsy that they fall asleep while eating or speaking. At other times, the patient may seem inattentive to questions, with poor eye contact, easy distractibility by irrelevant stimuli, and requiring questions to be repeated because of difficulty sustaining focus on the conversation. These fluctuations tend to occur throughout a 24-hour period so that a patient might be relatively alert and lucid with appropriate orientation to the environment for a few hours during different parts of the day, alternating with periods of confusion, incoherence, or somnolence. This waxing and waning of orientation and level of awareness might not be evident to an observer who interacts with the patient during only one of these periods during the day. In the acute hospital or nursing home setting, where clinical staff change with each shift, it is important for physicians to be alert to changing descriptions of the patient's mental state and behavior across different shifts to specifically look for this pattern of symptom fluctuation. It is not uncommon to find that hospital staff who work evening shifts and day shifts have different views of the patient's level of cognitive and behavioral disturbances.

The speech of the patient with delirium is often incoherent, rambling, irrelevant to the topic, and disorganized. Specific language impairments include dysarthria (impaired speech articulation), dysnomia (impaired naming), and dysgraphia (impaired writing ability). The patient's ability to reason abstractly, retain information and direct their thinking is impaired. As a result, in the medical setting, patients with delirium may temporarily lose the capacity for informed consent. Frequently, patients who are delirious have sleep–wake cycle reversals and may wake during the night believing it is time to get washed and dressed. Disorientation to the environment is common, with patients mistaking the hospital for home and beginning to wander out of the hospital bed looking for the kitchen or a family member.

Other features commonly associated with delirium include transient delusional thoughts and emotional disturbances such as paranoia, fear, and disruptive behaviors. Delusional thinking is usually paranoid in nature, with patients becoming fearful that routine or specialized medical care is being done to them with a nefarious purpose. Perceptual disturbances due to delirium can be among the most frightening symptoms to patients and to their families. These problems vary in severity and frequently include misinterpretations of items and people in the patient's environment (e.g., belief that the physical therapist is a family member or mistaking the bang of a closing door for a gunshot). Illusions, which are misperceptions of actual stimuli, are also common in delirium. An example of an illusion might be a delirious patient misperceiving an intravenous line to be a snake. Hallucinations are perceptions in the absence of actual stimuli and are usually visual, but they may also be tactile or auditory in nature. The hallucinations which occur in delirium range in severity from simple colored spots or geometric figures to moving objects, such as white handkerchiefs falling, to more complex phenomena, such as animals, people, monsters, panoramic views, and scenes acted out. Typically, these hallucinations are felt as threatening to patients. It is easy to see how they can engender feelings of fear and anxiety.

Disruptive behaviors can be present more or less continuously, or they can occur unpredictably. These behaviors range from disorganized, purposeless actions such as picking at bandages or repetitive vocalizations to pulling out Foley catheters or attempting to get out of bed and ambulate without assistance. Distorted perceptual experiences can lead a patient to incorrectly interpret a medical situation as dangerous, leading them to attempt to pull out intravenous lines or endotracheal tubes or to respond aggressively to a nurse trying to assist the patient. While disruptive behaviors can occur at any time of the day, they are more common at night.

When delirium is suspected, the process of making the diagnosis includes a careful history, focusing on the timeline of symptom development. A key feature that distinguishes the impairments of delirium from those of dementia is the acute development of symptoms. Delirium can present almost immediately after head trauma, or it may develop over a period of hours or days in a hospitalized patient with pneumonia or other infection. An older adult outpatient with metabolic disturbances or medication toxicity might develop symptoms more gradually over a period of days to weeks. Unlike other cases of medical diagnosis, important

aspects of the patient's history usually come from individuals other than the patient themselves. Speaking with family members of the patient or other knowledgeable informants who can provide a clear description of the patient's baseline level of cognitive functioning is crucial in establishing that an acute change has occurred. When delirium occurs in a hospitalized patient, it is important to review nursing notes to help establish the timeline of the abrupt onset of symptoms and the course of fluctuating symptoms. Other important aspects of the history include a careful review of all medications prescribed to the patient and the timing of when new medications were begun or when dosages were changed. A complete medication history review must include over-the-counter medications as well as prescription medications. In older patients, medications are the most common cause of delirium, with sedative-hypnotic, anticholinergic, opioid analgesic, and antidepressant medications being the most potentially problematic. A thorough history must also include an assessment of alcohol use, history of pain and its treatment, and any new physical symptoms.

The physical examination of the patient should include careful evaluation for possible underlying causes, with an assessment of vital signs, including oxygen saturation, and thorough cardiac and pulmonary examination. The neurologic examination should look for evidence of focal findings. Motor system abnormalities that can be seen in delirium include tremors, myoclonus, asterixis, increased deep tendon reflexes, and increased tone. Evidence of adrenergic system overactivity can be seen in delirium due to alcohol or sedative withdrawal and also with anticholinergic toxicity states. Signs of hyperadrenergia include tachycardia, hypertension, sweating, pallor, flushing, and pupil dilation.

The mental status examination of the patient begins with an assessment of the patient's level of awareness and arousal. It should be noted whether the patient is somnolent or lethargic, and if so, how much stimulation is required to arouse the patient. The patient's thinking and speech should be assessed, including whether speech is coherent or rambling and whether answers to questions are logic or disorganized. A number of simple tests can be used to evaluate the patient's level of attention. Often it is evident through interviewing the patient that they are having difficulty sustaining focus on the conversation and/or is being easily distracted by other stimuli in the room. A common test known as digit span requires patients to repeat five digits forward and three digits backward. An alternative approach would be to ask patients to recite the days of the week or months of the

year backward. In addition to impairment of awareness and attention, patients with delirium will have a change in at least one other area of cognitive functioning. This might include memory, learning, or disorientation. Perceptual disturbances, such as misinterpretation, illusions, and hallucinations, should be assessed. A bedside cognitive test can be used to screen patients who are alert enough to cooperate with formal testing. Commonly used bedside cognitive tests are the Mini-Mental State Examination (MMSE), Mini-Cog, and Montreal Cognitive Assessment (MoCA).

Several psychomotor phenotypes of delirium are described in DSM-5. Patients who have the hyperactive subtype of delirium exhibit hypervigilance, restlessness, distractibility, and agitation. Individuals with hyperactive delirium are easier to identify but may be more difficult to manage because of problematic behaviors, which can include refusing to cooperate with medical care, combativeness, and wandering. Patients with hypoactive delirium present primarily with withdrawal, lethargy, sparse speech, and decreased motor activity. Patients with mixed levels of activity may appear to have a normal level of psychomotor activity even though attention and awareness are impaired. This subtype also includes individuals who have a rapidly fluctuating level of psychomotor activity between hypoactive and hyperactive states.

A number of assessment instruments have been developed to diagnose delirium and evaluate its severity. A commonly used bedside tool is the Confusion Assessment Method or CAM. The CAM identifies key features of delirium and has been validated in many studies. Another quick tool that can be used is the 4A's Test (4AT). Unlike the CAM, the 4AT does not require special training to administer. The CAM-ICU and the ICDSC (Intensive Care Delirium Screening Checklist) have both been validated for use in the ICU setting for critically ill patients. The Delirium Rating Scale-Revised-98 (DRS-R-98) has also been validated in both general medical populations and in geriatric populations. While an assessment tool does not take the place of a mental status examination, it can be very useful as a screening measure to help detect patients who are likely to be delirious. Daily use of a standardized screening instrument, such as the CAM, can be important for prompt identification of acute changes and fluctuations in cognition and attention in hospitalized older patients who are at risk of developing delirium. This can also be used to train nurses or other caregivers to recognize delirium.

PATHOLOGY AND LABORATORY EXAMINATION

The syndrome of delirium is diagnosed on the basis of the clinical history and the examination of the patient at the bedside. The diagnosis of delirium requires a prompt and careful laboratory evaluation to determine the etiology or etiologies. Delirium frequently heralds serious medical illness and, therefore, should be responded to as a medical emergency. A standard laboratory evaluation of delirium is shown in Table 55.3g–3. As indicated in Table 55.3g–3, if the basic evaluation fails to reveal a likely cause, then other selected laboratory investigations may be initiated. Depending on the particular case, further workup may include a brain imaging study or a lumbar puncture for cerebrospinal fluid studies. For instance, a lumbar puncture should be done if there is concern about possible CNS infection, autoimmune disorder, or subarachnoid hemorrhage. A brain computed tomography (CT) or magnetic resonance imaging (MRI) should be done if there is a high possibility of stroke or head trauma causing brain hemorrhage. Arterial blood gas evaluation should be done if there is a concern for hypercarbia in a patient with chronic obstructive pulmonary disease. Detailed neuropsychologic testing is not usually obtained because the attentional impairment of delirium compromises the validity of higher-order testing.

Electroencephalography (EEG) has a characteristic pattern in delirium and typically shows generalized slow-wave activity in the delta and theta range. In hyperadrenergic states, such as alcohol or sedative withdrawal, the EEG will show increased low-voltage fast (beta) activity. However, the EEG is rarely useful in determining the underlying cause of delirium and is not routinely performed unless there is a suspicion of seizure activity or nonconvulsive status epilepticus.

Table 55.3g–3.
Laboratory Workup for Delirium in the Older Adult Patient

- Basic evaluation
  - Blood tests
    - Complete blood count (CBC) with differential and platelets
    - Chemistries:
      - Albumin
      - Blood urea nitrogen (BUN)
      - Creatinine (Cr)
      - Creatine phosphokinase (CPK)
      - Electrolytes: Sodium (Na^+), potassium (K^+), chloride (Cl^-), bicarbonate (HCO_3^-), calcium (Ca^{2+}), phosphate (phos), magnesium (Mg^{2+})
      - Glucose
      - Liver function tests
    - Erythrocyte sedimentation rate or C-reactive protein
    - Syphilis serology
    - Medication levels
    - Toxicology screen (serum and urine)
- Urinalysis (with culture and sensitivity testing, if indicated)
- Electrocardiogram
- Chest radiograph

Other laboratory studies to consider, depending on clinical indications: brain imaging (computed tomography or magnetic resonance imaging), electroencephalogram, arterial blood gas, cerebrospinal fluid studies, vitamin B_{12} level, folate level, thyroid-stimulating hormone, heavy metal screening, human immunodeficiency virus testing, and serum anticholinergic activity (available through research laboratories).

DIFFERENTIAL DIAGNOSIS

Although the symptoms of delirium can mimic a number of psychiatric conditions, including psychosis, depression, or mania, in the older adult patient, the most important differential diagnosis is between delirium and dementia. Population studies of brain donors have shown that there is an increased risk of accelerated cognitive decline in patients with both delirium and pathologic dementia burden (neurofibrillary tangles, amyloid plaques, vascular lesions, and Lewy bodies) compared to delirium alone or dementia alone. To distinguish between delirium and dementia requires

obtaining a thorough history from family members and caregivers or from nursing staff who have recently been caring for the patient and who can provide a description of the patient's baseline level of function and timeline of recent acute changes. Since dementia is a recognized risk factor for delirium, the two diagnoses often coexist in the same patient. Information from family members about the patient's premorbid functioning—such as when the patient last drove a car, balanced a checkbook, or dressed independently—can help identify a more slowly developing dementia. Description of a more rapid decline in general and cognitive functioning over days to weeks and/or a rapidly fluctuating course suggests delirium evolving in a patient with pre-existing dementia. For patients hospitalized on acute medical units, it is imperative to review reports from evening and night shift nursing staff in addition to day shift staff to look for fluctuations in attention, cognitive abilities, and behavior over the course of a 24-hour period. Table 55.3g–4 lists features that can help distinguish delirium from dementia.

Patients who are delirious can appear depressed or manic and frequently are anxious and psychotic. Patients with the hypoactive subtype of delirium tend to be withdrawn, minimally reactive, with minimal speech, poor oral intake, and flat affect, and can be mistaken as being depressed. While older adult patients who are depressed frequently exhibit impairment in short-term memory and in concentration, they do not experience fluctuations in awareness and rapid fluctuations in cognitive functioning that are characteristic of delirious patients. Conversely, patients with the hyperactive subtype of delirium may be agitated, incoherent, and psychotic and may be mistaken as manic. A patient who presents with an acute change in attention and cognition with fluctuating symptoms should be evaluated for delirium, whether or not the patient has a history of depression or bipolar illness, to prevent the possibility of not detecting a serious underlying medical disorder.

Table 55.3g–4.
Differential Diagnosis: Delirium versus Dementia

	Delirium	Dementia
Onset	Acute	Often insidious
Duration	Variable; usually brief	Chronic, unless reversible
Consciousness	Impaired, fluctuating	Normal
Orientation	Impaired	Variable
Memory	Impaired	Impaired
Attention	Impaired	May be normal
Thought	Disorganized; transient delusions; content-rich	Often stereotyped; content poor
Perception	Florid hallucinations (especially visual)	No hallucinations or simple hallucinations
Insight and judgment	Poor, but may return partially during lucid intervals	Variable, depending on etiology and stage
Mood and affect	Often anxious; may appear depressed	May be depressed or anxious
Sleep	Disturbed	May be normal
Electroencephalogram	Abnormal: generalized slowing and slow posterior dominant frequency	Normal or mild slowing of posterior dominant frequency

COURSE AND PROGNOSIS

An episode of delirium can be observed to progress through prodromal, overt, and resolving phases. During the prodromal period, there are typically symptoms such as anxiety, restlessness, irritability, mild confusion, difficulty concentrating, poor sleep, nightmares, daytime drowsiness, social withdrawal, increased sensitivity to light and noise, illusions, and hypnopompic and hypnagogic hallucinations. There is

growing recognition of subsyndromal delirium, in which patients present with some, but not all, of the characteristic features of delirium. The prodrome may persist as subsyndromal delirium, or it may evolve into overt delirium over a period of days or weeks. Patients with subsyndromal delirium have outcomes intermediate between those with no symptoms of delirium and those who meet the full diagnostic criteria.

Delirium that develops in the context of severe medical illness, such as sepsis, may progress to stupor, coma, and death if appropriate, and prompt treatment of the illness is not administered. With appropriate treatment of the underlying medical illness and metabolic abnormalities, delirium will generally resolve. During the resolution phase, psychotic symptoms lessen, sleep cycles normalize, and clarity of awareness returns but cognitive deficits may be more persistent. The stage of resolving delirium in older adult patients may last from days to months. Persistent delirium is not uncommon and has been seen in 20% of older adult patients exhibiting residual symptoms for up to 6 months. Persistent delirium is associated with poor functional recovery from surgery and from medical illnesses and is also associated with increased length of hospital stays and with higher medical costs. Patients who are recovering from delirium will usually require additional assistance for activities of daily living and close monitoring of their medical condition and cognitive functioning.

In the absence of neurodegenerative disease or dementia, the signs and symptoms of delirium usually resolve completely. In patients with Alzheimer disease or Parkinson disease, cognitive deficits can remain such that patients function below their previous baseline levels. Recent research has indicated that patients with Alzheimer disease may experience more rapid cognitive decline following an episode of delirium. In addition, there is also growing evidence that in vulnerable older adults, delirium can lead to permanent cognitive impairment and increases incident dementia. The pathophysiologic mechanism underlying delirium-induced dementia is not clear but may involve processes other than those associated with Alzheimer disease. A serious medical illness that leads to delirium can also be thought of as a “stress test” for the brain that can unmask underlying cognitive deficits that were not obvious previously.

Most patients who have had a serious episode of delirium retain little or no recall of events they experienced while delirious. Patients who had mild-to-moderate episodes of delirium are more likely to have memories of their experience. Some patients develop residual anxiety or even a post-traumatic stress disorder (PTSD) as a consequence of the fearful emotions

and frightening perceptual disturbances they experienced when they were delirious.

The presence of delirium is associated with a significant elevation in mortality risk for older adult patients, both during hospitalization and in the 6 to 12 months after discharge from the hospital. This association remains even after controlling for the severity of underlying illness and other confounding factors. Delirium symptoms that persist at discharge from the hospital are associated with a high rate of nursing home placement. Patients who have experienced an episode of delirium and have recovered remain at increased risk for a recurrent future episode of delirium.

PREVENTION

In recent years, there has been considerable interest in efforts to prevent delirium. Nonpharmacologic delirium prevention protocols have been shown to reduce the incidence of delirium. The most widely used strategy is a multicomponent nonpharmacologic approach devised by Sharon Inouye and colleagues, known as the Hospital Elder Life Program (HELP). This multidimensional strategy has been used for hospitalized patients with diverse medical problems. The HELP interventions include cognitive reorientation, therapeutic activities and early mobilization (such as daily exercise and walking), reduced use and reduced doses of psychoactive drugs, nonpharmacologic promotion of sleep, maintenance of oral hydration and adequate nutrition, and provision of appropriate hearing and vision aids.

Delirium prevention efforts have also focused on patients undergoing surgery as well as in the ICU since delirium is a common syndrome in these settings, especially in older adults. Studies have looked at patient baseline characteristics as well as intraoperative and postoperative management and their association with delirium. Evidence indicates that the route of intraoperative anesthesia (e.g., general, spinal, or epidural) does not affect the development of delirium. However, the total dose of anesthetic drugs may have a role in causing delirium. A double-blind, randomized study found that using lighter sedation for older adult patients undergoing hip fracture repair surgery led to a 50% drop in the risk of postoperative delirium. In addition, minimizing the use of benzodiazepines and certain opioid pain medications, especially meperidine, in the postoperative period can help decrease the incidence of delirium. Studies in critical care settings have shown early physical and occupational

therapy during breaks in sedation in mechanically ventilated patients led to shorter delirium duration. Similarly, earlier mobilization of surgical patients led to improved functional status and decreased the number of days spent in the ICU. These evidence-based preventative interventions have been grouped into recommended care bundles targeted to optimize patient recovery and outcomes. One such care bundle used in the ICU, called the ABCDEF bundle, has been associated with decreased risk of delirium.

ABCDEF is an acronym that stands for

- Assess
- Both spontaneous awakening and breathing trials
- Choice of sedation/analgesia
- Delirium assessment/management
- Early mobility/exercise
- Family engagement/empowerment.

Multiple studies have looked at pharmacotherapy as a means to prevent delirium in high-risk patients in ICU. A recent systematic review on antipsychotic agents found limited evidence supporting the routine use of haloperidol or second-generation antipsychotic drugs (olanzapine, risperidone) for the prevention of delirium. Similarly, there is no clear evidence for the use of cholinesterase inhibitors or melatonin in delirium prevention in non-ICU settings.

TREATMENT

The most important aspect of treatment is to identify and treat underlying medical illnesses and derangements causing delirium. In many cases, timely and appropriate medical treatment will be lifesaving to the patient. When delirium is detected in older adult patients, it should be considered a medical emergency, resulting in immediate workup to determine the underlying cause or causes and to initiate treatment. In older patients, a single cause for delirium usually cannot be identified, as delirium is more commonly multifactorial in etiology. Most of the time, an older patient with delirium will be hospitalized in order to adequately evaluate the patient and address treatable causes.

Table 55.3g–5 lists critical medical interventions which should be used in managing older adult patients with delirium. Besides diagnosing underlying medical causes, attention should be given to all possible contributors to the

delirious state, especially modifiable predisposing factors. These include the elimination of all unnecessary medications, treating hypoxemia and anemia, correcting vision and hearing impairments that lead to sensory deprivations, maintaining good hydration and nutrition, preventing urinary retention and fecal impaction, and minimizing pain. Reducing the use of indwelling urinary catheters can prevent catheter-associated urinary tract infections and associated delirium. Close monitoring is necessary for the patient's safety and to prevent aspiration, falls, or inadvertent self-harm. Physical restraints should be avoided as much as possible. The use of physical restraints has been associated with the worsening of psychotic symptoms and with medical complications such as deep vein thrombosis, pulmonary embolism, and cardiac dysrhythmias in delirious patients.

Table 55.3g–5.
Medical Interventions for Delirium in Older Adult Patients

Ensure Safety	Close Observation by a Family Member or Staff May Be Indicated
Ensure adequate hydration and nourishment	Patient cannot monitor intake or feeding; this usually means intravenous hydration is indicated Eating and drinking should be observed to ensure adequate intake and to avoid choking/aspiration
Ensure adequate oxygenation	Consider supplemental oxygen via nasal cannula to keep O_2 saturation >95%
Attention to bowel/bladder function	Watch intake/output Ensure regular bowel movements via an appropriate bowel regimen
Investigate common etiologies of delirium	Perform the following: Chest radiograph to rule out pneumonia Urinalysis to rule out urinary tract infection Physical/lab exam to rule out dehydration/electrolyte disturbance Consider medication effects (not just toxicity, but ANY medication linked temporally to delirium onset) Hold nonessential medications
Treat pain adequately	Recommended drugs include scheduled acetaminophen for mild pain and low-dose hydromorphone for severe pain Avoid meperidine
Increase activity level as appropriate and tolerated	Get the patient out of bed to the chair as soon as possible Include a written plan in the chart to maintain mobility

Table 55.3g–6 lists environmental and nonpharmacologic interventions that have been shown to be beneficial in the management of patients with

delirium. These include taking steps to help restore a normal sleep–wake cycle by minimizing light, noise, and disruptions during the night while increasing exposure to light and activity during the day. Many patients benefit from being moved closer to a window, where natural daylight and night cues can be appreciated. It is important for staff and family to be educated about appropriate ways to interact with the patient to promote cognitive functioning. Delirious patients should not be left alone for long periods. Family members and close friends of the patient should be encouraged to visit and should be allowed to stay with the patient overnight if they so desire. Hospital staff and family members should reorient the patient to time, place, and person frequently during the day. Both overstimulation and understimulation should be avoided, as either extreme can exacerbate symptoms of delirium. The patient should be given only one task to do at a time rather than multistep instructions. For patients who are anxious or fearful, frequent calm reassurance by family and staff can minimize agitation.

There are no FDA-approved medications to treat behavioral disturbances in delirium. The first-line approach to managing agitation and psychotic symptoms in delirium is to try the nonpharmacologic interventions previously described, including reorientation, support, and reassurance. Currently, there is limited evidence on the use of medications in treating or preventing delirium. However, pharmacologic treatment may be necessary for agitated delirious patients for whom verbal reassurance is inadequate and for patients who exhibit behaviors that are dangerous to themselves or others. Pharmacologic treatment may also be indicated for patients with psychotic symptoms causing significant fear and anxiety.

Table 55.3g–6.
Environmental Interventions for Prevention and Management of Delirium in Older Adult Patients

Appropriate Lighting	Bright During Day Dark at Night
Promote sleep at night	Low nighttime noise level Pagers and other electronic devices on silent mode Telephone ring turned down Television turned off Voices kept low Doors closed as patient care permits Minimize necessary awakenings
Frequent reorientation	Staff to reorient patient to time, place, and person verbally each shift Clock and calendar in room Familiar possessions in room
Education	Family to be educated about the cause, course, and prognosis of delirium Staff to be educated about behavioral dysregulation in delirium and its management
Promote sensory function	Hearing aids on and function checked Glasses on and cleaned
Comfort/reassurance	Personal effects from home at bedside Family and close friends encouraged to visit and stay with patient, if possible Frequent reassurance provided to patient

In deciding which medication to use in treating behavioral symptoms of delirium, it is important to determine whether alcohol or sedative withdrawal is a cause of delirium. For patients experiencing alcohol or sedative withdrawal delirium, benzodiazepines are the medications of choice. Lorazepam or oxazepam may be preferable to chlordiazepoxide, especially in patients with decreased liver metabolism, because they are

not metabolized by the liver and have shorter half-lives. It should be noted that benzodiazepines are not without adverse effects, especially in older adult individuals. These drugs can affect respiration and hemodynamics and can cause dysrhythmias. They can increase confusion and the risk of falls and, therefore, hip fractures. Paradoxical reactions, in which increased agitation and disinhibition are seen rather than sedation, are observed with greater frequency among patients with liver disease or low serum albumin levels. In the treatment of alcohol or sedative withdrawal, a common dosing guideline for lorazepam is as follows. The severity of withdrawal is monitored using a structured instrument such as the Clinical Institute Withdrawal Assessment for Alcoholism, revised (CIWA-Ar).

Clinical Institute Withdrawal Assessment for Alcoholism, revised (CIWA-Ar):

Day 1: Lorazepam 1 to 2 mg is given orally, intravenously, or intramuscularly every 4 hours on a scheduled basis.

Day 2: This dose is decreased by 50%.

Day 3: The dose is decreased again by 50% on day 3.

Score the CIWA-Ar every 4 hours. If the score increases to greater than 8 to 10, then the frequency of lorazepam doses is increased to every 1 to 2 hours until symptoms are controlled, then the original protocol is restarted. Patients with full-blown delirium tremens will likely require higher and more frequent doses.

A 78-year-old male was admitted to the emergency department after a 5-week alcohol binge. He was known to have a long history of alcohol dependence, with multiple prior episodes of delirium tremens and probably alcohol-related dementia. On admission, clinical examination and laboratory testing revealed malnutrition, urinary tract infection, and pneumonia. The patient was started on oral lorazepam but, within 24 hours, was transferred to the intensive care unit with tachycardia and visual and auditory hallucinations. A lorazepam infusion was started, along with a beta blocker for control of heart rate. Over the next 24 hours, the patient's condition stabilized. He was switched from the lorazepam infusion to intravenous bolus lorazepam with good control of symptoms. As his medical problems were treated, his mental state improved. The beta blocker was discontinued, and the lorazepam was tapered slowly over several weeks. He was discharged off medications 25 days after admission.

For delirious patients who are not experiencing alcohol or sedative withdrawal, benzodiazepines are avoided because they may exacerbate delirium and increase the risk of falls. Antipsychotic medications are the most studied class of drugs for delirium treatment. In non-ICU patients, the efficacy of these drugs is unclear, and review studies show no effect on delirium severity, symptom resolution, or mortality. Similarly, studies of patients in ICU indicate no significant treatment effects of antipsychotic medications on the duration of delirium, hypoactive/hyperactive delirium, or the number of days alive with/without coma. Other agents such as melatonin, ramelteon (a melatonin receptor agonist), and cholinesterase inhibitors have been suggested for delirium treatment, but there is limited consistent evidence supporting their use. However, expert consensus does support a limited role for drugs in the treatment of delirium, especially in patients with severe distress

For psychotic and behavioral symptoms, haloperidol, a typical antipsychotic, has been used due to its availability (it can be dosed orally and intravenously delivered) and, when dosed appropriately, has minimal adverse effects. It does not cause significant hypotension, is not anticholinergic, does not depress respiration, and does not cause or impair glucose regulation. The risk of QTc interval prolongation is minimized by staying within dosing guidelines and adhering to recommendations

regarding QTc interval checks. Before haloperidol is initiated, a baseline QTc interval is obtained. If the interval is 450 ms or greater in a male or 470 ms or greater in a female, intravenous haloperidol should not be used. Any patient whose QTc interval is prolonged beyond 25% of baseline during treatment should have haloperidol discontinued. There is evidence that intravenous haloperidol is less likely to cause extrapyramidal symptoms than oral doses of haloperidol.

A conservative but usually effective dosing schedule for an older adult delirious patient is as follows: haloperidol 0.25 mg to 0.5 mg intravenously every 8 hours on a scheduled basis, and 0.25 mg to 0.5 mg intravenously every 6 hours as needed to keep agitation and psychotic symptoms under control. If oral dosing of haloperidol is used, higher doses are given (e.g., 0.5 mg to 1 mg by mouth every 8 hours and 0.5 mg to 1 mg by mouth every 6 hours as needed). Younger patients may require and tolerate higher doses of medication. How long the acute dose of haloperidol is maintained depends on how the patient responds clinically. If the patient becomes calm and psychotic symptoms lessen within the first 12 to 24 hours (as usually happens), this dose of haloperidol is continued for 2 to 3 days and then is tapered over the next 2 to 3 days. If the patient does not become calm within this time frame, consideration should be given to a missed or inadequately treated medical condition prolonging delirium. In this case, haloperidol would likely be continued for a longer period.

Atypical antipsychotic medications have been shown to be just as effective as haloperidol in controlling symptoms of agitation and psychosis in delirious patients. These medications are generally well tolerated when used for acute episodes of delirium. One limitation is that they are given orally rather than intravenously.

The two atypical antipsychotic agents which are most commonly used for delirium in older adult patients are risperidone and quetiapine, with dosing schedules as follows:

Risperidone 0.25 to 0.5 mg twice daily on a scheduled basis and 0.25 to 0.5 mg every 6 hours on an as-needed basis.

Quetiapine 25 mg at bedtime to 25 mg twice daily on a scheduled basis and 25 mg every 6 hours on an as-needed basis.

An 84-year-old man was admitted from home with acute coronary syndrome. Medical history was significant for coronary artery disease, myocardial infarction, left carotid endarterectomy, chronic renal insufficiency, and renal cell carcinoma. He underwent three-vessel coronary artery bypass grafting. On the first postoperative day, he was noted to be irritable, combative, and confused. He told his family that he was brought to the hospital for “experimentation” and had persistent tactile hallucinations of leaves and other objects in his mouth. Nighttime restlessness progressed to nocturnal insomnia and agitation. The patient had marked fluctuations in alertness during the day, with worsening agitation in the evening hours. During his agitated episodes, he pulled out his intravenous line several times. During a period of relative lucidity, an Mini-Mental State Examination (MMSE) was performed, and he scored 10/30. A psychiatric consultant recommended 0.5 mg of haloperidol orally every 8 hours on a scheduled basis for symptomatic treatment of his hallucinations and agitation. Medical complications (which included dehydration, atrial fibrillation, hypotension, and pneumonia) were managed as they arose. Although agitation and psychotic symptoms were improved, the patient required intermittent one-to-one observation by staff. After 7 days, his mental state began to improve as his medical condition stabilized. He was discharged on postoperative day 17 with some residual memory problems and insomnia but without evidence of psychotic symptoms or agitation.

FUTURE DIRECTIONS AND COVID CONSIDERATIONS

Despite progress over the years in understanding delirium, we still need more studies to elucidate the neuropathology of delirium, which can aid in preventing and treating delirium. *Animal models* could be helpful in understanding the underlying pathophysiology of delirium. Studies have looked at the role of interleukins, neurotransmitters, hypoxia, and brain pathology on delirium—but more studies are needed. An animal model could also be helpful in testing preventive or treatment strategies. Understanding pathophysiology may aid in devising pharmacologic targets. More studies of pharmacologic agents are needed to help with delirium prevention or treatment, including psychotropics that have limited evidence

but continue to be used in multiple settings. Dexmedetomidine has also been looked at in the prevention or treatment of delirium in postoperative patients and should be explored further. Different approaches to sedation for surgery also are promising areas for investigation. In particular, using light sedation, where possible, seems to be less likely to cause delirium.

COVID-19, the coronavirus disease caused by severe acute respiratory syndrome coronavirus 2 (SARS-Cov-2), has also been implicated in causing high rates of delirium (up to 79.5% in ICU settings in the general population and up to 40% in non-ICU hospitalizations in older adults). There is limited evidence to elucidate the pathophysiologic role of COVID-19 in the development of delirium, but multiple mechanisms have been implicated, including systemic inflammation and/or direct brain entry of the virus. During the COVID-19 pandemic that arose in 2020, there were fears that best practices for delirium management would be compromised due to quarantine restriction requirements for inpatient care. Particularly early in the pandemic, shortages of personal protective equipment (PPE), changes to staff hierarchy and priorities, and restricted physical bedside presence affected adherence to delirium preventative protocols. These changes may have favored increased use of sedation and prolonged use of already limited ventilator resources. Early reports of COVID-19 cohorts suggested more widespread use of benzodiazepines for sedation and that COVID-19 patients often developed a severe delirium phenotype. At the present time, little is known about the impact of possible deviations from usual delirium management protocols on the course of COVID-19 delirium in older adults.

Clearly, more research is needed to fully understand the impact of the virus on the geriatric population.

Another area requiring future research is evaluating methods of improving the quality of life following delirium, as delirium is associated with functional decline and worsening disability in older adults. A collaborative approach to delirium prevention needs to be advocated with a focus on delirium prevention/treatment protocols. Strategies like the ABCDEF bundle and HELP protocol have shown benefits in decreasing delirium, but more studies of interventions that can help prevent or treat delirium are needed. Improved approaches to the prevention and treatment of delirium are needed to limit impairments and adverse outcomes on the physical, cognitive, and psychological functioning of older adults.

55.3h Schizophrenia and Other Psychotic Disorders

Carl I. Cohen, M.D., and Paul D. Meesters, M.D.

Over the past century, the vast majority of schizophrenia studies have primarily involved young adult patients, and only about 1% of the literature on schizophrenia is dedicated to issues of older adults. In this chapter, we examine early-onset and late-onset schizophrenia (LOS) in older adults and how they can be distinguished from other psychotic disorders in later life.

HISTORY AND COMPARATIVE NOSOLOGY

Emil Kraepelin's description of "dementia praecox" as a disorder of progressive decline with onset during adolescence or early adulthood greatly influenced the subsequent conceptualization of schizophrenia. Nonetheless, Kraepelin later questioned the term *dementia praecox* after observing that the onset of this disorder was not limited to younger patients, nor was the course necessarily progressive. He used the term *paraphrenia* to describe a subset of patients with an onset of delusions and hallucinations that were primarily paranoid and with a better prognosis. This group of patients had several symptoms like those of dementia praecox but with less alteration of emotion and volition. Kraepelin was said to refer to paraphrenia as the "darkest area of psychiatry."

Approximately 20% to 25% of patients with schizophrenia have an onset of the disorder after age 40. There has been considerable vacillation in diagnostic criteria regarding the age of onset. Martin Roth and colleagues introduced the idea that LOS could be a distinct entity after applying the term "late paraphrenia" to a group of patients with an onset of the disorder after the age of 60. Years later, the term "late paraphrenia" was included in the ninth edition of the International Statistical Classification of Diseases and Related Health Problems (ICD-9). The use of the terms "paraphrenia" and "late paraphrenia" led to some confusion because Kraepelin did not consider late age of onset a feature of paraphrenia, and paraphrenia is a more inclusive term and not synonymous with schizophrenia.

The early editions of the Diagnostic and Statistical Manual of Mental Disorders did not specify the age of onset criteria for schizophrenia. DSM-I and DSM-II included the category "Involutional Psychotic Reaction" for psychotic symptoms occurring during the involutional period, and DSM-II used the terms "involutional state" or "involutional paraphrenia" to describe a delusional condition with onset during the involutional period. In contradistinction, the DSM-III restricted the diagnosis of schizophrenia to onset before age 45, whereas the DSM-III-R included a late-onset category for initial presentations after age 44. The ICD-9 included the diagnosis of "Paraphrenia" and listed "Involutional Paranoid State" and "Paraphrenia, Involutional" as approximate synonyms. However, the ICD-10, DSM-IV, DSM-IV-TR, DSM-5, and the DSM-5-TR did not include separate diagnostic categories or criteria for LOS.

The omission of a late-life category is problematic since there is evidence that late-onset disorders, especially those arising after age 60, may differ clinically from earlier-onset cases. In 2000, an international expert group published a consensus report that proposed that

schizophrenia be termed “Late-Onset Schizophrenia” and “Very–Late-Onset Schizophrenia-Like Psychosis” for disorders that have an onset between ages 40 and 60 and after the age of 60, respectively.

EPIDEMIOLOGY

Epidemiologic studies from the United States and the United Kingdom place the prevalence of schizophrenia at 0.6% to 1% in persons aged 45 and over and 0.1% to 0.5% in those aged 65 and over. Based on insurance claims data of persons aged 65 years and older, the prevalence estimates were 0.55% for men and 0.84% for women, with an overall prevalence of 0.71%. In the United States, by 2025, roughly three-quarters of a million people, or approximately one-fourth to one-third of all persons with schizophrenia, will be aged 55 and over; by 2060, their proportion may reach 40%. Worldwide, the number of people aged 60 years and older with schizophrenia will expand to an estimated 10 million people by 2050.

EARLY-ONSET SCHIZOPHRENIA

Schizophrenia typically develops in the second or third decade of life. Despite lower life expectancies than their age peers, increasingly more persons with schizophrenia are surviving into later life. It is estimated that nearly two-thirds of persons with schizophrenia aged 60 and over have an early-onset disorder.

Course and Outcome of Early-Onset Schizophrenia

There are several key points about course and outcome that have emerged in recent years that are relevant to the care of older adults with schizophrenia:

First, determining the outcome of schizophrenia can be a daunting task since it is dependent on definitions of the outcome, historical context, methods of assessment, diagnostic criteria, geographical settings, sociodemographic differences, age of onset, responsiveness to medications, and length of hospitalization Thus, Hegarty and colleagues looked at longitudinal studies of outcome in schizophrenia (all age groups) across the 20th century and found a mean improvement rate of 28% during the first quarter of the century, 49% in mid-century, and 36% in the last two decades.

Second, there is an increasing consensus that outcomes in schizophrenia are multidimensional and encompass clinical and social elements. A comprehensive view of outcomes in older adults should include symptoms, functionality, a combination of symptoms and functionality ("clinical recovery"), and positive health ("successful aging") based on physical, social, and psychological well-being. The symptom outcomes include positive and negative symptoms (sometimes combined into "clinical remission"), depression, and cognitive functioning. The social functioning outcomes include community or social integration, adaptive functioning (e.g., activities of daily living), and quality of life (QoL).

Third, there is substantial heterogeneity in the outcomes of schizophrenia in later life. Despite scarce data, some findings suggest that the diversity seen in younger individuals might be even greater in older age. Long-term studies observing the symptoms and functioning in EOS suggest that the course of schizophrenia may not be as pessimistic as previously thought, and findings tend to challenge the notion implied in the term "dementia praecox." Ten studies of hospitalized patients who were reinterviewed after hospital discharge (mean of 22 to 37 years postdischarge) conducted 30 to 50 years ago found recovery rates ranging from 12% to 55% based on a single assessment in later life. The investigators used varying diagnostic criteria and social indicators. Several cross-sectional studies conducted during the early part of this century found clinical remission rates ranging from 29% to 49% and clinical recovery rates of 22% in older adults with schizophrenia, nearly all of whom were living in community settings. However, longitudinal studies were less optimistic, with only about a quarter of persons displaying persistent clinical remission and about one-eighth attaining persistent clinical recovery. The latter was consistent with findings in young and mixed-age samples that found a median rate of clinical recovery of 13.5%.

Fourth, outcome measures are relatively distinct from each other and may need to be viewed as separate targets for intervention. A study in New York City of community-dwelling older adults with schizophrenia aged 55 and over who had early-onset disorder found that the shared variance among clinical remission, depressive symptoms, cognitive functioning, and community integration ranged from 0% to 22%, with a median value of 5%. The relative independence among outcomes suggests a variegated pattern of outcome and, consequently, the need for more targeted, personalized care. Indeed, when the investigators subsequently looked at five outcome measures over 52 months (remission, community integration, depression,

cognitive functioning, and self-health), they found various combinations of favorable outcomes, as well as differences in the number of favorable outcomes, attained: 9%, 17%, 22%, 24%, 22%, and 6% had favorable outcomes in none, one, two, three, four, or all five outcome measures, respectively.

Fifth, although schizophrenia has been thought to be largely quiescent or have a steady end-stage in later life, recent longitudinal data shows this is not true. About two-fifths of persons fluctuate between being in and out of clinical remission, and between one-fourth and one-third of persons fluctuate between varying states of clinical recovery, depression, cognitive dysfunction, and community integration.

The final point is that the course in later life can be understood within the recovery model of mental illness. As noted above, while most persons do not achieve persistent clinical recovery, many display fluctuations in their symptoms and functioning. Based on longitudinal data from the NYC community study described above, Cohen and Reinhardt devised a five-tier taxonomy of late-life course trajectories among persons living in the community. On the two extremes, 12% showed persistent recovery, and 18% were unable to ever attain symptom remission or social integration. The remainder showed various combinations of remission and social integration. Hence, most older persons are in various states of recovery ("recovering"), and targeted approaches to address their specific clinical and social needs may advance their progress along the recovery continuum. Although the extremes of this continuum attract the most attention, most older patients with schizophrenia can be identified at some point in between these extremes, moving with time in one direction or the other.

While a prediction of the long-term course of the illness in an individual cannot be accurately made, the general factors associated with favorable outcomes include female gender, later onset of symptoms, less severe negative symptoms, and better premorbid functioning. However, with age, the strength of association between these variables and outcome weakens. Consequently, predicting a probable long-term course for schizophrenia patients is difficult. Apart from the relatively small group of poor outcome patients who worsen over time and who are largely found among long-term institutionalized patients in state hospitals or nursing homes (about 15% of all older adults with schizophrenia), most older community-dwelling persons with schizophrenia have been found to have

a nondeteriorating course accompanied by fluctuations over time in individual outcome dimensions.

Symptom Dimensions of Outcome. In the previous section, we discussed some of the findings of hybrid or global measures of outcome, such as “clinical remission,” which combines various positive and negative symptoms, and “clinical recovery,” which combines remission and community integration. Below, we focus on key individual measures that comprise the dimensional framework in Section III of the DSM-5-TR. The DSM-5-TR authors contend that the dimensional assessment may assist with treatment planning, prognostic decision-making, and research on pathophysiology. In time, the dimensional model is expected to gain more traction in the care and research affecting older adults with schizophrenia.

POSITIVE SYMPTOMS. Long-term studies of outcomes have demonstrated that there is an improvement in positive symptoms with age. In the NYC community sample described above, roughly three-fifths of patients living in the community demonstrated favorable outcomes for positive symptoms. On 52-month follow-up, nearly half maintained persistently low or absent positive symptoms, and about one-third fluctuated between the presence and absence of positive symptoms.

NEGATIVE SYMPTOMS. Negative symptoms are thought to predominate the clinical picture of schizophrenia in later life. However, estimating negative symptoms in older schizophrenia patients can be challenging, as the clinical picture is often confounded by depression, demoralization, cognitive decline, medication effects, and poverty. The few studies of negative symptoms in community-dwelling older adults found prevalence rates of between one-quarter to one-half of the sample. Notably, longitudinal data from the New York City sample found that slightly over two-fifths of people fluctuated between the presence and absence of negative symptoms. Thus, contrary to earlier notions of schizophrenia progressing to a “burnt-out” state in later life, negative symptoms do not typically dominate the clinical picture, appear to be no higher than in younger schizophrenia populations, and fluctuate more than positive symptoms over time.

COGNITION. It is well established that older adults with schizophrenia have more cognitive deficits than their age-matched peers, with levels of

cognitive deficits being nearly two standard deviations below control participants. Rajji and coauthors found that compared to healthy controls, persons with schizophrenia, aged 19 to 79, had lower scores in overall cognition and each cognitive domain except for social cognition. However, the rate of decline across the age groups was similar to that observed in the healthy control groups. Consequently, schizophrenia is no longer viewed as a neurodegenerative disorder ("dementia praecox") but rather as a neurodevelopmental disorder in which deficits arise around the time of onset and do not progress beyond the expected effect of aging. While the rate of cognitive decline in schizophrenia may be similar to age-matched controls, the pre-existing deficits accrued at disease onset result in an earlier crossing of the diagnostic threshold into a major neurocognitive impairment (dementia).

Within-group longitudinal data of middle age and older adults with schizophrenia in the community showed considerable heterogeneity: a majority of persons seemed to be cognitively stable; however, about one-fifth of persons showed a more rapid decline, and one-fifth showed improvement, often rising from dementia to near-normal levels. Worse cognition (global and/or domain-specific) is strongly associated with diminished functional competence and community adaptation; more modest correlations have been found with older age, female gender, lower education, living in an institution, longer duration of illness, earlier age of onset, and higher levels of positive and negative symptoms.

Several recent epidemiologic studies have found prevalence rates of dementia diagnosis in persons with schizophrenia of 2 to 20 times that of their age peers, although the actual prevalence rates ranged from 1.8% to 64%, with rates of 70% at age 80 in one study. Friedman and coinvestigators found accelerated cognitive decline experienced by chronically institutionalized persons with schizophrenia beginning at age 65, but the decline in cognition was substantially less than in Alzheimer disease (AD). Patterns of decline, neuropathology, and polygenetic findings did not resemble those of AD, even among more chronically hospitalized groups. Rajji and associates' review of older schizophrenia patients concluded that the findings of cognitive decline at age 65 found in institutionalized persons do not seem to apply to those who have been living in the community.

The fact that the course of decline and the underlying neuropathology differs from AD and that as many as one-fifth of persons show substantial improvements in cognition over time suggests that rendering a diagnosis of

a major neurocognitive disorder may be inappropriate. As in the case of depression described below, the employment of the dimensional perspective described in the DSM-5-TR may help resolve these thorny diagnostic issues.

DEPRESSION. Among the studies on depression in older adults with schizophrenia, prevalence rates of depression ranged from 11% to 75%, depending on the severity criteria that were used. At all levels of depression, the prevalence was significantly greater than their age peers in the general population, although rates were similar to those of younger persons with schizophrenia. Because there is a substantial minority of persons who do not experience depression, it may be inappropriate to consider depression to be a core feature of the disorder, although it is a common feature with prevalence rates that remain high throughout the lifespan. Longitudinal data from the New York City sample showed that persistent depression (defined as the presence of syndromal or subsyndromal depression) occurred in 44% of persons, 30% remained persistently nondepressed, and 26% fluctuated between depression and nondepression.

The potential for suicide remains high in later life. Among depressed persons aged 40 and over with schizophrenia, 23% had current suicidal ideation, and 49% had made a previous attempt. In another study that included depressed and nondepressed persons with schizophrenia aged 55 and over, 13% had current suicidal ideation, and 30% had made a suicidal attempt during their lifetime.

Social and Adaptive Functioning

COMMUNITY INTEGRATION AND SOCIAL FUNCTIONING. Social functioning is a critical outcome indicator. Social functioning refers to the ability to establish and maintain relationships with friends and family as well as to undertake work and leisure activities. Adaptive functioning refers to the ability to function independently. A review by Meesters and colleagues concluded that the majority of older schizophrenic patients are well behind their healthy age-peers in various aspects of social and adaptive functioning, such as social roles, social support, and social skills. At the same time, considerable heterogeneity among patients can be found, and cognitive functioning had a major impact on social functioning, outweighing clinical symptoms. Other factors associated with better adaptive functioning

include fewer negative symptoms, better physical health, and independent living. Long-term studies indicate that social functioning often improves in older schizophrenia patients, although, as with other domains, there may be movement in favorable and unfavorable directions over time.

A more recent body of work has focused on community integration in schizophrenia. Community Integration can be conceptualized as a "normalization" of functioning in society and comprises assessments of functioning and perceived QoL within several dimensions, viz., independence, physical, psychological, and social integration. In a cross-sectional study in New York City, a community comparison group of older adults had roughly twice the level of high community integration than those with schizophrenia (41% vs. 23%). In a longitudinal study using the same sample, 34% of schizophrenia persons fluctuated between high and low community integration, suggesting that there is a movement toward improved social integration in later life but also the potential for increased social isolation and diminished functioning.

QUALITY OF LIFE. QoL indicates an individual's self-perception of their position in life concerning their goals, expectations, and worries. It is an indicator of individuals' self-appraisal of their condition. Among older individuals with schizophrenia, lower QoL is associated with depression, positive and negative symptoms, cognitive deficits, financial strain, poor social support, and impaired social skills. Lower QoL may also predict suicidality. Although QoL indices are lower in older community-dwelling schizophrenia patients than their age peers matched for race and income, the absolute difference between the groups is small, and both scored in the moderate range of QoL and substantially higher than persons with chronic pain. Like other outcome measures, there is a fluctuation between good QoL and poor QoL. The New York City group found that 28% of persons moved between favorable and less favorable QoL outcomes, 40% had persistently favorable QoL, and only 32% had persistently less favorable QoL. Over time, many older adults with schizophrenia appear to find ways to adapt to their illness and, despite ongoing symptoms, value their QoL and find "wellness within illness."

In summary, the research data on the symptom and social outcome dimensions of schizophrenia in older patients provide some support for optimism in later life. However, based on recent longitudinal studies, we have a more nuanced understanding of the dynamics of various domains. Thus, as noted above, a favorable outcome in one category does not

necessarily result in a favorable outcome in another category. This should lead to a more personalized care approach to treatment that will include a combination of biologic and psychosocial methods.

Medical Comorbidity and Mortality

Life expectancy is reduced by 15 to 20 years for people with schizophrenia. The mortality rate in schizophrenia is two to three times higher than in the general population, and this mortality gap has increased in recent decades. Although persons with EOS who live into old age should be considered to be survivors, the differences in mortality rates between persons with schizophrenia and their age peers persist into later life, perhaps even into their 80s. On the other hand, a review by Copeli and Cohen found that older adults with schizophrenia consistently showed lower age-adjusted mortality rates compared to middle-aged and younger persons with schizophrenia. While the mortality rate from suicides and accidents is elevated in older individuals with schizophrenia versus their age peers, natural causes of death account for the largest part of the reduction in life expectancy.

It is unclear as to why there are differences in mortality rates between older adults with schizophrenia and their age peers. Copeli and Cohen's review found inconsistent findings regarding differences in the prevalence of serious medical disorders between them. For example, compared to their age peers, older adults with schizophrenia had increased mortality rates and greater prevalence of respiratory diseases; no differences in mortality and prevalence of diabetes; higher mortality rates but no differences in the prevalence of cardiovascular disease; and considerable variability with respect to cancer, with incidence rates being equal or perhaps lower, but mortality rates being higher. Some of the differences in mortality can be attributed to lifestyle factors (e.g., poor diets, smoking, diminished physical activity), being in lower socioeconomic classes, and the impact of antipsychotic medications, especially second-generation antipsychotics. Some of the excess morbidity and mortality may be due to high rates of inflammation and oxidative stress reported among persons with schizophrenia. Moreover, they seem to be at risk for undetected or inadequately treated medical conditions that may be secondary to individual or systemic factors. A Danish Registry study found that persons with schizophrenia aged 70 and over did not differ from controls regarding chronic medical illnesses, but they were significantly less likely to receive

medication for cardiovascular diseases; hospital admissions and the number of days hospitalized were equal to controls, but with significantly fewer general medical outpatient contacts. Finally, diminished insight regarding their symptoms and illness management may contribute to inadequate healthcare.

Biologic Features

Numerous neuroimaging cross-sectional studies support structural brain alterations in schizophrenia patients and controls. These include diminished gray matter in frontal, temporal, and postcentral cortical regions and increased ventricular size, and white matter reductions in the corpus callosum, although these findings have been inconsistent. Schnack and coinvestigators compared MRI scans for healthy subjects and persons with schizophrenia (age range 16 to 67 years) and found that there was an "accelerated" pattern of brain aging in people with schizophrenia at illness onset and during the initial 5 years; after that time, the rates of decline were comparable between the two groups, although the brain gap stayed constant.

Concerning neuropathology studies, a review by Centorino and Schultz concluded that postmortem studies have been even more mixed and complex than the neuroimaging studies, and no clear neuropathologic lesions have been demonstrated in older populations. Nguyen and colleagues' review found that a majority of studies reported abnormal biomarker levels among older individuals with schizophrenia, including senescence-related indices of inflammation, telomere length, oxidative stress, metabolic health, gene expression, synaptic function, and testosterone, suggesting that schizophrenia is associated with aging-related biochemical abnormalities. About one-fourth of these studies observed age-related changes in schizophrenia, especially in markers of receptor/synaptic function and gene expression. Schizophrenia patients with greater disease severity and longer illness duration had higher levels of inflammatory and oxidative stress biomarkers and shorter telomere lengths. These studies must be interpreted cautiously because of inconsistencies in study designs, especially in the failure to control for potentially confounding variables such as smoking, substance abuse, exercise, diet, access to health care, and use of antipsychotic agents.

Treatment

There are only a few controlled studies assessing treatment approaches in older schizophrenia patients. Optimal treatment for older patients with schizophrenia will likely involve a targeted combination of pharmacology, nonpharmacologic therapy, and community-based approaches.

Somatic Approaches. Reviews of various open studies, along with the few controlled studies in older adults with schizophrenia, found somewhat mixed results for first-generation antipsychotics but more consistently favorable results with second-generation antipsychotics. Khan and colleagues provided an update on an earlier consensus paper and recommended risperidone (2 to 3 mg/day) as the first-line treatment for late-life schizophrenia; the second-line treatments are quetiapine (100 to 200 mg/day), olanzapine (5 to 15 mg/day), and aripiprazole (10 to 15 mg/day). For those with a late-onset disorder, the starting dose for antipsychotics should be ¼ of the typical adult dose, and the maintenance dose should typically be ⅓ to ½ of the adult dose.

Several studies found that estrogen treatment in postmenopausal women with schizophrenia resulted in diminished symptom severity. One controlled study suggested that citalopram may be effective for treating middle-aged and older schizophrenia adults with subsyndromal depression.

A literature review of electroconvulsive therapy (ECT) in older persons with schizophrenia identified six prospective studies and one case series; participants were between 49 and 96 years old. The authors concluded that bilateral ECT was effective as an acute and maintenance treatment in this population that had the onset of their illness earlier in life. ECT was not effective in those with very–late-onset psychosis, possibly due to the high prevalence of comorbid brain pathology other than schizophrenia. Transcranial magnetic stimulation and deep brain stimulation have not been studied systematically in the older age group.

The long-term use of antipsychotic medications has raised numerous concerns. Because of the pharmacokinetic and pharmacodynamic changes associated with aging, older people are more prone to the adverse effects of medications, for example, cardiovascular, orthostasis, metabolic, anticholinergic, extrapyramidal, sedation, falls, and neuroleptic malignant syndrome. In a middle-aged sample, higher lifetime antipsychotic dose years were associated with poorer cognitive performance. Gray matter volume decreases on MRI in people with schizophrenia are correlated with cumulative exposure to antipsychotic

treatments, while no effects were observed for the duration of illness or illness severity.

Some older adults with schizophrenia may need little or no medication, either because symptoms have abated or because medication has been ineffective. Consequently, several writers have proposed trials to gradually taper or discontinue medications. Graff-Guerrero and coauthors' study of persons aged 50 and over found antipsychotic dose reduction was feasible in patients with stable illness and was accompanied by diminished adverse effects and improved illness severity measures. This may have been due to the lower therapeutic window of D2/3R occupancy that was needed in older persons (50% to 60%) than what had been reported in younger patients (65% to 80%).

Nonpharmacologic Approaches. Because many persons with schizophrenia, especially early-onset cases, do not make full recoveries with medication alone, a variety of nonpharmacologic strategies have been devised specifically for this population. The first generation of nonpharmacologic approaches focused on delivering group-based psychosocial skills training that enhances social cognition and perception, verbal communication, social skills, and interpersonal problem-solving skills. Random control studies found significantly favorable outcomes for several programs that have targeted middle-aged and older adults. The second generation of model programs focused on illness self-management and wellness techniques. Self-management strategies train older patients to assume greater responsibility for their physical health as well as improve coping abilities to deal with psychiatric stress.

There are emerging technologies that will enable older adults with schizophrenia to improve their health, age in place, and receive age-friendly care. These technologies encompass a variety of modalities, such as humanoid care robots, smart home systems and devices, personal devices, and software that enable telehealth connectivity. In-home sensing and monitoring devices address everything from medical needs such as fall detection and medication adherence to personal or "quantified self" measurements targeted to calorie and step counting, sleep quality, and air quality.

Community-Based Approaches. In older adult patients with chronic mental illnesses, Assertive Community Treatment (ACT) teams have engaged patients in treatment more successfully and had fewer dropouts

from treatment versus comparison groups. Several model programs have combined collaborative care and case management strategies to address the medical and psychiatric issues facing many patients, as well as facilitate communication between the mental health team and the primary care providers. Collaborative care integrates mental health, primary care, and pertinent community supports and has the potential to ease the accessibility issues faced by older adults and to foster cross-discipline knowledge transfer to address complex clinical situations such as severe depression or suicidality. Case manager strategies typically use persons with clinical backgrounds to provide guidance, counseling, and skills training to older clients concerning psychiatric and physical health. They can also assist in guiding more appropriate care by primary care providers and enhance interdisciplinary communication.

LATE-ONSET SCHIZOPHRENIA

Epidemiology

A review of schizophrenia in later life found that slightly less than one-quarter of patients with schizophrenia had an onset of the disorder after age 40, with 13% in the fifth decade of life, 7% in the sixth decade, and 3% in later decades. A Dutch case-register study reported a 1-year prevalence rate of 0.55% for schizophrenia in persons over age 59 years, of which 64% had EOS and 35% had LOS. These figures suggest that the loss of early-onset individuals (to death or recovery) may be partially compensated by the influx of cases with a later onset. The epidemiologic study of LOS is complicated by several factors, including the use of various definitions of “late onset,” uncertainty in the determination of the age of onset, and questions regarding a correct diagnosis.

LOS affects women between 2 and 10 times more often than men. The robustness of this finding, coupled with the higher incidence rates of EOS in men, has led to the hypothesis that estrogen-mediated dopaminergic inhibition may protect younger women from schizophrenia, whereas the relative estrogen deficiency associated with menopause may be related to the increased incidence of LOS in women. A majority of treatment interventions with estrogen in postmenopausal women with schizophrenia have shown an improvement in symptoms. However, the incidence of schizophrenia is still considerably higher in younger versus older women.

Thus, an alternative hypothesis is that older men may be protected in some way.

The precise etiology of LOS, with an age of onset of between 40 and 60, and very late-onset schizophrenia-like psychosis (VLOS), with onset over age 60, is largely unknown. The International LOS Group concluded that schizophrenia with onset in middle age is a neurodevelopmental disorder and that differences with EOS are more of degree than of kind. The group also postulated that VLOS had some features that suggested a neurodegenerative component, including more brain abnormalities and neuropsychological deficits. A potential problem with this tripartite classification system is its reliance on age rather than clinical presentation, and some persons over 60 can resemble earlier-onset cases.

Overall, symptom presentation in EOS and LOS is more similar than different. Most studies have found that patients with LOS did not differ significantly from those with EOS regarding the severity of positive symptoms, although a large study by Vahia and colleagues found that late-onset patients had less severe positive symptoms and general psychopathology. This study also found that both groups had similar negative, depressive, and deficit symptoms.

Both EOS and LOS have cognitive deficits at presentation. Most studies have reported that, like EOS, cognitive deficits in LOS generally remain stable over time. There is less consensus on the nature and severity of these cognitive deficits. Some studies have reported fewer severe cognitive deficits in LOS as compared to EOS; others have found no differences in severity. No consistent biologic markers of schizophrenia with a later onset have been identified, although one study found raised C-reactive protein concentrations in people with LOS and VLOS.

A review of neuroimaging studies that compared EOS and LOS found differences in 8 of 10 studies, but there were inconsistencies across the studies. Similarly, measures of event-related brain potentials and neurofibrillary tangle densities found no differences between EOS and LOS groups.

Limited data exist specifically examining functioning in LOS. Patients demonstrated significantly greater disability in various areas of social functioning compared to healthy controls. Although marriage rates are higher in persons with LOS compared to EOS, social isolation was greater when comparing LOS patients to the general population. While some studies found that LOS was less frequently associated with a family history of schizophrenia than EOS, a more recent study reported no appreciable

differences. Familial association of schizophrenia appears to be more common in EOS and LOS than in VLOS.

While differences between early-onset schizophrenia and LOS are more subtle, VLOS is a special case. VLOS is rare, with a reported annual incidence of 27 per 100,000 men and 48 per 100,000 women. Previous findings examining age have been mixed, showing both increased and decreased VLOS incident rates with advancing age. The clinical presentation of VLOS includes many striking features. One of them is a high prevalence of partition delusions. In this type of delusion, a person is convinced that people, objects, or radiation can pass through impermeable structures (walls, windows, doors). Hallucinations often involve multiple sensory domains (e.g., auditory, visual, tactile, olfactory). Formal thought disorders and negative symptoms, core symptoms of schizophrenia at a younger age, are infrequent, which has further fueled criticism of whether VLOS should be considered as a subgroup of schizophrenia. Mood disruption often occurs in VLOS, but adequate research to confirm this is lacking. Patients tend to be agitated and combative about their paranoid psychotic experiences.

The pattern of cognitive dysfunction is a focus in the debate on whether VLOS is a primarily neurodegenerative disorder. Nonetheless, like schizophrenia starting at a younger age, cognitive dysfunction in VLOS affects mainly frontal-subcortical cognitive domains. Memory disorders relate to learning new information, but retention of information is usually unaffected. This finding stands in contrast to the retention disorders that characterize cortical dementias like AD. Limited data exist on the longitudinal course of cognitive dysfunction in VLOS, and most studies had relatively short follow-ups. An often-cited Australian study that assessed cognition over 5 years found conversion to dementia in 9 of the 19 subjects. However, these findings were criticized for possibly including patients with early-stage dementia with psychotic features. Neuroimaging studies in VLOS have been very few but did not convincingly demonstrate a neurodegenerative substrate. Genetic factors have not been implicated in the etiology of VLOS.

In clinical practice, patients for whom VLOS is considered a differential diagnosis constitute a heterogeneous population, with only a proportion of them developing dementia with time. Like LOS, in VLOS, there is a broad differential diagnosis with other disorders involving psychotic symptoms in later life. A more conclusive diagnosis of VLOS, therefore, can be made only after a sufficient follow-up period.

Table 55.3h–1 provides an outline of the features that distinguish the three categories of schizophrenia.

Course and Prognosis

The course of LOS is often chronic but may be interrupted by partial remissions and exacerbations. Most studies have reported that in LOS, as in EOS, cognitive deficits tend to remain relatively stable over time, apart from changes associated with normal aging. The overall prognosis of LOS may be better than that of EOS. Patients may be quite responsive to antipsychotics used in lower doses. However, mortality rates, especially from suicide, exceed that in the general population and are probably comparable to those in EOS.

Treatment

Concerning LOS, a Cochrane report, updated in 2013, concluded that there is a paucity of trial-based evidence upon which to base guidelines for the treatment of LOS and that there is a need for good quality-controlled clinical trials. Howard and colleagues reported that a low dose of the antipsychotic drug amisulpride (100 mg) was effective and well-tolerated as a treatment for VLOS. Many of the pharmacologic and psychosocial recommendations for EOS can be applied to LOS, although expert guidelines suggest lower doses of antipsychotic medications may be needed in the latter.

Psychosocial treatment is a vital aspect of the management of LOS, and treatments specifically designed for older adults with schizophrenia, such as cognitive behavioral therapy and social skills training, have shown promise. The ability to engage patients who often lack insight into their disorder requires an assertive and multidisciplinary approach.

DIFFERENTIAL DIAGNOSIS OF PSYCHOTIC DISORDERS IN LATER LIFE

Making a diagnosis of schizophrenia in later life can be challenging. The onset of hallucinations and delusions in older adults can arise de novo or be associated with mood disorders, sensory deficits, polypharmacy, substance abuse, medical disorders, or dementia. The lifetime risk of developing psychotic symptoms in late life has been estimated to be up to 23%, primarily due to incident dementia. The prevalence of psychotic

symptoms in noncognitively impaired older people has been estimated to be between 1% and 13.4%, with a median prevalence of 3.6%. One review study from Western Europe found the prevalence of psychotic symptoms among noncognitively impaired older adults increased with advancing age, so that rates were under 2% in persons aged 65 to 74, but 4% and 7% in those aged 85 to 94 and 95 to 104, respectively. The prevalence of psychosis in late-life in clinical populations is appreciable and is observed in 5% to 15% of geriatric psychiatry inpatients and up to 62% of nursing home patients. The clinician must be able to distinguish between “primary” psychosis (not attributable to other medical disorders) and “secondary” psychosis (attributable to other medical disorders), which account for 40% and 60% of cases in older adults, respectively. It is essential to obtain an accurate history and appreciate the time course of the disorder. Table 55.3h–2 lists the principal etiologies and time trajectories of psychotic disorders in older adults.

Table 55.3h–1.
Features Differentiating the Schizophrenia Subcategories

	Early-Onset Schizophrenia (EOS)	**Late-Onset Schizophrenia (LOS)**	**Very–Late-Onset Schizophrenia-Like Psychosis (VLOS)**
Age of onset	<40	40 to 60	>60
1-year prevalence among persons age 60+ (Dutch Catchment Area Study)	0.55%	0.14%	0.05%
Gender	Male = Female	Female > Male	Female >> Male
Family history of schizophrenia spectrum disorder	Present	Present	Absent
Cognitive decline	Deficits present at illness onset with age-related decline (stable vs. peers)	Deficits present at illness onset with age-related decline (stable vs. peers)	Substantial decline in a significant minority
Positive symptoms	▶ Severity of positive symptoms at onset but some improvement in later life ▶ Variety of positive symptoms ▶ Auditory hallucinations > visual hallucinations	Current level and characteristics of positive symptoms similar to older adults with EOS	▶ Lower severity of positive symptoms vs. EOS ▶ Visual hallucinations > auditory hallucinations

			▶ Other hallucinations such as tactile and olfactory are more common ▶ More somatic delusions ▶ More partition and persecutory delusions Auditory hallucinations with accusatory running commentaries
Negative symptoms	Present	Present	Absent
Thought disorder	Present	Present	Absent
Depression	Present	Present	Less common
Mortality vs. age peers	Higher	Higher	Higher
Antipsychotic dosage	May need higher dosages	Lower doses may be effective	Very low doses may be effective
Nonpharmacologic treatment	Psychosocial skills training; self-management techniques	No controlled studies	No controlled studies

Mood Disorder

Differentiating schizophrenia from mood disorder with psychotic features and schizoaffective disorder can be difficult because mood disturbances

are common during the prodromal, active, and residual phases of schizophrenia. As described earlier, prevalence rates of cooccurring clinical depression have been found in up to three-quarters of older persons with schizophrenia, although mood symptoms may not meet the criteria for major depression. Furthermore, mood-congruent or mood-incongruent psychotic features may occur in major depression or bipolar disorder, although in both disorders, psychotic features tend to be more mood-congruent, for example, grandiosity, erotomania, special powers among bipolar individuals and delusions of poverty, guilt, sin, or physical illness in depressed persons. Auditory hallucinations occur less commonly in depression and may be vague or condemnatory. Catatonic features are more commonly seen in severe depressive disorders, and a history of mood symptoms may help to discriminate between conditions based on DSM-5-TR criteria. Mood disorder with psychotic features beginning after 40 years of age is differentiated from LOS by its affective symptoms that precede psychotic symptoms.

Table 55.3h–2.
Causes of Psychotic Symptoms in Older Adults

Etiology	Primary vs. Secondary Psychosis	Prevalence Among Psychotic Disorders	Time Course
Affective disorders	Primary	38%	Weeks to months
Schizophrenia spectrum and delusional disorders	Primary	3%	Months to decades
Major neurocognitive disorders (all types)	Secondary	40%	Months to years
Medical disease	Secondary	7%	Days to months
Delirium	Secondary	7%	Hours to days
Drug toxicity (substance abuse/medications)	Secondary	4%	Hours to months

Adapted from Reinhardt M, Ghoneim D, Murante T, et al. Schizophrenia spectrum and other psychotic disorders. In: Tampi RR, Tampi DJ, Boyle LL, eds. *Psychiatric Disorders in Late in Life. A Comprehensive Review.* Springer Nature; 2018:205–216.

Schizoaffective Disorder

It can be tricky to distinguish schizophrenia with depressive symptoms from schizoaffective disorder. The key difference is that in schizoaffective disorder, a *major* mood disorder must be present. The mood symptoms must occur simultaneously with the active-phase symptoms of schizophrenia, and they must be present for a substantial proportion of the total active and residual periods of the illness. Additionally, delusions or hallucinations must be present for at least 2 weeks in the absence of prominent mood symptoms. If the mood symptoms have a duration that is brief in relation to the total duration of the disturbance or do not meet the full criteria for a major depressive disorder, manic disorder, or mixed episode, then a diagnosis of schizoaffective disorder cannot be made. In the DSM-5-TR, clinicians must determine if a major depression has been

present for a “majority” of the active and residual portions of the schizophrenia illness. Thus, clinicians must decide based on the life history of the illness, whereas previously, clinicians tended to look at discrete episodes. For geriatric psychiatrists, accurately determining what proportion of a 30 or 40-year illness involved major depression or manic symptoms is nearly impossible. Also, over the course of the illness, some older persons who had major depressive symptoms may attain persistently lower levels of depression, and consequently, they may no longer be considered to have schizoaffective disorder. The DSM-5-TR acknowledges the potential transience of the diagnosis and that some individuals will convert from schizoaffective disorder to another disorder as mood symptoms become less prominent. For these reasons, the DSM-5-TR states that there is growing evidence that schizoaffective disorder is not a distinct nosologic category.

Delusional Disorder

Delusional disorders can generate diagnostic conundrums. Persecutory, somatic, or erotomanic delusions in the older adult patient are typically secondary to another neuropsychiatric disorder (e.g., schizophrenia, mood disorder, or dementia); however, occasionally, a primary delusional disorder is implicated. Delusional disorders are rare in later life, with a prevalence rate of 0.03% to 0.04% and a lifetime risk of between 0.05% to 0.46% (the DSM-5-TR estimates the lifetime prevalence at 0.2%), which is well below lifetime risks for schizophrenia and bipolar illness. Delusional disorders usually first appear in the middle to late adulthood. The overall prevalence of delusional disorders is slightly higher among women than among men, and the average age of onset is earlier for men (40 to 49 years) than for women (60 to 69 years). There are no clear neuroanatomical changes associated with delusional disorder. There is mixed evidence that hearing or visual abnormalities might play a role in the development of delusional disorders. Family, twin, and adoption studies have suggested that a close association between delusional disorder and schizophrenia is unlikely, although rates of familiar schizophrenia may be higher than in the general population.

Delusional disorder is differentiated from schizophrenia by a lack of prominent hallucinations and an absence of deterioration in areas of functioning outside the delusional scope. The delusions are necessarily nonbizarre and involve situations that may occur in real life, such as theft,

suffering from a disease, or spousal infidelity. For example, delusions that are seen commonly in older adult patients include skin infestation by insects; that internal organs are cancerous; that the person is being spied on, followed, or poisoned; and that the spouse is unfaithful. One study found that nearly half of patients had persecutory delusions. Consequently, a delusional disorder may be difficult to differentiate from schizophrenia with prominent paranoid ideation, especially in instances in which disorganized speech, disorganized behavior, or flat or inappropriate affect are less prominent. Nonetheless, the presence of auditory hallucinations or bizarre delusions seen in schizophrenia should differentiate the disorder. Furthermore, poor psychosocial functioning in delusional disorder is directly related to the delusional beliefs themselves, but marital and social functioning may be compromised. While subtle cognitive deficits may be found, intellect is generally maintained. Like schizophrenia, the course of the disorder varies among those afflicted, with perhaps one-third experiencing remission and two-thirds a prolonged course. Many avoid treatment, although among those who take antipsychotic medication, improvement has been reported in more than four-fifths of patients.

Psychosis Associated With Cognitive Disorders, General Medical Conditions, or Delirium

A patient who presents with psychotic symptoms after the age of 40, particularly if the symptoms develop after the age of 60, requires a thorough evaluation for underlying medical and neurologic disorders. Dementia is a common disorder in older adult persons, and 50% to 60% with a diagnosis of dementia of the Alzheimer type may experience psychotic symptoms at some point during their dementia. Delusions in AD tend to be nonbizarre, episodic, and preceded by cognitive decline. Typically, delusions in AD involve someone stealing from them or entering their house. Visual hallucinations are more common in AD than in schizophrenia, while auditory hallucinations are less common. Other neurocognitive disorders such as Lewy body Dementia and Parkinson Disease with Dementia may have higher rates of hallucinations and delusions than AD, whereas vascular and frontotemporal dementias have lower rates of psychotic symptoms.

Psychosis due to a general medical condition is diagnosed from the history, physical examination, or laboratory tests that show the delusions or hallucinations are the direct physiologic result of a general medical

condition. Metabolic disturbances and neurologic and endocrinologic disorders are the most common causes of psychotic symptoms.

The diagnosis of delirium is established through observation of an acute change in mental status. and is characterized by a fluctuating deficit in attention, with changes in cognition that are not better explained by another neurocognitive disorder. The diagnosis of delirium remains reliant on clinical acumen, despite multiple efforts to establish diagnostic biomarkers. Behavioral symptoms are very common during delirium, including hallucinations and delusions, sleep disturbances, aberrant behavior, and affective lability. Hallucinations and delusions are common in delirium, with prevalence rates ranging from 40% to 70% for hallucinations, which are more frequently visual, and from 24% to 79% for delusions, which are more commonly paranoid types.

Substance-Induced Psychotic Disorder

About half of persons aged 65 and over drink alcohol, and one-fourth of those aged 85 and over continue to drink. Illicit drug use has been estimated at 10% to 15% of persons aged 50 to 64 and 5% among those aged 65 and over. At least one prescribed medication is taken by 87% of older adult adults, and 38% take five or more medications; about two-fifths use over-the-counter medications. These older adults are at greater risk for adverse effects because of polypharmacy, changes in metabolism and neuroreceptor sensitivity, and comorbid physical and neurologic disorders. Several different substances, such as amphetamines, cocaine, and phencyclidine, can produce symptoms like those of schizophrenia, such as delusions, hallucinations, or a mixture of positive and negative symptoms. Many substances can induce psychotic symptoms during withdrawal states, that is, benzodiazepines, barbiturates, and alcohol. Ideally, substance-induced psychotic disorders would be differentiated from schizophrenia after a period of abstinence; however, other evidence, such as whether the psychotic symptoms appear to be exacerbated by the substance and decrease when it has been discontinued or whether the psychotic symptoms have been instigated and maintained by the substance use, need to be considered.

55.3i Personality Disorders

Marc E. Agronin, M.D.

Multiple normative and pathologic changes during the aging process affect personality, and these same forces apply to the consideration of personality disorders in late life. These disorders represent a heterogeneous array of chronic affective and behavioral disturbances that cause enormous personal and interpersonal distress and pose significant challenges to clinical management, especially in the setting of comorbid medical and psychiatric conditions. Changing and inherently limited diagnostic schemes combined with a general lack of previous study make it difficult to understand and plot the trajectory of a given personality disorder in late life. Clinical perspectives on personality stability versus change will vary depending on the methods of assessment. There is limited empirical evidence and a range of unsubstantiated opinions as to whether personality disorders persist with minimal or no change, convert into more age-appropriate forms with similar levels of pathology, or remit over time. Understanding all of these factors is critical to improving diagnosis and optimizing clinical management.

DEFINITIONS

Defining the concept of *personality* itself is key to a fuller understanding of personality disorders. According to the *Bantam Medical Dictionary*, personality is “an enduring disposition to act and feel in particular ways that differentiate one individual from another.” George Vaillant qualifies this definition, suggesting that the enduring aspects of personality, which he terms *temperament,* consist largely of various inherited elements such as personality traits and IQ. He bases this belief on longitudinal studies of core personality traits (e.g., extroversion, introversion) that have generally found stability with aging. On the flip side, Vaillant holds that elements of personality or *character* defined by adaptive styles can change

significantly with aging, affected by both “environment and maturation.” Putting together both elements of stability and change, Henry Murray’s statement that “the history of the personality is the personality” is most helpful when considering aged individuals. Lacking accurate longitudinal data from an older individual’s younger days, the average clinician is forced to make decisions about personality functioning based on more recent history.

The distinction between normal and abnormal personalities is based largely on the expression of certain personality *traits* (as opposed to more acute psychopathologic symptoms) that are repeatedly associated with unhappiness, interpersonal conflict, and/or occupational dysfunction. Although everyone has a unique personality with relative strengths and weaknesses, the current diagnostic model requires the categorization of certain personalities as pathologic along the lines of various subtypes. This categorical model has been criticized for the ways in which it provides pejorative labels and obscures the richness of personality. In late life, it is particularly problematic given the large number of physical and psychosocial stresses that can distort an individual’s pattern of adaptation.

An alternative dimensional approach was proposed but not adopted in the *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition (DSM-5). Personality disorders are defined in DSM-5 as chronic psychiatric disorders characterized by enduring and pervasive patterns of inflexible and maladaptive inner experiences and behaviors. These dysfunctional features are rooted in early development, deviate from cultural expectations, and lead to significant social and occupational impairment across several spheres of function: perception and interpretation of experiences, emotional expression, interpersonal relations, and impulse control.

There are 10 subtypes of personality disorders listed in the DSM-5 classification, grouped into three broad phenomenologic clusters: cluster A, the *odd* cluster, includes paranoid, schizoid, and schizotypal subtypes; cluster B, the *dramatic* cluster, includes antisocial, borderline, histrionic, and narcissistic subtypes; and cluster C, the *anxious* cluster, includes avoidant, dependent, and

obsessive-compulsive subtypes. Depressive and passive-aggressive (or negativistic) personality disorders were two subtypes that were listed in the appendix of the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition text revision or DSM-IV-TR but are no longer included in DSM-5. Each personality subtype is defined by 8 to 10 diagnostic criteria, and an individual must meet a specified number of them in any combination in order to qualify for a diagnosis. Individuals may demonstrate a single disorder or a combination of maladaptive traits from several disorders. Individuals who have symptoms characteristic of a personality disorder in general, but do not meet the criteria for any specific disorder, may be diagnosed as having an *unspecified personality disorder.*

Although there are several designated pediatric categories for personality disorders, there are no equivalent, age-adjusted geriatric subtypes, despite growing evidence that changes in both personality and personality disorders in late life can lead to enduring but *different* patterns of personality dysfunction. However, when personality change results from physical damage to the brain from substance abuse or a medical condition, the term *personality change due to another medical condition* can be used (with the medical condition specified and then coded separately), with several designated subtypes: labile, disinhibited, aggressive, apathetic, and paranoid. Common causes of personality change include traumatic head injury, stroke, endocrine dysfunction, encephalitis, and Alzheimer disease.

EPIDEMIOLOGY

Community-based epidemiologic studies have found rates of personality disorders in adults ranging from 10% to 20%, with the 2001–2002 National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) Data for 16,884 adults ages 50 and older yielding a rate of 10.7% for at least one personality disorder. Another set of NESARC data found a rate of 14.5% of one or more personality disorders in older adults. These rates increase two- to threefold in individuals being treated in both outpatient and inpatient

psychiatric settings for comorbid psychiatric diagnoses, particularly major depression. For example, a study of 546 older adult psychiatric inpatient admissions found personality disorders in 13% of all patients, which increased to 24% of those diagnosed with major depression. In all studies, the method of diagnosis has produced variations in prevalence rates. Epidemiologic surveys and more impressionistic clinical diagnoses have generally found higher rates of personality disorders and yet a more limited spectrum of subtypes compared to criterion-based structured clinical interviews.

The most common personality disorders seen across late-life studies have been paranoid, avoidant, dependent, and obsessive-compulsive subtypes. The most common subtype in the NESARC data sets was obsessive-compulsive personality disorder at 6.5% to 7.6%, followed by narcissistic personality disorder at 3.9% and paranoid personality disorder at 2.5%. In late life, nearly two-thirds of those diagnosed with a personality disorder also meet the criteria for two or more subtypes or for the unspecified category. It is important to bear in mind that the lifelong course of specific subtypes will influence prevalence. For example, a decrease in the prevalence of antisocial personality disorder in late life no doubt results from increased rates of remission, death, institutionalization, and avoidance of psychiatric settings with age. Decreasing rates of other personality disorders in late life may be due to the fact that they are difficult to differentiate from other specific psychiatric diagnoses or may change in ways that obscure their recognition.

There are limited data on the prevalence of personality disorders in long-term care settings, due to the great difficulty obtaining longitudinal data, in addition to the challenge of interviewing individuals who may be suffering from varying degrees of cognitive impairment. One survey that based diagnoses on clinical interviews found that nearly 11% of a modest sample of nursing home residents had a primary or secondary diagnosis of personality disorder. An identical diagnostic rate was found in a sample of intellectually disabled adults older than 40 years who were admitted to a long-term care institution—although, in that study, the congenital diagnosis might call into question the personality disorder diagnoses.

A review of referrals to a nursing home found that 15% were for unspecified personality problems, although it is not clear how many of these individuals had actual personality disorders. Rates for personality disorder subtypes in long-term care facilities have not been established in any study.

DIAGNOSIS

In spite of the very specific diagnostic criteria provided by DSM-5, clinicians immediately encounter a plethora of diagnostic challenges when assessing older individuals. Sometimes the older personality, viewed from an ageist stance, is erroneously believed to be more dependent, stubborn, hypochondriacal, and less adaptive in the face of stress compared to younger personalities. Such an attitude may lead clinicians to view many disordered behaviors as normal in late life, preventing accurate diagnosis. At the same time, many clinicians might not consider the possibility of a personality disorder in an older patient or might be daunted by the large number of diagnostic criteria. As a result, these diagnoses are often deferred or merely lumped under an unspecified category. Lack of knowledge either of specific criteria or how to apply them in late life has been shown to create discrepancies between largely impressionistic clinical diagnoses and those determined through more rigorous structured interviews.

The criteria themselves foster misdiagnosis since they were developed for adults and do not take into consideration age-associated changes in lifestyle and behaviors that render many of them obsolete in later life. For example, the diagnosis of antisocial personality disorder includes criteria such as “repeatedly performing acts that are grounds for arrest,” “repeated physical fights or assaults,” and “consistent irresponsibility” with work or financial obligations. For an older person who is retired from work, residing in congregate living or a long-term care facility with limited mobility, or physically frail, these criteria will simply not apply. Diagnostic criteria for borderline personality disorder, such as self-injurious behaviors and self-damaging impulsivity with respect to spending, sex, driving,

or eating, are also less applicable to older adults, who in general tend to be less impulsive. As of yet, there are no geriatric criteria that can be substituted, and attempts by clinicians to make diagnoses based on fewer criteria or to “age-adjust” other criteria threaten the very validity of the diagnosis. Several age-specific tools with reasonable accuracy have been developed to address evolving diagnostic symptoms, including the Gerontological Personality Disorders Scale. Researchers have also suggested that dimensional rather than categorical models may be more useful across ages.

Not surprisingly, an analysis of data from the National Epidemiologic Survey on Alcohol and Related Conditions, which studied over 43,000 individuals, found that young and old adults endorsed nearly 30% of personality disorder criteria differently, despite having equal degrees of personality dysfunction. The end result was that older adults were more likely to have schizoid and obsessive-compulsive personality disorder diagnoses, while younger adults were more likely to have avoidant and dependent personality disorder diagnoses. The same diagnostic criteria, then, yielded different disorders based on age.

Another diagnostic dilemma is the need for accurate longitudinal descriptions of a personality on which to base the diagnosis. Unlike symptoms of most other psychiatric disorders, which are readily reported or observed, personality disorder symptoms can be more difficult to elicit through self-report given their pejorative nature, and when observed, require repeated encounters across different settings to be accurate and reliable. Instead, clinicians often have to rely on clinical records, which typically lack longitudinal data, or on existing informants who can rarely provide critical information dating back to an older patient’s young adulthood.

An important caveat for any clinician attempting to make a late-life diagnosis is that personality dysfunction does not necessarily indicate a personality disorder. Significant, repeated, and sometimes devastating losses in late life, such as the death of a spouse or of a series of close friends, a chronic debilitating illness, chronic pain, physical disability, the loss of finances or livelihood, or the overall loss of personal attributes that once defined an individual (e.g.,

strength, beauty, athletic, or sexual prowess), can lead to severe adjustment reactions that mimic personality disorders. Without clear longitudinal information, it is difficult to determine whether a patient with pervasive dysfunctional interpersonal relations, for example, is demonstrating a lifelong pattern or a more recent reaction to life events. Many symptoms of major depression and generalized anxiety disorder overlap with depressive, negativistic, avoidant, and depressive symptoms of several personality disorders. Similarly, symptoms of persistent bipolar mania can mimic antisocial, narcissistic, and borderline traits. For this reason, personality disorder diagnoses are best deferred during episodes of acute psychiatric syndromes. Perhaps one of the most difficult decisions to make is whether changes in demeanor brought on by neurocognitive disorders and associated neuropsychiatric syndromes such as apathy are merely expressions of the underlying disorder or represent a true personality change.

CLINICAL FEATURES AND COURSE

Since its inception in 1952, iterative versions of the DSM have provided a heterogeneous and fluid array of personality disorder subtypes up until the more enduring categorization that appeared in the third edition of the DSM (DSM-III) in 1980. Despite the relative stability in the nomenclature since then, the DSM has never been clear on the course of personality disorders into late life, only suggesting that several remain relatively unchanged while others attenuate. The possibility of a late-onset personality disorder is not addressed in the DSM, aside from the diagnosis of a personality change disorder. Unfortunately, there are limited data on most subtypes, and current thinking rests largely on case studies.

For the clinician working with older adult individuals with known or suspected personality pathology, the main question is: What do these disorders look like in late life? Are they fundamentally the same as in previous years, or does aging change them in ways that either attenuate symptoms and cause remission or lead to similar

degrees of pathology but with novel, age-appropriate manifestations? Consider the following clinical vignette.

Mr. L was an 82-year-old man who suffered from brittle diabetes, morbid obesity, and chronic obstructive lung disease. After his wife died, Mr. L was unable to manage his own care needs and had to be admitted to an assisted living facility (ALF). He was oxygen dependent and used an electric scooter to get around. Mr. L quickly established a reputation as a rude and aggressive man. He would badger other residents and staff in the elevator when they did not get out of his way quickly. He would make unrealistic demands of the waiters in the dining room and insult them when he did not get his way. He accused the nursing staff of deliberately withholding treatment after one of his medications went missing from his tray. Over time, the staff grew increasingly tired of his verbally abusive and disruptive behaviors and was afraid to help him since he often threatened to sue them for shoddy care. They described him as a difficult, paranoid, and hateful person.

These behaviors built into a crisis one day when Mr. L became enraged at a deaf resident standing in front of him in the elevator who could not hear him berating her for moving out of his way. He pushed her down and ran over her foot with his scooter, causing a serious skin laceration and bruise. He completely denied his actions, however, accusing the injured woman of deliberately feigning injury after blocking his scooter and getting bumped. He screamed at all staff who tried to intervene and threatened to kill anyone who got in his way. As a result, Mr. L was hospitalized involuntarily and not allowed to return to the ALF.

Additional information on Mr. L indicated that he had been an extremely aggressive but quite successful real estate broker as a young and middle-aged man. His daughter estranged herself from him due to his abusive behaviors, and his son limited his contact with his father, whom he described as arrogant, paranoid, and verbally abusive to those who disagreed with him. Mr. L's behaviors were chronic but seemed to have improved in the several years prior to his becoming ill, perhaps because his

business success enabled him to get involved in several gratifying philanthropic endeavors. However, with the onset of illness and then the death of his wife, he could not cope with being dependent on others for help. He was completely unable to trust staff or forge stable relationships in the ALF and became increasingly angry, depressed, and paranoid. Having to adjust to institutional living proved impossible, and his brittle coping style was eventually overwhelmed, resulting in a crisis characterized by aggression and paranoid accusations. Putting together known history and current observations, Mr. L's clinical team diagnosed him with a paranoid and narcissistic personality disorder.

In this clinical vignette, several themes appear that characterize the course and prognosis of many personality disorders throughout life. First, dysfunctional behaviors do not arise de novo but have a history and have pervaded the individual's life in one form or another since young adulthood. In many cases, there may be long periods of increased stability in middle age that represent symptomatic remission, typically bolstered by stable relationships, successful occupational pursuits, and intensive therapeutic assistance. Not all personality disorders, however, will benefit from these stabilizing factors—particularly those with avoidant, schizoid, and schizotypal features. As seen in the illustrative case, major late-life stresses can exacerbate existing pathologic traits or lead to the reemergence of previous traits in ways that are different in kind but equally problematic as earlier in life. Lacking a longitudinal history and based strictly on observed behaviors, many personality-disordered individuals are typically diagnosed with major depression, bipolar disorder, or even late-onset schizophrenia, given the intensity of their symptoms. Although these diagnoses may present comorbidly, they are driven in part by the underlying personality disorder.

Cluster A Disorders

In late life, the diagnostic criteria for the three odd cluster disorders coalesce around a lack of desire for and openness toward

interpersonal relationships. The tendency of the paranoid personality disorder to read malevolent intent into the actions of others leads to a lifetime of angry conflicts with others, while the aloof and strange demeanor of the schizoid and schizotypal individual precludes the formation of close relationships. As a result, odd cluster personality disorders tend to enter later life without the benefit of past interpersonal experiences that can, for less dysfunctional individuals, teach social skills and provide emotional support. It is believed that the pathologic cognitive and behavioral patterns of the odd cluster disorders tend to remain the same or even worsen with aging, with some conversion to schizophrenia spectrum disorders.

Paranoid, schizoid, and schizotypal individuals face age-associated stresses with variable responses. On the one hand, the lack of close relationships means that these individuals may feel a less emotional impact from the inevitable loss of family members or longstanding social contacts. However, when medical illness and disability occur, these same individuals often have great difficulty seeking help and coping with forced dependency on others, especially when placed in long-term care institutions. The result is often the increased expression of longstanding dysfunctional behaviors and defense mechanisms, including paranoid ideation, social isolation, and odd or idiosyncratic beliefs or rituals. There may also be an increased risk of psychosis to the extent that these disorders are considered potential precursors for late-onset schizophrenia.

Cluster B Disorders

Although lumped together under the “dramatic” cluster domain, these four personality disorders are heterogeneous in both expression and course over the life cycle. A central theme, however, is that while their psychopathology results in severe and, in some cases, deadly consequences, there is potential for symptomatic quiescence, improvement, or even remission in middle age when there are significant personal or occupational achievements or the presence of consistent interpersonal relationships. In addition, individuals with

more personal, social, and/or financial resources and with less psychiatric comorbidity tend to fare better. By the same token, age-associated losses in relationships, social and occupational roles, physical attributes such as strength and beauty, and financial status can reverse many of these gains and prove devastating to the personality. For those individuals who had improved over their lifetimes, the stress of major losses can lead to the reemergence of previous dysfunctional cognitive and behavioral patterns, but in ways not always recognizable by the current diagnostic nomenclature. These relapses are inevitably complicated by comorbid psychiatric disorders such as major depression, neurocognitive disorders, anxiety disorders, and substance-related and addictive disorders.
